Remark 11.41 (General demand). The linear form is not needed for the sign. Let $N = 3$ and let $r(p_1, p_2)$ be the outsider's best response, with partial derivatives $r_1, r_2 > 0$ (strategic complements) and $r_1 + r_2 < 1$ (the usual stability condition). If the symmetric insiders raise both prices by Δp_I, the mean value theorem gives $\Delta p_O = (r_1 + r_2)\big|_{\tilde{p}}\,\Delta p_I$ at some intermediate price vector $\tilde{p}$. Then $0 < \Delta p_O < \Delta p_I$. Deneckere and Davidson (1985) show for a broad class of demand systems that merging firms raise prices by more than outsiders. How much outsiders respond depends on how fast elasticities change with price (Crooke et al., 1999).

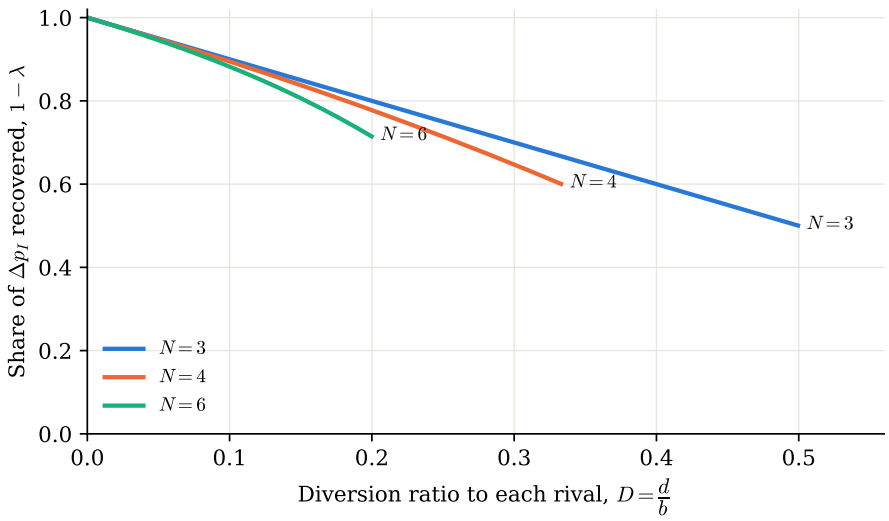

Figure 11.13: Share of the insiders' price increase recovered by a DiD estimator that uses an outsider as the control, $1-\lambda$ from (11.79), against the diversion ratio to each rival $D=\frac{d}{b}$. Each curve ends where $b=(N-1)d$. The bias is largest when the products are close substitutes, which is when the merger matters most.

11.6.3 Event windows and transitory selection

The *event window* is the set of months used before and after the merger. It should be long enough to capture the price change and short enough to avoid contamination by other events. Ashenfelter and Hosken (2010) prefer a window that drops the three months before and after consummation and uses equal spans of data on the two sides. Dropping the months near the merger avoids the question of exactly when the parties start pricing jointly. The law prohibits joint pricing before closing, yet Kim and Singal (1993) find that many airlines raised fares before their mergers were consummated (Ashenfelter and Hosken, 2008, footnote 47). The symmetric design protects against a subtler problem, which we now formalize following Heckman and Robb (1985) and Ashenfelter and Card (1985).

Suppose that without the merger log prices follow $y_{jt}(0)=\alpha_j+\tau_t+u_{jt}$. Here τ_t is common to all products and u_{jt} is a transitory deviation. Mergers may be triggered by transitory events. A price war, for example, depresses u_{jt_0} and may push firms to merge. The General Mills purchase of the Chex brands was announced just after a widely reported price war in ready-to-eat cereal in April 1996 (Ashenfelter and Hosken, 2008, p. 15).

Definition 11.42 (Time reversibility)**.** A stationary process $\{u_t\}$ is *time reversible* if, for every $s\geq 1$, the pairs (u_{t_0+s},u_{t_0}) and (u_{t_0-s},u_{t_0}) have the same joint distribution.

Every stationary Gaussian process is time reversible. Its joint distributions depend only on the autocovariance function, and the autocovariance at lag s equals the autocovariance at lag $-s$.

Proposition 11.43 (Symmetric windows remove transitory selection)**.** *Suppose $\{u_{jt}\}_t$ is stationary, time reversible and independent of α_j. Suppose the event A_j that product j's owner merges at t_0 depends only on α_j, on u_{jt_0} and on variables independent of the process $\{u_{jt}\}$. Then for every $s\geq 1$,*

$$\mathbb{E}\left[u_{j,t_0+s}-u_{j,t_0-s}\mid A_j\right]=0.$$

Proof. Condition first on (α_j, u_{jt_0}) and use the law of iterated expectations:

$$\mathbb{E}\big[u_{j,t_0+s} \mid A_j\big] = \mathbb{E}\Big[\mathbb{E}\big[u_{j,t_0+s} \mid \alpha_j, u_{jt_0}\big] \mid A_j\Big] = \mathbb{E}\Big[\mathbb{E}\big[u_{j,t_0+s} \mid u_{jt_0}\big] \mid A_j\Big].$$

The second equality uses the independence of the process from α_j and from the other variables in A_j. By time reversibility $\mathbb{E}[u_{j,t_0+s} \mid u_{jt_0}] = \mathbb{E}[u_{j,t_0-s} \mid u_{jt_0}]$. Applying the same two steps in reverse gives $\mathbb{E}[u_{j,t_0-s} \mid A_j]$. □

The proposition implies that a comparison of month $t_0 + s$ with month $t_0 - s$ has no transitory selection bias. So does any average of such comparisons over $s = k, \dots, K$. An asymmetric window does not have this property. Let u_{jt} be a Gaussian AR(1) process with coefficient 0.8, and suppose mergers follow price wars, so that $\mathbb{E}[u_{jt_0} \mid A_j] = -\mu < 0$. Then $\mathbb{E}[u_{j,t_0\pm s} \mid A_j] = -(0.8)^s\mu$. Compare months 4 to 15 after the merger with months 4 to 6 before it. The average post-merger deviation is -0.159μ and the average pre-merger deviation is -0.333μ. The estimate is biased upward by 0.174μ, because the recovery from the price war is attributed to the merger. The symmetric window guards against this, at the cost of discarding data. Ashenfelter and Hosken (2010) also report a symmetric window that keeps the months near the merger and an asymmetric window that uses all available data. The window mattered little except for the cereal merger (Ashenfelter and Hosken, 2008, p. 26).

Windows also determine which effects we measure. A short window captures the short-run price response. Cost savings may take longer to reach prices. Focarelli and Panetta (2003) find that the price effects of the bank mergers they study were reversed by efficiency gains after about three years. Long windows, on the other hand, mix the merger with entry, new products and repositioning, which grow more important as time passes (Ashenfelter and Hosken, 2008, footnote 49).

11.6.4 Measuring prices and drawing inferences

Unit values versus price indices. A brand is sold in several package sizes $k = 1, \dots, K$ with prices per unit p_{kt} and unit sales q_{kt}. The *unit value* or average revenue of the brand is

$$P_t^{AR} = \frac{\sum_k p_{kt} q_{kt}}{\sum_k q_{kt}} = \sum_k \omega_{kt}\, p_{kt}, \qquad \omega_{kt} = \frac{q_{kt}}{\sum_l q_{lt}}.$$

Its change between two periods decomposes as

$$P_1^{AR} - P_0^{AR} = \sum_k \omega_{k0}\,(p_{k1} - p_{k0}) + \sum_k (\omega_{k1} - \omega_{k0})\, p_{k1}.$$

The first term is a price change at fixed quantity weights. The second is a composition effect. If buyers shift toward large packages, which are cheaper per unit, the unit value falls even when every package price rises. A *Stone price index* with fixed revenue weights $\bar{w}_k$ removes the composition term:

$$\ln P_t^S = \sum_k \bar{w}_k \ln p_{kt}, \qquad \ln P_1^S - \ln P_0^S = \sum_k \bar{w}_k\,(\ln p_{k1} - \ln p_{k0}).$$

Ashenfelter and Hosken (2010) construct five price measures for cereal, syrup and feminine hygiene products. They are the unit value, two revenue-weighted average prices with first-year

or last-year weights, and two Stone indices with the same weights. They aggregate weekly data to months to dampen the effect of household stockpiling during sales (Hendel and Nevo, 2006). Scanner data also record retail prices. A merger of manufacturers changes wholesale prices, and retail prices change by the retailers' pass-through of the wholesale change.

Clustered errors. In (11.76) the regressor $Post_t$ takes the same value for every product and region in a month. Common monthly shocks then make the errors of a month correlated, and conventional standard errors are too small (Moulton, 1987).

Lemma 11.44 (Moulton factor)**.** *Let $y_{it} = \beta_0 + \beta x_t + e_{it}$ for $i = 1, \dots, m$ observations in each of T months, with $e_{it} = v_t + w_{it}$, where v_t and w_{it} are independent with mean zero and variances σ_v^2 and σ_w^2. Let $\rho_e = \frac{\sigma_v^2}{\sigma_v^2 + \sigma_w^2}$. Then the variance of the OLS estimator $\hat{\beta}$ is $1 + (m-1)\rho_e$ times the conventional formula that treats the errors as independent.*

Lemma 11.44 is the special case of Proposition A.56 with months as clusters of size m. The error components make the errors homoskedastic with variance $\sigma_v^2 + \sigma_w^2$, independent across months and equicorrelated within a month with correlation ρ_e. The regressor is constant within a month, so its intra-cluster correlation is $\rho_x = 1$. Then (A.85) gives the factor $1 + (m-1)\rho_e$.

With 64 regions and an intra-month correlation of only 0.1, the factor is 7.3, and the correct standard error is 2.7 times the conventional one. Ashenfelter and Hosken (2010) cluster by month. Clustering by month also requires enough months, and serial correlation across months is a further concern in DiD designs (Bertrand et al., 2004).

11.6.5 Which mergers can we study? Selection by the agencies

The agencies screen proposed mergers and block or modify those they expect to raise prices. As Section 11.1.2 showed, about 97% of the mergers filed from 1991 to 2004 went ahead without a full investigation, and most of the rest were modified, abandoned or blocked. Retrospective samples therefore contain only cleared mergers. A simple model shows what such samples can reveal.

Assumption 11.45 (Screening on a noisy signal)**.** Merger m has a true price effect Δ_m. The agency observes a signal $S_m = \Delta_m + \eta_m$ and clears the merger if $S_m \le \bar{s}$. The pair (Δ_m, η_m) is jointly normal and independent across mergers, with Δ_m of mean μ_Δ and variance $V_\Delta > 0$, and η_m of mean zero and variance V_η, independent of Δ_m.

Proposition 11.46 (What cleared mergers reveal)**.** *Under Assumption 11.45,*

$$\mathbb{E}[\Delta_m \mid S_m \le \bar{s}] \;\le\; \mathbb{E}[\Delta_m \mid S_m = \bar{s}] \;\le\; \mathbb{E}[\Delta_m \mid S_m > \bar{s}],$$

and $\mathbb{E}[\Delta_m \mid S_m \le \bar{s}] \le \mu_\Delta$, the average effect without enforcement.

Proof. Joint normality gives the linear conditional expectation

$$\mathbb{E}[\Delta_m \mid S_m = s] = \mu_\Delta + k\,(s - \mu_\Delta), \qquad k = \frac{V_\Delta}{V_\Delta + V_\eta} \in (0, 1],$$

which is increasing in s. Averaging an increasing function over $s \le \bar{s}$ gives at most its value at $\bar{s}$, and averaging over $s > \bar{s}$ gives at least that value. Finally, μ_Δ is a weighted average of the cleared and blocked means, so it lies between them. □

A random sample of cleared mergers therefore gives a lower bound on the price effect of a typical merger in a world without enforcement (Carlton, 2009). That bound says little about policy, because most proposed mergers raise no competitive concern. The informative object is the effect of the *marginal merger*, $\mathbb{E}[\Delta_m \mid S_m = \bar{s}]$. If it is positive, enforcement under a consumer-welfare standard is too lenient at the margin. If it is negative, enforcement is too strict (Ashenfelter et al., 2013). Both studies below target the margin. Ashenfelter and Hosken (2010) pick cleared mergers that look most problematic from public information. Their estimates therefore bound from above the effects of other cleared mergers and from below the effects of blocked ones. Ashenfelter et al. (2013) study a merger that was nearly challenged. Two caveats apply. Researchers see public concentration measures, which are a noisy proxy for the agency's signal. And samples are also selected by data availability, which favors consumer products and formerly regulated industries such as airlines, banking and hospitals.

11.6.6 Stock-market event studies

Before scanner data, retrospectives used stock prices. The method of abnormal returns is developed in Section A.13, and Section 9.6.1 applies it to airline entry. Its application to mergers, due to Eckbo (1983) and Stillman (1983), looks at the merging firms' *rivals*. A merger that raises market power, through unilateral or coordinated effects, raises rivals' profits. A merger that makes the merged firm a more efficient and tougher competitor lowers them. News that raises the chance of the merger (the announcement) and news that lowers it (an antitrust complaint) therefore move rivals' values in opposite directions under each hypothesis. Table 11.15 lists the predictions.

Table 11.15: Predicted abnormal returns of rival firms

Hypothesis	Merger announcement	Antitrust complaint
Market power (higher post-merger prices)	+	−
Efficiency (merged firm a tougher rival)	−	+
Information (merger reveals industry-wide gains)	+	0

Notes: Signs of rivals' cumulative abnormal returns. Under the information hypothesis the announcement reveals profitable opportunities, such as scale economies or the value of rivals as future targets, that a complaint against one merger does not withdraw.

Eckbo (1983, p. 269) studies the rivals of 65 challenged horizontal mergers. On average they earned an abnormal return of 2.45 percent over the 31 days around the merger proposal, more than three standard deviations from zero. Over the 31 days around the antitrust complaint their average return was 1.78 percent, about one standard deviation from zero, so they did not lose. Eckbo concludes that the data generally reject the collusion hypothesis (p. 242). He reads the rivals' gains at the proposal as news of cost savings that they can also achieve. He calls this the productive efficiency hypothesis, which corresponds to the information row of Table 11.15. Stillman (1983, p. 240) studies the rivals of 11 challenged horizontal mergers attempted between 1964 and 1972. Only in the merger of Sterling Drug and Lehn and Fink did their returns broadly follow the market-power pattern. In nine of the 11 mergers the rivals showed no abnormal returns of any kind. These designs have known limits. Rival returns mix the three hypotheses. News may be anticipated, so the window captures only part of it. Rivals are often diversified firms, and the affected market can be a small part of their value. Many relevant rivals are not publicly traded. Woolley (1989) applies the method to 29 merger-related events in hospital chains between 1969 and 1985. Vita and Schumann (1991) criticize his choice of

events and rivals and note that listed chains own a small share of hospitals (Dafny, 2005, p. 11). McAfee and Williams (1988) study the 1979 acquisition of Kalvar by Xidex, two producers of duplicate microfilm. The FTC challenged the merger in September 1980 (p. 201). McAfee and Williams cite Barton and Sherman (1984), who find that the ratio of vesicular to diazo prices paid by the federal government rose about 25 percent after the merger (McAfee and Williams, 1988, p. 200). An event study of the rivals' returns nevertheless shows no evidence of harm (pp. 202–203). Asker and Nocke (2021, p. 231, n. 137) reach a similar verdict on the literature that runs from Eckbo (1983) and Stillman (1983) to Duso et al. (2007). Most authors in it are cautious about what an event study reveals about the competitive effects of a particular merger. In the words of Kaplow and Shapiro (2007), an event study "measures the expectations of investors about merger effects, not the actual effects of mergers." The method has worked best for patterns across large samples of mergers, as in Duso et al. (2007). For these reasons modern retrospectives measure prices directly.

11.6.7 Five consumer-product mergers: Ashenfelter and Hosken (2010)

Question and design. Ashenfelter and Hosken (2010) ask whether the mergers that the agencies let through raised consumer prices.[4] Their design follows Proposition 11.46. They search the Merger Yearbook for consummated mergers in consumer-product industries between 1997 and 1999 whose parties sold substitutes in concentrated markets. The period is fixed by the data, because the vendor sold scanner data only for the previous five years. Three of the five selected mergers went through without government action: Procter and Gamble's purchase of Tambrands, Aurora Foods' purchase of Kraft's Log Cabin syrup, and Pennzoil's purchase of Quaker State. Two were modified by the FTC: General Mills' purchase of Ralcorp's branded cereals and the merger of Guinness and Grand Metropolitan into Diageo. All five produced highly concentrated markets (HHI above 1,800) with HHI increases above 100 points, the 1992 Guidelines' presumption of harm.

The authors argue that these mergers sit near the enforcement margin. In the FTC's investigations of fiscal years 1996–2003, 46% of markets had post-merger HHI below 3,000 and 51% had increases below 800 points. All five mergers have post-merger HHIs below 3,000 and HHI changes between 200 and 1,000 points, so they sit near the median of the investigated markets (p. 12). The FTC acted in 25% of investigated markets with post-merger HHI below 2,500 (four of the five mergers) and in 44% of markets with increases below 800 (pp. 11–12).

The five mergers. Procter and Gamble bought Tambrands for $1.85 billion in July 1997, adding the leading tampon (Tampax) to the leading sanitary pad (Always). The Justice Department reviewed the deal and took no action. Guinness and Grand Metropolitan combined their spirits portfolios in a transaction valued at about $36 billion. The FTC found harm in premium scotch and premium gin and required the sale of the Bombay gins and Dewar's scotch to Bacardi for $1.9 billion. Pennzoil bought Quaker State for $1 billion in December 1998, combining two of the five premium motor-oil brands. General Mills bought the Chex cereals for $570 million in January 1997. Ralcorp kept its private-label business, the largest in the country, and the FTC's modifications let Ralcorp make private-label Chex at once. Aurora, owner of Mrs. Butterworth's, bought Log Cabin for $222 million in July 1997, joining two of the three major syrup brands (pp. 12–16). Table 11.16 reports shares and concentration, and Table 11.5 in Section 11.2.3 checked the reported changes in concentration against $2s_As_B$.

[4] We use the NBER working-paper version (Ashenfelter and Hosken, 2008). Table numbers and page references follow it.

Table 11.16: Five consumer-product mergers: concentration and aggregate price effects

				Aggregate price effect	
Transaction (industry)	Shares (%)	HHI	ΔHHI	Private label	Branded
General Mills / Ralcorp (cereal)	28, 4	2,357	238	0.032	0.057
				(0.005)	(0.005)
Pennzoil / Quaker State (motor oil)	29, 9	2,189	517	0.052	0.014
				(0.013)	(0.011)
P&G / Tambrands (feminine protection)	25, 19	2,815	959	0.070	0.023
				(0.008)	(0.007)
Aurora / Log Cabin (pancake syrup)	15, 19	1,990	589	0.004	0.012
				(0.011)	(0.005)
Guinness / Grand Met (liquor), overall	21, 22	2,026	935	0.027	−0.010
				(0.003)	(0.003)
gin				0.022	−0.021
				(0.005)	(0.003)
scotch				0.071	0.031
				(0.006)	(0.002)
vodka				0.011	−0.021
				(0.003)	(0.005)

Notes: Shares are pre-merger revenue shares of the acquirer and the target, in that order (for syrup, Aurora then Philip Morris's Log Cabin). HHI is the post-merger HHI and ΔHHI its change, from pre-merger revenue data, with private labels treated as one participant. Price effects are the revenue-weighted averages (11.78) of the product-level estimates of β_2 in (11.76), using the private-label or the branded control group. Standard errors in parentheses assume zero covariances among the components. The data come from IRI's food channel (64 regions) for cereal, feminine protection and syrup, its mass-merchandiser channel (10 regions) for motor oil, and its drug-store channel (5 regions) for liquor. Source: Ashenfelter and Hosken (2008), Tables 2 and 13.

Data. The data are weekly revenue and unit sales by Universal Product Code (UPC), purchased from Information Resources Inc. (IRI) and aggregated to months. IRI projects sales for each channel and metropolitan area from a sample of stores. The authors choose for each merger the channel that best represents consumer purchases. Food products use the food channel in 64 InfoScan markets. Motor oil uses the mass-merchandiser channel in 10 markets, because consumers who change their own oil buy it there. Liquor uses the only available source, a drug-store sample with complete data for five markets in three states. The markets are San Francisco, San Diego, Los Angeles, Chicago and Phoenix, which limits external validity (pp. 16–18). Motor oil is priced as revenue per quart for each brand and weight. Spirits are priced separately for the 750 ml and 1.75 litre bottles. The other categories use the five price measures of Section 11.6.4.

Estimation. The price equation (11.76) is fitted by OLS separately for each merging product, with standard errors clustered by month. The preferred specification uses the unit value, the symmetric window that drops three months on each side, and one of two control groups. The *private-label control* uses the store brands closest to each merging product. These are private-label motor oil, feminine hygiene products and maple-flavored syrup, private-label gin, scotch and vodka for the spirits, and private-label cereals in the same IRI segments for cereal. The *branded control* uses close branded substitutes, such as the three other premium motor oils (Havoline, Valvoline and Castrol). The authors treat the branded estimates mainly as a specification check, for the reason given in Proposition 11.39 (pp. 23–24). They also report regressions with no control group.

Results. Table 11.16 gives the aggregate effects (Table 13). With the private-label control, four

of the five mergers raised prices by roughly 3% to 7%. The estimates are 3.2 log points for General Mills and Chex, 5.2 for Pennzoil and Quaker State, 7.0 for Procter and Gamble and Tambrands, and 2.7 for Diageo. The syrup merger had no detectable effect (0.4). The branded control gives larger effects for cereal and syrup and smaller ones for the other three. The spirits merger illustrates the role of the control group. Scotch prices rose under both controls (7.1 and 3.1 log points), while gin and vodka rose relative to private labels and fell relative to branded rivals.

The product-level estimates show that the merged firms did not raise all prices together. Table 11.17 reproduces Table 3 for motor oil. Relative to private labels, Quaker State rose 8.1 log points and Quaker State Deluxe 6.1, while the much larger Pennzoil brand rose 3.9. In Table 3, Quaker State's increase ranks first among the 12 products compared, its own and the 11 branded controls. The text instead describes it as larger than all but one control brand (p. 28). Market shares moved accordingly. Quaker State lost 1.31 points of revenue share, 13.6% of its pre-merger share, while Pennzoil gained 4.22 points. Because Pennzoil's gain exceeded Quaker State's loss, it grew at the expense of rivals as well. The authors read this as a strategy of raising the price to customers loyal to Quaker State while holding the price of the larger brand (p. 29).

Table 11.17: Pennzoil and Quaker State: product-level price and share effects

	Price effect $\hat{\beta}_2$		Rank in control group		Change in revenue share	
Product	Branded	Private label	Branded	Private label	Points	Percent
Pennzoil	0.004	0.039	8/12	1/2	4.22	18.47
	(0.015)	(0.019)			(0.83)	
Quaker State	0.035	0.081	1/12	1/2	−1.31	−13.58
	(0.016)	(0.015)			(0.47)	
Quaker State Deluxe	0.021	0.061	4/12	1/2	−0.16	−5.95
	(0.021)	(0.022)			(0.13)	

Notes: Standard errors in parentheses. The rank orders the product's estimated price change among the control products in descending order: 8/12 means that seven control products had larger increases. Quantity shares move similarly (+4.46, −1.32 and −0.13 points). Monthly data from 10 regions of IRI's mass-merchandiser channel, January 1997 to December 2000, excluding October 1998 to March 1999. An observation is a product, city and month. The regressions have about 9,000 (branded control) and 2,000 (private-label control) observations. Source: Ashenfelter and Hosken (2008), Table 3.

The other mergers show the same selectivity (Tables 5, 7, 9 and 11). After buying Tambrands, Procter and Gamble raised the prices of Always liners and pads by 8.0 and 7.8 log points relative to store brands, and Tampax by 5.8. Relative to branded products the liner and pad increases were 6.1 and 4.5, and Tampax fell by 0.9. A later study of the same merger, Weinberg (2011), reports increases of 8 percent for Always pads and 5 percent for Tampax relative to private label (Asker and Nocke, 2021, p. 262). General Mills left the Chex prices almost unchanged (at most 0.8 log points under either control) and raised the prices of its own Cheerios and Wheaties brands. Cheerios rose 4.4 log points relative to store brands and 4.6 relative to branded cereals. Every scotch product rose relative to its private-label control, by 5.5 to 9.8 log points. For syrup, Log Cabin's 2.8 log point rise relative to branded syrups was not robust, and Mrs. Butterworth's prices did not change.

Robustness. For each merger, a summary table pools the estimates across windows, price measures and control groups (Tables 4, 6, 8, 10 and 12). For motor oil, all 18 estimates are positive. All nine private-label estimates have t-statistics above two, against three of the nine branded estimates. For feminine protection, 92% of the private-label estimates and 78% of

the branded ones are positive. About 90% of the cereal estimates are positive, and none of the negative ones is below −1%. For syrup, about two thirds fall between −1% and +1%. The choice of window mattered little except for cereal. The price measure left the signs unchanged and changed the magnitudes. With weekly data the cereal estimates depended heavily on the price measure, which points to stockpiling and package substitution (pp. 26–32). Regressions with no control group also show price increases after virtually every merger (Appendix Tables 3–7). For example, the no-control estimates for Quaker State and Always pads are 0.061 (0.016) and 0.053 (0.003).

Comparison with a merger simulation. The General Mills and Chex merger had been simulated by Nevo (2000b) with a random-coefficients demand model (Section 11.5). As cited by Ashenfelter and Hosken, the published simulation predicts increases before efficiencies of 12.2% for Chex, 1.1% for Cheerios, 0.8% for Honey Nut Cheerios and 0.1% for Wheaties (p. 32). The retrospective finds the opposite pattern: little change for Chex and increases for the General Mills brands. Possible reasons include the different data (quarterly data for 1988–1992 in the simulation), new product introductions, and the demand specification. The consent decree's provision for private-label Chex may also have restrained Chex pricing, an entry threat that a simulation with a fixed set of products cannot represent (footnote 60).

Interpretation and limitations. The best estimate of the price effect of mergers near the enforcement margin is positive and modest. This finding cuts against both camps in the enforcement debate. Advocates of less intervention expect the marginal merger to lower prices through efficiencies, and advocates of more intervention expect large increases (p. 35). The authors list three limitations themselves (p. 36). Consumer-product mergers are a small part of all mergers: 20 percent of the 8,013 filings in 1997 and 1998 shared the studied firms' two-digit industry codes. The design cannot capture longer-run efficiency effects or new products. Finally, the study examines only one kind of enforcement error, the failure to block harmful mergers, and leaves aside the blocking or deterrence of benign ones. Several further points deserve attention. The selection rests on public concentration measures, which may misjudge which mergers the agencies found marginal. The private-label control may itself be a substitute, especially in cereal, where Ralcorp kept a large store-brand business. The aggregate standard errors ignore covariances, as shown after (11.78). Retail scanner prices measure the merger's effect after retailers' pass-through. Finally, the results vary across products within a merger, so several products and specifications are tested for each merger, and some significant estimates will arise by chance.

Contribution. The paper turned merger retrospectives into a program-evaluation exercise with explicit attention to control groups, windows, price measurement and the selection of mergers. It shows that a cleared merger's effect can be concentrated on a few products, and it supplied the retrospective benchmarks later used to grade merger simulations.

11.6.8 A nearly blocked merger of appliance makers: Ashenfelter, Hosken and Weinberg (2013)

Question. Ashenfelter et al. (2013) estimate the price effects of Whirlpool's acquisition of Maytag.[5] The merger is a natural candidate for the marginal merger of Proposition 11.46.

[5]We use the NBER working-paper version (Ashenfelter et al., 2011). Table numbers follow it and may differ from the published article.

Commentators argued that the Justice Department would have challenged it a decade earlier, and the decision not to act came to symbolize lenient enforcement (Baker and Shapiro, 2008).

Background. In mid-2005 a group of private investors agreed to buy Maytag for $1.13 billion. The Haier Group, a Chinese appliance maker with little presence in the United States, then offered $1.3 billion. Whirlpool, the largest United States manufacturer, offered $1.4 billion on July 17, and Haier withdrew three days later. Whirlpool bought Maytag for $1.79 billion on March 30, 2006, after a long Justice Department investigation. The merger reduced the major appliance manufacturers from four (Whirlpool, Maytag, GE and Electrolux) to three. The Justice Department's closing statement of March 29, 2006, focused on washers and dryers and gave three reasons for not acting. GE and Electrolux had excess capacity, and the recent entrants LG and Samsung could expand imports. Large retailers had alternatives to resist price increases. The parties had substantiated large cost savings (printed pp. 4–6 and 21).

Market structure. Table 11.18 reproduces the pre-merger revenue shares. Whirlpool was the largest firm in dishwashers, dryers, refrigerators and washers, with 39% to 49% of revenue, and Maytag held 9% to 17%. The increase in the HHI matches $2 s_W s_M$ in every category up to rounding of the shares, within three points. In dryers, for example, $2 \times 48.8 \times 16.6 = 1{,}620$. The parties overlapped less in cooktops, freezers, ovens and ranges. Neither had more than 1 percent of freezer revenue, Maytag held 5 to 10 percent of the other three, and the implied HHI changes were 256 to 416 points. These four categories serve as comparison groups, restricted to brands not made by Whirlpool or Maytag.

Table 11.18: Whirlpool and Maytag: pre-merger revenue shares and concentration

Category	Whirlpool	Maytag	Largest rivals	HHI	ΔHHI
Treated categories					
Dishwashers	38.6	11.4	Electrolux 25.1, GE 12.5	2,453	880
Clothes dryers	48.8	16.6	GE 12.2, LG 9.6, Electrolux 8.9	2,983	1,620
Refrigerators	41.8	9.2	Electrolux 24.1, GE 10.9	2,595	770
Clothes washers	44.0	16.8	Electrolux 13.8, GE 10.5, LG 10.2	2,632	1,478
Comparison categories					
Cooktops	22.0	9.5	GE 20.8, Electrolux 19.1	1,571	416
Freezers	< 1	< 1	Electrolux 81.3, Haier 12.8	6,789	0
Ovens	32.5	6.3	GE 23.1, Electrolux 10.5	1,929	412
Ranges	24.7	5.2	Electrolux 37.6, GE 25.3	2,703	256

Notes: Revenue shares in percent from NPD data before the merger. HHI is the pre-merger HHI as labelled in the source. Neither party had more than 1% of freezer revenue before the merger. Kenmore, sold by Sears and partly made by Whirlpool, is not in the data. Source: Ashenfelter et al. (2011), Tables 1 and 2.

Data. The NPD Group supplied national monthly unit sales and revenue for each appliance model, identified by its stock-keeping unit (SKU), from January 2005 to September 2008. More than 14,000 SKUs enter during the period, and observed characteristics explain 85% to 95% of the variation in prices. Two features of the industry shape the design. First, most appliances have a life cycle of about a year. The authors estimate age profiles separately for each category,

$$\ln p_{jt} = \alpha_j + \sum_{k=2}^{25} \theta_k \, Age_{kjt} + \sum_{l=2}^{43} \delta_l \, Month_{lt} + e_{jt}, \tag{11.81}$$

$$\ln q_{jt} = \psi_j + \sum_{k=3}^{25} \lambda_k \, Age_{kjt} + \sum_{l=3}^{43} \gamma_l \, Month_{lt} + u_{jt},$$

where Age_{kjt} indicates that model j is k months old.[6] Prices of washers, dryers, dishwashers, refrigerators, freezers and ranges typically fall by more than 10% after a year, and monthly sales fall by about half. Ovens and cooktops show no such decline. The analysis therefore uses each model's first year only and controls for age by category. Second, many SKUs sell very few units. The sample keeps models with at least 1,000 units in their first 13 months (100 for freezers, ovens and cooktops). The retained models account for 90% to 99% of sales in the large categories (printed pp. 6–9).

Estimating equations. The baseline specification, fitted by OLS separately for each treated and comparison pair of categories, is

$$\ln p_{jt} = \beta_1 \, Maytag_j \, Post_t + \beta_2 \, Whirlpool_j \, Post_t + \sum_{k=3}^{13} \theta_k^T Age_{kjt}^T + \sum_{k=3}^{13} \theta_k^C Age_{kjt}^C + \sum_{l=2}^{43} \delta_l \, Month_{lt} + \alpha_j + e_{jt}. \quad (11.82)$$

It has separate age profiles for the treated (T) and comparison (C) categories, month effects and SKU fixed effects α_j. The SKU fixed effects have a cost. The interactions are collinear with α_j for any model sold only before or only after the merger. Equation (11.82) therefore identifies the effects only from models sold on both sides of the merger date. With one-year life cycles, these are old models, and the merged firm may have treated them differently from new ones. The authors therefore replace the fixed effects with observed characteristics and brand dummies, such as a stainless-steel indicator, size, capacity and cycles:

$$\ln p_{jt} = x_j^T \beta^T + x_j^C \beta^C + \sum_{l=2}^{43} \delta_l^C \, Month_{lt} + \beta_1 \, Maytag_j \, Post_t + \beta_2 \, Whirlpool_j \, Post_t + \sum_{k=3}^{13} \theta_k^T Age_{kjt}^T + \sum_{k=3}^{13} \theta_k^C Age_{kjt}^C + e_{jt}. \quad (11.83)$$

Here x_j^T is non-zero only for the parties' models and x_j^C only for comparison models. Standard errors are clustered by SKU. The check on this substitution is direct. On models sold both before and after the merger, the two specifications give estimates within 0.2 percentage points of each other against cooktops and ranges. Against cooktops, for instance, the Whirlpool dishwasher effect is 0.0432 with fixed effects and 0.0415 with characteristics (Appendix Table 1). The gaps reach 0.7 points against ovens and 1 to 2 points against freezers, well within one standard error (Appendix Tables 2–4). indicators.

The main specification splits each interaction by whether the model was introduced before (Old) or after (New) the merger, which adds 35% to 57% to the sample. A within-category variant compares the parties' models with rivals' models in the same category,

$$\ln p_{jt} = x_j \beta + \sum_k \theta_k \, Age_{kjt} + \sum_l \delta_l \, Month_{lt} + \beta_1 \, Maytag_j Post_t Old_j + \beta_2 \, Whirlpool_j Post_t Old_j + \beta_3 \, Maytag_j Post_t New_j + \beta_4 \, Whirlpool_j Post_t New_j + e_{jt}. \quad (11.84)$$

[6] In this subsection θ_k, δ_l, ψ_j, λ_k and γ_l are regression coefficients with no relation to their meanings elsewhere in the book.

By Proposition 11.39, the rival comparison is biased toward zero if rivals' models are substitutes. Finally, product variety is measured by the number of SKUs selling at least 100 units a month,

$$\ln SKU_{ft} = a + b\, WM_f + g\, Post_t + \delta^V\, WM_f\, Post_t + e_{ft}, \tag{11.85}$$

where f is either the merged firm ($WM_f = 1$) or all rivals together. The coefficient δ^V is the proportional change in the merged firm's product count relative to rivals.

Identification. The comparison categories identify the counterfactual price path. The design assumes that cooktops, freezers, ovens and ranges made by other firms would have followed the same age- and characteristic-adjusted price trend as the treated categories. All are durable goods bought with new homes and remodeling, so they share much of the demand shock from the housing market. The data are national, so there is no geographic variation. Identification rests entirely on comparisons across categories and, in (11.84), across firms within a category.

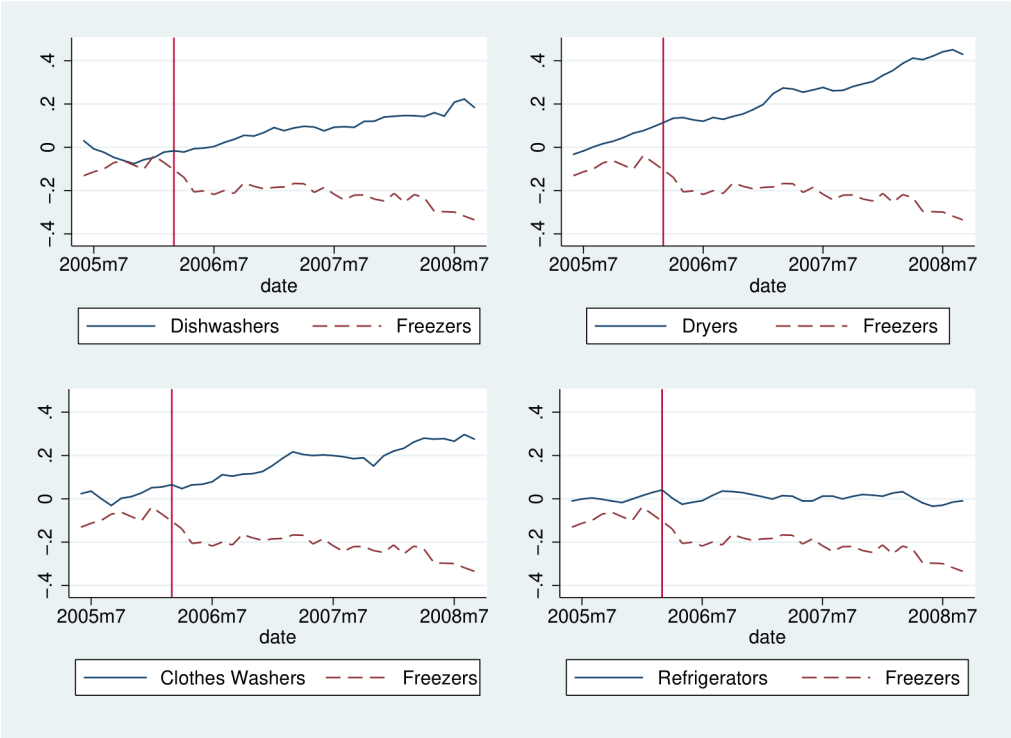

Figure 11.14: Average log prices of Whirlpool and Maytag appliances (solid) and of freezers (dashed), adjusted for product characteristics and age, May 2005 to September 2008. The vertical line marks consummation (March 30, 2006). Dishwasher, dryer and washer prices rise relative to freezers after the merger. Refrigerator prices do not. The averages pool old and new models. The vintage-split regressions of Table 11.19 find no increase for new washers. Source: Ashenfelter et al. (2011), Figure 5.

Results. Figure 11.14 plots adjusted prices against freezers. Table 11.19 reproduces the regression estimates for the four treated categories against each comparison category (Tables 3 to 6) and against rivals in the same category (Table 7). The clearest effects are for models introduced after the merger. New Whirlpool dryers rose by 13.3 to 17.1 log points relative to the comparison categories, all significant. New Maytag dishwashers rose by 4.8 to 7.4 log points, all significant at 5%. New Whirlpool refrigerators rose by 1.9 to 3.9 log points, significant except against freezers. The authors give this result little weight. They describe "a small price

increase, 2-4%, for Whirlpool refrigerators" that is "imprecisely estimated and not as robust as the findings for clothes dryers or dishwashers" (printed pp. 15–16). The within-category estimate is only 0.008 (0.009), and their abstract concludes that there were "no price effects for refrigerators or clothes washers" (PDF p. 1). Asker and Nocke (2021, p. 262) quote the same sentence from the published abstract. Washers show no increase. New Whirlpool washers in fact fell by 1.5 to 4.1 log points. Estimates for models introduced before the merger depend on the comparison category. They tend to be positive against cooktops and freezers and smaller or negative against ovens and ranges. The within-category comparison tells the same story: new Maytag dishwashers rose 8.2 log points and new Whirlpool dryers 7.3 log points relative to rivals' new models.

Market shares and variety. Table 11.20 reproduces Table 8. The merged firm's revenue share fell significantly in every treated category, by 4.6 points in dishwashers, 9.5 in dryers, 8.6 in refrigerators and 7.3 in washers. The fall is consistent with the price increases in dryers and dishwashers. It also occurred in refrigerators and washers, where prices did not rise, so it cannot be due to price alone. The merged firm cut its product line. The number of high-volume Whirlpool and Maytag SKUs fell by about 10 a month in dryers and washers and by about 12 in refrigerators. Relative to rivals, who expanded their lines, the merged firm's count fell by 22 to 53 log points.

Interpretation. The merged firm raised the prices of new Whirlpool dryers by about 14% and new Maytag dishwashers by about 7% (printed p. 22). By the authors' own reading, it did not raise refrigerator or washer prices. The washer result is the puzzle, because Whirlpool and Maytag had similar positions in washers and dryers. The authors point to a technological shift in washers. Buyers were moving from top-loading machines, where the parties were strong, to front-loading machines, where LG and Samsung competed strongly. The Justice Department's entry argument may thus have held for washers. For dryers and dishwashers the factors it cited did not keep prices at pre-merger levels. The fall in variety may be a further consumer cost that price studies miss (Berry and Waldfogel, 2001; Sweeting, 2010).

Limitations. The comparison categories are a judgment call. Freezers and ranges may respond differently to the 2006–2008 housing downturn than dryers and dishwashers, and the estimates for old models vary with the comparison category. The comparison categories are made by GE and Electrolux, which compete with the merged firm in the treated categories, so multimarket responses could reach them. Clustering by SKU allows serial correlation within a model. It does not allow for common monthly shocks across models in a category. Because the post-merger indicator varies only by month, such shocks would make the reported standard errors too small (Lemma 11.44). The data omit Kenmore, which Whirlpool partly supplied to Sears. Finally, the split by vintage is informative only if introductions after the merger are comparable to earlier ones in unobserved quality. The fixed-effect comparison can check this condition only for models sold on both sides of the merger date.

Contribution. The study supplies a retrospective of a merger chosen for being at the margin of enforcement. It shows that effects can be concentrated in new products, which a design based on SKU fixed effects would miss. It also documents a cut in variety alongside the price effects.

11.6.9 Hospital mergers and rival analysis with an instrument: Dafny (2009)

Question. Comparisons of merging and non-merging firms suffer from selection, because firms that merge differ from those that do not. Suppose financially distressed hospitals are

(2011), Table 8.

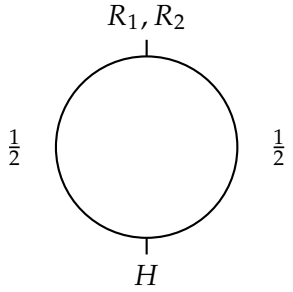
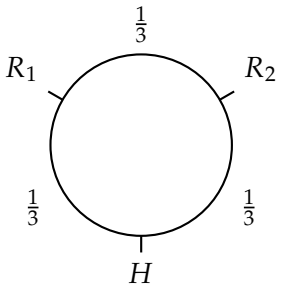
more likely to merge and would have cut costs and prices anyway. A comparison of merging and non-merging hospitals then attributes those cuts to the merger. Eckbo (1983) proposed *rival analysis*, which drops the merging firms and compares the outcomes of firms with merging rivals to those of firms without. With strategic complements, rivals raise prices when merging firms do. Rival analysis still suffers from selection, because markets with mergers differ from markets without them. Dafny (2009) combines rival analysis with an instrument for exposure to a rival's merger.[7] Hospitals are a natural setting, because a wave of hospital mergers in the 1990s met agencies that lost every court challenge.

Theory. The instrument rests on a spatial model, Salop's circular city (Salop, 1979). A unit mass of consumers is spread uniformly on a circle of circumference one. Each buys one unit, values it at v, and incurs a transport cost t per unit of distance. Marginal costs are zero. Two markets have three hospitals each: the hospital of interest H and two rivals R_1 and R_2. In market 1 the rivals are *co-located*, at the same point opposite H. In market 2 the three hospitals are evenly spaced (Figure 11.15).



Market 1: co-located rivals



Market 2: evenly spaced

Figure 11.15: The two hypothetical markets of the theory. Each circle has circumference one, and the fractions give the arc lengths between neighboring hospitals. In market 1 the rivals R_1 and R_2 are co-located opposite H. In market 2 the three hospitals are evenly spaced. Redrawn from Dafny (2005), Figure 1.

Consider market 1 before the rivals merge. Co-located rivals are undifferentiated Bertrand competitors, so they price at cost, $p_R = 0$. A consumer at distance x from H is at distance $\frac{1}{2} - x$

[7] We use the NBER working-paper version of 2005, revised October 2007 (Dafny, 2005). Page references are to its printed pages.

from the rivals. She buys from H if $p_H + tx \le t(\frac{1}{2} - x)$, that is if $x \le \frac{1}{4} - \frac{p_H}{2t}$. Counting both sides of H, its profit is

$$\pi_H = p_H \cdot 2\Big(\frac{1}{4} - \frac{p_H}{2t}\Big).$$

The first-order condition $\frac{1}{2} - \frac{2p_H}{t} = 0$ gives $p_H^* = \frac{t}{4}$. Now let the rivals merge into one firm R with price p_R. The indifferent consumer moves to $x = \frac{1}{4} - \frac{p_H - p_R}{2t}$, and

$$\pi_H = p_H \cdot 2\Big(\frac{1}{4} - \frac{p_H}{2t} + \frac{p_R}{2t}\Big).$$

The first-order condition is $\frac{1}{2} - \frac{2p_H}{t} + \frac{p_R}{t} = 0$. By symmetry $p_H = p_R$, so $p_H^* = \frac{t}{2}$. The merger of co-located rivals doubles H's price. Before the merger the rivals priced at cost. After it they price like a differentiated firm, and H responds to their higher price.

In market 2 the three hospitals are $\frac{1}{3}$ apart. Before the merger the standard symmetric Salop equilibrium gives $p_H^* = \frac{t}{3}$. Suppose that after the merger one rival facility closes and the other stays put, so H and R are $\frac{1}{3}$ apart on one side and $\frac{2}{3}$ on the other. H's demand is $\frac{1}{6} + \frac{p_R - p_H}{2t}$ on the short arc plus $\frac{1}{3} + \frac{p_R - p_H}{2t}$ on the long arc. Profit $p_H(\frac{1}{2} + \frac{p_R - p_H}{t})$ gives the condition $\frac{1}{2} + \frac{p_R}{t} - \frac{2p_H}{t} = 0$, so $p_H^* = \frac{t}{2}$ at the symmetric equilibrium. The increase is from $\frac{t}{3}$ to $\frac{t}{2}$, or 50%, against 100% in market 1. Mergers of co-located rivals raise prices more because the merger removes a fiercer pre-merger rivalry.

These formulas hold when t is small relative to v, so that every consumer buys and the hospitals compete for the marginal consumer. Market 1 requires $t < \frac{4v}{3}$ after the merger and market 2 requires $t < \frac{6v}{5}$. For larger t the marginal consumer's reservation value binds, and demand has a kink. Dafny's Appendix 1 gives the full solutions:

$$\text{Market 1:}\quad p_H^{*,pre} = \begin{cases} \frac{t}{4}, & t < \frac{8v}{3}, \\ 2v - \frac{t}{2}, & \frac{8v}{3} < t < 3v, \\ \frac{v}{2}, & t > 3v, \end{cases} \qquad p_H^{*,post} = \begin{cases} \frac{t}{2}, & t < \frac{4v}{3}, \\ v - \frac{t}{4}, & \frac{4v}{3} < t < 2v, \\ \frac{v}{2}, & t > 2v, \end{cases}$$

$$\text{Market 2:}\quad p_H^{*,pre} = \begin{cases} \frac{t}{3}, & t < 2v, \\ v - \frac{t}{6}, & 2v < t < 3v, \\ \frac{v}{2}, & t > 3v, \end{cases} \qquad p_H^{*,post} = \begin{cases} \frac{t}{2}, & t < \frac{6v}{5}, \\ v - \frac{t}{3}, & \frac{6v}{5} < t < \frac{3v}{2}. \end{cases}$$

In the middle ranges the hospitals price so that the consumer midway between them gets zero surplus. Take market 1 before the merger. Consumers within $\frac{v}{t}$ of the rivals buy from them at price zero. H can sell to everyone else only if the consumer at distance $\frac{1}{2} - \frac{v}{t}$ from H gets zero surplus from H. That condition gives $p_H = v - t(\frac{1}{2} - \frac{v}{t}) = 2v - \frac{t}{2}$.[8] Figure 11.16 plots the solutions with $v = 1$.

Dafny reports that with $v = 1$ the average price increase is 66.7% in market 1 and 40% in market 2 (footnote 37). We can reproduce these numbers as percentage gaps between average post-merger and average pre-merger prices. The averages are taken over the range of t in which

[8] For market 2 after the merger, the appendix gives $\frac{v}{2}$ for all $t > \frac{3v}{2}$. Our derivation differs on part of this range. For $\frac{3v}{2} < t < 3v$ the two remaining hospitals are local monopolists on the long arc but still compete on the short arc. Their symmetric equilibrium price is $\frac{2v}{5} + \frac{t}{15}$ for $\frac{3v}{2} < t < \frac{18v}{7}$ and $v - \frac{t}{6}$ for $\frac{18v}{7} < t < 3v$, and it is $\frac{v}{2}$ only for $t > 3v$. We checked numerically that these prices are equilibria and that $\frac{v}{2}$ is not. The difference lies outside the range used for the comparison in the text.

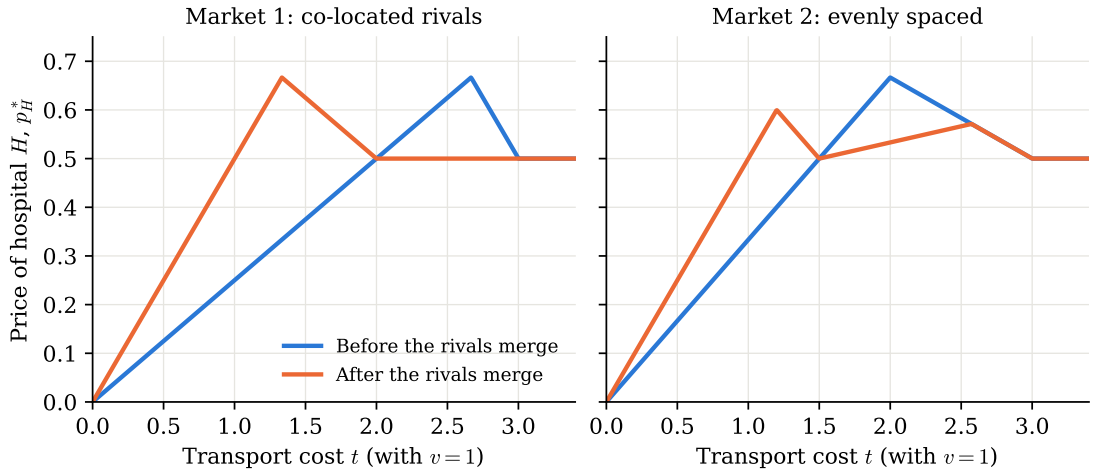


Figure 11.16: Equilibrium price of hospital H before and after its two rivals merge, as a function of the transport cost t, with $v = 1$. Left: co-located rivals. Right: evenly spaced hospitals, one of whose rival facilities closes after the merger. Solutions from Dafny (2005), Appendix 1, with the market-2 post-merger curve for $t > \frac{3}{2}$ derived in the footnote.

the post-merger hospitals still compete, $t < 2v$ in market 1 and $t < \frac{3v}{2}$ in market 2. In market 1 the average pre-merger price over $(0, 2)$ is 0.250 and the average post-merger price is 0.417. In market 2 the averages over $(0, \frac{3}{2})$ are 0.250 and 0.350. Two predictions follow. Co-located hospitals are more likely to merge, because they gain more market power and can cut duplicate departments. And a merger of co-located rivals raises the prices of nearby hospitals by more. The number of co-located rival pairs near a hospital is therefore a candidate instrument for exposure to rival mergers.

Setting. Until 1984 hospitals were paid largely on a cost-plus basis. Medicare's Prospective Payment System of 1984 paid a fixed amount per admission in each diagnosis-related group, and by 1989 most hospitals lost money on Medicare patients. Managed care rose from under 30% of private insurance in 1988 to nearly 95% by 1999, replacing fee-for-service payment with negotiated prices. There were 190 hospital mergers between 1989 and 1996, against 74 between 1983 and 1988. Since 1991 the agencies had tried to block seven hospital mergers and lost every time, often because courts accepted that non-profit hospitals would not exploit market power (printed pp. 8–9).

Data. Merger data come from Dranove and Lindrooth (2003), who identify 97 independent hospital mergers between 1989 and 1996. An independent merger combines two hospitals outside any system into a single entity that reports one set of accounts and surrenders a license. The sample starts from general, non-federal hospitals in the 1988 American Hospital Association survey, located in metropolitan areas or counties with more than 100,000 residents. Price comes from Medicare cost reports. It is non-Medicare inpatient revenue per case-mix-adjusted non-Medicare discharge, with charges deflated by each hospital's contractual discounts and Medicare's case-mix index as a proxy for the non-Medicare one. The tails at the 5th and 95th percentiles are censored. Co-location is measured from geocoded addresses. Two hospitals are co-located if they are within 0.3 miles as the crow flies and no more than five blocks apart. Of 213 hospitals within 0.3 miles of another, 191 (3.6% of 5,373) pass the map check (printed pp. 12–15).

Table 11.21 summarizes the two samples. In the All Hospitals sample of 4,487 hospitals, 178 (4.0%) merged and 163 (3.6%) were co-located. Eighteen of the 163 merged, a rate of 11% against 3.7% for other hospitals. The Rivals Sample contains the 877 non-merging hospitals with at least two rivals within 7 miles and complete price data. Of these, 118 had a merging rival (NMW, for non-merging with merging rivals) and 759 did not (NMWO). The two groups differ. NMW hospitals have nearly twice as many rivals, more Medicaid patients and slightly higher penetration of health maintenance organizations (HMOs). Their prices grew by −2.9% between 1985 and 1988, against 4.2% for NMWO hospitals. Treating rival mergers as exogenous would therefore understate their effect.

Table 11.21: Hospital mergers: sample means

	All hospitals	Rivals Sample		
		All	NMW	NMWO
1988 price ($ of 2000)	3,404	4,057	3,737	4,107
1997 price ($ of 2000)	3,851	4,091	3,823	4,133
$\ln p_{1988} - \ln p_{1985}$	0.064	0.032	−0.029	0.042
$\ln p_{1997} - \ln p_{1988}$	0.132	0.010	0.020	0.009
$\ln p_{2000} - \ln p_{1997}$	0.013	0.001	0.039	−0.005
Merged, 1989–1996 (%)	4.0			
Co-located (%)	3.6			
Number of rival mergers, R_i		0.156	1.161	0
Number of co-located rival pairs, Z_i		0.332	0.712	0.273
Number of rivals within 7 miles	3.16	7.37	12.03	6.64
Medicaid share of discharges (%)	11.4	11.2	15.1	10.6
County HMO penetration (%)	14.5	21.3	23.7	20.9
Hospitals	4,487	877	118	759

Notes: NMW (NMWO) are non-merging hospitals with (without) a rival within 7 miles that merged in 1989–1996. Price change variables are censored at the 5th and 95th percentiles. Characteristics are for 1988, HMO penetration for 1994. Selected rows. Source: Dafny (2005), Table 1.

Estimating equations. For hospital i in the Rivals Sample, let R_i be the number of rival mergers within 7 miles between 1989 and 1996. Let Z_i be the number of co-located rival pairs within 7 miles in 1988, excluding any pair to which i belongs. Let X_i be a vector of 1988 hospital and market characteristics. The outcome is the change in log price between 1988 and 1997, $\Delta \ln p_i$, which spans the year before the first merger to the year after the last. Because the instrument predicts whether but not when a rival merges, the design uses one long difference. The equations are

$$\text{first stage:} \qquad R_i = \pi Z_i + X_i^\top \omega_F + u_i, \tag{11.86}$$

$$\text{reduced form:} \qquad \Delta \ln p_i = \phi Z_i + X_i^\top \omega_R + \varepsilon_i^R, \tag{11.87}$$

$$\text{structural equation:} \qquad \Delta \ln p_i = \beta R_i + X_i^\top \omega + v_i. \tag{11.88}$$

Here ε_i^R is an error term.[9] The coefficient β is the effect of one rival merger on a hospital's price growth. OLS on (11.88) is biased if $\mathrm{Cov}(R_i, v_i) \neq 0$. The NMW and NMWO comparison above suggests that markets with mergers had weaker price growth for other reasons, which biases OLS downward.

The IV estimator. With one endogenous regressor and one instrument, the model is exactly identified. Let $\tilde{Z}_i$ be the residual from regressing Z_i on X_i. By the Frisch-Waugh-Lovell

[9] Here ε_i^R denotes a regression error, not an elasticity.

theorem, the OLS coefficients on Z_i in (11.86) and (11.87) are $\hat{\pi} = \frac{\sum_i \tilde{Z}_i R_i}{\sum_i \tilde{Z}_i^2}$ and $\hat{\phi} = \frac{\sum_i \tilde{Z}_i \Delta \ln p_i}{\sum_i \tilde{Z}_i^2}$. The IV estimator of β is

$$\hat{\beta}_{IV} = \frac{\sum_i \tilde{Z}_i \, \Delta \ln p_i}{\sum_i \tilde{Z}_i \, R_i} = \frac{\hat{\phi}}{\hat{\pi}}, \tag{11.89}$$

the ratio of the reduced-form coefficient to the first-stage coefficient. Substituting (11.88) shows $\hat{\beta}_{IV} = \beta + \frac{\sum_i \tilde{Z}_i v_i}{\sum_i \tilde{Z}_i R_i}$, which converges to β under two conditions (Appendix A). *Relevance* requires $\pi \neq 0$. *Exclusion* requires $\mathbb{E}[\tilde{Z}_i v_i] = 0$. Co-location of rivals must affect price growth only through the mergers it induces. Suppose the effect of a rival merger differs across hospitals and co-location never makes a merger less likely. IV then estimates a weighted average of the effects of the mergers that co-location induces (Imbens and Angrist, 1994).

Dafny defends exclusion on three grounds. Location is nearly fixed. There has been very little hospital entry since the Hill-Burton Act of 1946, so co-location in 1988 cannot reflect entry in anticipation of price growth during 1988–1996. Fewer than 1% of sample hospitals had a rival that exited, and controlling for exits leaves the results unchanged (footnote 27). The theory is then used to sign the most likely omitted factor, the growth of managed care. Managed care lowered buyers' willingness to pay, which acts like a fall in v. In the solutions above, v matters only in the kinked ranges, where the pre-merger price falls two for one with v in market 1 and one for one in market 2. Dafny argues that over the relevant range of t, prices are at least as sensitive to v where rivals are co-located. The spread of managed care should then, if anything, slow price growth in those markets and bias the estimate toward zero (printed p. 22). Finally, the exclusion restriction has testable implications, discussed next.

Results. Table 11.22 collects the main estimates. Co-location raises a hospital's own probability of merging by 6.6 percentage points (6.2 with state fixed effects). In the Rivals Sample one more co-located rival pair raises the number of rival mergers by 0.119 (0.112 with state fixed effects), against a mean of 0.16. The implied first-stage F statistic is about $(\frac{0.119}{0.018})^2 \approx 44$, so the instrument is strong. The reduced form for 1988–1997 is 0.045, against mean price growth of 0.010. The IV estimate is the ratio (11.89):

$$\hat{\beta}_{IV} = \frac{\hat{\phi}}{\hat{\pi}} = \frac{0.045}{0.119} \approx 0.376, \qquad e^{0.376} - 1 \approx 46\%.$$

The ratio of the rounded coefficients is 0.378. The paper reports 0.376, which equals the ratio of the unrounded coefficients (footnote 29). With state fixed effects the estimate is 0.301, or about 35%. A rival merger thus raised nearby hospitals' prices by about 40%, enough to move a hospital from the 25th to the 65th percentile of price growth. OLS gives 0.016 and −0.003, both insignificant, and a Hausman test rejects their equality with the IV estimates.

Tests of the exclusion restriction. The reduced forms in Panel B are falsification tests. Co-located rival pairs predict price growth only during the merger wave. Before it (1985–1988) the coefficient is small and negative, and after it (1997–2000) it is close to zero. The mergers thus appear to have caused a one-time increase in price levels, with no lasting change in trend. The pre-period test matters because NMW hospitals had lower pre-period growth in the raw data. An overidentification test uses two instruments, the numbers of rival pairs less than 0.2 miles apart and 0.2 to 0.3 miles apart. The statistic NR^2 from regressing the 2SLS residuals on all exogenous variables is 0.36, with a p-value of 0.55 under a $\chi^2(1)$ distribution (Hausman, 1983). Such a test has power only against violations that differ between the two distance bands.

Table 11.22: Hospital mergers: first stage, reduced forms and the effect of rival mergers

Equation	Dependent variable	Without state FE	With state FE	N
A. First stage: coefficient on co-location				
Own merger on own co-location	Merged, 1989–1996	0.066 (0.016)	0.062 (0.016)	4,487
Rival mergers on Z_i, (11.86)	R_i	0.119 (0.018)	0.112 (0.019)	877
B. Reduced form: coefficient on Z_i, (11.87)				
Placebo, before the wave	$\ln p_{1988} - \ln p_{1985}$	−0.016 (0.010)	−0.013 (0.011)	877
Treatment period	$\ln p_{1997} - \ln p_{1988}$	0.045 (0.014)	0.034 (0.015)	877
Placebo, after the wave	$\ln p_{2000} - \ln p_{1997}$	−0.008 (0.013)	−0.001 (0.014)	703
C. Effect of rival mergers on $\ln p_{1997} - \ln p_{1988}$, (11.88)				
IV, instrument Z_i		0.376 (0.132)	0.301 (0.147)	877
OLS		0.016 (0.026)	−0.003 (0.027)	877

Notes: Standard errors in parentheses. All specifications include the hospital characteristics (ownership, teaching status, Medicaid share, debt-to-asset ratio, occupancy, bed-size categories) and market characteristics (metropolitan-area population categories, HMO penetration, log per-capita income). Panel A, first row: All Hospitals sample, linear probability model. Other rows: Rivals Sample. Source: Dafny (2005), Tables 2, 3 and 4.

Robustness. Table 11.23 reports the main sensitivity checks. Across co-location definitions the 7-mile estimates range from 0.326 to 0.511. The market radius matters more. With a 5-mile radius the estimates more than double, and with 10 miles they are small and insignificant. Effects concentrated on the closest rivals are what the spatial model predicts, and they suggest that hospital markets are smaller than the 15 to 20 miles often assumed. Dropping all controls barely changes the estimate (0.352 against 0.380 in the baseline of the appendix table). By the logic of Altonji et al. (2005), this stability suggests that unobserved characteristics, if they relate to the instrument as the observed ones do, do not drive the result. Controlling for the number of rivals, dropping co-located hospitals, using a negative binomial first stage, or using price levels gives estimates of the same sign and similar size.

Table 11.23: Hospital mergers: sensitivity of the IV estimate

A. Market radius and co-location definition

	0.2 miles	0.3 miles	0.3 miles and ≤ 5 blocks	0.4 miles
5 miles (N = 722)	0.992 (0.687)	0.851 (0.340)	0.962 (0.377)	1.116 (0.603)
7 miles (N = 877)	0.511 (0.298)	0.326 (0.125)	0.376 (0.132)	0.431 (0.221)
10 miles (N = 1,041)	0.046 (0.082)	0.038 (0.050)	0.051 (0.054)	0.021 (0.072)

B. Specification checks (7 miles, 0.3 miles and ≤ 5 blocks)

Specification	Estimate	N
(1) Baseline	0.380 (0.132)	877
(2) No hospital or market controls	0.352 (0.132)	877
(3) Dependent variable not censored	0.402 (0.143)	877
(4) Dummies for the number of rivals	0.408 (0.198)	877
(5) Co-located hospitals dropped	0.326 (0.122)	816
(6) Negative binomial first stage	0.222 (0.099)	877
(7) Change in price level ($ of 2000)	1,566 (563)	877

Notes: 2SLS estimates of β in (11.88) without state fixed effects, standard errors in parentheses. Panel A, column 3, row 2 is the main specification of Table 11.22. Panel B, row 1 is printed as 0.380 in the appendix table and as 0.376 in the main table. Source: Dafny (2005), Table 5 and Appendix Table 1.

Interpretation. The estimates imply large price increases by the rivals of merging hospitals, about 40% per rival merger. Prior longitudinal studies, which compared merging and non-merging hospitals or treated rival mergers as exogenous, found no effect or a negative one (Connor and Feldman, 1998). The OLS estimates here reproduce that null, and the IV estimates show it to be a selection artifact. The magnitudes are close to those of structural models of hospital choice, which predict increases of 10% to 58% for hypothetical mergers in markets with few competitors (Capps et al., 2003; Gaynor and Vogt, 2003). Those predictions ignore rivals' responses and may be too low for that reason (footnote 35). The retrospective thus supports prospective structural analysis of hospital mergers. Combined with the 14% cost reductions that Dranove and Lindrooth (2003) find for the same type of merger, the results imply large profit gains for merging hospitals.

Limitations. The estimate is local. It measures the effect of the rival mergers that co-location induces, which are mergers of undifferentiated hospitals with unusually large gains in market power. It measures rivals' responses and says nothing direct about the merging hospitals' own prices, which may rise more or less. The specification is linear in the number of rival mergers and ignores distance within the 7-mile circle. The price measure relies on list charges, a contractual discount factor and the Medicare case-mix index. Prices are negotiated with insurers, so the outcome reflects bargaining between hospitals and managed-care plans, which the Salop model abstracts from (Gal-Or, 1999; Capps et al., 2003; Ho, 2009). Gowrisankaran et al. (2015) build this bargaining into a merger simulation for hospitals. They combine the simulation method of Section 11.5 with the Nash-in-Nash bargaining framework of Crawford and Yurukoglu (2012). They find that insurers' bargaining power can substantially counteract the market power that hospital mergers create (Asker and Nocke, 2021, p. 238). The exclusion restriction can fail if co-located hospitals sit in old urban cores whose demand evolved differently during the 1990s. The placebo regressions address this concern only for the years around the wave. Finally, the long difference uses only cross-sectional variation, so the timing of mergers is not exploited.

Contribution. The paper shows how to combine rival analysis with an instrument, so that a retrospective can address the selection of mergers. It produced the first observational evidence of large price effects of hospital mergers and showed that relevant hospital markets are small. It also lent support to the structural models used to evaluate proposed hospital mergers. The idea transfers to other industries in which distance in physical or product space shifts the propensity to merge.

11.6.10 What the retrospective literature finds

The three studies above are part of a growing literature. Asker and Nocke (2021, Section 3.7 and Appendix A) survey the retrospectives published between 2000 and 2020 in the leading general-interest journals and the main industrial organization journals. For each study they record the date of the transaction, the country and the industry, and they quote the sentence that best states the authors' conclusion. They chose quotes over a standardized measure of the price effect, because studies differ too much in units, outcomes and focus (p. 256, n. 201).

Three selection issues limit what the collection can teach (Asker and Nocke, 2021, pp. 255–256). First, the studied mergers were cleared by the authorities, so blocked and deterred mergers are absent (Section 11.6.5). Second, the studies come from industries where data are available, which tilts the sample toward consumer-facing markets and regulated industries with administrative data. Few retrospectives study intermediate goods. Third, the studied mergers tend to be large or to offer a chance to study some phenomenon of interest. The

collection is not a random sample of cleared mergers.

Five themes emerge (Asker and Nocke, 2021, p. 257).

(i) The price effects vary widely. Some prices rise, at times by a lot, others do not move, and some fall. Asker and Nocke find this range the most striking feature of the literature.

(ii) Few studies estimate the change in consumer welfare. Many treat price changes as a sufficient statistic.

(iii) The outcome variables differ. Most studies measure the prices of the merging firms' products. Some also measure rivals' prices, and others measure quantities or market shares.

(iv) Few studies examine longer-run dynamics. Focarelli and Panetta (2003) compare short-run and long-run price effects, and Igami and Uetake (2020) study innovation.

(v) Few retrospectives study product quality, variety, entry and exit, or investment.

Table 11.24 reproduces a selection of the entries, chosen to cover the range of industries and findings. Read together, the studies show that consummated mergers can harm consumers, which supports the value of merger review. The range of outcomes also argues for evaluating each merger in the context of its industry (Asker and Nocke, 2021, p. 257).

11.7 Does merger simulation work? The Swedish analgesics merger

A merger simulation (Section 11.5) makes a prediction that can be checked. If a simulated merger is later consummated, a retrospective of the kind developed in Section 11.6 measures its actual effects, and the two can be compared. Such validation studies are rare, because they need a merger that was simulated or could be simulated with pre-merger data, and post-merger data on the same market. Björnerstedt and Verboven (2016) carry out one for a merger of painkiller producers in Sweden. They built the simulation for the Swedish Competition Authority during its review, before the outcome was known. A few years later they compared its predictions with what happened.[10]

11.7.1 Question and setting

Question. Do the merger simulations used by competition authorities predict the price effects of actual mergers? And which modeling choices matter for the answer?

Setting. The market is over-the-counter analgesics in Sweden. Products differ by active substance (paracetamol, ibuprofen and acetylsalicylic acid, ASA, sold as aspirin), by administrative form (ordinary tablets and effervescent, or fizzy, tablets), and by brand, pack size and dose. In 2008 paracetamol held 42.1 percent of sales value, ibuprofen 29.0 percent and ASA 28.9 percent (Björnerstedt and Verboven, 2013, Table 1). Paracetamol and ibuprofen are sold mainly as tablets, and ASA mainly as fizzy tablets.

GlaxoSmithKline (GSK) notified its acquisition of AstraZeneca Tika (AZT) on December 22, 2008. The Swedish Competition Authority cleared it on April 3, 2009 (Björnerstedt and

[10] We use pp. 134, 137 and 147 of the published article, which contain its Figures 1 and 2 and its Table 6, and its abstract. The institutional facts, the data, the estimating equations, the instruments and the robustness checks come from the January 2013 working paper (Björnerstedt and Verboven, 2013). The published version adds random coefficients models and re-estimates the nested logit, so the working-paper numbers differ from those of its Table 6.

Table 11.24: A selection of merger retrospectives

Date	Country	Industry	Main finding	Study
Single transactions				
1987	USA	Airlines	Prices rose 5.0 to 6.0 percent on routes that one carrier served and the other could enter, more than half the rise on routes where the two had competed	Kwoka and Shumilkina (2010)
1997	USA	Tampons, pads	Always pads up 8 percent and Tampax up 5 percent relative to private label	Weinberg (2011)
1999	France	Supermarkets	Rivals' affected stores up about 2 percent (1.8 to 2.4), and the merging firms' prices up 4 to 5 percent	Allain et al. (2017)
1999	USA	Gasoline	No evidence of higher prices	Simpson and Taylor (2008)
2001	Sweden	Beer	Merging firms' prices roughly constant around the merger, other main brewers' prices up somewhat, divested beers down relative to both	Friberg and Romahn (2015)
2006	USA	Appliances	Increases for dishwashers and larger ones for dryers, none for refrigerators or washers. The merged firm's share and product count fell	Ashenfelter et al. (2013)
2008	USA	Airlines	Small fare effects where Delta and Northwest competed: insignificant in nonstop markets, 2.3 percent in connecting markets	Luo (2014)
Multiple transactions				
1989–1996	USA	Hospitals	Prices up roughly 40 percent after nearby rivals merge	Dafny (2009)
1990–1998	Italy	Retail banking	Adverse price changes are temporary, and in the long run efficiency gains dominate	Focarelli and Panetta (2003)
1993–2000	Canada	Mortgages	Significant average rise in interest rates, some borrowers unaffected, and lower price dispersion	Allen et al. (2014)
1996–2006	USA	Radio	Ad quantity down 11 percent and ad prices up 6 percent. Listener welfare up 0.2 percent, advertiser welfare down 21 percent	Jeziorski (2014)
1996–2015	Global	Hard disk drives	The rule that blocks mergers when three or fewer firms exist is reasonably close to maximizing discounted welfare	Igami and Uetake (2020)
1997–2010	USA	Dialysis	In more than 1,200 acquisitions, acquired facilities raised doses of highly reimbursed drugs, replaced skilled nurses with technicians and waitlisted fewer patients. Hospitalizations and mortality rose	Eliason et al. (2020)
1997–2012	USA	Hospitals	Of 28 mergers, 9 raised prices and 6 lowered them significantly relative to controls. Mean change 8.9 percent, median 9.6 percent	Garmon (2017)
1998–2000	USA	Consumer goods	Four of five mergers raised some prices, typically by 3 to 7 percent	Ashenfelter and Hosken (2010)
1998–2006	USA	Health insurance	Premiums about 7 percentage points higher by 2007 from rising local concentration, and monopsony power over physicians	Dafny et al. (2012)
2007–2011	USA	Hospitals	Of 366 mergers, prices up more than 6 percent when the hospitals were within about 5 miles, no effect beyond about 25 miles	Cooper et al. (2019)
2007–2008	USA	Grocery	Five mergers raised prices by more than 2 percent (four in highly concentrated markets), five lowered them by more than 2 percent, four had little effect	Hosken et al. (2018)

Notes: Paraphrased from the quotations collected by Asker and Nocke (2021, Appendix A, pp. 262–265), whose table lists the date of the transaction, the country, the industry and a quotation from each paper. The radio entry was also checked against the author's manuscript of Jeziorski (2014). The appliance, hospital (1989–1996) and consumer-goods entries are studied in Sections 11.6.7 to 11.6.9.

Verboven, 2013, p. 6). The two firms were the only sellers of paracetamol (Björnerstedt and Verboven, 2016, p. 137). AZT sold Alvedon, with 29.3 percent of 2008 sales value, and Reliv, with 2.2 percent. GSK sold Panodil, with 10.6 percent. McNeil led the other two segments, with Ipren in ibuprofen (19.1 percent) and Treo and Magnecyl in ASA (25.6 percent together). Nycomed, Meda and Bayer held the remaining 13.2 percent (Björnerstedt and Verboven, 2013, Table 2).

Until 2009 all sales went through the state pharmacy monopoly, Apoteket AB. It added a fixed percentage markup to the producers' wholesale prices and charged the same price in every pharmacy, so producers set retail prices indirectly (Björnerstedt and Verboven, 2013, pp. 6 and 9). The authority cleared the merger on two grounds. It judged that consumers choose brands more than substances. It also expected the deregulation of pharmacies, decided for 2009, to bring entry and stronger buyers. Its decision cited the authors' simulation as showing no significant price increase. The authors note that their simulations predicted an insignificant increase only in a scenario with large efficiencies (pp. 6–8). Entry after the deregulation was surprisingly slow (Björnerstedt and Verboven, 2016, p. 134). Ibuprofen and ASA are therefore the substitutes that discipline the paracetamol price.

Data. During its review the authority obtained monthly sales data for 1995 to 2008 from Apoteket. A product is a brand, form, pack size and dose, such as Alvedon tablets in packs of 30 pieces of 500 mg. An observation of product j in month t records the price p_{jt}, the volume q_{jt} and the revenue $r_{jt} = p_{jt}q_{jt}$. Prices include value-added tax and are the prices every consumer paid. The data are merged with monthly marketing expenditures by brand and with monthly counts of sick men and sick women from Statistics Sweden. The full sample has 11,185 product-months. The estimation sample keeps the three main substances and the two main forms. It has 7,240 product-months, about 43 products per month, and covers about 90 percent of sales value (Björnerstedt and Verboven, 2013, Section 2.3). Painkillers have no natural unit of consumption. The authors measure volume in tablets, in defined daily doses and in normal single doses, and they report results for tablets. Table 11.25 reproduces the main summary statistics. For the retrospective the authors later obtained the same data for 2008 to May 2011. The 2008 figures matched those of the original data (p. 10).

Table 11.25: Swedish analgesics: summary statistics of the estimation sample, 1995–2008

Variable	Mean	Std. dev.	Min.	Max.
Revenue r_{jt} (million SEK)	1.24	2.56	0.00	22.95
Price per tablet p_{jt} (SEK)	1.06	0.46	0.27	2.55
Tablets sold q_{jt} (million)	1.11	2.19	0.00	16.61
Marketing expenditures	564.1	1,445.7	0	13,536
Sick women	822.9	197.0	391	1,204
Sick men	524.5	108.0	254	763
Nominal GDP (billion SEK)	621.6	107.4	443.2	859.7

Notes: 7,240 product-months. Selected rows. The paper does not state the units of marketing expenditures and of the sickness counts. In December 2008 one euro was 10.8 SEK and one US dollar 8.0 SEK. Source: Björnerstedt and Verboven (2013), Table 3.

11.7.2 The retrospective evidence

Figures 11.17 and 11.18 show what happened. Paracetamol prices drifted up from about 1.39 kronor in April 2007 to about 1.50 at the end of 2008. Within two months of the merger they

jumped to about 1.99 and stayed near that level. Ibuprofen prices, at about 1.67, did not move at the merger. ASA prices rose modestly, from about 1.41 to about 1.55 kronor. These readings are taken from the figure. In logs the plotted paracetamol jump is about $\ln \frac{1.99}{1.50} \approx 0.28$, and the ASA increase is about $\ln \frac{1.55}{1.41} \approx 0.10$. The paracetamol share of the analgesics market fell from a peak of about 49% just before the merger to about 41%, then recovered to 43% to 45%. The ibuprofen share jumped from about 27% to about 32%, and the ASA share stayed near 24% to 26%. Consumers substituted mainly toward ibuprofen.

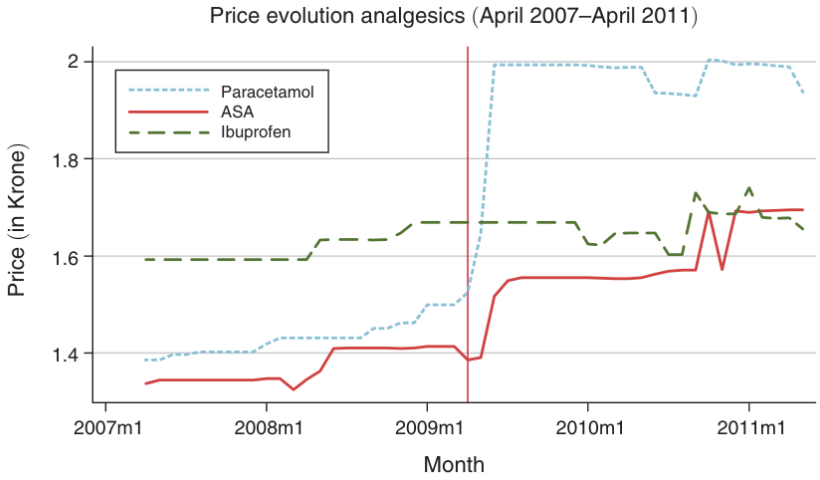

Figure 11.17: Average prices of paracetamol, ASA and ibuprofen analgesics in Sweden, April 2007 to April 2011, in kronor. The vertical line marks the merger (April 2009). Source: Björnerstedt and Verboven (2016), Figure 1.

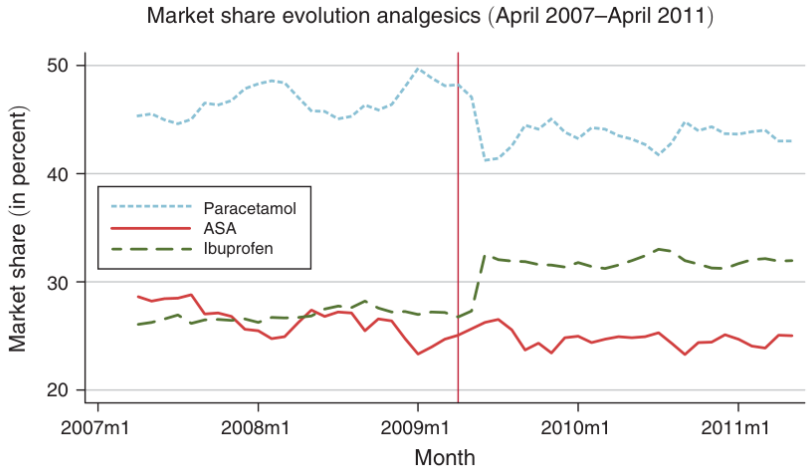

Figure 11.18: Market shares of paracetamol, ASA and ibuprofen analgesics in Sweden, April 2007 to April 2011, in percent. The vertical line marks the merger (April 2009). Source: Björnerstedt and Verboven (2016), Figure 2.

The stability of ibuprofen prices suggests that the paracetamol increase was not caused by a general cost or demand shock (Björnerstedt and Verboven, 2016, p. 134). A regression in the

spirit of Ashenfelter and Hosken (2010) makes the comparison precise:

$$\ln p_{gt} = \alpha_g + \beta_g \, PostMerger_t + e_{gt}. \tag{11.90}$$

Here p_{gt} is the average price of product group g in month t. The indicator $PostMerger_t$ equals one after the merger. The published version defines groups by substance and by substance and firm (p. 134). Each group has its own post-merger change β_g, which is more general than a common change for all control groups. The difference between the merging firms' β_g and a rival group's β_g is a DiD estimate of the merger effect. By Proposition 11.39, a rival control yields a lower bound when rivals raise prices in response.

The published version compares one year before and one year after the merger. The short window keeps out later effects of the deregulation (Björnerstedt and Verboven, 2016, p. 134 and eq. (1)). The article reports that the merging firms raised prices by 40 percent and that some outsiders raised prices by more than 10 percent (Björnerstedt and Verboven, 2016, abstract). Its Table 4 gives price changes of 39.7 percent for paracetamol, 0.1 percent for ibuprofen and 13.3 percent for ASA (p. 135). Table 11.28 reports the working paper's estimates, in log points. They compare two years on each side of the merger, April 2007 to April 2009 against May 2009 to May 2011, and define groups by substance and by firm (Björnerstedt and Verboven, 2013, Table 7).

The paracetamol price rose by 0.351 log points, or 42 percent. Ibuprofen prices did not move (0.001), and ASA prices rose by 0.100 log points, or 11 percent. With ibuprofen as the control the DiD estimate is 0.350. With ASA as the control it is 0.251, or 29 percent. Pooling the two rival substances into one control gives 0.30, or 35 percent (Björnerstedt and Verboven, 2013, fn. 17). The ASA increase is consistent with a rival response, so the ASA-based estimate understates the effect on paracetamol prices. Both merging firms raised prices by similar amounts, 0.356 log points for AZT and 0.379 for GSK. Among the outsiders, Bayer raised prices by 0.105 and McNeil by 0.084 log points. The regressions compare average log prices of product groups over the two windows, so they need not match the jump in the plotted average price.

The same design applied to volume shares shows where demand went. The paracetamol share fell by 3.3 percentage points, with a 95 percent confidence interval of 2.7 to 3.9 points. The ibuprofen share rose by 5.0 points, and the ASA share fell by 1.6 points. AZT lost 5.6 points, while GSK's loss of 0.3 points is insignificant. McNeil lost 2.7 points, and the other outsiders gained a little (Björnerstedt and Verboven, 2013, pp. 31–32).

11.7.3 The prospective models

The simulation has the structure of Section 11.5: estimate demand on pre-merger data, recover marginal costs from the pre-merger first-order conditions, change the ownership matrix, and solve for the new equilibrium. Two demand families are used, each in two versions.

Nested logit. Consumer i chooses among products $j \in \mathcal{J}$ and an outside good $j = 0$. Products are grouped into nests g, and each nest into subnests h. In the authors' maintained specification the nests are the two administrative forms, and the subnests are the substances within each form (Björnerstedt and Verboven, 2013, p. 20). We first present the one-level version, with nests g only. Its utility is

$$u_{ij} = \delta_j + \zeta_{ig} + (1 - \sigma)\epsilon_{ij},$$

where δ_j is mean utility, ϵ_{ij} is type-I extreme value, and ζ_{ig} has the distribution that makes $\zeta_{ig} + (1 - \sigma)\epsilon_{ij}$ extreme value (Cardell, 1997). The nesting parameter $\sigma \in [0, 1)$ measures the

correlation of tastes within a nest (Chapter 7). As in Section 11.4.2, let $H_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma}}$. Market shares are

$$s_j = s_{j|g}\, s_g, \qquad s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{H_g}, \qquad s_g = \frac{H_g^{1-\sigma}}{1 + \sum_{g'} H_{g'}^{1-\sigma}}, \tag{11.91}$$

and the outside share is $s_0 = \frac{1}{1+\sum_{g'} H_{g'}^{1-\sigma}}$.

Lemma 11.47 (Nested logit share derivatives)**.** *For products $j \neq k$,*

$$\begin{aligned}
\frac{\partial s_j}{\partial \delta_j} &= s_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j\right], \\
\frac{\partial s_j}{\partial \delta_k} &= -s_j\left[\frac{\sigma}{1-\sigma} s_{k|g} + s_k\right] \quad \textit{if } k \textit{ is in } j\textit{'s nest}, \\
\frac{\partial s_j}{\partial \delta_k} &= -s_j s_k \quad \textit{if } k \textit{ is in another nest.}
\end{aligned}$$

Proof. Taking logs of (11.91) gives $\ln s_j = \frac{\delta_j}{1-\sigma} - \sigma \ln H_g - \ln\left(1 + \sum_{g'} H_{g'}^{1-\sigma}\right)$. Section 11.4.2 computed the derivatives of the last two terms on the way to (11.41). The derivative of $\ln H_g$ with respect to δ_k is $\frac{s_{k|g}}{1-\sigma}$ for $k \in g$ and zero otherwise. The derivative of the log of the denominator is s_k for every inside product k. Hence $\frac{\partial \ln s_j}{\partial \delta_k}$ equals $\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j$ for $k = j$, $-\frac{\sigma}{1-\sigma} s_{k|g} - s_k$ for $k \neq j$ in the same nest, and $-s_k$ for k in another nest. Multiplying each by s_j gives the lemma. □

Inverting (11.91) gives the linear estimating equation $\ln s_j - \ln s_0 = \delta_j + \sigma \ln s_{j|g}$ (Chapter 7). The two-level version adds the subnests h within each nest g, with parameters $0 \leq \sigma_2 \leq \sigma_1 < 1$. Here σ_1 measures the correlation of tastes within a subnest and σ_2 within a nest. With unit demand its estimating equation is

$$\ln s_j - \ln s_0 = x_j \beta - \alpha\, p_j + \sigma_1 \ln s_{j|hg} + \sigma_2 \ln s_{h|g} + \xi_j, \tag{11.92}$$

where $s_{j|hg}$ is j's share of its subnest and $s_{h|g}$ the subnest's share of the nest (Verboven, 1996; Björnerstedt and Verboven, 2013, eq. (9)).[11] The authors also estimated the reverse order, with substances as nests and forms as subnests. It gave $\sigma_1 < \sigma_2$, which is inconsistent with random utility maximization, so they kept forms as the nests (p. 20). Let $\vartheta_1 = \frac{1}{1-\sigma_1} - \frac{1}{1-\sigma_2} \geq 0$, $\vartheta_2 = \frac{\sigma_2}{1-\sigma_2}$ and $s_{j|g} = s_{j|hg} s_{h|g}$. The share derivatives are

$$\begin{aligned}
\frac{\partial s_j}{\partial \delta_j} &= s_j\left[\frac{1}{1-\sigma_1} - \vartheta_1\, s_{j|hg} - \vartheta_2\, s_{j|g} - s_j\right], \\
\frac{\partial s_j}{\partial \delta_k} &= -s_j\left[\vartheta_1\, s_{k|hg} + \vartheta_2\, s_{k|g} + s_k\right] \quad \text{(same subnest)}, \\
\frac{\partial s_j}{\partial \delta_k} &= -s_j\left[\vartheta_2\, s_{k|g} + s_k\right] \quad \text{(same nest, other subnest)}, \\
\frac{\partial s_j}{\partial \delta_k} &= -s_j s_k \quad \text{(other nest)}.
\end{aligned}$$

[11] We verified (11.92) and the derivatives below numerically against the two-level share formulas.

Cross-elasticities are largest within a subnest, smaller between subnests of the same nest, and smallest across nests. Under the maintained order, the closest substitutes share both form and substance, and the most distant differ in form. The estimates in Table 11.26 below show this ordering.

Unit demand and constant expenditures. The two versions differ in how price enters utility and what a market share measures (Björnerstedt and Verboven, 2013, Section 3.1). Consumer i, with income y_i, gets utility $u_{ij} = x_j\beta + \xi_j + \alpha f(y_i, p_j) + \epsilon_{ij}$ from product j. Conditional on choosing j, she buys d_{ij} units, given by Roy's identity:

$$d_{ij} = -\frac{\frac{\partial f(y_i,p_j)}{\partial p_j}}{\frac{\partial f(y_i,p_j)}{\partial y_i}}.$$

Unit demand sets $f(y_i, p_j) = y_i - p_j$. Both derivatives have absolute value one, so $d_{ij} = 1$. Constant expenditures sets $f(y_i, p_j) = \frac{1}{\gamma}\ln y_i - \ln p_j$ for a constant $\gamma \in (0, 1)$. Then

$$d_{ij} = -\frac{-\frac{1}{p_j}}{\frac{1}{\gamma y_i}} = \frac{\gamma y_i}{p_j},$$

so the consumer spends the fraction γ of her income on the chosen product. In both versions the income term is common to all products of consumer i, so it drops out of the choice probabilities. These remain the nested logit formulas, now evaluated at the mean utilities given below. Summing d_{ij} times the choice probability over consumers gives aggregate demand. With unit demand $q_j = s_j M$, where M is the number of consumers. With constant expenditures $q_j = \frac{s_j B}{p_j}$, where $B = \gamma \sum_i y_i$ is the potential budget for the category.

In the *unit demand* version each consumer buys at most one unit. Mean utility is linear in price, $\delta_j = x_j\beta - \alpha p_j + \xi_j$, and shares are volume shares, $s_j = \frac{q_j}{M}$ for a potential number of units M. Since $\frac{\partial \delta_k}{\partial p_k} = -\alpha$, the elasticities in the one-level model are

$$\begin{aligned} \varepsilon_{jj} &= -\alpha\, p_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}s_{j|g} - s_j\right], \\ \varepsilon_{jk} &= \alpha\, p_k\left[\frac{\sigma}{1-\sigma}s_{k|g} + s_k\right] \text{ (same nest)}, \qquad \varepsilon_{jk} = \alpha\, p_k s_k \text{ (other nest)}, \end{aligned} \tag{11.93}$$

where $\varepsilon_{jj} < 0$ is the own-price elasticity in signed form. Elasticities are proportional to price. Expensive products have more elastic demand, and the own elasticity of a product rises as its price rises.

In the *constant expenditures* version each consumer spends a fixed budget on the category. Mean utility is linear in log price, $\delta_j = x_j\beta - \alpha \ln p_j + \xi_j$, and shares are value shares, $w_j = \frac{p_j q_j}{B}$ for a potential budget B. The formulas (11.91) now give w_j. Quantity is $q_j = \frac{B w_j}{p_j}$, so $\ln q_j = \ln B + \ln w_j - \ln p_j$, and $\frac{\partial \delta_k}{\partial \ln p_k} = -\alpha$. The quantity elasticities are

$$\begin{aligned} \varepsilon_{jj} &= -\alpha\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}w_{j|g} - w_j\right] - 1, \\ \varepsilon_{jk} &= \alpha\left[\frac{\sigma}{1-\sigma}w_{k|g} + w_k\right] \text{ (same nest)}, \qquad \varepsilon_{jk} = \alpha\, w_k \text{ (other nest)}. \end{aligned} \tag{11.94}$$

These depend on prices only through value shares, so they are roughly constant along the demand curve. The extra -1 in the own elasticity reflects the fixed budget. A higher price lowers the quantity bought even at an unchanged value share, and that lost quantity is diverted to no other product.

Substituting value shares into the inverted two-level system gives the constant-expenditure estimating equation

$$\ln w_j - \ln w_0 = x_j\beta - \alpha \ln p_j + \sigma_1 \ln w_{j|hg} + \sigma_2 \ln w_{h|g} + \xi_j, \tag{11.95}$$

where $w_0 = 1 - \sum_k w_k$ is the outside value share. Here $w_{j|hg}$ and $w_{h|g}$ are the value shares within the subnest and the nest (Björnerstedt and Verboven, 2013, eq. (10)). The equation differs from (11.92) in three ways. Price enters in logs, shares are measured in value, and the potential market is a budget B rather than a number of consumers. The authors note that this version had not been used in empirical work, although it is as easy to estimate as the unit-demand version (pp. 2–3).

The difference matters for mergers through pass-through (Section 11.4.4). Under unit demand, demand becomes more elastic as price rises, which restrains post-merger price increases. Under constant expenditures, the merged firm faces roughly constant elasticities and can push prices further. The contrast is the one between linear or logit demand and constant-elasticity demand in Figure 11.11.

Random coefficients. The nested logit restricts substitution to the hierarchy of nests and subnests. It also rules out correlated preferences along continuously measured characteristics (Björnerstedt and Verboven, 2016, p. 137). The published version therefore adds the random coefficients logit of Berry et al. (1995) (Chapter 8), again in unit-demand and constant-expenditure versions. Tastes for product characteristics vary across consumers, which yields more flexible substitution patterns. The model has four random coefficients, on the dummies for fizzy tablets, paracetamol and the branded products (Alvedon, Ipren and Treo), and on the constant (Björnerstedt and Verboven, 2016, p. 143). The price coefficient is common to all consumers (Table 5). The model needs no prior hierarchy of nests, and the branded-product coefficient allows the substitution among brands that the competition authority considered relevant.

Estimation and identification. Both nested logit equations, (11.92) and (11.95), are linear in parameters. The authors estimate them by linear instrumental variables on the panel of product-months (Björnerstedt and Verboven, 2013, Section 4.1). The regressors are price or log price, the two within-group shares, marketing expenditures and the numbers of sick women and sick men. The equations also include a time trend, month-of-year dummies and a fixed effect for each of the 56 products. The product effects absorb pack size, dose and other fixed characteristics. The potential market is twice the average amount bought over the period, in units for unit demand and in value for constant expenditures.

Price and the two within-group shares are endogenous, because they depend on ξ_j. The base instruments are counts of other products, overall and within the same firm, nest and subnest. The exclusion restriction is the usual one of Berry et al. (1995): the set of products on offer is uncorrelated with the demand shocks. With product effects in the equation, the counts vary only through the entry and exit of products over time. More rivals in a subnest lower a product's within-subnest share and its markup at fixed own quality, and these shifts identify α, σ_1 and σ_2. Marketing is treated as exogenous, on the argument that the product effects absorb its main correlation with ξ_j (pp. 20–21). The published version estimates the random coefficients models as in Chapter 8. The contraction mapping recovers mean utilities

from shares, and the parameters are estimated by GMM as in BLP (Björnerstedt and Verboven, 2016, p. 158). A first stage uses the instruments of Berry et al. (1995), sums of the characteristics with random coefficients over the firm's other products and over rivals' products. A second stage uses optimal instruments (Section A.5.5). The share integral is approximated by a nested quadrature rule (pp. 143–144 and n. 7).

Supply and simulation. Firms set prices in a multi-product Bertrand-Nash equilibrium. With Ω the ownership matrix and Δ the matrix of quantity derivatives with elements $\frac{\partial q_j}{\partial p_k}$, the first-order conditions are $q + (\Omega \odot \Delta)^\top (p - mc) = 0$. Marginal costs are recovered from these conditions at pre-merger prices. For a single-product firm under constant expenditures, profit is $(p_j - c_j)\frac{Bw_j}{p_j} = \left(1 - \frac{c_j}{p_j}\right) Bw_j$. Let $\eta_j = \frac{\partial \ln w_j}{\partial \ln p_j} < 0$. Setting the derivative of profit to zero gives

$$\frac{c_j}{p_j^2} w_j + \left(1 - \frac{c_j}{p_j}\right)\frac{\partial w_j}{\partial p_j} = 0 \quad \Longrightarrow \quad \frac{c_j}{p_j} + \left(1 - \frac{c_j}{p_j}\right)\eta_j = 0 \quad \Longrightarrow \quad L_j = \frac{p_j - c_j}{p_j} = \frac{1}{1 - \eta_j} = \frac{1}{|\varepsilon_{jj}|},$$

the inverse elasticity rule. The merger is simulated by joining AZT and GSK in Ω, with no efficiencies, and solving the post-merger conditions for prices. The authors solve them by fixed-point iteration, dampened when it fails to converge, and Newton's method gives the same results (Björnerstedt and Verboven, 2013, p. 18).

The working paper also allows *partial coordination*, in which each firm puts a weight $\phi \in (0, 1)$ on its rivals' profits before and after the merger. The zeros of Ω then become ϕ. This ϕ is unrelated to the coefficient ϕ of (11.87). The authors set $\phi = 0.75$, because it makes the implied pre-merger marginal costs consistent with cost information available to the authority (pp. 18 and 23).

11.7.4 Predictions and outcomes

Demand estimates. Table 11.26 reproduces the working paper's nested logit estimates. Both versions satisfy $1 \geq \sigma_1 \geq \sigma_2 \geq 0$, with strict inequalities. Products of the same form and substance are the closest substitutes, products of the same form and another substance come next, and products of another form are the most distant (Björnerstedt and Verboven, 2013, p. 21). Marketing raises demand in both versions, and demand peaks in December and March. The unit-demand version gives a negative coefficient on sick women, which the authors suspect picks up other effects. The implied elasticities differ sharply. The average own elasticity is −2.68 under constant expenditures and −12.4 under unit demand. The unit-demand range, from −24.1 to −3.9, is roughly proportional to the range of prices. The constant-expenditure range is narrow, from −2.84 to −1.91.

Predictions during the review. The authority received predictions for four scenarios in each version (Björnerstedt and Verboven, 2013, Table 5). Under constant expenditures and Bertrand conduct, the paracetamol price was predicted to rise by 34.0 percent, or by 4.7 percent with a 25 percent cut in marginal cost. Under partial coordination the predictions were 28.4 and −0.1 percent. Under Bertrand conduct, unit demand predicted 12.9 percent without the cost cut and 1.6 percent with it. Under partial coordination it predicted 16.1 and 9.0 percent. The implied pre-merger markups were 0.49 and 0.76 under constant expenditures, and 0.16 and 0.54 under unit demand. The authors preferred constant expenditures for two reasons. Its elasticities neither rise mechanically with price nor depend on the unit of consumption. Its

Table 11.26: Swedish analgesics: nested logit demand estimates in the working paper

	Constant expenditures		Unit demand	
	Estimate	Std. error	Estimate	Std. error

Notes: Linear IV estimates of (11.95) and (11.92) on 7,240 product-months, 1995–2008. Nests are forms and subnests are substances within a form. The paper reports the price coefficient as $-\alpha$. Price enters in logs under constant expenditures and in SEK per tablet under unit demand. Both regressions include 56 product fixed effects and month dummies. Robust standard errors. Standard errors of the elasticities use the delta method for an average product. Source: Björnerstedt and Verboven (2013), Table 4.

markups were also broadly in line with the variable costs reported by the parties, while the unit-demand markups were well below them (pp. 24–25).

The published estimates. Table 11.27 reproduces Table 6 of the published version, which re-estimates the nested logit and adds the random coefficients models. The four specifications imply very different demand. The average own-price elasticity is −2.43 in the constant-expenditure nested logit and −8.84 in the unit-demand nested logit. The random coefficients logit gives −2.05 and −3.61. Unit demand also produces a much wider range of own elasticities across products, from −5.16 to −15.45 in the nested logit, because elasticities are proportional to prices. Cross-elasticities are larger within a substance than across substances in every specification.

Table 11.27: Swedish analgesics: price elasticities, markups and predicted price effects

	Nested logit		Random coefficients logit	
	Constant expenditures	Unit demand	Constant expenditures	Unit demand
Brand-level price elasticities				
Own	−2.43	−8.84	−2.05	−3.61
Own (range)	(−3.05, −2.00)	(−15.45, −5.16)	(−2.61, −1.51)	(−6.52, −1.99)
Cross, same substance	0.30	2.12	0.12	0.36
Cross, different substance	0.05	0.28	0.05	0.19
Markups (percent)				
Paracetamol	48.5	17.3	59.0	44.7
Ibuprofen	45.0	11.8	55.7	32.3
ASA	59.1	22.9	66.5	44.5
Basic predicted price effects (percent)				
Paracetamol	41.1	15.9	21.29	9.34
Ibuprofen	1.2	0.5	0.75	0.76
ASA	1.5	0.6	0.81	0.45

Notes: All numbers are averages across products for December 2008, except the ranges in parentheses. Markups are Lerner indices $\frac{p-c}{p}$ implied by the pre-merger Bertrand-Nash conditions. The predicted price effects merge the two paracetamol sellers, with no efficiencies. Source: Björnerstedt and Verboven (2016), Table 6.

The markups follow from the elasticities. The inverse of the average own elasticity is 41% in the constant-expenditure nested logit, 11% in the unit-demand nested logit, 49% and 28% in the two random coefficients models. The reported markups are higher, for two reasons. Multi-product firms internalize cannibalization among their own products, which raises markups above the single-product rule. And the average of $\frac{1}{|\varepsilon_{jj}|}$ across products exceeds the inverse of the average elasticity, because the function $\frac{1}{x}$ is convex. The second effect is large under unit demand, where the inverse elasticities range from 6.5% to 19.4% in the nested logit.

Comparison with the outcome. The merging firms raised prices by about 40 percent (Section 11.7.2). The prediction made during the review, 34 percent under constant expenditures and Bertrand conduct, came close. The re-estimated constant-expenditure nested logit of Table 11.27 predicts 41.1 percent, almost exactly the outcome. The constant-expenditure random coefficients model predicts 21.3 percent, about half of it. The unit-demand models predict 15.9 and 9.3 percent, far too little, and so did the unit-demand prediction of 12.9 percent made during the review. The unit-demand nested logit also implies markups of 11.8% to 22.9%. Information available to the competition authority suggested that actual paracetamol margins were higher, which casts further doubt on the unit-demand specification (Björnerstedt and Verboven, 2016, p. 147).

The average price effect is only one prediction. Table 11.28 sets the working paper's preferred model against the outcomes for each substance and firm. Two predictions fail. First, the model predicted that GSK, the smaller paracetamol seller, would raise prices far more than AZT, by 59.8 against 21.3 percent. In the logit model a merger equalizes the markups of a firm's products, and the smaller firm starts with lower markups (Björnerstedt and Verboven, 2013, p. 26). In fact the two firms raised prices by similar amounts. Second, the model predicted rival price increases of at most 1.7 percent under Bertrand conduct. ASA prices rose by 11 percent, and Bayer and McNeil raised prices by about 9 to 11 percent. Every model in Table 11.27 predicts rival increases between 0.45 and 1.5 percent. Partial coordination raises the predicted rival increases to 2.5 to 4.1 percent, still below the outcomes. The shares tell the same story. The ASA share fell instead of rising, consistent with its price increase, and the paracetamol share fell by 3.3 points instead of the predicted 7.1.

Table 11.28: Swedish analgesics: predicted and actual effects of the merger

	Price			Volume share (points)		
	Predicted (%)		Actual	Predicted		Actual
	Bertrand	Partial	(log points)	Bertrand	Partial	
Substances						
Paracetamol	34.1	28.0	0.351 (0.007)	−7.1	−5.4	−3.3 (0.3)
Ibuprofen	0.7	4.1	0.001 (0.005)	3.7	2.7	5.0 (0.1)
ASA	0.8	3.0	0.100 (0.004)	3.3	2.7	−1.6 (0.3)
Firms						
AZT (merging)	21.3	19.5	0.356 (0.006)	−3.4	−2.7	−5.6 (0.5)
GSK (merging)	59.8	45.1	0.379 (0.009)	−3.7	−2.7	−0.3 (0.2)
Nycomed	0.6	4.0	0.012 (0.003)	1.3	0.9	0.1 (0.5)
Meda	0.1	2.7	0.029 (0.044)	0.6	0.5	1.1 (0.6)
McNeil	1.7	4.1	0.084 (0.005)	5.1	3.9	−2.7 (0.5)
Bayer	0.1	2.5	0.105 (0.008)	0.1	0.1	0.5 (0.1)

Notes: Predictions of the working paper's preferred model, the constant-expenditure nested logit estimated during the review, with no efficiencies. "Partial" is partial coordination with $\phi = 0.75$. Actual effects are the post-merger coefficients β_g of (11.90) and of the same regression for volume shares, comparing April 2007 to April 2009 with May 2009 to May 2011. Robust standard errors in parentheses. A change of 0.351 log points is a 42 percent increase. Source: Björnerstedt and Verboven (2013), Tables 6 and 7.

Why the specifications differ. Two forces separate the unit-demand and constant-expenditure predictions. The estimated elasticities differ, which changes margins and diversion. And the functional forms imply different curvature, which changes pass-through even at the same elasticities. A stylized calibration isolates the second force. Consider four products with prices normalized to one: two paracetamol products owned by different firms, one ibuprofen product and one ASA product, each substance a nest of a one-level nested logit. Inside shares are 12%, 12%, 13.5% and 12.5% of the potential market, with the rest going to the outside good. For a given own elasticity of −3 and a given diversion ratio D_{AB} between the paracetamol products, we choose (α, σ) separately in the two versions so that both match these targets. By construction both versions then imply the same pre-merger margins, the same upward pricing pressure and the same GUPPI. We then merge the paracetamol sellers.

Table 11.29 and Figure 11.19 show the result. With identical first-order information the constant-expenditure version predicts about twice the unit-demand increase at $D_{AB} = 0.30$ and almost three times at $D_{AB} = 0.45$. Over the range shown the ratio lies between 1.8 and 3.3. Upward pricing pressure cannot distinguish the two models, because it uses only first-order

Table 11.29: A stylized calibration: same elasticity and diversion, different curvature

						Predicted price rise (%)		
D_{AB}	Version	σ	α	Lerner index	GUPPI	Paracetamol	Ibuprofen	ASA
0.30	Unit demand	0.291	2.763	0.333	0.100	11.3	0.40	0.36
0.30	Constant expenditures	0.501	1.447	0.333	0.100	23.5	0.44	0.40
0.45	Unit demand	0.501	2.171	0.333	0.150	21.8	0.73	0.67
0.45	Constant expenditures	0.745	0.855	0.333	0.150	61.0	0.75	0.69

Notes: Our illustration, not a replication. One-level nested logit with substance nests, prices normalized to one, inside shares 12%, 12%, 13.5% and 12.5%, own elasticity of each paracetamol product −3. The GUPPI is $D_{AB}\,L$. No efficiencies. Our computation.

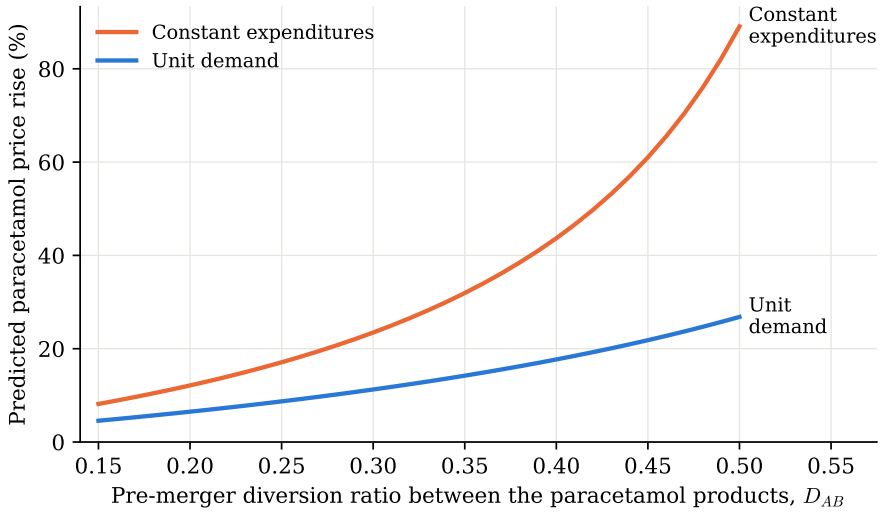

Figure 11.19: Predicted paracetamol price increase in the stylized calibration of Table 11.29, against the pre-merger diversion ratio between the two paracetamol products. Both versions match the same own elasticity (−3), diversion ratio and margins. The constant-expenditure version predicts 1.8 to 3.3 times the increase of the unit-demand version.

information. The simulation can, but only through an assumption about curvature that pre-merger data barely constrain. The calibration also reproduces the second pattern of Table 6. Rival price effects are below 1% in both versions, because nested logit with substance nests diverts little demand from paracetamol to each rival substance.

Robustness. The working paper reports sensitivity checks run during and after the review (Björnerstedt and Verboven, 2013, Sections 4.1 and 4.2). A potential market of 1.5, 4 or 6 times average sales, in place of 2, gave similar results. A coarser product definition, with about 20 brand-form products per month instead of 43, gave comparable findings. The full sample of 11,185 product-months gave the same conclusions as the estimation sample. Adding sums of the pack sizes and doses of other products to the instruments left the unit-demand results unchanged. Under constant expenditures it raised the elasticities and lowered the predicted price effects somewhat, without changing the qualitative conclusions. Treating marketing as endogenous gave closely comparable results. The reverse nesting order was rejected, as noted above.

Interpretation. The study delivers three lessons. First, the constant-expenditure nested logit got the size of the merging firms' price increase about right. It did so in the prediction made during the review, before the outcome was known, and again in the published re-estimation. Second, the choice between specifications that fit the pre-merger data comparably matters as much as the estimation itself. The unit-demand specifications implied implausibly elastic demand and low margins, and they under-predicted the price increase by half or more. Third, the models missed how the effects were distributed. They predicted very different increases for the two merging firms and small rival responses. The data show similar increases for the two merging firms and increases of about 10 percent for some rivals.

Several explanations are possible. After the merger the merged firm cut its pack sizes from 30 to 20 tablets, as the Swedish Medical Products Agency required. It lowered pack prices only slightly, for example from 41.5 to 38.5 kronor for one of its best-selling products. The firms attributed the higher price per tablet to the cost of smaller packs. The authors find this implausible, because ASA producers faced the same requirement without increases of similar size. The same requirement may explain part of the ASA increase (Björnerstedt and Verboven, 2013, p. 29). The published version considers a plausible post-merger cost increase and partial collusion as supply-side explanations (Björnerstedt and Verboven, 2016, abstract). Rivals may have coordinated on higher prices after the merger, a coordinated effect that a Bertrand model rules out (Section 11.8). The deregulation of pharmacies also changed retail conditions in the same period. Finally, GSK was the acquirer and may have favored its own brands after the merger. That would fit the small loss in its share (p. 32).

Critiques and related validation studies. A single merger is a small sample for grading a method. The retrospective benchmark rests on before-after comparisons of product-group prices, with rival controls whose prices themselves moved. The change in pack sizes at the time of the merger further complicates the comparison of prices per tablet. The predictions condition on the demand model's nest structure, which fixes how much substitution toward rival substances is possible. Simulations that impose small cross-substance diversion will under-predict rivals' responses whatever the curvature. Asker and Nocke (2021, p. 231) list four studies that grade merger simulations with ex post evaluations: Peters (2006), Weinberg (2011), Weinberg and Hosken (2013) and the present paper. They reach mixed conclusions. Peters (2006, pp. 627–628) simulates five airline mergers completed between August 1986 and November 1987. Standard simulations do not generally forecast the observed fare changes accurately. Unobserved supply-side changes account for most of the gap in almost every case (p. 645). Peters concludes that

departures from the assumed model of conduct play an important role. Weinberg and Hosken (2013, p. 1584) simulate two of the mergers of Section 11.6.7, Pennzoil and Quaker State in motor oil and Aurora and Log Cabin in syrup. For motor oil the simulated increases are typically below 5 percent, against direct estimates of 4 to 8 percent. For syrup the simulations typically predict 5 to 20 percent, while the merger had little effect on consumer prices. Ashenfelter and Hosken (2010) find that the cereal simulation of Nevo (2000b) predicted the wrong products to rise in price (Section 11.6.7). Houde (2012) compares a spatial simulation with a DiD estimate of the same gasoline transaction (Section 11.9).

Contribution. The paper is one of the few direct tests of merger simulation as used by competition authorities. It shows that simulations can predict the main effect of a merger when demand curvature is allowed to be realistic. It also introduced the constant-expenditure nested logit, a tractable alternative to unit demand for frequently purchased goods. Unit demand, the common default in discrete-choice models, can lead to large under-predictions even when the model fits the pre-merger data. Retrospectives such as those in Section 11.6 are therefore part of the toolkit for choosing among prospective models.

11.8 Coordinated effects: the MillerCoors joint venture

The merger analysis of Sections 11.4 and 11.5 holds the mode of competition fixed. The merged firm internalizes the competition among its own products, and every firm continues to set prices as a static Bertrand-Nash player. Antitrust agencies worry about a second channel as well. The introduction to this chapter distinguished the two channels informally, and we now state the distinction precisely.

Definition 11.48 (Unilateral and coordinated effects)**.** A merger has *unilateral effects* when it changes prices because the merged firm internalizes the competition among the products it now owns. All firms keep playing the same static Nash equilibrium. A merger has *coordinated effects* when it also changes conduct, so that the merged firm and its remaining rivals compete less aggressively with one another than static Nash pricing implies.

Asker and Nocke (2021, p. 238) make the definition operational. A merger has coordinated effects when it leads to prices that differ from those of a static Nash equilibrium. Any model of such effects therefore needs a continuation value, which usually takes the defect-and-punish form of the collusion models of Chapter 12. The idea is old. In the words of Stigler (1964), "[c]ollusion of firms can take many forms, of which the most comprehensive is outright merger". Section 7.2 of the 2010 Horizontal Merger Guidelines discusses the market conditions that facilitate collusion (U.S. Department of Justice and Federal Trade Commission, 2010), as Asker and Nocke (2021, p. 203, n. 67) note. Merger challenges invoke coordinated effects often. Richard Gilbert and Hillary Greene counted the merger complaints filed by the DOJ and the FTC between 1990 and 2014. In their count, as cited by Miller and Weinberg (2017), 60 percent alleged coordinated effects of some form (Asker and Nocke, 2021, p. 238, n. 154). Economists, by contrast, have concentrated on unilateral effects since the 1980s. Asker and Nocke attribute the focus to the analytical clarity of unilateral effects and to the lack of clear empirical examples that link mergers to more coordination (pp. 238–239). Section 11.8.1 sets out what the theory says, and the rest of the section studies one of the few empirical examples.

Miller and Weinberg (2017) provide one of the first structural estimates of the coordinated effects of a consummated merger. They study the 2008 joint venture that combined the US brewing operations of SABMiller and Molson Coors into a new firm, MillerCoors. Their method

nests static Bertrand-Nash pricing inside a model in which the merged firm and its largest rival put a weight κ on each other's profits. It then estimates κ from the post-merger prices. This section follows the paper from its question to its contribution. It derives every estimating equation, proves the properties of the estimator that the paper relies on, and reproduces Tables IV, V, VI and X.[12]

11.8.1 The theory of coordinated effects

The theory of coordinated effects comes from the repeated games of Chapter 12. The question is whether a change in market structure makes collusion easier to sustain, in the sense that it lowers the critical discount factor above which collusion is an equilibrium. We follow Asker and Nocke (2021, pp. 239–240), first in the symmetric benchmark and then with capacities.

Symmetric Bertrand competition. Let N symmetric firms sell a homogeneous good at constant marginal cost and set prices in every period of an infinitely repeated game with discount factor δ. Suppose all firms charge the monopoly price p^m and share the monopoly profit π^m equally, and any deviation triggers static Bertrand pricing at marginal cost forever. A firm that undercuts slightly takes the whole market for one period and earns close to π^m, and zero thereafter. Collusion is an equilibrium if and only if

$$\frac{1}{1-\delta}\cdot\frac{\pi^m}{N}\geq\pi^m \quad\Longleftrightarrow\quad 1\geq N(1-\delta) \quad\Longleftrightarrow\quad \delta\geq\underline{\delta}_N=1-\frac{1}{N}.$$

A merger from N to $N-1$ firms lowers the critical discount factor from $1-\frac{1}{N}$ to $1-\frac{1}{N-1}$, so collusion becomes sustainable for more discount factors. Under imperfect monitoring, the time the industry spends in the collusive state also falls with N. On this account, mergers facilitate collusion.

The model is special, because neither the deviation profit (π^m) nor the punishment profit (zero) depends on N. In richer models both can fall with the number of firms. A merger then raises both the gain from cooperating and the gain from deviating, and its effect on the critical discount factor is ambiguous. Firms also differ, and a merger does more than remove a competitor, since the merged firm obtains the partners' tangible and intangible assets.

Capacity constraints. Compte et al. (2002) show how asymmetries change the answer. Demand is one unit at any price up to the monopoly price of one, and zero above it. Firm i has zero marginal cost up to its capacity k_i, with $k_1\leq k_2\leq\cdots\leq k_N$. Write $\hat{k}_i=\min\{k_i,1\}$ for firm i's *effective capacity*, $\hat{K}=\sum_i\hat{k}_i$ for the sum of effective capacities, and $K_{-N}=\sum_{i<N}k_i$ for the capacity of all firms but the largest. Monitoring is perfect, and attention is restricted to equilibria in which each firm keeps the same market share ω_i along every continuation path. A merger of firms l and m combines their capacities into k_l+k_m and creates no efficiencies.

Proposition 11.49 (Capacities and collusion, Compte et al., 2002)**.**

(a) If $K_{-N}\geq 1$, perfect collusion at price one is sustainable if and only if $\delta\geq\underline{\delta}=\frac{\hat{K}-1}{\hat{K}}$, and the best shares are $\omega_i=\frac{\hat{k}_i}{\hat{K}}$. If $K_{-N}\geq 1$ holds before and after a merger of l and m, the merger weakly lowers $\underline{\delta}$, and strictly if and only if $k_l+k_m>1$.

[12] Page numbers in this section refer to the journal article. We change three pieces of the paper's notation to keep the book consistent. The paper's nesting parameter ρ is our σ (in this book ρ is pass-through). Its product, period and region effects σ_j, τ_t and μ_r are our φ_j, τ_t and υ_r. The paper writes utility as $+\alpha p$ with $\alpha<0$, while we write $-\alpha p$ with $\alpha>0$. The tables keep the paper's signs.

(b) If $K_{-N} < 1$, the largest firm's incentive constraint binds under the best allocation of shares, and $\underline{\delta} = \frac{\hat{k}_N}{\hat{K}}$. A merger involving the largest firm raises $\underline{\delta}$. A merger that does not involve the largest firm and does not create a new largest firm leaves it unchanged.

Proof of part (a). Every firm's rivals together have capacity at least $K_{-N} \geq 1$, so they can serve the whole market. In the static game the price is therefore zero and every firm earns zero, which is the harshest possible punishment. Under collusion firm i earns ω_i per period. Its best deviation prices just below one and sells $\hat{k}_i$, and it earns zero afterward. It does not deviate if and only if

$$\frac{\omega_i}{1-\delta} \geq \hat{k}_i \quad \Longleftrightarrow \quad \delta \geq 1 - \frac{\omega_i}{\hat{k}_i}.$$

Collusion is sustainable if and only if $\delta \geq \max_i \left(1 - \frac{\omega_i}{\hat{k}_i}\right)$, so the best shares maximize $\min_i \frac{\omega_i}{\hat{k}_i}$ subject to $\sum_i \omega_i = 1$. Because $\sum_i \hat{k}_i \cdot \frac{\omega_i}{\hat{k}_i} = 1$, a weighted average of the ratios $\frac{\omega_i}{\hat{k}_i}$ with weights $\frac{\hat{k}_i}{\hat{K}}$ equals $\frac{1}{\hat{K}}$. Their minimum is therefore at most $\frac{1}{\hat{K}}$, with equality when every ratio equals $\frac{1}{\hat{K}}$. Hence $\underline{\delta} = 1 - \frac{1}{\hat{K}}$. A merger replaces $\hat{k}_l + \hat{k}_m$ by $\min\{k_l + k_m, 1\}$, which is never larger and is strictly smaller if and only if $k_l + k_m > 1$. A smaller $\hat{K}$ lowers $1 - \frac{1}{\hat{K}}$. □

Part (b) requires optimal punishments with two phases, a low price in the first period of the punishment and a high price afterward. Static Nash pricing no longer holds the firms to their minmax payoffs (Asker and Nocke, 2021, p. 240, n. 156). We state part (b) without proof. The two parts reverse the symmetric intuition in different ways. In part (a) a merger helps collusion only by destroying effective capacity. In part (b) a merger that makes the largest firm larger makes the industry more asymmetric and hurts collusion. With capacities $(0.2, 0.3, 0.4, 1.0)$, for example, $K_{-N} = 0.9$ and $\underline{\delta} = \frac{1}{1.9} \approx 0.53$. A merger of the largest firm with the smallest gives $(0.3, 0.4, 1.2)$ and $\underline{\delta} = \frac{1}{1.7} \approx 0.59$. A merger of the two smallest gives $(0.4, 0.5, 1.0)$ and leaves $\underline{\delta}$ at 0.53.

What the theory can and cannot say. In a model with heterogeneous firms, a merger may thus help or hinder collusion, depending on the market and the merger. Outside very special models the conditions are not well understood, and the theory gives no robust mapping from a critical discount factor to the probability that collusion occurs (Asker and Nocke, 2021, p. 240). Kaplow and Shapiro (2007) put the problem sharply. Supergame theory with patient players predicts collusion for almost any market structure, so it "proves too much" (n. 159). It is not surprising that courts in the last twenty years have been reluctant to block mergers on coordinated-effects grounds, unless the industry had been cartelized before. Conversely, a merger in an industry that is already cartelized may do little harm, and its efficiencies may benefit society. Röller and Steen (2006) study a cartel in the Norwegian cement industry between 1955 and 1968. It allocated market shares by capacity, which led to overinvestment in capacity. The 1968 merger of the industry's two firms solved the coordination problem and removed the incentive to overinvest. Relative to wasteful collusion, this merger to monopoly raised welfare, although competition would have raised it more (n. 160). Recent research gives the concern a firmer empirical basis, and Miller and Weinberg (2017) is its leading example (p. 240).

11.8.2 The question

The economic question is why the prices of the largest domestic beers rose after the joint venture, and whether the rise reflects a change in how the remaining brewers compete. The

joint venture combined the second and third largest US brewers. A standard merger simulation predicts that the merged firm raises its prices, that rivals raise theirs a little through strategic complementarity, and that efficiencies push in the other direction. The data show something the standard model struggles to produce. The price of Bud Light, the flagship of the largest rival, rose by about as much as the prices of Miller Lite and Coors Light. The prices of the leading imports did not rise.

The question matters for three reasons. First, it tests the maintained assumption of every merger simulation in Section 11.5, namely that post-merger conduct is static Nash. Second, it separates three forces that act on post-merger prices at the same time: unilateral effects, coordinated effects and cost efficiencies. Third, the US Department of Justice (DOJ) cleared the joint venture on the strength of its expected efficiencies. The paper can ask whether that decision was right under different welfare standards.

The answer has three parts (Miller and Weinberg, 2017, pp. 1781 and 1788). The estimated internalization parameter is between 0.25 and 0.37 and is significantly different from zero, so post-merger Nash-Bertrand pricing is rejected. The joint venture produced large marginal-cost savings for MillerCoors, which roughly offset its unilateral effects. Coordination raised the prices of all three domestic brewers well above their no-merger levels, so consumers lost while total surplus rose slightly.

11.8.3 The industry and the event

The US beer market has many brands but few large brewers. Around the time of the joint venture, five firms controlled about 80 percent of US retail revenue. Anheuser-Busch InBev (ABI), the owner of Budweiser and Bud Light, was the largest, with about 35 percent. SABMiller (Miller) and Molson Coors (Coors) were the next two. Grupo Modelo (Corona) and Heineken together held about 15 percent. Real beer prices fell between 2000 and 2008. Table 11.30 lists the 13 brands in the paper's sample by owner.

Table 11.30: Brewers and brands in the Miller and Weinberg sample

Brewer (after June 2008)	Brands (row number in Table 11.32)	Origin
ABI	Bud Light (1), Budweiser (2), Michelob (9), Michelob Light (10)	Domestic
MillerCoors: Coors brands	Coors (3), Coors Light (4)	Domestic
MillerCoors: Miller brands	Miller Genuine Draft (11), Miller High Life (12), Miller Lite (13)	Domestic
Modelo	Corona Extra (5), Corona Light (6)	Imported
Heineken	Heineken (7), Heineken Light (8)	Imported

Notes: Each brand is sold in 6, 12 and 24 packs, and a product is a brand and package size. Before June 2008 the Miller and Coors brands belonged to separate firms. The brand list is the row list of Miller and Weinberg (2017, Table V). Ownership is as described in the text.

The joint venture was announced on October 9, 2007 (Ashenfelter et al., 2015, p. 9) and consummated in June 2008 (Miller and Weinberg, 2017, p. 1768). It combined the US operations of SABMiller and Molson Coors, with a combined share of about 30 percent. The DOJ reviewed it as a merger and approved it on June 5, 2008. It found that efficiencies from combining the brewing operations would outweigh any adverse competitive effect (Asker and Nocke, 2021, p. 241, n. 161). The savings were in shipping and distribution. Coors brewed in two locations and Miller in six. Moving Coors production into Miller plants let the venture brew beer closer to many of its 48 regional markets (Asker and Nocke, 2021, pp. 219–220). The same investigation also surfaced documents that pointed to leader-follower pricing in the industry

(p. 241). Miller and Weinberg (2017, p. 1788) consider a scenario with unilateral effects and efficiencies but no coordination. They describe it as the one "deemed most likely by the DOJ in its decision to clear the merger."

Three institutional features matter for what follows. First, US beer is sold through a *three-tier system*: brewers sell to independent distributors, who sell to retailers. The model of the paper lets brewers sell directly to consumers and treats the retail sector in a supplemental appendix (Miller and Weinberg, 2017, p. 1779). Second, InBev acquired Anheuser-Busch in November 2008, five months after the joint venture (Miller and Weinberg, 2017, p. 1784). Third, Anheuser-Busch held a large equity stake in Grupo Modelo during the sample period. Figure 11.2 records it as 50.3 percent before ABI bought the rest of Modelo in a $20.1 billion deal. That acquisition came in 2013, after the sample period (Miller and Weinberg, 2017, p. 1767). The second and third facts reappear in the assessment in Section 11.8.11.

11.8.4 Facts and hypotheses

Figure 11.20 reproduces the paper's Figure 1. It plots the average log real price of a 12 pack of five flagship brands from 2001 to 2011, in 2010 dollars. Before the joint venture, Miller Lite, Coors Light and Bud Light move almost in lockstep and drift down. After June 2008 all three jump by roughly 6 log points and stay at the higher level through 2011.[13] Corona Extra and Heineken keep falling. In the paper's words, the imports "do not exhibit any persistent increase and instead continue along a downward trend" (Miller and Weinberg, 2017, p. 1769). The price gap between domestic beers and imports therefore shrinks.

Miller and Weinberg (2017, p. 1769) single out two features of the figure. The price of Bud Light rises by roughly the same amount as the prices of Miller Lite and Coors Light. The prices of the Modelo and Heineken brands do not rise, at least not persistently. They list four explanations that are consistent with these facts.

(H1) ABI and MillerCoors *coordinate* after the merger and compete less aggressively with each other.

(H2) *Unilateral effects* alone explain the data. Demand could make domestic beer prices strong strategic complements of one another and weak strategic complements of import prices. Then ABI would follow MillerCoors up even under Nash pricing, while importers would not.

(H3) *Institutional practices* explain the data. Retailers might price Bud Light, Miller Lite and Coors Light equally whatever happens to costs and demand, out of habit or under pressure from brewers.

(H4) The *Great Recession* explains the data. The recession began at about the time of the merger. Lower incomes could make domestic beer demand less elastic, for example through down-market substitution from imports.

The paper weighs (H4) with a fact. Sales of the domestic brands fell in both absolute and relative terms during the recession, which is hard to square with consumers trading down to them (Miller and Weinberg, 2017, n. 5).

[13] The 6 log point jump is our reading of the figure, from about 2.25–2.27 before June 2008 to about 2.29–2.33 afterwards. Asker and Nocke (2021, p. 242), who reproduce the figure, describe the jump as an 8 percent increase in the prices of all three brands. The paper itself states an increase of about 8 percent (Miller and Weinberg, 2017, p. 1768), so we report both. The paper notes the brief dip in Miller Lite prices just after the merger in its footnote 5.

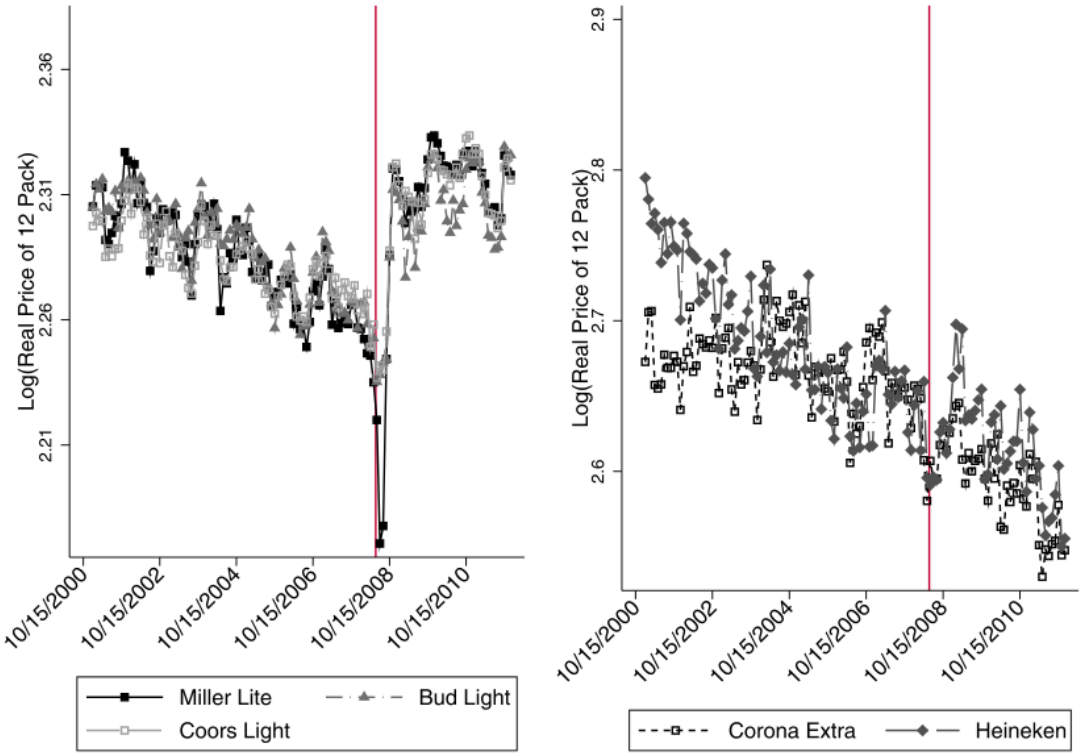

Figure 11.20: Average retail prices of flagship 12 packs, 2001–2011. The left panel shows Miller Lite, Bud Light and Coors Light, and the right panel shows Corona Extra and Heineken. The vertical axis is the natural log of the price in real 2010 dollars, and the vertical line marks the consummation of the joint venture in June 2008. Source: Miller and Weinberg (2017), Figure 1.

The test the paper builds follows from (H1) and (H2). If unilateral effects alone explain the data, an estimated demand system plus Nash pricing should reproduce the post-merger price of Bud Light. If they cannot, a model with partial internalization of the ABI-MillerCoors pricing externality should fit better. The test therefore requires a demand system rich enough to give (H2) a fair chance, and a supply model in which Nash pricing is a special case. The logic is the same as in the conduct-parameter literature of Chapter 3. The new element is a change in conduct at a known date, caused by a known change in market structure.

11.8.5 Theory: partial internalization of pricing externalities

We first develop the supply model in general form. Consider one market and drop the region and period indices. There are J products and F firms, and firm f sells the products in $\mathcal{J}_f$. Market size is M, the share of product j is $s_j(p)$, marginal cost mc_j is constant, and firm f's variable profit is

$$\pi_f(p) = M \sum_{k \in \mathcal{J}_f} (p_k - mc_k)\, s_k(p). \tag{11.96}$$

Assumption 11.50 (Partial internalization)**.** (i) Firm f chooses the prices of its products to maximize

$$V_f(p) = \pi_f(p) + \sum_{g \neq f} \kappa_{fg}\, \pi_g(p), \tag{11.97}$$

taking the prices of other firms as given, with weights $\kappa_{fg} \in [0,1]$ and $\kappa_{fg} = \kappa_{gf}$. (ii) A Nash equilibrium of the game with payoffs V_f exists and is interior.

Section 11.5.1 stated the resulting first-order conditions without proof, and the worked example of Section 11.5.2 used them. The weight κ_{fg} is the fraction of rival g's profit that firm f counts as its own. With all weights equal to zero, the model is the multiproduct Bertrand-Nash model of Chapter 4. With $\kappa_{fg} = 1$, firms f and g maximize their joint profit, exactly as if they had merged. Intermediate weights have two readings. The first is literal: if firm f owns a share of firm g's equity, its owners gain from g's profit (O'Brien and Salop, 2000). The second is a reduced form for tacit coordination, which is the reading Miller and Weinberg (2017, p. 1779) adopt. They call κ the "post-merger internalization of coalition pricing externalities."

Proposition 11.51 (First-order conditions with partial internalization)**.** *Let Δ be the $J \times J$ matrix with (j,k) element $\frac{\partial s_j}{\partial p_k}$, and let $\Omega(\kappa)$ be the matrix with (j,k) element $\kappa_{f(j)f(k)}$, where $f(j)$ is the owner of product j and $\kappa_{ff} = 1$. Under Assumption 11.50 equilibrium prices satisfy*

$$s(p) + \big(\Omega(\kappa) \odot \Delta(p)^{\top}\big)(p - mc) = 0, \tag{11.98}$$

and, when the matrix is invertible, the markup vector is

$$p - mc = b(p;\kappa) \equiv -\big[(\Omega(\kappa) \odot \Delta(p))^{\top}\big]^{-1} s(p). \tag{11.99}$$

Proof. Take $j \in \mathcal{J}_f$. Differentiating (11.97) with (11.96) gives

$$\begin{aligned} \frac{\partial V_f}{\partial p_j} &= M\Big[s_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k)\frac{\partial s_k}{\partial p_j}\Big] + \sum_{g \neq f} \kappa_{fg}\, M \sum_{k \in \mathcal{J}_g} (p_k - mc_k)\frac{\partial s_k}{\partial p_j} \\ &= M\Big[s_j + \sum_{k=1}^{J} \kappa_{f(j)f(k)}\,(p_k - mc_k)\,\Delta_{kj}\Big]. \end{aligned}$$

The second line uses $\kappa_{ff} = 1$ and collects all products into one sum. Setting the derivative to zero and dividing by $M > 0$ gives $s_j + \sum_k \Omega_{jk}(\Delta^\top)_{jk}(p_k - mc_k) = 0$ for every j. Stacking the J equations gives (11.98). Symmetry of the weights makes $\Omega(\kappa)$ symmetric, so $\Omega \odot \Delta^\top = (\Omega \odot \Delta)^\top$, and solving for $p - mc$ gives (11.99). □

Equation (11.99) is the markup formula of Chapter 8 (Equation (8.71)) with the ownership matrix replaced by $\Omega(\kappa)$. Miller and Weinberg (2017, eq. (9)) write it as $p_t = mc_t - [\Omega_t(\kappa) \circ (\frac{\partial s_t}{\partial p_t})^\top]^{-1} s_t$, which is the same object. In their application the weight is nonzero only for pairs of ABI and MillerCoors products after the merger. Let $\mathcal{J}_A, \mathcal{J}_M, \mathcal{J}_O$ and $\mathcal{J}_H$ be the products of ABI, MillerCoors, Modelo and Heineken, and write $\mathbf{1}$ for a matrix of ones of the conformable size. Ordering products by firm, the post-merger matrix is

$$\Omega^{post}(\kappa) = \begin{bmatrix} \mathbf{1}_{AA} & \kappa \mathbf{1}_{AM} & 0 & 0 \\ \kappa \mathbf{1}_{MA} & \mathbf{1}_{MM} & 0 & 0 \\ 0 & 0 & \mathbf{1}_{OO} & 0 \\ 0 & 0 & 0 & \mathbf{1}_{HH} \end{bmatrix}. \tag{11.100}$$

Before the merger the Miller and Coors blocks are separate, so Ω^{pre} is block diagonal with five blocks. The paper illustrates with a hypothetical region in which ABI, Miller, Coors and Modelo each sell one product (Miller and Weinberg, 2017, eq. (10)):

$$\Omega_{t_1^*} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \qquad \Omega_{t_2^*} = \begin{bmatrix} 1 & \kappa & \kappa & 0 \\ \kappa & 1 & 1 & 0 \\ \kappa & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \tag{11.101}$$

where t_1^* is a pre-merger period and t_2^* a post-merger period. Miller and Coors fully internalize each other after the merger, ABI and MillerCoors internalize each other with weight κ, and Modelo prices as a Nash player. The last feature is a restriction. The paper imposes it for Modelo and Heineken on the basis of qualitative evidence (Miller and Weinberg, 2017, p. 1779).

Remark 11.52 (κ and the conduct parameter). In a homogeneous-good market with N symmetric firms, constant marginal cost c and inverse demand $P(Q)$, let each firm maximize $\pi_i + \kappa \sum_{j \neq i} \pi_j$ over its output. The first-order condition is

$$P(Q) + q_i P'(Q) - c + \kappa P'(Q) \sum_{j \neq i} q_j = 0.$$

At a symmetric equilibrium $q_i = \frac{Q}{N}$ and $\sum_{j \neq i} q_j = \frac{(N-1)Q}{N}$, so

$$P(Q) - c + \theta \, Q P'(Q) = 0, \qquad \theta = \frac{1}{N} + \kappa \, \frac{N-1}{N}.$$

This is the conduct-parameter form of Chapter 3. The weight $\kappa = 0$ gives Cournot ($\theta = \frac{1}{N}$) and $\kappa = 1$ gives monopoly ($\theta = 1$). The internalization weight is thus a conduct parameter, and the critique of Corts (1999) applies to it. Section 11.8.11 returns to this point.

The next result says how κ changes pricing incentives at pre-merger prices. It extends the upward pricing pressure (UPP) of Section 11.4 to partial internalization. Write $D_{jk} = -\frac{\Delta_{kj}}{\Delta_{jj}}$ for the diversion ratio from j to k and $m_k = p_k - mc_k$ for the margin.

Proposition 11.53 (Pricing pressure with partial internalization)**.** *Suppose pre-merger prices satisfy* (11.98) *with* Ω^{pre}*, and evaluate the post-merger objectives at pre-merger prices and costs. Then the post-merger pricing pressure on each product is:*

$$\text{ABI product } j \in \mathcal{J}_A: \quad UPP_j = \kappa \sum_{k \in \mathcal{J}_M} m_k D_{jk}, \tag{11.102}$$

$$\text{Miller product } j: \quad UPP_j = \sum_{k \in Coors} m_k D_{jk} + \kappa \sum_{k \in \mathcal{J}_A} m_k D_{jk}, \tag{11.103}$$

$$\text{import } j \in \mathcal{J}_O \cup \mathcal{J}_H: \quad UPP_j = 0.$$

The expression for a Coors product exchanges the roles of Miller and Coors in (11.103)*.*

Proof. Take $j \in \mathcal{J}_A$. At pre-merger prices the pre-merger condition holds: $s_j + \sum_{k \in \mathcal{J}_A} m_k \Delta_{kj} = 0$. The post-merger derivative of $\frac{V_A}{M}$ with respect to p_j is the same expression plus $\kappa \sum_{k \in \mathcal{J}_M} m_k \Delta_{kj}$. At pre-merger prices it therefore equals $\kappa \sum_{k \in \mathcal{J}_M} m_k \Delta_{kj}$. Dividing by $-\Delta_{jj} > 0$ converts it into dollars per unit, as in Section 11.4:

$$\frac{\kappa \sum_{k \in \mathcal{J}_M} m_k \Delta_{kj}}{-\Delta_{jj}} = \kappa \sum_{k \in \mathcal{J}_M} m_k D_{jk}.$$

For a Miller product the post-merger objective adds the Coors products with weight one and the ABI products with weight κ, and the same steps give (11.103). Import objectives do not change. □

Under Nash pricing ($\kappa = 0$) ABI faces no direct pressure. Its prices rise only through strategic complementarity, because MillerCoors's higher prices raise the demand for ABI's products. With $\kappa > 0$, ABI faces pressure equal to κ times the pressure it would face if it had merged with MillerCoors. This is the sense in which coordination makes the largest rival behave like a partial merger partner. Efficiencies enter the MillerCoors expressions as a credit $E_j mc_j$, exactly as in Proposition 11.26.

Coordination also changes how rivals respond to the merged firm's efficiencies. In the Nash model a cost reduction at MillerCoors lowers MillerCoors's prices, and strategic complementarity then lowers ABI's prices. With $\kappa > 0$ there is a countervailing force. A larger MillerCoors margin raises the value to ABI of the sales it diverts to MillerCoors, so ABI wants to raise its price. Figure 11.21 shows the result in the logit illustration of Example 11.34, which is also the example of Miller and Weinberg (2017, p. 1780). Three symmetric single-product firms face logit demand with price 1.00, marginal cost 0.70, inside shares of 0.20 and an outside share of 0.40, and firms 1 and 2 merge. At $\kappa = 0$ the rival price p_3 rises with the merged firm's cost c_M, with slope 0.061 at $c_M = 0.6$. At $\kappa = 0.5$ the slope is -0.148.[14] The figure also previews the identification argument of Section 11.8.8. The merging-firm price p_M and the rival price p_3 trace two families of curves that cross. An observed pair (p_M, p_3) therefore pins down both the internalization weight and the efficiency. For example, the pair (1.09, 1.08) reported in the paper's third case corresponds to $\kappa = 0.53$ and $c_M = 0.68$ in our computation (Remark 11.35 discusses this case).

[14] These slopes and the contours in Figure 11.21 are our computations.

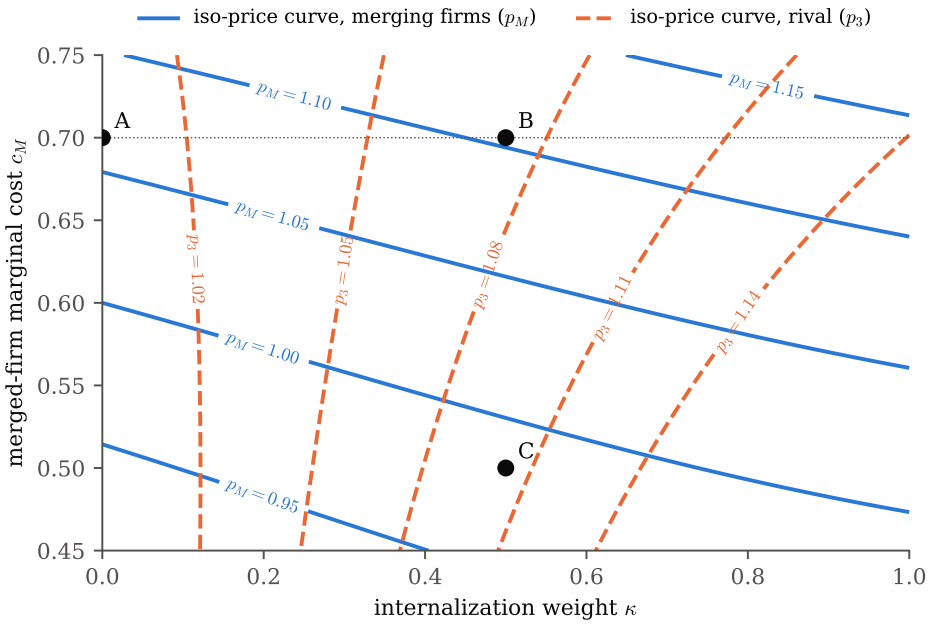

Figure 11.21: Identification of the internalization weight and the efficiency in the logit illustration. Three symmetric firms with logit demand start at price 1.00, marginal cost 0.70 and shares 0.20 (outside share 0.40). Firms 1 and 2 merge and both get marginal cost c_M, and the merged firm and firm 3 put weight κ on each other's profits. Solid curves are combinations of (κ, c_M) that give the same merging-firm price p_M. Dashed curves give the same rival price p_3. Point A is post-merger Nash pricing without efficiencies, $p = (1.064, 1.064, 1.006)$. Point B has $\kappa = 0.5$, $p = (1.104, 1.104, 1.073)$. Point C has $\kappa = 0.5$ and $c_M = 0.5$, $p = (0.983, 0.983, 1.103)$. Our computations.

11.8.6 Data

The underlying data are weekly retail scanner data from supermarkets, collected by IRI (Asker and Nocke, 2021, p. 241, n. 162). The estimation samples aggregate them to months and quarters. A product j is a brand and package size, with 13 brands sold in 6, 12 and 24 packs. A market is one of 39 geographic regions r in one period t. The descriptive evidence spans 2001 to 2011. The estimation samples start in 2005, the first year of the household data described below (Miller and Weinberg, 2017, p. 1768). The baseline sample has 94,656 brand-size-region-month observations, and a quarterly version has 31,784 brand-size-region-quarter observations (Table IV notes). Both samples exclude the twelve months from June 2008 to May 2009, so the estimates compare settled pre-merger and post-merger periods. Prices are in real 2010 dollars. Markups are reported on an "equivalent-unit basis" (Miller and Weinberg, 2017, p. 1781). The average markup of \$3.60 equals 34 percent of the retail price, which implies an average price near \$10.60 per equivalent unit, close to the 12-pack prices in Table X.

Three further ingredients complete the data (Miller and Weinberg, 2017, p. 1774). Household incomes D_i come from 500 draws per region and year from the American Community Survey (ACS), available for 2005 to 2011 (p. 1768). Market size M_{rt} is set 50 percent above the maximum unit sales observed in the region. The outside good collects brands outside the sample (such as craft beers), beer sold outside supermarkets, and other beverages such as wine. Placing these products in the outside good makes their prices non-strategic in the model. Period fixed effects absorb the trend toward craft beer. The cost side uses the distance between each brand's brewery and each region, multiplied by an index of diesel prices (Miller and Weinberg, 2017, p. 1779).

11.8.7 Demand: the random coefficients nested logit

Utility. Household i in region r and period t chooses one of the inside products $j = 1, \dots, J_{rt}$ or the outside good $j = 0$. There are two groups $g \in \{0, 1\}$: group 1 contains the inside goods and group 0 the outside good. In book notation the indirect utility of an inside good is

$$u_{ijrt} = \delta_{jrt} + \mu_{ijrt} + \zeta_{igrt} + (1 - \sigma)\epsilon_{ijrt}, \tag{11.104}$$

$$\delta_{jrt} = x_j\beta - \alpha p_{jrt} + \varphi_j^D + \tau_t^D + \xi_{jrt}, \tag{11.105}$$

$$\mu_{ijrt} = \Pi_1 D_i\, p_{jrt} + D_i\, x_j \pi, \tag{11.106}$$

and $u_{i0rt} = \epsilon_{i0rt}$ (Miller and Weinberg, 2017, eqs. (4)–(5)). The mean utility δ_{jrt} contains product fixed effects φ_j^D, period fixed effects τ_t^D and the unobserved demand shock ξ_{jrt}. Because the characteristics x_j do not vary over time, φ_j^D absorbs $x_j\beta$. The deviation μ_{ijrt} interacts income with price and with the characteristics $x_j = (1, \text{calories}_j, \text{import}_j, \text{package size}_j)$, whose coefficients are $\pi = (\Pi_2, \Pi_3, \Pi_4, \Pi_5)^\top$. Household i's price coefficient is therefore

$$\alpha_i = \alpha - \Pi_1 D_i, \tag{11.107}$$

so a positive Π_1 means richer households are less price sensitive. The shock ϵ_{ijrt} is i.i.d. type-I extreme value. The group shock ζ_{igrt} has the distribution of Cardell (1997), which makes $\zeta_{igrt} + (1 - \sigma)\epsilon_{ijrt}$ extreme value. The *nesting parameter* $\sigma \in [0, 1)$ measures the correlation of a household's tastes for inside goods. A larger σ means less substitution between the inside goods and the outside good.

The specification has two departures from the models of Chapters 7 and 8. Heterogeneity enters only through observed income, with no unobserved random coefficients. This is the random coefficients nested logit (RCNL) of Brenkers and Verboven (2006) and Grigolon and Verboven (2014). The nest is a single inside-good group, with no subnests for light beers, domestic beers or package sizes.

The nested logit special case. With $\Pi = 0$ the model is a one-level nested logit. We derive its shares and inversion, since the RCNL applies the same algebra household by household. Drop the market subscripts, set $\delta_0 = 0$, and define the *inclusive value* of the inside group,

$$I_1 = (1-\sigma)\ln\sum_{k=1}^{J}\exp\left(\frac{\delta_k}{1-\sigma}\right). \tag{11.108}$$

The nested logit choice probabilities (Chapter 7) are

$$s_{j|g} = \exp\left(\frac{\delta_j - I_1}{1-\sigma}\right), \qquad s_g = \frac{e^{I_1}}{1+e^{I_1}}, \qquad s_0 = \frac{1}{1+e^{I_1}}, \qquad s_j = s_{j|g}\, s_g, \tag{11.109}$$

where $s_{j|g}$ is the share of j among inside goods and s_g is the inside share.

Proposition 11.54 (Nested logit inversion)**.** *In the nested logit model,*

$$\ln s_j - \ln s_0 = \delta_j + \sigma \ln s_{j|g}. \tag{11.110}$$

With (11.105)*, the estimating equation is*

$$\ln s_{jrt} - \ln s_{0rt} = -\alpha p_{jrt} + \sigma \ln s_{jrt|g} + \varphi_j^D + \tau_t^D + \xi_{jrt}, \tag{11.111}$$

which is the paper's equation (7) in book notation.

Proof. Take logs of $s_j = s_{j|g}s_g$ and use (11.109):

$$\ln s_j = \frac{\delta_j - I_1}{1-\sigma} + I_1 - \ln(1+e^{I_1}), \qquad \ln s_0 = -\ln(1+e^{I_1}).$$

Subtract the second equation from the first:

$$\ln s_j - \ln s_0 = \frac{\delta_j}{1-\sigma} - \frac{\sigma}{1-\sigma} I_1.$$

The unobserved inclusive value can be eliminated with the within-group share. From (11.109), $\ln s_{j|g} = \frac{\delta_j - I_1}{1-\sigma}$, so $I_1 = \delta_j - (1-\sigma)\ln s_{j|g}$. Substituting,

$$\ln s_j - \ln s_0 = \frac{\delta_j}{1-\sigma} - \frac{\sigma\delta_j}{1-\sigma} + \sigma \ln s_{j|g} = \delta_j + \sigma \ln s_{j|g}.$$

Substituting (11.105), with $x_j\beta$ absorbed by φ_j^D, gives (11.111). □

Equation (11.111) is linear in (α, σ) and the fixed effects. Both the price and the within-group share are endogenous, since a high ξ_{jrt} raises the product's share among inside goods and, through the pricing equation, its price. Estimation therefore needs at least two

excluded instruments. Column (i) of Table IV estimates (11.111) by two-stage least squares (Corollary 8.21).

The nested logit derivatives follow from the same expressions, and they agree with Lemma 11.47 for a single inside nest. Using $\frac{\partial I_1}{\partial \delta_k} = s_{k|g}$ and $s_g s_{k|g} = s_k$,

$$\frac{\partial \ln s_j}{\partial \delta_k} = \frac{\mathbf{1}\{j=k\} - s_{k|g}}{1-\sigma} + s_{k|g} - s_g s_{k|g} = \frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{k|g} - s_k.$$

Since $\frac{\partial \delta_k}{\partial p_k} = -\alpha$, the share derivatives are

$$\frac{\partial s_j}{\partial p_k} = -\alpha s_j \left[\frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{k|g} - s_k \right], \qquad \frac{\partial s_0}{\partial p_k} = \alpha s_0 s_k. \tag{11.112}$$

The elasticities are

$$\varepsilon_{jj} = -\alpha p_j \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j \right], \qquad \varepsilon_{jk} = \alpha p_k \left[\frac{\sigma}{1-\sigma} s_{k|g} + s_k \right] \quad (k \neq j). \tag{11.113}$$

The cross elasticity ε_{jk} does not depend on j, so within the inside group substitution is proportional to shares. This is the independence of irrelevant alternatives inside the nest. Dividing the cross derivatives by the own derivative gives the diversion ratios

$$D_{jk} = \frac{s_{k|g}\left[\sigma + (1-\sigma) s_g\right]}{1 - \sigma s_{j|g} - (1-\sigma) s_j}, \qquad D_{j0} = \frac{(1-\sigma) s_0}{1 - \sigma s_{j|g} - (1-\sigma) s_j}. \tag{11.114}$$

The first expression is (11.41) with one inside nest, since $s_k = s_{k|g} s_g$. For small products the outside diversion is close to $(1-\sigma)s_0$. A nesting parameter near one therefore sends almost all of a product's lost sales to other beers.

Remark 11.55 (Market elasticity, own elasticity and outside diversion). When price enters utility linearly with a coefficient common to all products for each household, the matrix Δ is symmetric. This holds for the nested logit, by (11.112), and for the RCNL below. Let all inside prices rise by the same amount $\mathrm{d}p$. Then

$$\mathrm{d}s_j = \Big(\Delta_{jj} + \sum_{k \neq j} \Delta_{jk}\Big)\mathrm{d}p = \Big(\Delta_{jj} + \sum_{k \neq j} \Delta_{kj}\Big)\mathrm{d}p = \Delta_{jj}\Big(1 - \sum_{k \neq j} D_{jk}\Big)\mathrm{d}p = \Delta_{jj}\, D_{j0}\, \mathrm{d}p.$$

A uniform rise of $\mathrm{d}p$ therefore changes the sales of product j by $\varepsilon_{jj} D_{j0} \frac{\mathrm{d}p}{p_j}$ percent. When prices are similar, the market elasticity is close to a share-weighted average of $\varepsilon_{jj} D_{j0}$. Table IV satisfies this relation closely at the medians. For column (i), $-3.81 \times 0.298 = -1.14$ against a reported -1.10. For column (ii), $-4.74 \times 0.1296 = -0.61$ against -0.60. Columns (iii) to (v) give -0.74, -0.62 and -0.72 against -0.72, -0.60 and -0.69.

Market shares with random coefficients. With $\Pi \neq 0$ the nested logit holds for each household. Let $V_{ijrt} = \delta_{jrt} + \mu_{ijrt}$ and define the household's inclusive values

$$I_{i0rt} = 0, \qquad I_{i1rt} = (1-\sigma) \ln \sum_{k=1}^{J_{rt}} \exp\left(\frac{V_{ikrt}}{1-\sigma}\right), \qquad I_{irt} = \ln\left(1 + e^{I_{i1rt}}\right). \tag{11.115}$$

Applying (11.109) to household i and averaging over the $N_{rt} = 500$ simulated households gives

$$s_{jrt} = \frac{1}{N_{rt}} \sum_{i=1}^{N_{rt}} \underbrace{\frac{\exp\left(\frac{V_{ijrt}}{1-\sigma}\right)}{\exp\left(\frac{I_{i1rt}}{1-\sigma}\right)}}_{s_{ij|g}} \underbrace{\frac{\exp(I_{i1rt})}{\exp(I_{irt})}}_{s_{ig}}, \tag{11.116}$$

which is the paper's equation (6). The first fraction is the household's probability of choosing j among inside goods, because $\exp(\frac{I_{i1rt}}{1-\sigma}) = \sum_k \exp(\frac{V_{ikrt}}{1-\sigma})$. The second is its probability of buying beer. These inclusive values are those of McFadden (1978). The household-level derivatives follow from (11.112) with α_i in place of α:

$$\Delta_{jk} = \frac{\partial s_j}{\partial p_k} = -\frac{1}{N} \sum_{i=1}^{N} \alpha_i \, s_{ij} \Big[\frac{\mathbf{1}\{j = k\}}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{ik|g} - s_{ik} \Big]. \tag{11.117}$$

Households differ in α_i and in their choice probabilities, so the aggregate cross elasticities depend on which households buy which products. This breaks the proportional substitution of (11.113). Income also shifts the attractiveness of beer and of particular characteristics, which lets the recession move demand.

Inversion and the dampened contraction. For trial values of the nonlinear parameters $\theta_2 = (\sigma, \Pi)$, the mean utilities δ_{rt} in each market solve $s^{obs}_{rt} = s_{rt}(\delta_{rt}; \theta_2)$. The BLP contraction of Chapter 8 need not converge in this model. The paper follows Grigolon and Verboven (2014), who iterate

$$\delta^{h+1} = \Phi(\delta^h), \qquad \Phi(\delta) = \delta + (1-\sigma)\big[\ln s^{obs} - \ln s(\delta; \theta_2)\big]. \tag{11.118}$$

The factor $1 - \sigma$ dampens each step (Remark 8.19). The next result shows why it is needed and why it works.

Proposition 11.56 (Dampened contraction in the RCNL)**.** *For every δ, the Jacobian of Φ in (11.118) has strictly positive elements*

$$\frac{\partial \Phi_j}{\partial \delta_k} = \frac{1}{s_j} \frac{1}{N} \sum_{i=1}^{N} s_{ij} \big[\sigma s_{ik|g} + (1-\sigma) s_{ik}\big], \tag{11.119}$$

and its row sums equal

$$\sum_k \frac{\partial \Phi_j}{\partial \delta_k} = 1 - (1-\sigma) \frac{1}{s_j} \frac{1}{N} \sum_{i=1}^{N} s_{ij} \, s_{i0} < 1. \tag{11.120}$$

Without dampening, the diagonal element of the Jacobian of $\delta + \ln s^{obs} - \ln s(\delta)$ is $-\frac{\sigma}{1-\sigma}$ plus terms that vanish as the shares go to zero.

Proof. Differentiate (11.116). Household i's nested logit gives $\frac{\partial s_{ij}}{\partial \delta_k} = s_{ij}[\frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{ik|g} - s_{ik}]$, as in the derivation of (11.112). Hence

$$\begin{aligned}(1-\sigma)\frac{\partial \ln s_j}{\partial \delta_k} &= \frac{1}{s_j} \frac{1}{N} \sum_i s_{ij} \big[\mathbf{1}\{j=k\} - \sigma s_{ik|g} - (1-\sigma) s_{ik}\big] \\ &= \mathbf{1}\{j=k\} - \frac{1}{s_j} \frac{1}{N} \sum_i s_{ij} \big[\sigma s_{ik|g} + (1-\sigma) s_{ik}\big],\end{aligned}$$

where the second step uses $\frac{1}{N}\sum_i s_{ij} = s_j$. Since $\frac{\partial \Phi_j}{\partial \delta_k} = \mathbf{1}\{j = k\} - (1-\sigma)\frac{\partial \ln s_j}{\partial \delta_k}$, this gives (11.119). Every term is positive because all choice probabilities are positive. For the row sum, use $\sum_k s_{ik|g} = 1$ and $\sum_k s_{ik} = 1 - s_{i0}$:

$$\sum_k \left[\sigma s_{ik|g} + (1-\sigma)s_{ik}\right] = \sigma + (1-\sigma)(1-s_{i0}) = 1 - (1-\sigma)s_{i0}.$$

Averaging with weights $\frac{s_{ij}}{N s_j}$ gives (11.120). Without dampening the diagonal element is $1 - \frac{\partial \ln s_j}{\partial \delta_j}$. The leading part of $\frac{\partial \ln s_j}{\partial \delta_j}$ is $\frac{1}{1-\sigma}$, so the diagonal element is $1 - \frac{1}{1-\sigma} = -\frac{\sigma}{1-\sigma}$ plus terms proportional to the shares. □

The sup norm of a matrix with nonnegative elements is its largest row sum, so (11.120) makes Φ a local contraction everywhere. The global argument then proceeds as for the BLP contraction in Theorem 8.15. Without dampening the map expands. At the paper's estimate $\sigma \approx 0.83$, the diagonal element is near $-\frac{0.83}{0.17} \approx -4.9$, so plain iteration overshoots and diverges. The proposition also gives the speed of convergence. The modulus is close to $1 - (1-\sigma)s_0$, so convergence slows as σ approaches one. In the plain nested logit the Jacobian elements are $\sigma s_{k|g} + (1-\sigma)s_k$, which are small when there are many products.

The GMM estimator. The demand parameters are $\theta^D = (\alpha, \sigma, \Pi, \varphi^D, \tau^D)$. Given θ_2, the inversion delivers $\delta_{jrt}(\theta_2)$ and (11.105) gives the structural error

$$\xi_{jrt}(\theta^D) = \delta_{jrt}(\theta_2) + \alpha p_{jrt} - \varphi^D_j - \tau^D_t. \tag{11.121}$$

With a vector of instruments z_{jrt}, the moment condition is $\mathbb{E}[z_{jrt}\,\xi_{jrt}(\theta^D_0)] = 0$, and the estimator minimizes

$$\hat{\theta}^D = \arg\min_{\theta^D} \; \xi(\theta^D)^\top Z\, W Z^\top \xi(\theta^D), \tag{11.122}$$

where Z stacks the instruments and W is a weighting matrix. The parameters that enter linearly, α and the fixed effects, are concentrated out by linear instrumental variables for each θ_2 (Proposition 8.20), so the nonlinear search runs over (σ, Π) only. The paper uses two-stage least squares for the nested logit and GMM for the four RCNL specifications. Standard errors are clustered by region (Table IV notes).

Instruments and identification. The paper uses five sets of excluded instruments. Each is excluded from (11.105) and is meant to move a particular endogenous object.

(i) The distance between the brewery and the region, in miles times a diesel price index, shifts marginal cost and hence price. Product fixed effects absorb a brand's average distance. Identification therefore comes from changes in diesel prices and in shipping routes over time, including the post-merger reallocation of production.

(ii) A post-merger indicator interacted with $\mathbf{1}\{j \in \mathcal{J}_A \cup \mathcal{J}_M\}$ shifts the markups of ABI and MillerCoors through the change in ownership and conduct. The exclusion restriction requires that the merger did not shift the unobserved demand for these brands relative to imports.

(iii) The number of products in the market, interacted with the same indicator, captures variation in the choice set. It moves within-group shares and competitors' prices, and it identifies σ.

(iv) The sum of the distances of the products in the market, also interacted, collects rivals' cost shifters. These move rivals' prices and hence $s_{j|g}$.

(v) Mean regional income interacted with characteristics such as calories and import status varies across regions and over time. This variation identifies Π.

The logic matches Section 8.6. Price needs a cost shifter or a markup shifter. The nesting parameter needs variation in the within-group share that is unrelated to ξ, which choice-set variation provides. The income interactions need variation in the distribution of D_i across markets.

Results. Table 11.31 reproduces Table IV. All five specifications include product and period fixed effects. Column (i) is the nested logit, and columns (ii) to (v) are RCNL specifications on monthly or quarterly data that differ in which income interactions they include.

Notes: Standard errors clustered by region in parentheses. The paper writes utility as $+\alpha p$, so its price coefficient is negative. In our notation (11.105) the coefficient on $-p$ is 0.1312, 0.0887, and so on. The nesting parameter is ρ in the paper. Column (i) is estimated by 2SLS and columns (ii) to (v) by GMM. Columns (i), (ii) and (iv) use 94,656 brand-size-region-month observations, and columns (iii) and (v) use 31,784 brand-size-region-quarter observations. The samples exclude June 2008 to May 2009. All regressions include product (brand × size) and period fixed effects. Elasticities and diversion are medians over all observations. The standard error (0.006) on Π_5 in column (v) is as printed. It is probably a misprint for 0.0006, since the same coefficient has standard error 0.0007 in column (iv) and every other interaction is reported to four decimals. The nested logit price coefficient in column (i) has a t-ratio of $\frac{0.1312}{0.0884} \approx 1.5$, as printed. Source: Miller and Weinberg (2017, Table IV, p. 1777).

Five features of the table matter for the merger analysis. First, the income-price interaction Π_1 is positive in both specifications that include it. By (11.107), richer households are less price sensitive. The other interactions say that richer households are more likely to buy one of the sample beers ($\Pi_2 > 0$), prefer higher-calorie beers ($\Pi_3 > 0$) and imports ($\Pi_4 > 0$), and prefer smaller packages ($\Pi_5 < 0$).

Second, the nesting parameter is large. It is 0.63 in the nested logit and between 0.78 and 0.83 in the RCNL specifications. By (11.114), the outside diversion is roughly proportional to $1-\sigma$. The ratio $\frac{1-0.8299}{1-0.6299} = 0.46$ is close to the ratio of the median outside diversions in columns (ii) and (i), $\frac{12.96}{29.80} = 0.43$. In the RCNL only 12 to 17 percent of the sales a product loses go to the outside good, so most lost sales stay with other sample beers.

Third, demand for individual products is elastic, with median own elasticities between -3.8 and -6.1. A rough check uses (11.113) with small shares, where $\varepsilon_{jj} \approx -\frac{\alpha p_j}{1-\sigma}$. With a price near \$10 per equivalent unit, column (i) gives $-\frac{0.1312 \times 10}{0.3701} \approx -3.5$, close to the reported median of -3.81. Fourth, the market as a whole is inelastic, with median market elasticities between -0.60 and -1.10. Brewers acting jointly would therefore gain from higher prices, which is the incentive that coordination exploits.

Fifth, the price coefficient of the nested logit is imprecise (standard error 0.0884), while the RCNL coefficients are precise. The J-statistics of Hansen's overidentification test (Hansen, 1982) are between 13.75 and 14.15 in the four GMM specifications. The table does not report the degrees of freedom, but the text gives eight for columns (ii) and (iii) and seven for columns (iv) and (v) (p. 1776). The implied p-values are 0.083, 0.089, 0.053 and 0.049 (our computation), so the test narrowly rejects column (v) at the 5 percent level.

Table 11.32 reproduces Table V, the mean elasticities for 12 packs under RCNL-1. The cell in row i and column k is the percentage change in the quantity of product i when the price of product k rises by one percent. The lower panel aggregates over categories. For a category B that excludes the column product k, the entry is

$$\Big(\sum_{j \in B, j \neq k} \frac{\partial s_j(p)}{\partial p_k} \Big) \frac{p_k}{\sum_{j \in B, j \neq k} s_j(p)}. \tag{11.123}$$

The paper reads the table as evidence that RCNL-1 relaxes the logit restriction substantially (Miller and Weinberg, 2017, p. 1777). Own elasticities tend to be larger for more expensive products, a pattern the income-price interaction allows but does not impose. Consumers of Bud Light substitute disproportionately toward Budweiser, Coors Light and Miller Lite and toward larger packs (0.356 for 24 packs against 0.307 for 6 packs). Consumers of Corona Extra substitute disproportionately toward Heineken (0.311) and smaller packs (0.275 for 6 packs against 0.222 for 24 packs).

A skeptical reading is also possible, and it matters for the estimate of κ. The variation within a column is modest. Column (3) lies between 0.014 and 0.019 and column (8) between 0.042 and 0.048, so substitution remains close to proportional to shares. Bud Light is about as close a substitute for Michelob Light (0.345 in row 10) as for Miller Lite (0.344 in row 13). Yet only Miller Lite belongs to the other domestic firm. The outside-good row is tiny because the large $\hat{\sigma}$ keeps lost sales among inside goods. The model has no light-beer or domestic nest that could make Bud Light, Miller Lite and Coors Light especially close substitutes. These patterns determine how much of ABI's post-merger price rise unilateral effects can explain, and therefore how much is left for κ.

11.8.8 Supply and the estimation of the internalization weight

Marginal cost. The supply model is Proposition 11.51 with $\Omega_t(\kappa)$ as in (11.100) in post-merger periods and Ω^{pre} before. Marginal cost is

$$mc_{jrt} = w_{jrt}\gamma + \varphi_j^S + \tau_t^S + v_r^S + \eta_{jrt} \tag{11.124}$$

Notes: The cell in row i and column k is the percentage change in the quantity of product i with respect to the price of product k. Column numbers refer to the products in the rows. Own elasticities are in bold. Means are taken across year-month-region combinations. Category entries are computed by (11.123) and exclude the column product. For example, a 1 percent rise in the price of a Bud Light 12 pack raises the sales of other 12 packs by 0.320 percent. Source: Miller and Weinberg (2017, Table V, p. 1778).

(Miller and Weinberg, 2017, eq. (11)). The vector w_{jrt} contains two variables. The first is an indicator for MillerCoors products in post-merger periods, with coefficient γ_1. The second is the distance from the brewery to the region times the diesel index, with coefficient γ_2. The two channels let the merger lower costs through shorter shipping distances and through "residual cost synergies unrelated to distance" (Miller and Weinberg, 2017, p. 1779). The terms φ_j^S, τ_t^S and υ_r^S are product, period and region fixed effects, and η_{jrt} is an unobserved cost shock. Marginal cost does not depend on output. The paper notes that an upward-sloping marginal cost for ABI would bias $\hat{\kappa}$ upward. ABI's price would then rise with the demand that MillerCoors diverts to it. The paper reports little evidence of capacity constraints at ABI (Miller and Weinberg, 2017, n. 13).

The implied cost shock and the moment condition. The supply parameters are $\theta^S = (\kappa, \gamma)$ together with the cost fixed effects. Demand is estimated first, and supply takes $\hat{\theta}^D$ as given. Substituting (11.99) into (11.124) gives the cost shock implied by trial parameters,

$$\eta_{jrt}^*(\theta^S; \hat{\theta}^D) = p_{jrt} - b_{jrt}(p_{rt}; \kappa, \hat{\theta}^D) - w_{jrt}\gamma - \varphi_j^S - \tau_t^S - \upsilon_r^S, \tag{11.125}$$

where $b_{rt}(p_{rt}; \kappa, \hat{\theta}^D) = -[(\Omega_t(\kappa) \odot \Delta_{rt})^\top]^{-1} s_{rt}$ is evaluated at observed prices and shares and the estimated demand.[15] The markup is endogenous in (11.125), because a high cost shock raises price and changes the shares and derivatives that enter b. The excluded instrument is

$$z_{jrt} = \mathbf{1}\{j \in \mathcal{J}_A \cup \mathcal{J}_M\} \times \text{Post}_t, \tag{11.126}$$

[15] This is the paper's equation (12). As printed there, the bracketed markup term carries a minus sign. The paper's equation (9) implies $mc = p + [\Omega \circ (\frac{\partial s}{\partial p})^\top]^{-1} s$, so the term should enter with a plus sign, which is what (11.125) does with b defined as a positive markup.

an indicator for ABI and MillerCoors products in post-merger periods. Identification rests on the moment condition $\mathbb{E}[z_{jrt}\,\eta^*_{jrt}(\theta_0^S)] = 0$, and the method-of-moments estimator is

$$\hat{\theta}^S = \arg\min_{\theta}\ \eta^*(\theta;\hat{\theta}^D)^\top z z^\top \eta^*(\theta;\hat{\theta}^D) \tag{11.127}$$

(Miller and Weinberg, 2017, eq. (13)). The fixed effects and γ enter linearly. For each trial κ they are estimated by ordinary least squares, so the nonlinear search is over κ alone. Standard errors are clustered by region and adjusted for the first-stage demand estimates (Wooldridge, 2010).

What identifies κ. The paper explains the identifying variation in words (Miller and Weinberg, 2017, p. 1780). The estimate of κ is positive if ABI's post-merger prices exceed what the unilateral effects of the merger can explain. A positive κ also raises MillerCoors's prices, so γ_1 is negative if MillerCoors's post-merger prices are lower than unilateral effects and κ imply. The instrument is valid if changes in ABI's unobserved costs, before versus after the merger, do not differ systematically from those of Modelo and Heineken. The next proposition makes this argument exact in a simplified version of the model. It shows that the estimator is a difference in differences applied to implied marginal costs.

Proposition 11.57 ($\hat{\kappa}$ as a difference in differences of implied costs)**.** *Suppose the products fall into three groups, ABI (A), MillerCoors (M) and imports (I), observed in every period of a pre-merger and a post-merger window. Let the cost function contain product effects, period effects and the MillerCoors post-merger indicator, with no distance variable and one region. Write $c_{jt}(\kappa) = p_{jt} - b_{jt}(\kappa)$ for implied marginal cost, and for any variable y and group G define*

$$\bar{\Delta}_G\, y = \frac{1}{N_G}\sum_{j\in G}\Big(\frac{1}{T_1}\sum_{t\,\in\,post} y_{jt} - \frac{1}{T_0}\sum_{t\,\in\,pre} y_{jt}\Big).$$

Here N_G is the number of products in G, and T_0 and T_1 are the numbers of pre-merger and post-merger periods. Then the moment condition in (11.127) holds at $\hat{\kappa}$ if and only if

$$\bar{\Delta}_A\, c(\hat{\kappa}) = \bar{\Delta}_I\, c(\hat{\kappa}), \quad \textit{equivalently} \quad \bar{\Delta}_A\, p - \bar{\Delta}_I\, p = \bar{\Delta}_A\, b(\hat{\kappa}) - \bar{\Delta}_I\, b. \tag{11.128}$$

The cost parameter is then $\hat{\gamma}_1 = \bar{\Delta}_M\, c(\hat{\kappa}) - \bar{\Delta}_I\, c(\hat{\kappa})$.

Proof. Let W be the matrix of included regressors (product dummies, period dummies and $M \times \text{Post}$) and Q_W the matrix that takes residuals from a least squares regression on W. Concentrating out the linear parameters gives $\eta^*(\kappa) = Q_W\, c(\kappa)$. The sample moment is therefore $z^\top Q_W c(\kappa) = (Q_W z)^\top c(\kappa)$, by symmetry and idempotency of Q_W. Since $z = A\times\text{Post} + M\times\text{Post}$ and $M \times \text{Post}$ is a column of W, we have $Q_W z = Q_W(A \times \text{Post})$.

Define the contrast vector d. Its elements are $\frac{1}{N_A T_1}$ for A products in post-merger periods and $-\frac{1}{N_A T_0}$ for A products in pre-merger periods. They are $-\frac{1}{N_I T_1}$ and $\frac{1}{N_I T_0}$ for I products in post-merger and pre-merger periods, and zero for M products. Two facts finish the proof. First, d is orthogonal to every column of W. Its elements sum to zero over the periods of each product, over the products of each period, and over the M observations. Hence $Q_W d = d$. Second, $A \times \text{Post} - \lambda d$ lies in the column space of W for some scalar $\lambda > 0$, unrelated to earlier uses of the symbol. To see this, look for product effects a_G (common within a group), period effects e_0 and e_1, and a coefficient ℓ on $M \times \text{Post}$ that reproduce $A \times \text{Post} - \lambda d$ cell by cell. The A and I cells require

$$e_1 - e_0 = 1 - \lambda\Big(\frac{1}{T_1} + \frac{1}{T_0}\Big)\frac{1}{N_A}, \qquad e_1 - e_0 = \lambda\Big(\frac{1}{T_1} + \frac{1}{T_0}\Big)\frac{1}{N_I},$$

which hold with $\lambda = [(\frac{1}{T_1} + \frac{1}{T_0})(\frac{1}{N_A} + \frac{1}{N_I})]^{-1} > 0$. The levels a_A and a_I then follow, and the M cells are matched by a_M and ℓ. Together the two facts give $Q_W(A \times \text{Post}) = \lambda Q_W d = \lambda d$. The moment is therefore $\lambda\, d^\top c(\kappa) = \lambda[\bar{\Delta}_A c(\kappa) - \bar{\Delta}_I c(\kappa)]$, which is zero if and only if (11.128) holds. The second form follows from $c = p - b$, and the import markups b_I do not depend on κ because the import rows of $\Omega(\kappa)$ contain no κ. Finally, the least squares coefficient on $M \times \text{Post}$ equals the post-pre change of M's implied cost minus the change estimated for the period effects from the A and I products. At $\hat{\kappa}$ the A and I changes are equal, which gives the formula for $\hat{\gamma}_1$. □

The proposition turns the paper's verbal argument into a formula. The left side of the second form of (11.128) is the observed rise in ABI's prices relative to imports. The right side is the rise in ABI's markup relative to imports implied by the model. At $\kappa = 0$ the right side is the unilateral effect on ABI, which comes only from MillerCoors's higher prices and the induced shift in ABI's shares. If ABI's relative price rose by more, the Nash model attributes the gap to a rise in ABI's marginal cost. The estimator rejects that explanation by assumption, because the identifying restriction is parallel trends in unobserved marginal costs between ABI and the importers. It raises κ until the implied markup absorbs the gap. The importers play the role of the control group, and ABI the role of the treated group. MillerCoors drops out of the estimating moment for κ because its own post-merger indicator absorbs its cost change. In the full model, distance and region effects turn the comparison into a regression-adjusted difference in differences, but the logic is the same. Figure 11.21 shows the same identification in the logit illustration, where the rival's price locates κ and the merging firms' price then locates the efficiency.

Results. Table 11.33 reproduces Table VI. Each column uses the demand estimates of the corresponding column of Table 11.31.

Table 11.33: Baseline supply estimates (Miller and Weinberg 2017, Table VI)

Demand model Data frequency Variable	Parameter	NL-1 Monthly (i)	RCNL-1 Monthly (ii)	RCNL-2 Quarterly (iii)	RCNL-3 Monthly (iv)	RCNL-4 Quarterly (v)

Distance	γ_2	0.142 (0.046)	0.168 (0.059)	0.163 (0.059)	0.169 (0.060)	0.148 (0.049)

Notes: Method of moments with the instrument $\mathbf{1}\{j \in \text{ABI} \cup \text{MillerCoors}\} \times \text{Post}_t$. Standard errors clustered by region in parentheses. Samples as in Table 11.31: 94,656 monthly observations in columns (i), (ii) and (iv) and 31,784 quarterly observations in columns (iii) and (v), excluding June 2008 to May 2009. All regressions include product (brand × size), period and region fixed effects. Source: Miller and Weinberg (2017, Table VI, p. 1781).

The estimates of κ are positive and significant in all five columns, so "the null of Nash-Bertrand competition in the post-merger periods is easily rejected" (Miller and Weinberg, 2017, p. 1781). With RCNL demand the estimates range from 0.249 to 0.342. Read literally, ABI and MillerCoors internalize between roughly a quarter and a third of their price effects on each other's profits. Full joint profit maximization is also rejected. In column (ii) the t-statistic for $\kappa = 0$ is $\frac{0.264}{0.073} = 3.6$ and the one for $\kappa = 1$ is $\frac{1-0.264}{0.073} = 10.1$ (our calculations). The nested logit gives the largest estimate, 0.374. A plausible reason is its smaller σ, which implies weaker

substitution among inside goods. Unilateral effects on ABI are then smaller, and more of the price rise is left for κ.

The markups implied by RCNL-1 are large (Miller and Weinberg, 2017, p. 1781). Across all observations the average brewer markup is \$3.60 per equivalent unit, 34 percent of the retail price. After the merger the markups on ABI 12 packs are about \$0.70 higher, those on Miller 12 packs about \$1.40 higher and those on Coors products about \$1.80 higher. The MillerCoors increases combine higher prices and lower costs. Import markups change little.

The cost estimates are economically plausible. The distance coefficients of 0.148 to 0.169 in the RCNL columns imply that costs that scale with shipping distance account for 2 to 3 percent of the retail price on average. The paper compares this with an estimate by Tremblay and Tremblay (2005, p. 162) that taxes and shipping made up 17 percent of the retail price in 1996. The fixed effects absorb part of that share. The MillerCoors post-merger indicator measures a cost reduction common to all regions, which the paper attributes to distributional savings beyond the distance measure. Table VI reports this coefficient as -0.526 to -0.722 across the RCNL columns. The text summarizes the RCNL estimates as a reduction of \$0.66 to \$0.70 (Miller and Weinberg, 2017, p. 1781). Finally, the level of marginal cost is sensitive to retail market power, which acts like a per-unit tax paid by brewers, while brewer markups are largely unaffected (Miller and Weinberg, 2017, n. 14).

11.8.9 Counterfactuals and welfare

Scenarios. The paper decomposes the effects of the merger with the RCNL-1 estimates (Miller and Weinberg, 2017, p. 1786). It recomputes equilibrium under four counterfactual scenarios and compares them with the data. Each scenario switches three channels on or off. Unilateral effects are the move from Ω^{pre} to $\Omega^{post}(0)$. Coordinated effects are the move from $\kappa = 0$ to $\hat{\kappa}$. Efficiencies are the merger-related reductions in MillerCoors's marginal cost. They come from shorter shipping distances and from a downward shift common to all regions (Miller and Weinberg, 2017, p. 1781). Removing them raises the cost of Coors Light by \$0.60 to \$1.30, depending on the region (p. 1782). The counterfactual without efficiencies therefore also restores the pre-merger shipping distances.

(i) The observed outcome: coordinated effects, unilateral effects and efficiencies. Prices are data, and markups and costs come from the estimates.

(ii) The merger with coordinated and unilateral effects, without efficiencies.

(iii) The merger with unilateral effects and efficiencies, without coordination.

(iv) The merger with unilateral effects only.

(v) No merger.

For each scenario s and each market in the post-merger period, the counterfactual prices solve

$$p^s = mc^s + b(p^s; \Omega^s). \tag{11.129}$$

Here Ω^s is $\Omega^{post}(\hat{\kappa})$, $\Omega^{post}(0)$ or Ω^{pre}. The cost vector mc^s is either the estimated post-merger cost or the cost with the efficiency terms removed. Scenario (i) needs no computation. The estimated costs are defined as $p - b(p; \Omega^{post}(\hat{\kappa}))$, so the model reproduces the data exactly. The welfare statistics are computed for 2011 on all products (Table X notes).

Welfare measures. Producer surplus is the brewers' variable profit, $PS = M \sum_j (p_j - mc_j) s_j$. Consumer surplus uses the inclusive value. For household i the nested logit generating

function is $G(y) = y_0 + (\sum_{k=1}^{J} y_k^{\frac{1}{1-\sigma}})^{1-\sigma}$. The expected maximum utility of a generalized extreme value model is $\ln G(e^{V_{i0}}, \ldots, e^{V_{iJ}})$ plus Euler's constant (McFadden, 1978). With $V_{i0} = 0$,

$$\mathbb{E}\Big[\max_j u_{ij}\Big] = \ln\left(1 + \left(\sum_{k=1}^{J} \exp\left(\frac{V_{ik}}{1-\sigma}\right)\right)^{1-\sigma}\right) + \text{const} = I_i + \text{const},$$

because $(\sum_k \exp(\frac{V_{ik}}{1-\sigma}))^{1-\sigma} = e^{I_{i1}}$. Dividing utility by the marginal utility of income α_i converts it into dollars. The change in consumer surplus between scenarios s and s' in a market is therefore

$$\Delta CS = M \frac{1}{N} \sum_{i=1}^{N} \frac{I_i^s - I_i^{s'}}{\alpha_i}. \tag{11.130}$$

This is the log-sum formula of Chapter 7, applied household by household. It requires $\alpha_i > 0$ for every simulated household and no income effects.[16] Total surplus is $TS = CS + PS$.

Results. Figure 11.22 reproduces the paper's Figure 4, the price of Miller Lite 12 packs under each scenario, and Table 11.34 reproduces Table X. Figure 11.23 redraws the table as percent changes relative to no merger.

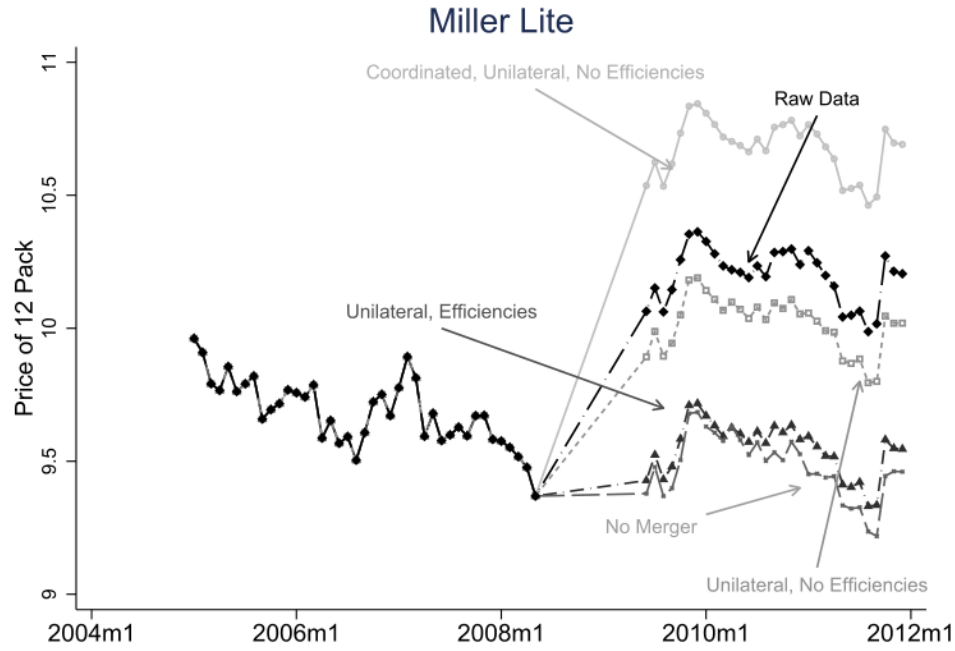

Figure 11.22: Counterfactual prices for Miller Lite 12 packs. The series before mid-2008 is the raw data. After the excluded transition year, the figure shows the raw data and four counterfactual scenarios. They are no merger, unilateral effects with efficiencies, unilateral effects without efficiencies, and coordinated and unilateral effects without efficiencies. Each point is the average price across the 39 regions. Source: Miller and Weinberg (2017), Figure 4.

[16] The paper's tables report welfare changes in percent and do not state the formula. Equation (11.130) is the standard one for this model. By (11.107), $\alpha_i > 0$ requires $D_i < \frac{\alpha}{\Pi_1}$, which equals $\frac{0.0887}{0.0007} \approx 127$ income units under RCNL-1. Income is household income per member in 2010 dollars, with a mean of \$38,000, and D_i is its deviation from the mean (Miller and Weinberg, 2017, pp. 1768 and 1773). The paper does not state the scale of D_i in estimation. If D_i is measured in thousands of dollars, the bound is a per-member income of about \$165,000.

Table 11.34: Results from the counterfactual analysis, 2011 (Miller and Weinberg 2017, Table X)

Coordinated effects	yes	yes	no	no	no
Unilateral effects	yes	yes	yes	yes	no
Efficiencies	yes	no	yes	no	no
	(i)	(ii)	(iii)	(iv)	(v)
Retail prices (dollars)					
ABI	10.03	10.14	9.38	9.55	9.43
Miller	8.94	9.37	8.28	8.72	8.19
Coors	10.18	10.85	9.56	10.22	9.26
Brewer markups (dollars)					
ABI	4.45	4.56	3.81	3.97	3.84
Miller	4.52	4.32	3.83	3.63	3.05
Coors	4.25	4.06	3.61	3.41	2.68
Welfare statistics (percent change relative to column (v))					
Producer surplus	22.1	19.1	10.3	8.2	base
ABI	10.3	19.8	−0.08	9.3	base
Miller	37.8	20.2	24.6	9.1	base
Coors	47.8	12.9	34.7	3.5	base
Consumer surplus	−3.7	−5.3	−0.2	−2.1	base
Total surplus	1.3	−0.6	1.8	−0.1	base

Notes: Prices and markups are volume-weighted means for the 12-pack flagship brands of ABI, Miller and Coors. Welfare statistics are percent changes relative to the no-merger scenario (v), marked "base" (the paper prints a dash), computed on all products. Column (i) uses the raw data and the supply estimates, and columns (ii) to (v) are counterfactuals computed with RCNL-1. All statistics are for 2011. Source: Miller and Weinberg (2017, Table X, p. 1788).

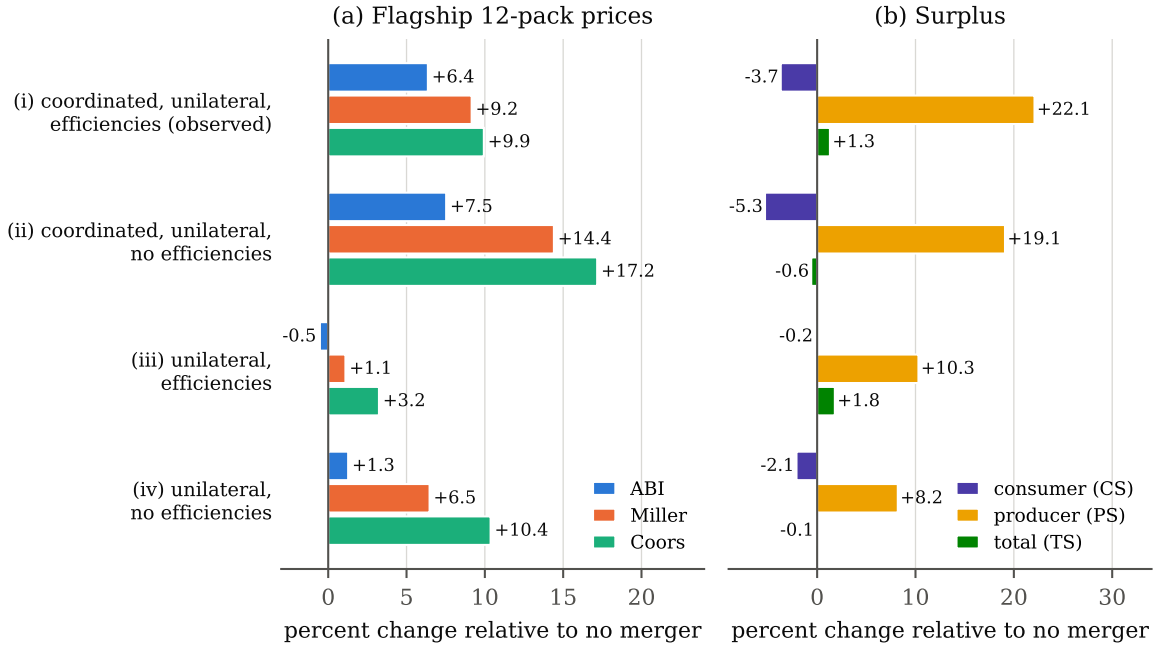

Figure 11.23: The counterfactual analysis of Table 11.34 relative to no merger. Panel (a) shows the percent change in the volume-weighted price of each brewer's flagship 12 packs, computed from the table's prices. Panel (b) shows the percent changes in consumer (CS), producer (PS) and total (TS) surplus reported in the table. Our computations from Miller and Weinberg (2017), Table X.

Prices under no merger lie well below the raw data and roughly continue the pre-merger trend (Figure 11.22). The comparisons between columns isolate each channel. All differences below are our calculations from Table 11.34.

Unilateral effects are large. Moving from column (v) to column (iv) raises the Coors flagship price by \$0.96 (10.4 percent) and the Miller price by \$0.53 (6.5 percent). ABI's price rises by only \$0.12 (1.3 percent), through strategic complementarity. Consumer surplus falls by 2.1 percent.

Efficiencies are also large, and they roughly offset the unilateral effects. Moving from column (iv) to column (iii) lowers the Coors price by \$0.66 and the Miller price by \$0.44. ABI's price falls by \$0.17, to slightly below its no-merger level. With unilateral effects and efficiencies, consumer surplus is only 0.2 percent below the no-merger level and total surplus is 1.8 percent above it. This is the outcome the DOJ expected when it cleared the joint venture. The prices of Table 11.34 also reveal the size of the efficiency. Price minus markup is ABI's implied marginal cost, which stays at \$5.57 to \$5.59 in every column. Miller's implied cost is \$5.05 to \$5.14 without efficiencies and \$4.42 to \$4.45 with them. Comparing scenarios that differ only in efficiencies, (ii) with (i) and (iv) with (iii), Miller's implied cost falls by \$0.63 and \$0.64. Both are close to $\hat{\gamma}_1 = -0.654$ in RCNL-1.

Coordination adds a roughly uniform increment to the prices of all three brewers. Comparing column (i) with column (iii), and column (ii) with column (iv), coordination raises the flagship price by \$0.59 to \$0.66 for each brewer, with and without efficiencies. Relative to no merger, the observed prices are 6.4 percent higher for ABI, 9.2 percent for Miller and 9.9 percent for Coors. Consumer surplus is 3.7 percent lower, so coordination accounts for about 3.5 percentage points of the consumer loss. Without efficiencies the loss would have been 5.3 percent.

Coordination is what makes the merger profitable for ABI. With unilateral effects and efficiencies alone, ABI's producer surplus falls by 0.08 percent, because a more efficient MillerCoors takes sales from it. With coordination it rises by 10.3 percent. The merging parties gain in every scenario, by 24.6 to 47.8 percent with efficiencies.

The welfare verdict depends on the standard. With coordination, total surplus is still 1.3 percent above the no-merger level, so "the antitrust clearance of the merger could be justified under a total welfare standard" (Miller and Weinberg, 2017, p. 1788). Under a consumer surplus standard the merger harmed buyers. The four columns also reveal the size of consumer surplus relative to total surplus. Solving $TS\% = w\,CS\% + (1-w)\,PS\%$ for the weight w gives 0.81 in every column, so consumer surplus is about 81 percent of total surplus in the no-merger benchmark. A 1 percent loss to consumers therefore weighs about four times as much as a 1 percent gain to brewers.

11.8.10 Robustness

The paper's main robustness evidence is the spread across the five demand specifications. The estimate of κ stays between 0.249 and 0.374 across nested logit and RCNL demand, monthly and quarterly data, and different sets of income interactions (Table 11.33). The cost coefficients are similarly stable. Four further checks bear on the main threats.

(a) A supplemental appendix adds a retail sector. Retail market power changes the level of brewers' marginal costs but leaves brewer markups largely unaffected (Miller and Weinberg, 2017, n. 14).

(b) An increasing marginal cost at ABI would bias $\hat{\kappa}$ upward. The paper finds little evidence that ABI faced capacity constraints over the sample period (Miller and Weinberg, 2017,

n. 13).

(c) Two specifications ask whether the Great Recession, rather than the merger, triggered softer competition (Miller and Weinberg, 2017, Section 5.4). With a separate κ for each post-merger month, the estimates rise over time as the economy recovers (their Figure 3). The second specification lets κ vary with demeaned regional mean income $\bar{D}_{rt}$ (unrelated to the aggregate diversion $\bar{D}$ of Definition 11.25),

$$\kappa_{rt} = \frac{\exp(a_P \, \text{Post}_t + a_D \, \bar{D}_{rt})}{1 + \exp(a_P \, \text{Post}_t + a_D \, \bar{D}_{rt})}.$$

Here a_P and a_D are scalar parameters (the paper's a and b). Under RCNL-3, $\hat{a}_P = 0.456$ (0.088) and $\hat{a}_D = 0.033$ (0.039), which does not support countercyclical coordination. Under RCNL-1 the estimates are noisier, $\hat{a}_P = 0.475$ (0.641) and $\hat{a}_D = -0.198$ (1.024) (pp. 1785–1786). The authors conclude: "Given the totality of the evidence, we view the merger as the most likely catalyst of softer price competition" (p. 1786).

(d) The paper's conclusion states that the price increases of MillerCoors and ABI, "in both absolute terms and relative to their competitors," are "visually evident and confirmed with econometric analysis" (Miller and Weinberg, 2017, p. 1788). The econometric analysis regresses the log real retail price on post-merger indicators for MillerCoors products, for ABI products and for all products (Miller and Weinberg, 2017, eq. (1)). The regression includes product-by-region fixed effects and a linear time trend. The fullest specification adds product-specific trends and regional employment and earnings and drops the year after the merger (Table II, column (iv)). Its MillerCoors and ABI coefficients, which measure price changes relative to the imports, are 0.069 and 0.062, each with a standard error of 0.007. The descriptive regressions also support the power of the supply instrument (p. 1780).

11.8.11 Assessment

The paper's central finding is robust within its framework. Given the estimated demand system and the assumption of parallel cost trends, ABI's post-merger prices are too high for Nash pricing. Whether the finding means that the merger caused tacit coordination depends on several assumptions, which the literature and the paper itself discuss.

What κ measures. By Remark 11.52, κ is a conduct parameter, and the critique of Corts (1999) applies. Suppose firms play a repeated game in which the degree of cooperation varies over time. A single estimated weight then summarizes average behavior, and it need not measure the true degree of collusion (Chapter 3). The paper acknowledges the point and notes that a nonzero κ still rejects post-merger Nash pricing (Miller and Weinberg, 2017, n. 12). The same footnote cites Bresnahan (1989) and Porter (1983a) on identification with regime shifts. A related concern is that κ is not a structural primitive. Repeated-game theory (Chapter 12) predicts that the sustainable degree of cooperation depends on costs, asymmetries and the number of firms. Scenario (ii) removes the efficiencies but holds κ at $\hat{\kappa}$. The efficiencies changed MillerCoors's costs and margins, and with them the gains from cooperation and from deviation. The data do not reveal the value of κ without efficiencies, so scenario (ii) is best read as a partial counterfactual.

Price leadership. The internalization weight summarizes outcomes. It leaves open the mechanism that produces them. Documents from the DOJ's review pointed to leader-follower

pricing, and the paper discusses qualitative evidence of price leadership that surfaced in other beer litigation (Asker and Nocke, 2021, pp. 241–242). In follow-on work, Miller et al. (2021) investigate this price-leadership mechanism (Asker and Nocke, 2021, p. 242, n. 166). In their model the leader, ABI, announces supermarkups over Bertrand prices, and a coalition of ABI, Miller and Coors (later MillerCoors) adopts them (Miller et al., 2021, pp. 3124 and 3140). Their model gives a mechanism for the coordinated effects that the conduct parameter detects. It also connects this case to the evidence on price leadership and tacit coordination in Chapter 13.

Confounds at the time of the merger. The identifying assumption is parallel trends in unobserved marginal costs between ABI and the importers (Proposition 11.57). Several events in the excluded window could violate it. InBev took control of Anheuser-Busch in November 2008 (Miller and Weinberg, 2017, p. 1784), which could have changed ABI's costs or its pricing policy independently of the joint venture. A change in ABI's objectives that raised its prices would load onto $\hat{\kappa}$. The paper notes that the price increases of its Figure 1 predate the close of that deal (n. 16). Exchange rates moved sharply in late 2008. The monthly average rate rose from 10.1 pesos per dollar in August 2008 to 13.4 in December (Board of Governors of the Federal Reserve System, 2026). Corona is shipped from Mexico (Miller and Weinberg, 2017, n. 4), so import costs measured in dollars need not have followed ABI's domestic costs. If import costs fell relative to ABI's, the model reads ABI's relative price rise as a markup and $\hat{\kappa}$ is biased upward. The recession is a further confound. The income interactions and the period effects absorb part of it, and the domestic sales decline argues against pure down-market substitution. A recession that changed the relative demand for domestic and imported beer in ways the income interactions miss would still bias the estimate.

Retailers and the three-tier system. The model treats brewers as setting retail prices. In practice brewers set prices to distributors, who set prices to retailers. Hypothesis (H3), equal retail prices for the three flagship light beers, is a retail convention. The structural model can only attribute such a pattern to brewer conduct. The retail appendix shows that brewer markups are robust to retail market power, which addresses the level of costs but not retail pricing conventions.

The Nash restriction on imports. The supply model forces Modelo and Heineken to price as Nash players. The paper motivates this with qualitative evidence (Miller and Weinberg, 2017, pp. 1773 and 1779). The DOJ's complaint against ABI's acquisition of Modelo alleges that Modelo declined to match many of the price increases led by ABI. Modelo instead followed a "Momentum Plan" designed to grow its share by shrinking its price gaps with domestic premium brands. The complaint does not address Heineken's pricing, and the paper notes that Heineken's retail prices are similar to Corona's (p. 1773). Anheuser-Busch's equity stake in Modelo, mentioned in Section 11.8.3, would by itself justify a positive weight between ABI and Modelo in the sense of O'Brien and Salop (2000). Since the importers are the control group in Proposition 11.57, any softening of their own conduct after the merger would change the comparison.

Dependence on substitution patterns. The estimate of κ is the part of ABI's price rise that unilateral effects cannot explain, so it inherits every restriction of the demand model. Table 11.32 shows substitution close to proportional to shares, with no special closeness among the domestic light beers. If Bud Light, Miller Lite and Coors Light were closer substitutes than the RCNL implies, the Nash model would predict a larger response of ABI to MillerCoors's price increase. Less of the rise would then be left for κ. A model with a light-beer or domestic nest, or with unobserved random coefficients, would test this. The nested logit column is consistent with

this direction. Its weaker substitution among inside goods comes with the largest estimate, $\hat{\kappa} = 0.374$.

Measuring efficiencies. The MillerCoors post-merger indicator absorbs any change in MillerCoors's implied costs relative to the importers. It therefore measures efficiencies as a residual, and anything else that lowered MillerCoors's implied costs would be counted as an efficiency. Independent evidence comes from Ashenfelter et al. (2015). They correlate post-merger price changes across regions with the predicted change in concentration and the predicted reduction in shipping distances. Larger increases in concentration went with larger price increases, and larger reductions in shipping distance went with smaller ones (Asker and Nocke, 2021, p. 220). The timing also differed. Market-power effects arrived faster than the efficiencies, and cost reductions were "not fully incorporated into pricing until about two years after the merger's approval" (p. 220). A residual measured soon after the merger may therefore understate the long-run efficiency. The study gives direct evidence that the efficiencies were real. Whether they were specific to the merger is less clear, as Section 11.1.3 discusses.

Contribution. Miller and Weinberg (2017) changed the empirical analysis of mergers in three ways. First, they showed how to test the conduct assumption that every merger simulation maintains. They nested Nash pricing in a model with a post-merger internalization weight and identified the weight from a consummated merger, with non-merging rivals as controls. Second, they decomposed observed post-merger prices into unilateral effects, coordinated effects and efficiencies, and showed that the decomposition reverses the welfare verdict between total and consumer surplus standards. Third, they provided structural evidence for the agencies' concern that a merger can soften competition between the merged firm and its rivals. The authors call this evidence "somewhat novel in the empirical literature." That literature "has focused much more on understanding how mergers affect the unilateral pricing incentives of firms, holding the equilibrium concept fixed" (Miller and Weinberg, 2017, p. 1788). The case complements the validation exercise of Section 11.7. There a unilateral-effects simulation underpredicted the observed price increase of the merging firms' rivals, and here a structural model attributes a similar rival response to coordination.

11.9 Beyond short-run prices: spatial markets, repositioning and investment

The merger simulations of Section 11.5 hold three things fixed. They fix the set of products and their characteristics. They fix each firm's capacity. They also summarize substitution with a demand system in which location plays no explicit role. This section studies three papers that relax one of these restrictions each. Houde (2012) builds the geography of a retail market into demand and checks a merger simulation against a difference-in-differences estimate of the same merger. Sweeting (2010) documents how merging radio stations change their programming, a dimension that a price-only analysis ignores. Pesendorfer (2003) models capacity investment and uses investment choices to infer the cost savings that mergers produced.

11.9.1 Spatial competition and the Ultramar-Sunoco transaction: Houde (2012)

Question. How much does a merger of retail outlets raise prices when consumers are mobile? Houde (2012) argues that the relevant location of a gasoline buyer is the whole route she drives between home and work, not her home address. Two stations far apart can then be

close substitutes if many commuters pass both. Substitution depends on the road network and on the direction of traffic. The paper asks two questions. Does a demand model built on commuting paths fit the data better than the usual home-address model? Does a merger simulation based on it predict the price effects of an observed merger, as measured by a retrospective difference-in-differences study?

The second question matters for the methodological debate of Sections 11.6 and 11.7. A retrospective estimate is transparent but tied to one sample and one control group. A simulation can evaluate any counterfactual but rests on a demand model. Comparing the two on the same merger is a validation exercise in the spirit of LaLonde (1986), who compared nonexperimental estimators with an experimental benchmark. Here the demand model is estimated without the supply restrictions that the merger imposes, so the comparison is a true out-of-sample test.

Setting. The market is the Quebec City census metropolitan area between 1991 and 2001. Five major brands were present: Shell, Esso, Petro-Canada, Irving and Ultramar. Ultramar was the leading chain and the only firm with a refinery near the city. The 1990s brought a large reorganization of North American gasoline retailing. Technology raised the efficient size of stations, the value of small repair garages fell, and new environmental rules forced owners to replace underground storage tanks. The number of stations in Quebec City fell by 30 percent, from 382 in 1991 to 283 in December 2001, mostly through exit by stations of the major chains (Houde, 2012, p. 2152).

Two further facts shape the analysis. Prices are tightly clustered. Over most of the period the interquartile range of prices was below one cent per litre (cpl), about 1.5 percent of the average price. Retail margins over the rack price, the wholesale price posted at the terminal, ranged between 8 and 15 percent of the price for most of the period. There were also two price wars. The first, in the summer of 1996, followed excess capacity and a low-price guarantee campaign by Ultramar. In 2000 average margins fell to zero after several stations priced at a regulated price floor, introduced by a provincial law of December 1996 (Houde, 2012, pp. 2152–2153).

Data. The station data come from Kent Marketing, a survey firm that visits every station at the end of each survey period and reads the volume sold off the pump meters. The panel has 46 bimonthly periods between 1991 and 2001, with only the fourth period observed in the first four years. It contains 14,263 station-period observations on 429 station sites. Observed characteristics include the size of the convenience store, a repair-shop indicator, the numbers of service islands and pumps, opening hours, brand, type of service and a car wash. The price is the posted unleaded price on the survey day, deflated by the regional consumer price index. Average volume was 4,934 litres per day (standard deviation 3,289), and the average real price was 63.83 cpl (Table 1). About 8 percent of the sample stations refused the survey in some or all periods. Their characteristics and prices are observed, and Houde imputes their volumes by linear regression on neighborhood shares, predicted traffic, population density, location, prices, characteristics and lagged sales (Houde, 2012, p. 2151, n. 12).

Table 1 also shows how much the stations changed over the decade. From fall 1991 to fall 2001 average volume rose from 3,949 to 6,271 litres per day, and the number of pumps from 7.77 to 11.37. The share of full-service stations fell from 0.54 to 0.28. The average absolute deviation of a station's price from the period mean fell from 0.90 to 0.13 cpl, as most stations came to post the modal price (Houde, 2012, p. 2152).

The geography comes from three sources. A road network with more than 30,000 street segments gives travel times, and a shortest-path algorithm gives each commuter's route. Origin-destination surveys from 1991, 1996 and 2001 give the number of commuters between traffic zones, by purpose and mode. Census and labor-force data give the population and

the income distribution of each residential area. Commuters who cross the city on highways are proxied by occupied hotel rooms. Before estimating any model, Houde (2012, Figure 2) compares station sales with two crude predictions. If consumers buy at random from stations within half a minute of their commuting path, predicted and observed shares have a correlation near 0.3 in every period. If they buy at random near home, the correlation is near zero or negative.

Model. Consumer i commutes from home location s_i to work location d_i along the fastest route $r(s_i, d_i)$. The route takes time $t(s_i, d_i)$ and covers $m(s_i, d_i)$ kilometers. Station j sits at location l_j. The consumer buys from one of the J stations or takes the outside option $j = 0$, which is to commute without a car. Her indirect utility is (Houde, 2012, eq. (1))

$$u_{ij} = \begin{cases} x_j\beta + (\bar{\alpha} + \alpha_y y_i)\, p_j + \lambda_1\, \mathcal{D}\big(r(s_i, d_i), l_j\big) + \xi_j + \epsilon_{ij}, & j = 1, \ldots, J, \\ -\lambda_0\, Long(s_i, d_i) + \epsilon_{i0}, & j = 0. \end{cases} \tag{11.131}$$

Here x_j collects station characteristics, brand and period dummies, ξ_j is unobserved station quality, y_i is the log hourly wage, and ϵ_{ij} is type-I extreme value. The indicator $Long(s, d)$ equals one when home and work lie in different traffic zones. Houde writes $C(s, d)$ for it, and we rename it to avoid confusion with cost functions. Long commuters are more likely to drive, so we expect $\lambda_0 > 0$. The paper writes the price term as $+(\bar{\alpha} + \alpha_y y_i)\, p_j$ (eq. (1) and p. 2157), and the estimated $\bar{\alpha}$ is negative (Table 3). In the sign convention of this book the consumer's price coefficient is therefore $\alpha_i = -(\bar{\alpha} + \alpha_y y_i)$. The symbols λ_0 and λ_1 are local to this subsection.

The novel object is the *detour* $\mathcal{D}$. It measures the extra driving time needed to stop at l on the way from s to d:

$$\mathcal{D}\big(r(s, d), l\big) = t(s, l) + t(l, d) - t(s, d). \tag{11.132}$$

A station on the route costs no extra time. The standard single-address model is nested as the special case in which the consumer starts and ends at home, $\mathcal{D}^h(s, l) = 2\, t(s, l)$. Transport costs make utility fall with the detour, so we expect $\lambda_1 < 0$. Figure 11.24 illustrates the difference between the two metrics.

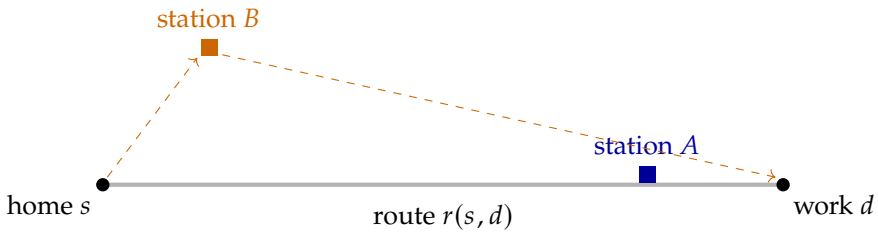

Figure 11.24: Two distance metrics in the demand model of Houde (2012). Station A lies on the commuter's route near her workplace, so it requires no detour although it is far from home. Station B is close to home but off the route. The commuting metric ranks A closer, and the home metric ranks B closer.

Gasoline demand is inelastic at the individual level. A consumer of type (s, d) who buys at all buys $\bar{q}(s, d) = \bar{q}_0 + \bar{q}_1 m(s, d)$ litres, where $\bar{q}_1$ is fixed at the average fuel use of a city car and $\bar{q}_0$ is estimated. Houde writes c_0 and c_1 for these parameters. The text fixes $\bar{q}_1$

at 0.10 litres per kilometer (p. 2156), while Tables 3 and 4 list the fixed value as 0.2. The paper does not reconcile the two numbers. With $T_{s,d}$ commuters between s and d, market size is $M = \sum_s \sum_d \bar{q}(s,d)\, T_{s,d}$ (eq. (2)). Write the inside utility net of the logit shock as $V_{ij} = \delta_j + (\bar{\alpha} + \alpha_y y_i) p_j + \lambda_0 Long(s_i, d_i) + \lambda_1 \mathcal{D}(r(s_i, d_i), l_j)$, where $\delta_j = x_j\beta + \xi_j$. Adding $\lambda_0 Long$ to every inside option normalizes the outside utility to zero. The choice probability and station demand are (eqs. (3)–(4))

$$P_{ij} = \frac{\exp(V_{ij})}{1 + \sum_{k=1}^{J} \exp(V_{ik})}, \qquad Q_j(p) = \sum_s \sum_d \bar{q}(s,d)\, T_{s,d} \int P_j\big(r(s,d), y\big)\, dF(y \mid s), \tag{11.133}$$

where $F(y \mid s)$ is the wage distribution in home area s. The integral is computed by simulation.

Houde also estimates a discrete-continuous alternative, in which each consumer's quantity responds to price through Roy's identity. The demand results are unchanged. The supply results, however, imply that firms behave as strategic substitutes after a simulated merger, so that competitors cut their prices. Houde attributes this to conditional demand that is inelastic for most consumers and treats the functional form as inaccurate (Houde, 2012, p. 2157, n. 24).

The commuting structure determines substitution through the following algebra. Write $a_i = \bar{\alpha} + \alpha_y y_i < 0$ and let $\sum_i h_i(\cdot)$ denote the sum over consumer types, with weights $h_i = \bar{q}(s_i, d_i) T_{s_i,d_i}\, \mathrm{d}F(y_i \mid s_i)$. The logit derivatives are $\frac{\partial P_{ij}}{\partial p_j} = a_i P_{ij}(1 - P_{ij})$ and $\frac{\partial P_{ik}}{\partial p_j} = -a_i P_{ij} P_{ik}$. Summing over types gives the diversion ratio from j to k of Definition 4.10:

$$\begin{aligned} D_{jk} = -\frac{\frac{\partial Q_k}{\partial p_j}}{\frac{\partial Q_j}{\partial p_j}} &= \frac{\sum_i h_i(-a_i) P_{ij} P_{ik}}{\sum_i h_i(-a_i) P_{ij}(1 - P_{ij})} \\ &= \sum_i \underbrace{\frac{h_i(-a_i) P_{ij}(1 - P_{ij})}{\sum_{i'} h_{i'}(-a_{i'}) P_{i'j}(1 - P_{i'j})}}_{\text{weight of type } i} \frac{P_{ik}}{1 - P_{ij}}. \end{aligned} \tag{11.134}$$

For each type the diversion is the logit ratio $\frac{P_{ik}}{1 - P_{ij}}$ of Chapter 7, proportional to k's share. Aggregate diversion averages these ratios with weights that are large for the types who buy at j and are price sensitive. Station k therefore captures much of j's lost volume when the commuters who patronize j also pass close to k. This is how the road network enters the substitution matrix, and why stations far apart can be close substitutes. A home-address model weights types by where they live and misses this channel.

Estimation. The parameters $(\bar{q}_0, \lambda_0, \lambda_1, \alpha_y, \bar{\alpha}, \beta)$ are estimated by the nested fixed point GMM method of Berry (1994) and Berry et al. (1995) (Chapter 8). Two sets of moments are combined. The first follows Nevo (2001) and uses station-location fixed effects. Write $\xi_{jt} = \bar{\xi}_j + \tilde{\xi}_{jt}$, where $\bar{\xi}_j$ is the permanent quality of the site (ease of access, side of the street) and $\tilde{\xi}_{jt}$ a transitory shock. With $\tilde{w}_{jt}$ the within-station deviation of a variable, the moments are (eq. (5))

$$\bar{g}^1_n(\theta) = \frac{1}{n} \sum_{j,t} \tilde{\xi}_{jt}(\theta)\, \tilde{W}^1_{jt}, \tag{11.135}$$

where $\tilde{W}^1_{jt}$ contains the within-transformed station characteristics, the excluded instruments z_{jt} and period dummies.

The second set is a micro moment that disciplines the outside option. The 2001 origin-destination survey reports the share of commuters between each pair of zones who drive. The model predicts the same share as one minus the probability of the outside option, $U_{sd}(\theta)$. With $\hat{U}_{sd}$ the observed share, the moments are (eq. (6))

$$\bar{g}^2_{n_2}(\theta) = \frac{1}{n_2} \sum_{s,d} \left(U_{sd}(\theta) - \hat{U}_{sd}\right) W^2_{sd}, \tag{11.136}$$

with W^2_{sd} a constant, the long-commute indicator and simulated income. These moments force the model to reproduce a reduced-form regression estimated on 3,000 simulated survey respondents (eq. (7)):

$$\hat{U}_i = \underset{(0.033)}{0.247} + \underset{(0.0141)}{0.0495}\, y_i + \underset{(0.0163)}{0.315}\, Long_i, \qquad R^2 = 0.47. \tag{11.137}$$

The intercept pins down $\bar{q}_0$ and hence market size, the income slope pins down α_y, and the long-commute slope pins down λ_0. The weighting matrix allows for serial and spatial correlation in $\tilde{\xi}_{jt}$. With 46 periods and more than 300 stations, the inner loop is costly. Houde inverts demand with a derivative-free quasi-Newton algorithm, which is faster than the contraction mapping of Berry et al. (1995). The inner-loop tolerance is 10^{-12}, tightened to 10^{-14} for the standard errors (Houde, 2012, p. 2160, n. 27).

Instruments and identification. Two parameters need excluded variation: the price coefficient $\bar{\alpha}$ and the transport cost λ_1. Prices are endogenous because firms see ξ_{jt} and because frequent price changes make the survey-day price a noisy measure of the price that generated the period's volume. The transport cost enters nonlinearly, and it is identified by how a station's sales respond to changes in its neighbors.

The identifying assumption is that the transitory quality shock $\tilde{\xi}_{jt}$ evolves independently of the characteristics of nearby stations, conditional on location fixed effects. The industry reorganization supplies the variation. Stations closed, opened and were rebuilt for reasons of technology and regulation that were unrelated to local demand shocks. Entry, exit and remodeling involve large sunk costs, so they plausibly respond to $\bar{\xi}_j$ but not to $\tilde{\xi}_{jt}$. Cross-sectional versions of this argument, which assume that location quality is independent of neighbors' characteristics, would bias the transport cost toward zero if stations locate at high-traffic, high-quality sites (Houde, 2012, p. 2160).

Competitors' characteristics are weak instruments for price, because cross-sectional price dispersion is small. Rack prices vary mostly over time and are absorbed by period effects. Houde therefore exploits small differences in the posted rack prices of two suppliers. Sunoco supplied the Quebec City terminal until 1997, and the independent wholesaler Olco took over afterward. The instruments interact the Sunoco and Olco rack prices with indicators for a Sunoco or Olco station in the neighborhood of station j. Table 2 of the paper defines four instrument sets. Specification (1) uses the count and average size of competitors on the same street and the average competitor size within 0.1, 0.33 and 1 kilometer (5 instruments). Specification (2) uses the rack-price interactions (4 instruments). Specification (3) combines the two, and specification (4) adds the fractions of competitors with various amenities (25 instruments in that set). Two stations share a street if they have a street in common and are within five minutes of each other. The first-stage F-statistics exceed 10 for specifications (2) and (3).

Demand results. Table 11.35 reproduces the estimates of the multi-address (commuting) model and of the single-address (home) model. The two models differ most in the transport cost. In

the commuting model λ_1 is negative, large and precise, except in specification (2), which uses only the cost instruments. In the home model it is positive in every specification, so consumers would prefer stations farther from home. The correlations in Figure 2 of the paper explain the sign. Large stations sit at the intersections of major commuting routes, often far from where people live, so the home model can rationalize their sales only with a small or positive transport cost.

Notes: Reproduced from Houde (2012, Tables 3 and 4), with the paper's signs (a negative $\bar{\alpha}$ means that utility falls with price, a negative λ_1 that it falls with the detour). Standard errors robust to serial and spatial correlation in parentheses. The commuting-distance coefficient $\bar{q}_1$ is fixed. Both tables list it as 0.2, although the text fixes it at 0.10 litres per kilometer (p. 2156). The income row is the coefficient on the log hourly wage, scaled as in the paper. Columns use the instrument sets (1) to (4) described in the text. All specifications include location, time and brand fixed effects and time-varying station characteristics. The travel cost is the ratio of λ_1 to the price coefficient at the median wage. There are 14,263 observations on 429 stations in every column.

The price coefficient implies station-level own-price elasticities between −10 and −15, which fits a market of nearly homogeneous products. The ratio of λ_1 to the price coefficient prices a minute of detour. Its median is about 5 cpl per minute in specification (3). For a 20-litre purchase, Houde converts this into about \$0.9 per minute of shopping, or \$54 per hour, four times the average hourly wage (Houde, 2012, p. 2163). He reads the number as an upper bound

on the value of time, because the detour measure ignores congestion and the cost of re-planning a route. A large transport cost does not mean that consumers face few options. The average consumer passes 10 stations within one minute of her route, and long commuters pass more.

The J-statistics favor the commuting model. Its statistics are below the 5 percent χ^2 thresholds in specifications (1) to (3) and slightly above it in (4). The single-address model's statistics are roughly twice as large and exceed the thresholds in all specifications except (2). Specification (3) of the commuting model is the preferred specification and the basis of the merger analysis.

Tables 5 and 6 of the paper describe the implied substitution matrix on a 10 percent random sample of station pairs. Cross-price elasticities are very skewed. Their mean is 0.025 and their median 0.0013, while the 99th percentile is 0.397 and the maximum 5.26. Each station has two or three close competitors, located within about 1.25 minutes and sharing more than 70 percent of traffic. Table 6, column 3, regresses normalized cross elasticities on pair characteristics. The coefficient on the share of common traffic is 0.449 (0.0178), on driving time −0.00105 (0.0000716), and on sharing a street 0.0611 (0.00812), with $R^2 = 0.453$. Commuting patterns and driving times alone explain about half of the variation in substitution.

The transaction. In March 1996 Ultramar and Sunoco announced a swap of retail networks. Ultramar acquired 127 Sunoco stations in Quebec, and Sunoco acquired 88 Ultramar sites in Ontario. Sunoco had no refinery in Quebec, while Ultramar wanted to sell more of its Saint-Romuald refinery's output locally. The Competition Bureau had studied the proposal in December 1995 and deemed it unlikely to lessen competition substantially. Sunoco stopped supplying its Quebec City terminal on January 1, 1997, and Olco began selling unbranded gasoline from it. The first Sunoco station was rebranded in the second quarter of 1997, and the paper dates the merger to January 1997 (Houde, 2012, p. 2167).

The transaction is *vertical* in form and horizontal in effect. From January 1997 Ultramar supplied the former Sunoco stations, and through its contracts it controlled their retail prices. In Quebec City, Sunoco had 12 stations in December 1996. Ultramar went from 50 to 62 stores and from 16 to 20 percent of the market. Table 7 of the paper tracks the rebranding. Sunoco-branded stations numbered 12 in January 1997 and 6, 3 and 0 in January 1998, 1999 and 2000. Over the same dates, 0, 5, 8 and 10 stations carried the Ultramar brand after rebranding. Of the 313 stations active in January 1997, 5.3 percent lay within half a minute of a Sunoco station, 6.3 percent within one minute and 10.1 percent within 1.5 minutes. The common-street neighborhood, made of stations that share a street with a Sunoco station, contained 31.4 percent. These neighborhoods overlap, so the fractions do not add up.

Supply and marginal costs. Majors sell through company-owned stations, commission agents and lessee dealers. In the first two the supplier sets the retail price. In 2001 between 52 and 72 percent of branded stations were company-owned (Houde, 2012, p. 2168). Ultramar used commission contracts throughout and so acted as a vertically integrated chain. The other majors set station-specific wholesale prices weekly and gave lessees a price-support clause that guaranteed a minimum margin. Houde therefore assumes *resale price maintenance* (RPM): each brand supplier f chooses the retail prices of all its stations $\mathcal{J}_f$ (eq. (8)),

$$\max_{\{p_j\}_{j\in\mathcal{J}_f}} \sum_{j\in\mathcal{J}_f} (p_j - c_j)\, Q_j(p_f, p_{-f}).$$

Let Δ^Q be the Jacobian of station volumes, with (j,k) element $\frac{\partial Q_j}{\partial p_k}$, and let Ω be the brand ownership matrix. In the stacked form of Section 11.5, the first-order conditions and the

implied marginal costs are

$$Q(p) + \left(\Omega \odot \Delta^{Q}\right)^{\top}(p - c) = 0 \quad \Longrightarrow \quad c = p + \left[(\Omega \odot \Delta^{Q})^{\top}\right]^{-1} Q(p). \tag{11.138}$$

Houde writes the same condition as $Q + (\Omega * \Delta)(p - c) = 0$ with $\Delta_{ij} = \frac{\partial Q_j}{\partial p_i}$, which is our transposed Jacobian (eqs. (9)–(10)).

Table 8 of the paper compares sales-weighted Lerner indices $\frac{p-c}{p}$ under four conduct assumptions. With the commuting model they are 0.0970 when every station prices independently, 0.101 when station owners price jointly, 0.1036 under RPM and 0.2684 under joint profit maximization. The observed margin over the average rack price, net of consumption taxes, is 0.0898. The RPM markups are close to this benchmark and imply a station marginal cost about one percentage point below the rack price. The home model gives 0.1414, 0.1504, 0.1576 and 0.858 under the same four assumptions, so its RPM markups are about 50 percent higher than those of the commuting model. The comparison excludes 2000, 2001 and the summer of 1996.

Houde then decomposes marginal cost into a supplier-period wholesale component and station characteristics,

$$c_{jt} = Z_{jt}\zeta + w_{f(j),t} + \eta_{jt}. \tag{11.139}$$

The equation is estimated by OLS with supplier-by-period fixed effects on the sample before 2000, excluding the 1996 price war (eqs. (10)–(11)). Each regular pump lowers marginal cost by 0.0231 cpl (0.0061), and full service raises it by 0.171 (0.08). A car wash lowers it by 0.152 (0.062), and a repair shop raises it by 0.236 (0.082). The coefficient on the absence of a convenience store is printed as 117 (0.062). Given the standard error and the text, which says that stations with a convenience store have lower costs, it must be 0.117. Lessee dealers are not significantly different from company-owned stations, 0.088 (0.072), and $R^2 = 0.92$. The fixed effects $\hat{w}_{f,t}$ track the posted rack price closely after 1993 (Figure 3 of the paper). Independents face wholesale costs a little more than one cent above Ultramar's. The decomposition lets the simulation give former Sunoco stations Ultramar's upstream cost, which measures the efficiency side of the transaction.

Merger simulation. The simulation uses only pre-merger data. For each survey period, Houde solves the RPM equilibrium with the former Sunoco stations added to Ultramar's ownership set, holding marginal costs fixed. He then measures the simulated price change in four treatment neighborhoods around Sunoco stations: within half a minute, one minute, 1.5 minutes, and on a common street. The control group is all other stations. The difference between the average changes in the two groups is the simulated analogue of a difference-in-differences coefficient. The paper describes the simulated periods in two ways. The text covers every period from 1995 to 1997 except June and July 1996 (p. 2171). The notes to Tables 9 and 10 cover January to December 1996, excluding June. Both versions leave out the price war of summer 1996, and the numbers below are those of the tables.

Table 9 of the paper reports average simulated price changes of 0.406, 0.343, 0.219 and 0.101 cpl in the four treatment groups. The matching control groups change by 0.019, 0.019, 0.019 and 0.011 cpl. The simulated difference-in-differences effects are therefore 0.388, 0.325, 0.200 and 0.090 cpl, decreasing quickly with distance. Table 11.36 decomposes the half-minute effect. The *direct effect* is the price change at stations supplied by Ultramar after the merger, which internalize the diversion between Ultramar and former Sunoco outlets. The *indirect effect* is the response of competitors to those price increases.

Four features of the simulation stand out. Former Sunoco stations raise prices by 0.526 cpl on average, with a range from about 0.2 to nearly 1 cpl across stations. Giving them Ultramar's

Table 11.36: Simulated effects of the Ultramar-Sunoco merger on prices (cpl), half-minute neighborhood

Notes: Reproduced from Houde (2012, Table 10). Average simulated price changes between January and December 1996, in cents per litre. Numbers in parentheses are standard deviations of the simulated changes across stations, which measure heterogeneity, not sampling error. "In" and "Out" refer to stations within and beyond half a minute of a Sunoco station. Direct effects are computed at Ultramar, Sunoco and Sergaz stations, and indirect effects at all other stations. Chain: resale price maintenance by brand suppliers. Owner: station owners set prices. Cost adjusted: former Sunoco stations get Ultramar's upstream cost. Restricted choice set: consumers choose among the 10 stations closest to their route.

lower upstream cost reduces this by only about 0.05 cpl, because Sunoco was estimated to be almost as efficient. Ultramar stations outside the half-minute neighborhood raise prices by 0.102 cpl, so a retrospective study that used them as controls would understate the direct effect (0.460 against a difference of 0.357). This is the control-group bias of Proposition 11.39. Finally, competitors respond very little, raising prices by 0.026 cpl. Houde attributes this to the logit shock, which spreads substitution over all stations and the outside good. When consumers can choose only among the 10 stations nearest to their route, the competitors' response more than doubles, to 0.064 cpl, while the direct effect barely changes.

Figure 11.25 shows where the price effects come from. Ultramar stations that compete closely with a Sunoco station raise prices most, and the relation with the maximum cross elasticity is almost linear. The competitors' responses follow the same pattern on a scale about fifteen times smaller and with more noise. Single-station owners react more strongly to a close competitor's price increase than multi-station chains do.

Retrospective analysis. The difference-in-differences design follows Hastings (2004). Let N_j^d indicate that station j lies in neighborhood d of a Sunoco station, and let T_t indicate periods from 1997 on. The indicator S_{jt} marks stations supplied by Ultramar after the merger (Ultramar, former Sunoco and Sergaz stations). The two regressions are (eqs. (12)–(13))

$$p_{jt} = \gamma\, N_j^d T_t + Z_{jt}\omega + \mu_j + \tau_t + u_{jt}, \tag{11.140}$$

$$p_{jt} = \gamma_0\, N_j^d T_t S_{jt} + \gamma_1\, N_j^d T_t (1 - S_{jt}) + Z_{jt}\omega + \mu_j + \tau_t + u_{jt}, \tag{11.141}$$

with station fixed effects μ_j, period effects τ_t and time-varying characteristics and sales volume in Z_{jt}. The coefficient γ is the average merger effect in the neighborhood, γ_0 the direct effect and γ_1 the competitive effect. Identification requires that, absent the merger, prices in treated

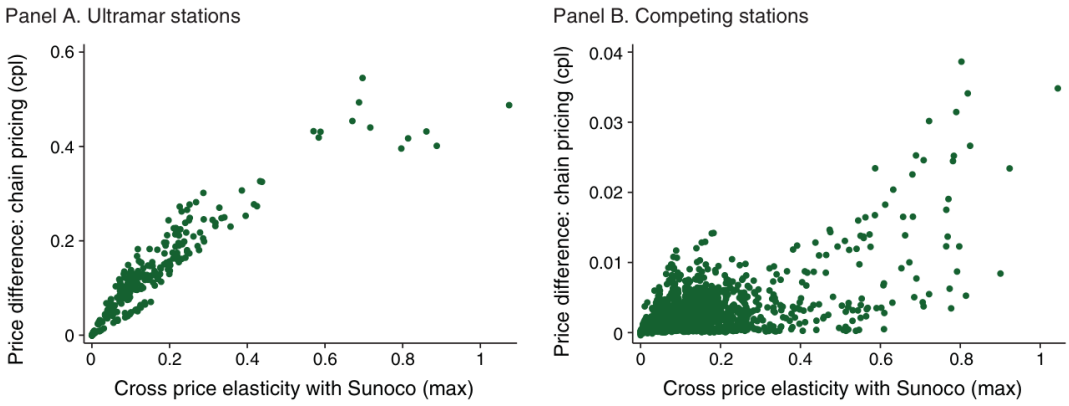

Figure 11.25: Simulated post-merger price changes (chain pricing, cpl) at Ultramar stations (panel A) and at competing stations (panel B), plotted against each station's maximum cross-price elasticity with a Sunoco station. Note the different vertical scales. Source: Houde (2012), Figure 4.

and control neighborhoods would have moved in parallel. A national swap negotiated for other reasons is plausibly unrelated to local demand shocks. The price-floor regulation introduced in 1997 must also have affected treated and control stations alike. Standard errors are clustered by location.

Table 11.37 reports the estimates. Every specification finds a price increase in the treated neighborhoods, so the market-power effect dominated any efficiency gain. The aggregate half-minute effect ranges from 0.156 to 0.433 cpl depending on the sample. Average retail margins were about 4 cpl at the time, so the merger raised margins by at most 11 percent and prices by about 0.7 percent. In US units the increase is at most 1.75 cents per gallon. It is smaller than the 5 cents of Hastings (2004) and larger than the 1 cent of Taylor et al. (2010) (Houde, 2012, p. 2176). The effect comes mostly from stations supplied by Ultramar, with direct effects between 0.2 and 0.5 cpl. The competitive effect is imprecise and sometimes negative. It becomes significant only in the sample that extends to 1998, when more stations had been rebranded. In the 1995–1997 sample with the price war, the effect declines with the size of the neighborhood. In the 1995–1998 sample, which drops the price war and adds the rebranding period, it declines much less (Panel B). Houde attributes the flatter profile to the rebranding periods in that sample (p. 2177).

Comparing simulation and retrospective estimates. The two methods agree on the main magnitude. The simulation predicts 0.38 cpl in the half-minute neighborhood, and the aggregate retrospective estimates in Table 11.37 range from 0.16 to 0.43 cpl. Both attribute most of the effect to the merging chain's internalization of diversion between its old and new stations. Both find larger effects where Ultramar and Sunoco stations competed for the same commuters.

They disagree in two ways that point to the model's weak spot. The retrospective competitive effect is larger in one sample, and the observed effect falls more slowly with distance. The simulated effect falls from 0.388 to 0.090 cpl across the four neighborhoods, while the estimated effect falls from 0.433 to 0.266 cpl in the sample with the price war. The logit shock makes simulated competitor responses too small, a limitation common to most differentiated products models with idiosyncratic shocks (Chapter 8). Without the price war, the retrospective estimate (about 0.2 cpl) is below the simulated one (about 0.38 cpl, given as 0.37 in the paper's discussion). The gap may indicate efficiencies larger than those estimated.

Table 11.37: Retrospective estimates of the Ultramar-Sunoco merger effect on prices (cpl)

Panel A. Direct and competitive effects, half-minute neighborhood (Table 11)

	(1)	(2)	(3)	(4)	(5)	(6)
Sample	95/97	95/97	95/97	95/97	95/98	95/98
1996 price war included	Yes	Yes	No	No	No	No
Merger × direct		0.501		0.202		0.211
		(0.121)		(0.077)		(0.079)
Merger × competitive		0.0384		−0.106		0.325
		(0.178)		(0.164)		(0.169)
Merger (aggregate)	0.433		0.156		0.229	
	(0.119)		(0.079)		(0.074)	
Observations	5,778	5,778	5,457	5,457	7,287	7,287

Panel B. Aggregate effect by neighborhood definition (Table 12)

	95/97, price war included	95/98, price war excluded
Within half a minute	0.433 (0.119)	0.229 (0.074)
Within one minute	0.419 (0.110)	0.216 (0.064)
Within 1.5 minutes	0.290 (0.108)	0.223 (0.059)
Common street	0.266 (0.084)	0.175 (0.067)

Notes: Reproduced from Houde (2012, Tables 11 and 12). Dependent variable: station price. The merger variable is a Sunoco station in the neighborhood times years from 1997. The direct effect applies to post-merger Ultramar brands (Sunoco, Sergaz and Ultramar), the competitive effect to all other stations in the neighborhood. All regressions include location and time fixed effects and time-varying controls. Standard errors clustered by location in parentheses. Panel B has 5,778 observations in the first column group and 7,287 in the second. The note to the paper's Table 11 says that columns 2 to 6 exclude the 1996 price war. The text (p. 2176) and the sample sizes show that only columns 3 to 6 do, and we follow the text.

The retrospective design has its own weaknesses, which the simulation helps diagnose. The estimates are sensitive to the sample, and the version with the price war may capture the end of the war in neighborhoods where Ultramar was active, a second treatment. Controls are contaminated because distant Ultramar stations also raise prices. The simulation also explains why two studies of the same California merger reached different answers. Hastings (2004) found price increases of about 5 cents per gallon after ARCO acquired the Thrifty chain, and Taylor et al. (2010) found about 1 cent with different price data. Simulated effects are very heterogeneous across stations. Samples that omit the acquired stations or over-represent the acquirer's stations among controls can understate the effect. Dropping Sunoco stations from the averages in Table 11.36 would cut the direct effect by more than half (Houde, 2012, pp. 2178–2179).

Limitations and critiques. Several assumptions deserve scrutiny. Total gasoline consumption is inelastic, so the model captures station choice and car use but not driving more when gasoline is cheap. The price used for estimation is a single survey-day snapshot in a market where prices change weekly, and the analysis assumes the cross-sectional price distribution is stable within periods. Routes are deterministic shortest paths without congestion, and income is assumed independent of workplace. The RPM assumption makes suppliers the price setters at lessee stations. The merger is small, with 12 acquired stations, which limits the power of the retrospective test. The logit shock, as Houde emphasizes, understates the substitution between close competitors despite a large transport cost.

Contribution. The paper makes three contributions. It shows how to put a realistic geography into a BLP-style demand model by treating commuting paths as consumer locations. It shows that this changes the estimates of transport costs and markups substantially, and that the resulting markups match an external benchmark, the rack margin. It offers one of the cleanest validations of merger simulation against a retrospective estimate of the same merger, complementing Peters (2006), Weinberg and Hosken (2013) and the analgesics study of Section 11.7. The same market reappears in Chapter 13, where Clark and Houde (2013) study a gasoline cartel in Quebec.

11.9.2 Mergers and product repositioning in music radio: Sweeting (2010)

Question. Merger analysis usually treats the set of products as fixed. In many industries a merged firm can change its products quickly, and Sweeting (2010) asks what it does with them. The question has policy weight. If merging firms reposition their products, models with fixed products will mispredict price and welfare effects. Rivals may also lose from a merger without synergies, which contradicts the standard Bertrand prediction that rivals gain (Section 11.4).

What theory predicts. One-dimensional location models give stark and opposite answers. With price competition and quadratic transport costs, two independent firms locate at the ends of the line to soften price competition (d'Aspremont et al., 1979). A merger then reduces differentiation, because the joint owner no longer needs to soften competition between its own products. Without price competition and with a fixed audience, independent firms cluster at the center, the minimal differentiation of Hotelling (1929). A joint owner gains nothing from duplication and spreads its products to avoid cannibalization, a point that goes back to Steiner (1952). Reality lies between these extremes. Gandhi et al. (2008) compute equilibria of a location-then-price game and show that a merged firm may move its products apart and toward rivals, which mitigates the price increase.

Setting. The 1996 Telecommunications Act relaxed local ownership caps for radio stations, and the industry consolidated rapidly. Radio is a two-sided market. Listeners pay an implicit price by hearing commercials, and advertisers pay for listeners. The Department of Justice reviewed radio mergers solely for their effect on advertising prices. It required divestitures in some deals but did not consider effects on listeners or programming variety (Sweeting, 2010, p. 8). Programming changes are cheap within a format. Music licenses are blanket licenses whose fees are a fixed share of revenue, so playlist overlap does not affect costs.

Data. Station characteristics, ownership histories and Arbitron audience shares come from the BIAfn MediaAccess Pro database. Playlists come from Mediabase airplay logs for the first week (Monday to Friday) of each month from April 1998 to December 2001, for 1,094 music stations. The data contain 133,994 station-day logs. The stations belong to seven formats (Adult Contemporary, Album Oriented Rock/Classic Rock, Contemporary Hit Radio/Top 40, Country, Oldies, Rock, Urban) and 148 markets. In 2001 they had revenues of $6.5 billion and an average audience of 13 million. A station plays on average 1,367 songs by 177 artists in a five-day week, and 10,542 artists appear at least once.

The estimation sample has 740 stations in market-formats with at least two sample stations. These form 688 pairs in the same market-format, which experience 46 changes in common ownership. Of these, 31 are mergers, that is, switches from separate to common ownership. By type of transaction, 24 come from deals confined to one market-format and 8 from transactions spanning more than 7 market-formats. Another 14 come from divestitures that the Department of Justice required. Market shares convert Arbitron's average quarter-hour shares into shares of total listening time.

Measuring product positions. Each station's playlist in week w is a vector $a_i \in \mathbb{R}_+^{\mathcal{M}}$, where $\mathcal{M}$ is the set of artists and a_{im} is the share of station i's songs by artist m. Two measures of the distance between stations i and j are used. The *unique-artist measure* is the average share of each station's songs by artists the other station does not play:

$$d_{ij}^{UA} = \frac{1}{2}\Big[\sum_{m:a_{jm}=0} a_{im} + \sum_{m:a_{im}=0} a_{jm}\Big] \in [0,1]. \tag{11.142}$$

The *angle measure* treats each artist as a dimension and measures the angle between the two playlist vectors, normalized by its maximum for nonnegative vectors:

$$d_{ij}^{A} = \frac{2}{\pi}\arccos\left(\frac{a_i^\top a_j}{\|a_i\|\,\|a_j\|}\right) \in [0,1]. \tag{11.143}$$

The angle measure distinguishes stations that play the same artists in different proportions, which matters in formats where almost every station plays the current hits. The two measures have a within-pair correlation of 0.65. The distance between a pair (i,j) and a third station k in the same market-format is $\min\{d_{ik}, d_{jk}\}$.

Example 11.58 (Computing the distance measures)**.** Suppose there are three artists X, Y and Z. Station i plays them 10, 0 and 5 times, so $a_i = \left(\frac{2}{3}, 0, \frac{1}{3}\right)$. Station j plays Y and Z equally, so $a_j = \left(0, \frac{1}{2}, \frac{1}{2}\right)$. Artist X is unique to i and artist Y is unique to j, so

$$d_{ij}^{UA} = \frac{1}{2}\left[\frac{2}{3} + \frac{1}{2}\right] = \frac{7}{12} \approx 0.583.$$

For the angle, $a_i^\top a_j = \frac{1}{6}$, $\|a_i\| = \frac{\sqrt{5}}{3}$ and $\|a_j\| = \frac{1}{\sqrt{2}}$, so the cosine is $\frac{1}{\sqrt{10}} \approx 0.316$. The angle is 1.249 radians and $d_{ij}^{A} = \frac{2}{\pi} \times 1.249 \approx 0.795$.

The cross-section already suggests the main pattern. Commonly owned pairs have an average unique-artist measure of 0.66, against 0.55 for separately owned pairs. A commonly owned station thus devotes about 20 percent more of its playlist to artists absent from its sister station. Separately owned stations are not minimally differentiated either. Pairs of format duopolists in the same market are more differentiated than pairs of format monopolists in different markets of the same Census division. In Adult Contemporary, for example, the angle measures are 0.721 and 0.619 (Table 3(a)). This rules out the model without price competition, in which duopolists would cluster. The finding that common owners differentiate more is in turn at odds with the standard two-product model with price competition, in which a merger brings products closer together.

Estimating equation. The main specification is a fixed effects regression on station pairs in the same market-format (Sweeting, 2010, eq. (1)):

$$d_{ijw} = CO_{ijw}\,\beta_1 + N_{ijw}\beta_2 + T_{ijw}\beta_3 + \mu_{ij} + \varepsilon_{ijw}. \tag{11.144}$$

Here d_{ijw} is the distance between stations i and j in week w, and CO_{ijw} indicates a common owner. The controls N_{ijw} are dummies for the numbers of stations and of sample stations in the market-format, T_{ijw} are week-by-format dummies, and μ_{ij} is a pair fixed effect. The coefficient β_1 is identified by within-pair changes in ownership, while pairs without changes help identify the time and market-structure effects. Standard errors are clustered by market-format, which allows for correlation across pairs that share a station.

The same template is applied to other outcomes. For positioning relative to rivals, the dependent variable is the distance between a pair and a third station. The treatment is then common ownership of the pair by a firm that does not own the third station, with a fixed effect for each pair-third-station triplet. For variety, the dependent variable is the log number of artists played in a market-format. For audiences, it is the pair's combined market share with quarter-by-format effects. For prices, it is the commercial load of a station in an hour.

Identification. No instrument for ownership changes is available. The causal reading rests on three arguments. First, timing. Figure 11.26 shows no trend in differentiation or audiences before mergers and clear changes within six to twelve months after them. Second, similar effects appear for small and large transactions. A deal covering dozens of markets is unlikely to be driven by conditions in one market-format. Third, mergers and demergers produce changes of opposite sign, although they presumably occur for different reasons.

Main results. Table 11.38 collects the key estimates. Common owners differentiate their stations. The angle measure rises by 0.055 and the unique-artist share by 7.2 percentage points, 13 percent of the separately owned mean. The effect is at least as large in market-formats with three or more observed stations, where rivals might constrain repositioning. Common owners also move their stations closer to competitors. The distance from the pair to a third station falls by 0.055 on the angle measure and by 6.1 percentage points on the unique-artist measure. Only the first estimate is significant, at the 10 percent level. Variety does not rise. The number of artists in a market-format rises by 6.9 percent only when one firm owns all observed stations, and the number of owners has no significant effect.

Listeners follow the playlists. Common ownership raises the pair's combined share by 3.1 percent, significant at the 10 percent level. Figure 11.26(c) shows a rise of almost 10 percent within a year, lagging the playlist changes by a few months. The gain occurs only for pairs that face competitors. Their combined share rises by 0.0011, about 8 percent of the average pair's share, while the combined share of the other stations in the format falls by 0.0012. The

Table 11.38: Ownership changes and positioning, audiences and commercial loads in radio

Panel A. Differentiation between commonly owned stations (Table 4)

	All pairs	3 or more stations	2 stations
Angle measure	0.055 (0.014)	0.068 (0.022)	0.043 (0.018)
Unique-artist measure	0.072 (0.019)	0.080 (0.024)	0.069 (0.033)
Observations	15,792	10,216	5,576

Panel B. Positioning relative to competitors and variety (Table 5)

	Angle distance	Unique-artist distance	Log number of artists
Pair has same owner	−0.055 (0.033)	−0.061 (0.040)	
All stations same owner			0.069 (0.030)
Number of owners			0.009 (0.025)
Observations	14,475	14,475	8,942

	Commercial blocks per hour	Commercial minutes per hour
Owns other stations in format	0.044 (0.044)	0.178 (0.193)
Commonly owned competitors	0.008 (0.062)	−0.056 (0.370)
Observations	960,634	960,634

Notes: Reproduced from Sweeting (2010, Tables 4 to 7). Standard errors clustered by market-format in parentheses, except in Panel C columns (5) and (6), where they come from a bootstrap that resamples markets. Panel A: pair fixed effects, week-by-format and number-of-station dummies. Panel B: pair-third-station fixed effects in the first two columns, market-format fixed effects in the third. Panel C: station-pair fixed effects and quarter-by-format dummies. Columns (2) and (4) exclude pairs that change ownership as format duopolists. Column (3) excludes pairs that change ownership with three or more stations in the format. Columns (2) to (4) drop the two quarters after an ownership change. Shares are fractions of total listening. Panel D: station-format-hour fixed effects and year, month and day-of-week interactions with format.

merging stations' gain is the rivals' loss. Rivals also leave the format. Common ownership reduces the number of competing sample stations by 0.26 relative to a mean of 1.1, and the number of all competing stations by 0.36 relative to a mean of 2.6.

Prices do not move. The average commercial load is 11.95 minutes per hour. Common owners slightly increase their loads and stations facing common owners slightly reduce them, but neither effect is significant. These changes go the wrong way to explain the shift in audiences, so repositioning, not price, is the channel.

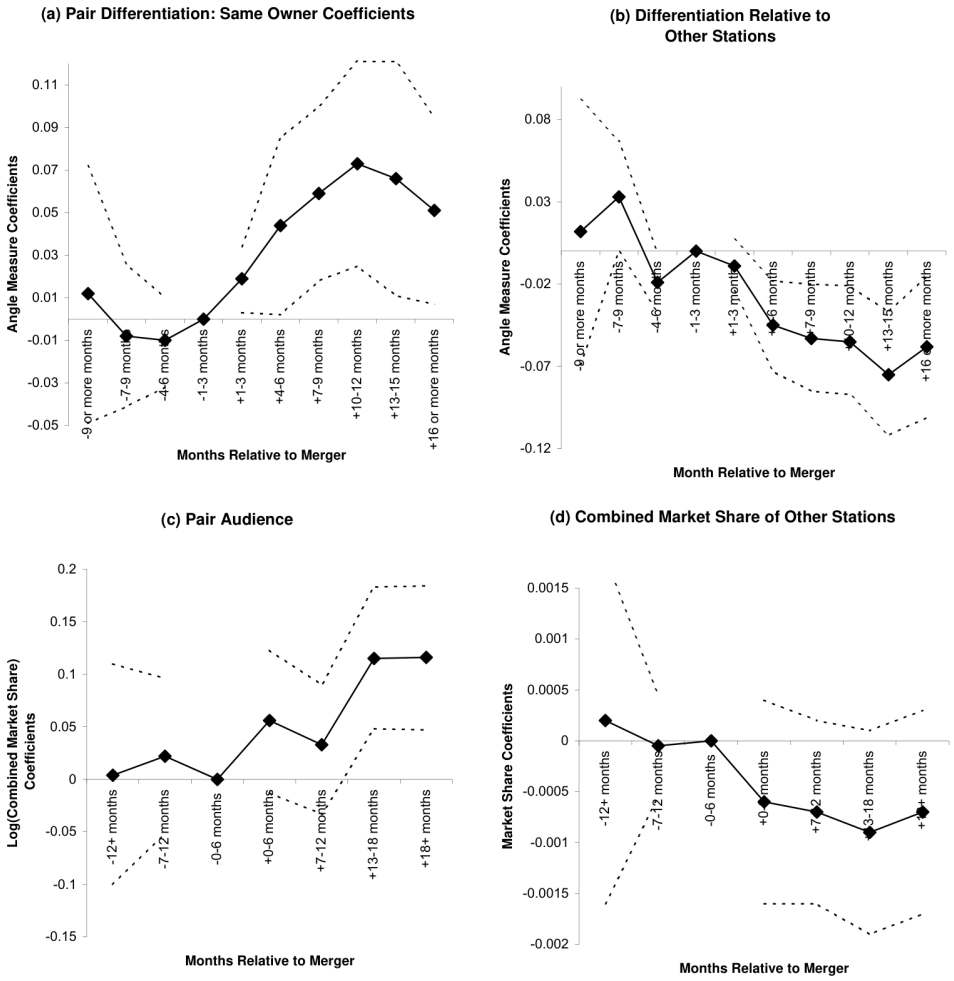

Figure 11.26: Timing of changes around mergers in music radio. Coefficients on dummies for time relative to the merger, with 95 percent confidence intervals (dashed). Panels (a) and (b) use the angle measure, for differentiation within the merging pair and between the pair and other stations. Panels (c) and (d) show the log combined share of the pair and the combined share of other stations. Pairs that ever switch from common to separate ownership are excluded. Source: Sweeting (2010), Figure 1.

Robustness. Section 4 of the paper rules out several alternative explanations. National ownership might raise quality through economies of scope. In a station-share regression, however, the log number of same-format stations owned nationally has a coefficient of −0.0003 (0.0070), while local common ownership keeps a coefficient of 0.0554 (0.0230) (Table 8). Changes in signal power or transmitter height do not drive the audience gains. Excluding pairs with

technical changes raises the share coefficient to 0.038 (0.022), and to 0.098 (0.017) when the two quarters after a change are dropped. Results by format agree in sign in 19 of 21 cases (Table 9). Pairs that merge resemble other pairs before the merger on three of four outcomes (Table 10). Results are similar for large and small transactions and for mergers and demergers (Table 11). In data covering all formats and 281 rated markets, owning another station in the same market-format raises a station's share by 4.6 percent (0.022). The number of owners has no effect on total format listening (Table 12).

Interpretation. The merged firm separates its own stations to reduce cannibalization, as a Hotelling owner without price competition would. It also moves them toward rivals and takes their listeners. It does not use the new positions to serve unserved tastes or to soften competition. Three implications follow for merger analysis. Models that hold products fixed will misstate the effects of mergers, and repositioning may help explain why such models often predict post-merger prices poorly (Peters, 2006). Rivals can be harmed by a merger without synergies, so their complaints do not by themselves signal that the merger is pro-competitive. This contrasts with the logic of Section 11.3. Aggregate variety can stay constant even when the merging firms differentiate, so studies of format counts such as Berry and Waldfogel (2001) see only part of the adjustment. The welfare effect of the repositioning remains open, since moving closer to rivals transfers listeners without creating variety (Chapter 10).

Limitations and contribution. The study is descriptive and lacks an instrument for ownership. It measures positions with playlists only, ignoring talk and personality programming. It covers relatively successful music stations in larger markets. The industry is unusual in ways that Sweeting (2010, pp. 25–26) lists: horizontal differentiation dominates, listening is inelastic, price competition through commercials is weak, and playlist changes do not affect costs. The paper's contribution is a set of stylized facts that structural models of endogenous product choice should match.

Structural merger simulations with repositioning have since followed, each adapted to its industry (Asker and Nocke, 2021, pp. 236–237). Li et al. (2019) study airline mergers. A first-stage entry model, in which a carrier chooses between nonstop and connecting service on a route, is attached to a nested logit demand model. Wollmann (2018) also uses a first-stage entry model, to study how a merger changes the product mix in the US market for commercial vehicles. Fan (2013) lets merging newspapers adjust their prices and three dimensions of quality. Because the characteristics are continuous, repositioning adds first-order conditions for them to the pricing conditions of Section 11.5.1. Mazzeo et al. (2018) add a product-selection stage to a standard simulation and explore its effects in a range of simulations. Draganska et al. (2009) study assortment choice more broadly.

These studies agree with Sweeting that a merger can change the incentives to offer particular products, and that allowing for repositioning changes the estimated effect on consumer welfare. They disagree on the direction of the bias from ignoring it. Repositioning or entry by a rival adds competitive pressure, while the merged firm's exit from a product space removes it and adds to the harm. Which force dominates depends on the industry (Asker and Nocke, 2021, p. 237).

11.9.3 Mergers and capacity investment in the paper industry: Pesendorfer (2003)

Question. In industries where capacity is the main strategic variable, a merger changes the allocation of capital and the incentives to invest. A study of short-run prices or outputs can then mismeasure the merger's effects. Pesendorfer (2003) studies the wave of 31 horizontal

mergers in the US paper and paperboard industry between August 1984 and July 1987. He models capacity investment, uses firms' investment choices before and after the wave to infer the cost changes that mergers produced, and computes the implied welfare effects. The wave followed the 1984 revision of the Merger Guidelines, which signaled a friendlier stance toward mergers.

The investment model. There are n firms producing a homogeneous good. Firm i starts with capacity K_i and chooses investment x_i, which may be negative (scrapping). Capacity depreciates by the factor $\vartheta \in (0,1)$, so the post-investment capacity is $\vartheta K_i + x_i$. Adding capacity costs $r(x_i)$, while scrapping is free. Production cost is $C_i(\cdot)$ with marginal cost $c_i(\cdot)$. Plants run at full capacity, an assumption that fits an industry whose utilization averaged 93 percent, so industry output is $Q = \sum_j (\vartheta K_j + x_j)$. Firms discount the future by $\delta \in (0,1)$. Pesendorfer writes β for the discount factor and δ for depreciation, and we rename both to follow Chapter 12. Firm i's payoff is the discounted stream of future profits from the new capacity, minus investment cost (eq. (1)):

$$\Pi_i(x) = \frac{\delta}{1-\delta}\Big[(\vartheta K_i + x_i)\,P\Big(\sum_j (\vartheta K_j + x_j)\Big) - C_i(\vartheta K_i + x_i)\Big] - r(x_i)\,\mathbf{1}\{x_i > 0\}. \tag{11.145}$$

The model is a one-shot investment game. Without depreciation ($\vartheta = 1$) and with linear investment cost, its equilibrium coincides with that of a dynamic game in which all investment occurs at once.

Proposition 11.59 (Equilibrium investment, after Pesendorfer, 2003, Proposition 1)**.** *Let $MR_i = P(Q) + (\vartheta K_i + x_i)P'(Q)$ be firm i's marginal revenue from capacity. Assume that an equilibrium exists, marginal revenue decreases in own capacity, c_i is nondecreasing, and r is increasing and convex. In an equilibrium, each firm's investment satisfies*

$$\begin{aligned} x_i > 0: &\quad \frac{\delta}{1-\delta}\big[MR_i - c_i\big] = r'(x_i), \\ x_i < 0: &\quad MR_i - c_i = 0, \\ x_i = 0: &\quad 0 \le \frac{\delta}{1-\delta}\big[MR_i - c_i\big] \le r'(0), \end{aligned} \tag{11.146}$$

where c_i is evaluated at $\vartheta K_i + x_i$.

Proof. Holding rivals' choices fixed, Π_i is concave in x_i on each side of zero under the stated assumptions. For $x_i \neq 0$ its derivative is $\frac{\delta}{1-\delta}[MR_i - c_i] - r'(x_i)\mathbf{1}\{x_i > 0\}$, and an interior optimum sets it to zero, which gives the first two lines. At $x_i = 0$ the payoff has a kink. The left derivative is $\frac{\delta}{1-\delta}[MR_i - c_i]$ and the right derivative subtracts $r'(0)$. Zero is optimal when the left derivative is nonnegative, so scrapping does not pay, and the right derivative is nonpositive, so investing does not pay. This gives the third line. Pesendorfer writes the three cases compactly as $x_i\{[MR_i - c_i]\frac{\delta}{1-\delta} - r'(x_i)\mathbf{1}\{x_i > 0\}\} = 0$ (eq. (2)). □

Inverting (11.146) gives marginal cost as a function of observables (Corollary 2, eq. (3)):

$$c_i = MR_i - \frac{1-\delta}{\delta}\,r'(x_i)\,\mathbf{1}\{x_i > 0\} \quad (x_i \neq 0), \qquad c_i \in \Big[MR_i - \frac{1-\delta}{\delta}\,r'(0),\ MR_i\Big] \quad (x_i = 0). \tag{11.147}$$

The right-hand side depends on industry capacity and investment, the firm's own capacity and investment, demand and the investment cost function. Marginal revenue falls with own

capacity. So for a given capacity, a firm that invests more must have a lower marginal cost. This is the inference the empirical work exploits: changes in investment after a merger reveal changes in the merged firm's costs. Investment is measured as $x_i = K_i' - \vartheta K_i$, where K_i' is next period's capacity. With $\vartheta < 1$ a firm that keeps capacity constant invests a positive amount, so the interval case rarely arises.

Merger analysis in a linear example. To see what the model implies, Pesendorfer specializes it. We follow Section 11.3.2 and write the demand intercept as a.

Assumption 11.60 (Linear investment model)**.** (i) Demand is $P(Q) = a - bQ$. (ii) $\frac{\delta}{1-\delta} = \vartheta = 1$. (iii) Unmerged firms have constant marginal cost c, and the merged firm has constant marginal cost c_m. (iv) Investment cost is linear, $r(x) = rx$. (v) Initial capacities are at Cournot levels, $K_i = K^c \equiv \frac{a-c}{b(n+1)}$.

Under (ii) the payoff is one period's profit minus investment cost. Before the merger, all firms hold K^c, the price is $P^0 = c + \frac{a-c}{n+1}$, each firm earns $\frac{(a-c)^2}{b(n+1)^2}$, and no firm wants to invest or scrap. Two firms then merge, and the merged firm m holds $2K^c$.

Proposition 11.61 (A profitable merger without synergies)**.** *Let Assumption 11.60 hold with $c_m = c$, and suppose $\frac{a-c}{2(n+1)} \le r$. Then the post-merger game has an equilibrium in which the merged firm scraps $\frac{K^c}{2}$ and no outsider invests. The price rises to $c + \frac{3}{2}\frac{a-c}{n+1}$, and the merging firms' joint profit rises by $\frac{1}{4b}\left(\frac{a-c}{n+1}\right)^2 > 0$.*

Proof. Use $b(n+1)K^c = a - c$ throughout. Suppose outsiders choose $x_i = 0$ and the merged firm chooses x_m. Industry output is $nK^c + x_m$. An outsider's marginal revenue minus cost is

$$MR_i - c = a - c - b(nK^c + x_m) - bK^c = (a-c) - b(n+1)K^c - b\,x_m = -b\,x_m.$$

The merged firm's is

$$MR_m - c = a - c - b(nK^c + x_m) - b(2K^c + x_m) = -\frac{a-c}{n+1} - 2b\,x_m.$$

This is negative at $x_m = 0$, so the merged firm scraps until $MR_m = c$:

$$x_m = -\frac{a-c}{2b(n+1)} = -\frac{K^c}{2}.$$

Its payoff is concave, and investing is never optimal because $MR_m - c - r < 0$ for $x_m \ge 0$. Given x_m, each outsider has $MR_i - c = \frac{a-c}{2(n+1)} \ge 0$, so scrapping does not pay. Investing does not pay if this gain is at most r, which is the stated condition. So $x_i = 0$ is a best response.

Industry output is $\left(n - \frac{1}{2}\right)K^c$, and the margin is

$$P - c = (a-c) - \left(n - \frac{1}{2}\right)\frac{a-c}{n+1} = \frac{3}{2}\,\frac{a-c}{n+1}.$$

The merged firm sells $\frac{3}{2}K^c$, so its profit is $\frac{3}{2}\frac{a-c}{n+1} \times \frac{3}{2}\frac{a-c}{b(n+1)} = \frac{9}{4b}\left(\frac{a-c}{n+1}\right)^2$. Before the merger the two firms earned $\frac{2}{b}\left(\frac{a-c}{n+1}\right)^2$. The difference is $\frac{1}{4b}\left(\frac{a-c}{n+1}\right)^2$. □

Pesendorfer (2003, Remark 3) states the result under the condition $n+1 > \frac{a-c}{r}$, which implies the weaker condition used above. The mechanism is the asymmetry between expanding and contracting capacity. The merged firm can withdraw capacity at no cost, while outsiders

would have to pay r per unit to fill the gap. If $r = 0$, outsiders expand freely, every firm sets $MR = c$, and the post-merger outcome is Cournot with $n - 1$ firms. A two-firm merger is then unprofitable for $n \geq 3$ (Proposition 11.4). For any $r > 0$, however, a profitable merger exists once n is large enough (Pesendorfer, 2003, p. 7, n. 6).

Example 11.62 (Investment makes the merger profitable)**.** Let $a = 10$, $b = 1$, $c = 2$, $n = 4$ and $r = 1$. Cournot capacities are $K^c = 1.6$, the price is $P^0 = 3.6$ and each firm earns 2.56. After a merger of two firms, the merged firm scraps 0.8 units, outsiders' marginal gain from investing is $0.8 < r$, and the price rises to 4.4. The merged firm earns $2.4 \times 2.4 = 5.76$, a gain of 0.64 over the combined 5.12. Pesendorfer's sufficient condition would require $r > 1.6$, so the example lies in the region covered only by the weaker condition. With costless expansion the outcome would be Cournot with three firms, a price of 4.0 and a merged profit of 4.0, a loss of 1.12. Costly expansion makes the merger profitable precisely because rivals do not replace the withdrawn capacity, so consumers face a higher price than in the Cournot benchmark.

The example shows a general feature. The post-merger margin is $\frac{3}{2}\frac{a-c}{n+1}$, while the Cournot margin with $n-1$ firms is $\frac{a-c}{n}$. The first is larger whenever $n > 2$. Pesendorfer's three remaining remarks describe what investment reveals about costs and welfare.

Proposition 11.63 (Investment and merger cost savings, Remarks 4 to 6)**.** *Let Assumption 11.60 hold.*

(a) If the merged firm does not change its capacity after the merger ($x_m = 0$), then no outsider does either, and $2c - P^0 - r \leq c_m \leq 2c - P^0$. In particular $c_m < c$.

(b) If $c_m = c$, industry capacity falls and the merger reduces total welfare.

(c) If $x_m = 0$, consumer surplus is unchanged and total welfare rises.

Proof. (a) With $x_m = 0$ and symmetric outsiders, an outsider's marginal gain is $-b(n-1)x_i$. A positive x_i would require this to equal $r > 0$, and a negative x_i would require it to equal zero, so $x_i = 0$. The merged firm's marginal revenue at $x_m = 0$ is $a - b(n+2)K^c = P^0 - 2(P^0 - c) = 2c - P^0$. Zero investment requires $0 \leq MR_m - c_m \leq r$, which is the stated band. Since $P^0 > c$, $c_m \leq 2c - P^0 < c$.

(b) Suppose instead that total investment $X = \sum_j x_j$ is positive. An outsider's marginal gain is $-b(X + x_i)$, which cannot equal $r > 0$ when $x_i > 0$ and $X > 0$, so $x_i \leq 0$. The merged firm's is $-\frac{a-c}{n+1} - b(X + x_m)$, which is negative when $x_m > 0$ and $X > 0$, so $x_m \leq 0$. Then $X \leq 0$, a contradiction. If $X = 0$, the merged firm's marginal gain at any $x_m \geq 0$ is negative, so it scraps. Outsiders would then have to invest, but an outsider with $x_i > 0$ has marginal gain $-b\,x_i < 0 < r$. Hence $X < 0$. Output falls below the pre-merger level, at which price exceeds the common marginal cost, so total surplus falls.

(c) By part (a), output is unchanged, so price and consumer surplus are unchanged. Producer surplus rises because the merged firm produces the same capacity at $c_m < c$. □

Part (a) connects the investment model to Proposition 11.12. If nobody adjusts capacity, output and price are unchanged, so the merger must be at least price-neutral. The merged firm's cost must then lie at or below the price-neutral level $2c - P^0$ of the Cournot analysis. In Example 11.62, $2c - P^0 = 0.4$, an 80 percent cost reduction. Unchanged investment after a merger thus reveals large savings. Consumer surplus and producer surplus are defined as usual (eqs. (4)–(5)):

$$CS = \int_0^Q P(z)\,\mathrm{d}z - Q\,P(Q), \qquad PS = \sum_i \left[K_i P(Q) - C_i(K_i) - r(x_i)\mathbf{1}\{x_i > 0\}\right]. \tag{11.148}$$

Data. Plant-level annual capacities by product for 1978–1992 come from Lockwood's Directory of the Paper and Allied Trades, supplemented by Census price data. Products fall into nine categories: newsprint, packaging papers, groundwood printing, coated papers, uncoated papers, other papers, tissue, linerboard and boxboard. Products within a category are largely homogeneous, and about 80 percent of capacity is in plants producing a single category, so each category is treated as a separate market. Newsprint is dropped because about half of US newsprint capacity is imported from Canada. The geographic market is the United States, with exports of about 15 percent of production and imports of about 12 percent in 1991.

Table 1 of the paper summarizes the industry. The average number of firms per category fell from 70.6 in 1978 to 60.4 in 1992. The five largest firms held on average 56.1 percent of capacity in 1992, from 41 percent in newsprint to 75 percent in tissue. Capacity grew by about 20 percent over the period, at about 0.7 percent a year before 1987 and 2.4 percent after. About 40 percent of capacity expansions at existing firms came through horizontal acquisitions, and about 40 percent of the 819 plants were involved in at least one merger. The 1984–1987 wave included Champion International's acquisition of St. Regis ($1.8 billion), Jefferson Smurfit's of Container Corporation ($1.2 billion) and International Paper's of Hammermill ($1.1 billion). The Federal Trade Commission blocked James River's acquisition of Barlow Rand in February 1988. Every category had at least one merger in the wave.

Descriptive evidence. Merged firms' outcomes vary widely. Table 3 regresses the merged firm's share, relative to its share at the merger, on time since the merger and its square. In the pooled data the coefficients are -3.66 ($t = 5.9$) and 0.35 ($t = 3.0$), with $R^2 = 0.04$ and 1,112 observations. The share falls to about 90 percent of its initial level after about five years and then recovers. About two-thirds of acquirers lose share and one-third gain. Probit models of annual investment decisions on 9,352 firm-years show that a merger raises the probability of changing capacity. The coefficient on the relative size of the acquired firm is 0.7589 ($t = 3.5$), and the coefficient on an acquisition two to five years earlier is 0.6004 ($t = 2.4$). The effect works mostly through scrapping, with coefficients of 0.8017 ($t = 2.9$) and 0.7027 ($t = 2.2$), while the effects on investing are positive but insignificant (Table 4). About 24 percent of firms change capacity in a given year, three-quarters of them upward.

Estimation. Costs are estimated in two steps for three-year windows before and after the wave, since new capacity takes two to three years to become usable. The wave is assumed to have been unanticipated when the earlier investments were made. The first step estimates constant-elasticity inverse demand for each category,

$$\ln P_t = \alpha_x x_t + \gamma \ln Q_t + u_t, \qquad u_t = \varrho\, u_{t-1} + v_t, \quad |\varrho| < 1, \tag{11.149}$$

with gross domestic product as the demand shifter x_t and wages of paper workers as the instrument for output. The second step computes each firm's marginal revenue $\widehat{MR}_i = \hat{P}(Q) + \hat{P}'(Q) K_i$ and recovers its marginal cost from (11.147). The discount factor is 0.95 per year. The investment cost has a linear and a quadratic term calibrated to reported costs of investment projects in the trade press. The base specification sets the depreciation factor to 0.999 with linear coefficient 26.50 and quadratic coefficient 0.005, and four alternatives vary these values.

Cost results. Acquiring firms have lower estimated marginal costs than unmerged firms before the wave, and the gap widens after it. In groundwood printing, for instance, the median difference between acquiring and unmerged firms grows from $4.39 to $8.01 per ton, and the mean difference from $6.97 to $12.87 (Table 5A). The median gap widens in all eight

categories and the mean gap in seven, the exception being boxboard. To separate merger effects from industry-wide cost changes, Pesendorfer assigns each cost estimate its percentile in the distribution of unmerged firms' costs, before and after the wave. Figure 11.27 shows the result. About 90 percent of acquiring firms move to lower percentiles, and about 10 percent do not. The Champion-St. Regis merger is an example of expected synergies that did not materialize.

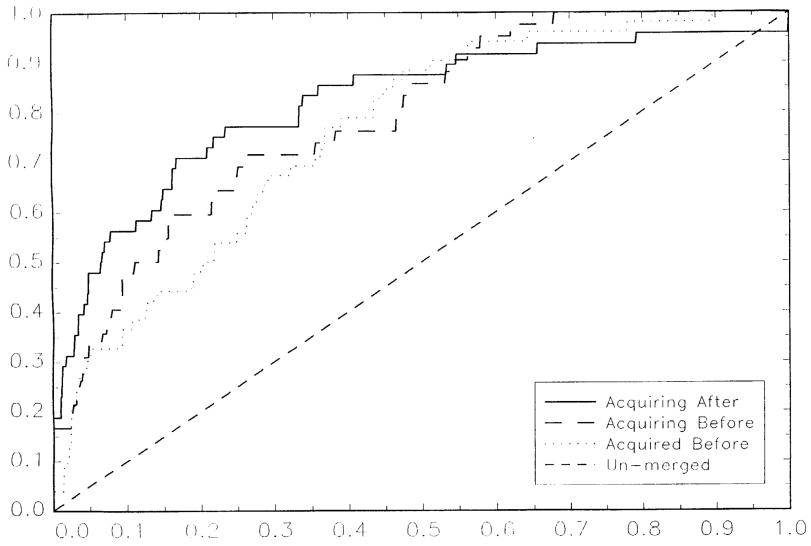

Figure 11.27: Distribution of estimated marginal costs, pooled across paper categories. Each firm's cost is expressed as its percentile in the cost distribution of unmerged firms (horizontal axis). The curves are cumulative distribution functions (vertical axis) for acquiring firms after and before the merger wave and for acquired firms before it. The dashed diagonal is the distribution of unmerged firms. Curves farther above the diagonal indicate lower relative costs. The image is rotated from the working-paper version. Source: Pesendorfer (2003), Figure 2.

Welfare. For the counterfactual without mergers, each merging firm's cost is projected to its post-wave level using its percentile in the unmerged distribution. The merged firm is replaced by its components with these costs, the investment equilibrium of (11.146) is recomputed, and the changes in consumer and producer surplus follow from (11.148). Standard errors come from repeated draws of the projection error. Table 11.39 reproduces the base specification.

Summing over categories, the wave raised total welfare by $583.5 million in the base specification, with $213.6 million going to consumers and $369.9 million to producers. The sums across the five specifications range from $454 million to $583 million for total welfare and from $244 million to $527 million for producer surplus. The text of the paper gives a consumer range of $58 million to $210 million, while the table's columns sum to between −$58.6 million and $213.6 million. Merged firms gained $469.3 million and unmerged firms lost $99.4 million. The text reports the merged firms' gain as $468.3 million in two places and $469.3 million in a third. The table sums to the latter. The paper describes the packaging-paper figure as an increase in annual total welfare (Pesendorfer, 2003, p. 19), so the totals are best read as annual flows. Gains to merged firms are positive in every category in the base specification. Pesendorfer states that these gains are positive in six of eight categories, with insignificant losses in some specifications for groundwood printing and boxboard (Pesendorfer, 2003, p. 21). His Table 6 also shows insignificant losses in one specification each for uncoated papers (−703 thousand) and linerboard (−26,638 thousand). Only packaging, coated, other papers and

Table 11.39: Welfare effects of the 1984–1987 paper merger wave (thousands of 1986 dollars)

Category	Total welfare	Consumer surplus	Producer surplus	Merged firms	Unmerged firms

Notes: Reproduced from Pesendorfer (2003, Table 6, specification (1): depreciation factor 0.999, linear investment-cost coefficient 26.50, quadratic 0.005), working-paper version. Standard deviations from the projection error in parentheses. The table reports categories only. The sums and ranges are our calculations from all five columns of the table. The other specifications use (0.950, 26.50, 0.005), (0.999, 36.50, 0.007), (0.999, 53.00, 0) and (0.999, 0, 0.010).

tissue show gains in every specification. Pesendorfer reads the positive gains as support for the model, since profitability was not imposed in estimation.

Interpretation and critiques. The welfare gains rest on estimated cost reductions, and their distribution deserves attention. Tissue alone accounts for 51 percent of the total welfare gain and 52 percent of the merged firms' gain. The tissue category had a single acquiring firm (Table 2), whose estimated cost advantage over the median unmerged firm grew from \$5.71 to \$143.04 per ton (Table 5A). The headline number thus depends heavily on one firm's inferred cost decline. More generally, marginal costs are residuals of a first-order condition, so any misspecification of demand, of the investment cost function or of conduct is loaded into the cost estimates. The model is static and assumes the wave was unanticipated. It treats each category as a national homogeneous-good market with full utilization. The percentile projection assumes that, absent mergers, each firm would have kept its relative position. Mergers are taken as given, so firms that merged may differ from others in ways that also explain later cost changes.

Contribution. The paper shows that the investment channel can reverse two conclusions of static Cournot theory. Mergers without synergies can be profitable, and the price effect of a merger depends on rivals' ability to add capacity. It also shows how revealed investment behavior can identify merger efficiencies, an idea that complements the retrospective price studies of Section 11.6. Dynamic models of mergers with investment, such as Berry and Pakes (1993) and Gowrisankaran (1999), develop the same concerns with richer state spaces.

11.10 Merger policy with merger choice

The standard approach to merger review evaluates each proposed merger on its own. An authority with a consumer surplus standard approves a merger if and only if it does not lower consumer surplus. This rule ignores that firms choose which merger to propose, while the authority sees only the proposal. Nocke and Whinston (2013) show that the choice changes the optimal policy. If firms prefer larger mergers for reasons unrelated to consumers, the authority should hold larger mergers to a stricter standard. Lyons (2003) first identified the problem. Armstrong and Vickers (2010) analyze delegated choice among projects that are ex ante identical. Nocke and Whinston (2010) show that a myopic consumer surplus standard is optimal in a dynamic setting when possible mergers are disjoint, that is, involve different firms. We follow the working-paper version of Nocke and Whinston (2013), whose numbering may differ from the published article.

11.10.1 The model

Firms $i \in \mathcal{N} = \{0, 1, \ldots, N\}$ produce a homogeneous good with constant marginal costs c_i and compete in quantities. Inverse demand $P(Q)$ satisfies, for all Q with $P(Q) > 0$,

$$P'(Q) < 0, \qquad P'(Q) + QP''(Q) < 0, \qquad \lim_{Q \to \infty} P(Q) = 0. \tag{11.150}$$

These conditions imply a unique Cournot equilibrium that is stable: each best response $b_i(Q_{-i})$ has slope in $(-1, 0)$, so if some firms want to produce less, industry output falls. All firms are active, and the pre-merger outputs satisfy $P(Q^0) + P'(Q^0)q_i^0 = c_i$. Write $P^0 = P(Q^0)$, $s_i^0 = \frac{q_i^0}{Q^0}$ and $\pi_i^0 = (P^0 - c_i)q_i^0$.

Firm 0, the acquirer, can merge with one target $k \in \mathcal{K} = \{1, \dots, K\}$. Targets are ordered by decreasing cost, $c_1 > c_2 > \cdots > c_K$, so a higher k means a larger pre-merger share. We call merger k *larger* than merger j if $k > j$. The change in the naively computed Herfindahl index, which keeps all shares fixed and adds the merging shares, is

$$\Delta HHI^{naive}(M_k) = (s_0^0 + s_k^0)^2 - (s_0^0)^2 - (s_k^0)^2 = 2 s_0^0 s_k^0, \tag{11.151}$$

the formula of (11.7). A larger merger thus has a larger naive increase in concentration.

Merger k is feasible with probability $\phi_k \in (0, 1]$, independently across targets. If feasible, it yields a post-merger marginal cost $\bar{c}_k$ drawn from a distribution G_k with support $[c^L, c_k^H]$ and no mass points. A feasible merger is $M_k = (k, \bar{c}_k)$. After merger M_k the outputs solve $P(Q(M_k)) + P'(Q(M_k)) q_i(M_k) = c_i$ for nonmerging firms and the same condition with $\bar{c}_k$ for the merged firm. All firms remain active. The changes in consumer surplus and in the merging parties' joint (bilateral) profit are

$$\Delta CS(M_k) = \int_0^{Q(M_k)} P(z)\,\mathrm{d}z - P(Q(M_k))Q(M_k) - CS^0, \qquad \Delta\Pi(M_k) = \pi_k(M_k) - (\pi_0^0 + \pi_k^0). \tag{11.152}$$

A merger is *CS-neutral* if $\Delta CS = 0$, CS-increasing if it is positive, CS-decreasing if it is negative, and CS-nondecreasing if it is not CS-decreasing. The status quo M_0 gives zero changes. Let $\mathcal{F}$ be the realized set of feasible mergers, including M_0.

The timing has four stages. The authority commits to an approval set $\mathcal{A} = \{M_k : \bar{c}_k \in \mathcal{A}_k\} \cup \{M_0\}$, where each $\mathcal{A}_k \subseteq [c^L, c_k^H]$ is a union of closed intervals. Nature draws $\mathcal{F}$. Firms bargain over which merger to propose. The authority approves the proposal if it lies in $\mathcal{A}$, and firms compete. The authority observes every characteristic of the proposed merger but nothing about mergers that are not proposed, and only one merger can be proposed.

Bargaining follows the offer game of Segal (1999). Firm 0 makes a take-it-or-leave-it offer of a price t_k to one target. Setting t_k to make the target indifferent, firm 0 captures the whole bilateral gain $\Delta\Pi(M_k)$. The proposed merger is therefore

$$M^*(\mathcal{F}, \mathcal{A}) = \begin{cases} \arg\max_{M_k \in \mathcal{F} \cap \mathcal{A}} \Delta\Pi(M_k) & \text{if } \max_{M_k \in \mathcal{F} \cap \mathcal{A}} \Delta\Pi(M_k) > 0, \\ M_0 & \text{otherwise.} \end{cases} \tag{11.153}$$

The authority chooses $\mathcal{A}$ to maximize $\mathbb{E}_{\mathcal{F}}\left[\Delta CS(M^*(\mathcal{F}, \mathcal{A}))\right]$. One assumption avoids trivial cases. Each merger's cost support contains CS-increasing and CS-nonincreasing outcomes, $\Delta CS(k, c_k^H) \le 0 < \Delta CS(k, c^L)$.

11.10.2 Three lemmas on the shape of merger outcomes

Because the good is homogeneous, a merger raises consumer surplus if and only if it raises industry output. The first lemma characterizes CS-neutral mergers. It restates Proposition 11.12 and Corollary 11.14 in the notation of this section.

Lemma 11.64 (CS-neutral mergers)**.** *Suppose merger M_k is CS-neutral. Then (i) no nonmerging firm changes its output, and the merged firm produces $q_0^0 + q_k^0$. (ii) The merged firm's margin equals the sum of the partners' margins,*

$$P^0 - \bar{c}_k = (P^0 - c_0) + (P^0 - c_k), \quad \text{so} \quad \bar{c}_k = \hat{c}_k \equiv c_k - (P^0 - c_0) < \min\{c_0, c_k\}. \tag{11.154}$$

(iii) The merger is profitable, $\Delta\Pi(M_k) > 0$. (iv) It raises aggregate profit.

Proof. A CS-neutral merger leaves Q, and hence P and P', unchanged. Each nonmerging firm's first-order condition then gives the same output, and the merged firm produces the rest, $q_0^0 + q_k^0$. Its first-order condition is $P^0 + P'(Q^0)(q_0^0 + q_k^0) = \bar{c}_k$. Adding the partners' pre-merger conditions gives $2P^0 + P'(Q^0)(q_0^0 + q_k^0) = c_0 + c_k$. Subtracting the first equation from the second gives $P^0 = c_0 + c_k - \bar{c}_k$, which is (11.154). Part (iii) is Corollary 11.14: the merged profit exceeds $\pi_0^0 + \pi_k^0$ by $(P^0 - c_0)q_k^0 + (P^0 - c_k)q_0^0 > 0$. For (iv), nonmerging firms' profits are unchanged because their prices and outputs are unchanged. □

Lemma 11.65 (Lower post-merger cost)**.** *Conditional on merger M_k, a lower $\bar{c}_k$ raises industry output, consumer surplus and the merged firm's profit.*

Proof. Summing the N post-merger first-order conditions gives $NP(Q)+QP'(Q) = \bar{c}_k+\sum_{i\neq 0,k} c_i$. The left side decreases in Q, because its derivative is $(N+1)P' + QP'' < 0$ by (11.150). A lower $\bar{c}_k$ lowers the right side, so Q rises, and so does consumer surplus. For the profit, define the *cumulative best reply* $\tilde{q}(Q;c) = -\frac{P(Q)-c}{P'(Q)}$, the output at which a firm with cost c satisfies its first-order condition when industry output is Q. Its derivative in Q is

$$\frac{\partial \tilde{q}}{\partial Q} = -1 + \frac{(P-c)P''}{(P')^2} = -1 - \frac{\tilde{q}\,P''}{P'} = -\frac{P' + \tilde{q}P''}{P'} < 0,$$

using $P - c = -P'\tilde{q}$ and $P' + qP'' < 0$ for $q \leq Q$. Nonmerging outputs $\tilde{q}(Q;c_i)$ therefore fall when $\bar{c}_k$ falls. The merged firm's profit is $\max_q[P(Q_{-m}+q) - \bar{c}_k]q$, where Q_{-m} is rivals' output. By the envelope theorem its derivative in $\bar{c}_k$ is $-q_m + q_m P'(Q)\frac{dQ_{-m}}{d\bar{c}_k}$. Both terms are negative, since $P' < 0$ and rivals' output rises with $\bar{c}_k$. □

Lemma 11.65 implies that merger M_k is CS-increasing if $\bar{c}_k < \hat{c}_k$ and CS-decreasing if $\bar{c}_k > \hat{c}_k$. The third lemma is the key to the paper. It shows that firms' proposal incentives are biased toward larger mergers.

Lemma 11.66 (Firms prefer larger mergers)**.** *Suppose mergers M_j and M_k, with $k > j \geq 1$, induce the same nonnegative change in consumer surplus. Then the larger merger induces a larger gain in bilateral profit: $\Delta\Pi(M_k) > \Delta\Pi(M_j) > 0$.*

Proof. Each firm's first-order condition gives $P - c_i = -P'q_i$, so its profit is

$$\pi_i = (P - c_i)q_i = -P'(Q)\left[\tilde{q}(Q;c_i)\right]^2. \tag{11.155}$$

Equal consumer surplus means equal industry output $\bar{Q}$. Industry output depends only on the sum of active firms' costs, by the summed first-order condition in the proof of Lemma 11.65. So both mergers reduce the partners' combined cost by the same amount, $\gamma \equiv c_k - \bar{c}_k = c_j - \bar{c}_j$. Since $\frac{\partial \tilde{q}}{\partial c} = \frac{1}{P'}$, the difference in the merged firms' profits is

$$\begin{aligned}\pi_k(M_k) - \pi_j(M_j) &= -P'(\bar{Q})\left\{\left[\tilde{q}(\bar{Q};c_k-\gamma)\right]^2 - \left[\tilde{q}(\bar{Q};c_j-\gamma)\right]^2\right\} \\ &= -P'(\bar{Q})\int_{c_j}^{c_k} 2\,\tilde{q}(\bar{Q};c-\gamma)\,\frac{1}{P'(\bar{Q})}\,\mathrm{d}c = 2\int_{c_k}^{c_j}\tilde{q}(\bar{Q};c-\gamma)\,\mathrm{d}c.\end{aligned} \tag{11.156}$$

The same steps applied to pre-merger profits give

$$\pi_k^0 - \pi_j^0 = 2\int_{c_k}^{c_j}\tilde{q}(Q^0;c)\,\mathrm{d}c. \tag{11.157}$$

Now consider, for any $c \in [c_k, c_j]$, a merger of firm 0 with a firm of cost c that yields cost $c - \gamma$. It raises output from Q^0 to $\bar{Q}$, so it weakly lowers each nonmerging firm's output and weakly raises the merging firms' joint output. Hence

$$\tilde{q}(\bar{Q}; c - \gamma) \geq \tilde{q}(Q^0; c_0) + \tilde{q}(Q^0; c) > \tilde{q}(Q^0; c).$$

The integrand of (11.156) exceeds that of (11.157) at every c, so $\pi_k(M_k) - \pi_j(M_j) > \pi_k^0 - \pi_j^0$. Subtracting π_0^0 from both merged profits and rearranging gives $\Delta\Pi(M_k) > \Delta\Pi(M_j)$. Finally, $\Delta\Pi(M_j) > 0$ because a CS-nondecreasing merger has $\bar{c}_j \leq \hat{c}_j$, and Lemmas 11.64 and 11.65 imply that it is at least as profitable as the CS-neutral merger. □

The intuition comes from (11.155). Profit is quadratic in output, so a given cost saving is worth more to a firm that produces more. To leave consumers equally well off, both mergers need the same absolute cost saving, and the larger merger applies it to a larger output base. Firms therefore value larger mergers more than consumers do.

Lemmas 11.64 to 11.66 fix the geometry of the problem. Plot each possible outcome of merger k as a point $(\Delta\Pi, \Delta CS)$. As $\bar{c}_k$ varies, the points trace a *merger curve*. Each curve slopes upward (Lemma 11.65) and crosses the horizontal axis at a positive profit (Lemma 11.64). On and above the axis, the curve of a larger merger lies to the right of the curve of a smaller one (Lemma 11.66). An immediate consequence is the following.

Corollary 11.67 (Nocke and Whinston, 2013, Corollary 1)**.** *If two CS-nondecreasing mergers M_j and M_k with $k > j \geq 1$ satisfy $\Delta\Pi(M_k) \leq \Delta\Pi(M_j)$, then $\Delta CS(M_k) < \Delta CS(M_j)$.*

Proof. Suppose $\Delta CS(M_k) \geq \Delta CS(M_j)$. By Lemma 11.65 there is a cost $\bar{c}_k' \geq \bar{c}_k$ with $\Delta CS(k, \bar{c}_k') = \Delta CS(M_j)$. Lemma 11.65 and then Lemma 11.66 give $\Delta\Pi(M_k) \geq \Delta\Pi(k, \bar{c}_k') > \Delta\Pi(M_j)$, a contradiction. □

Figure 11.28 draws the merger curves for the linear example studied below. The curves are close to parallel in this example, and the larger merger's curve lies to the right at every nonnegative ΔCS.

11.10.3 The optimal approval policy

For a policy $\mathcal{A}$, let $\bar{a}_k = \max \mathcal{A}_k$ be the highest approved cost for target k. The merger $(k, \bar{a}_k)$ is the *marginal merger*, and $\underline{\Delta CS}_k = \Delta CS(k, \bar{a}_k)$ and $\underline{\Delta\Pi}_k = \Delta\Pi(k, \bar{a}_k)$ are the lowest consumer surplus and profit changes among approved mergers with target k.

The natural benchmark is the *naive policy*, which approves every CS-nondecreasing merger, $\mathcal{A}_k = [c^L, \hat{c}_k]$. It is not optimal. Suppose the authority tightens the standard for the largest merger K only, approving it only if $\Delta CS \geq \varepsilon$ for a small $\varepsilon > 0$. The two policies differ only when the naive policy would lead to merger K with $\Delta CS \in [0, \varepsilon)$. In that event, the naive policy delivers at most ε. The tighter policy leads firms to propose the next most profitable acceptable merger, which involves a smaller target. Its expected consumer surplus gain stays bounded away from zero as $\varepsilon \to 0$, because some smaller merger is CS-increasing with positive probability. For small ε the tighter policy therefore does better. The main result characterizes the optimal policy.

Proposition 11.68 (Optimal merger policy, Nocke and Whinston, 2013, Proposition 1)**.** *Any optimal approval policy has three properties. (i) It approves the smallest merger M_1 if and only if*

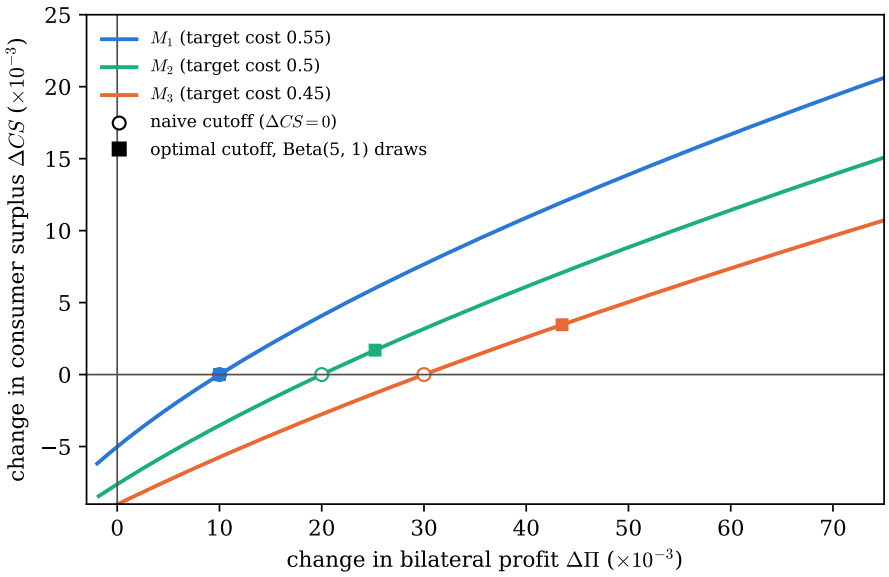

Figure 11.28: Merger curves in $(\Delta\Pi, \Delta CS)$ space for Example 2 of Nocke and Whinston (2013): inverse demand $P = 1 - Q$, acquirer cost $c_0 = 0.5$ and targets with costs 0.55, 0.5 and 0.45. Each curve traces the outcomes of one merger as the post-merger cost $\bar{c}_k$ varies from 0.2 to slightly above c_k. Open circles mark the naive cutoffs, at which $\Delta CS = 0$. Squares mark the optimal cutoffs when post-merger costs follow the Beta(5, 1) distribution described in the text. Our computation.

it is CS-nondecreasing. (ii) It approves with positive probability only mergers with targets in a set $\mathcal{K}^+ = \{1, \dots, \hat{K}\}$*, where* $\hat{K}$ *may equal* K*. (iii) It satisfies*

$$0 = \underline{\Delta CS}_1 < \underline{\Delta CS}_2 < \cdots < \underline{\Delta CS}_{\hat{K}}. \tag{11.158}$$

The minimum acceptable gain in consumer surplus is zero for the smallest merger, strictly positive for every larger merger and increasing in the size of the merger. The largest mergers may never be approved.

Proof sketch. The argument has six steps, each of which improves on a policy that violates a property.

Step 1. An optimal policy approves no CS-decreasing merger. Removing such mergers from $\mathcal{A}$ matters only when one of them would have been proposed. Firms then propose another acceptable merger, which is CS-nondecreasing or the status quo, so expected consumer surplus rises.

Step 2. Every CS-nondecreasing smallest merger is approved. Adding such mergers matters only when one of them becomes the most profitable acceptable merger. Otherwise firms would propose the next most profitable acceptable merger, which by Corollary 11.67 raises consumer surplus by less.

Step 3. The marginal merger satisfies an indifference condition. Let $E_k^{\mathcal{A}}(\bar{a}_k)$ be the expected consumer surplus change from the merger firms would propose if $(k, \bar{a}_k)$ were rejected, conditional on $(k, \bar{a}_k)$ being feasible and the most profitable acceptable merger. Then

$$\underline{\Delta CS}_k = E_k^{\mathcal{A}}(\bar{a}_k). \tag{11.159}$$

If the left side were smaller, rejecting mergers with costs just below $\bar{a}_k$ would raise expected consumer surplus. If it were larger, approving mergers with costs just above $\bar{a}_k$ would raise it.

Step 4. Marginal profits increase with size: $\underline{\Delta\Pi}_j \le \underline{\Delta\Pi}_k$ for $j < k$ in $\mathcal{K}^+$. If the order were reversed, some unapproved merger with target j would give more consumer surplus than the approved marginal merger with target k. Rejecting either leads to the same expected outcome, so approving the first would help.

Step 5. Marginal consumer surplus increases strictly with size. Suppose $\underline{\Delta CS}_j \ge \underline{\Delta CS}_k$ for $j < k$. By Step 3, $\underline{\Delta CS}_k$ equals the expected surplus of the next most profitable acceptable merger. If that merger has profit between $\underline{\Delta\Pi}_j$ and $\underline{\Delta\Pi}_k$, then by Step 4 it involves a smaller target and gives more than $\underline{\Delta CS}_j$. If its profit is below $\underline{\Delta\Pi}_j$, then by Step 3 for target j its expected surplus is exactly $\underline{\Delta CS}_j$. The weighted average then exceeds $\underline{\Delta CS}_j$, a contradiction.

Step 6. If target j is never approved, no larger target is. The most efficient merger with j gives more consumer surplus than the most efficient merger with $j+1$. Merging with the higher-cost target j leaves a lower sum of costs in the industry, hence more output. A nonmonotonicity argument like that of Step 5 then applies. The appendix of the paper gives the formal proof. □

Proposition 11.68 gives the authority a reason to discriminate among mergers by a statistic it can observe before any analysis. In the baseline model, a larger merger is one with a larger naive change in concentration, $2s_0^0 s_k^0$, and the optimal policy demands more from it. This rationale differs from the usual one for concentration screens (Section 11.2). Higher concentration predicts larger harm in Cournot models, but here the screen corrects for the bias in firms' choice of which merger to propose. The policy is a delegation rule. It accepts some CS-increasing mergers with large targets less often than a merger-by-merger review would, in exchange for steering firms toward the smaller mergers that consumers prefer.

11.10.4 Cutoff policies, a numerical example and comparative statics

The indifference condition (11.159) links the policies for different targets, so it does not by itself deliver the optimal policy. The problem simplifies if the optimal policy is a *cutoff policy*, which approves merger k if and only if $\bar{c}_k \le \bar{a}_k$. Then the cutoffs follow by recursion. Set $\bar{a}_1 = \hat{c}_1$. For $k = 2, \dots, K$, consider the best acceptable merger among targets $1, \dots, k-1$, conditional on its profit being at most $\Delta\Pi(k, \bar{a}_k)$. Set $\bar{a}_k$ at the largest cost at which $\Delta CS(k, \bar{a}_k)$ equals the expected consumer surplus from that merger. If no such cost exists, merger k and all larger mergers are never approved.

The optimal policy need not have this form. In Example 1 of the paper, the smaller merger is always feasible and gives $(\Delta\Pi, \Delta CS) = (5, 5)$ with probability 0.9 and $(1, 1)$ with probability 0.1, so its expected consumer surplus gain is $0.9 \times 5 + 0.1 \times 1 = 4.6$.[17] The larger merger's curve passes through $\Delta CS = 4.6$ before it reaches $\Delta\Pi = 5$. For costs between these two points the larger merger would always be proposed, yet it would give less than 4.6. The authority rejects it there and approves it at both higher and lower costs, so the approval set is not an interval. Proposition 2 of the paper gives a sufficient condition, checkable in applications, under which the recursive cutoff policy is optimal.

Example 11.69 (Nocke and Whinston's Example 2)**.** Let $P(Q) = 1 - Q$ and four firms have costs $c_0 = c_2 = 0.5$, $c_1 = 0.55$ and $c_3 = 0.45$. With four Cournot firms, $Q^0 = \frac{4-2}{5} = 0.4$ and $P^0 = 0.6$. Outputs are $P^0 - c_i$, so pre-merger shares are $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{4}$ and $\frac{3}{8}$. The naive cutoffs are $\hat{c}_k = c_k - (P^0 - c_0) = c_k - 0.1$, that is, 0.45, 0.40 and 0.35. Each merger is feasible with

[17] The text of the paper attaches probability 0.9 to the outcome $(1, 1)$. Its Figure 8 and its value of 4.6 require probability 0.9 on $(5, 5)$.

probability $\phi_k = 0.75$. Conditional on feasibility, $\bar{c}_k = 0.2 + (\hat{c}_k - 0.2)X$, where X follows a Beta distribution with density proportional to $x^{\alpha_B - 1}$ on $[0, 1]$. A larger shape parameter α_B makes small efficiency gains more likely. The lower bound 0.2 keeps every firm active.

Table 11.40 reports the paper's results with our replication. We compute the recursive cutoffs by simulating 2 million draws of the feasible set and solving the indifference condition with a root finder. For $\alpha_B = 5$, the optimal cutoffs are $\bar{a}_2 = 0.383$ and $\bar{a}_3 = 0.316$, well below the naive 0.40 and 0.35. The optimal policy requires the medium merger to raise consumer surplus by 0.00170 and the large merger by 0.00346. It achieves 90.3 percent of the first-best gain, which a fully informed authority choosing the best feasible merger would obtain, while the naive policy achieves 79.8 percent. As α_B falls, large efficiencies become more likely, the first-best gain rises and the advantage of the optimal policy over the naive one shrinks.

Table 11.40: Optimal and naive merger policies in the linear example

α_B	Source	$\bar{a}_2$	$\bar{a}_3$	$\underline{\Delta CS}_2$	$\underline{\Delta CS}_3$	First-best gain (% of CS^0)	Naive (% of first best)	Optimal (% of first best)
5	Paper	0.383	0.316	0.00170	0.00346	6.44	79.83	90.30
	Replication	0.383	0.316	0.00170	0.00346	6.44	79.83	90.27
3	Paper			0.00170	0.00457	9.55	87.34	92.13
	Replication	0.383	0.305	0.00170	0.00457	9.55	87.35	92.15
1	Paper			0.00099	0.00571	18.15	93.67	94.10
	Replication	0.390	0.294	0.00098	0.00573	18.14	93.67	94.12

Notes: Paper rows from Nocke and Whinston (2013, Example 2 and Table 1), which report cutoffs only for $\alpha_B = 5$ and write α for the shape parameter. The smallest merger's cutoff is the naive one, $\bar{a}_1 = 0.45$, with $\underline{\Delta CS}_1 = 0$. Replication rows are our Monte Carlo computation with 2 million simulated feasible sets. Differences in the last digit reflect simulation error.

When the optimal policy has a cutoff form, two comparative statics follow (Propositions 3 and 4 of the paper). First, if merger k becomes less likely to be feasible, the standards for mergers up to k do not change, and the standards for larger approved mergers fall. A less likely alternative makes rejection less valuable, so the authority can be more lenient. As all feasibility probabilities go to zero, the optimal policy approaches the naive one. Second, if the acquirer becomes more efficient, all cost cutoffs fall. The authority then demands lower post-merger costs from every merger.

11.10.5 Extensions

Section 5 of the paper shows that the main result survives five changes to the model.

Other bargaining processes. The offer game gives firm 0 the whole bilateral gain. The same proposals arise if firm 0 obtains a fixed share of the gain from every target, as in alternating-offer bargaining with a common discount factor. With efficient bargaining among all firms, the proposed merger maximizes aggregate profit instead. Part (iv) of Lemma 11.64 still holds, and a version of Lemma 11.66 holds for aggregate profit. Lemma 11.65 needs an extra assumption, that a lower post-merger cost raises aggregate profit for CS-nondecreasing mergers. The same conclusions hold if only a subset of firms that includes all merger candidates bargains efficiently.

General sets of mergers. Suppose mergers may involve any set of firms, with $m_k \geq 2$ partners, and bargaining is efficient. Summing first-order conditions shows that aggregate profit is

proportional to the post-merger Herfindahl index,

$$\sum_i \pi_i(M_k) = \sum_i -P'(Q)\, q_i^2 = \left|Q^2 P'(Q)\right| HHI(M_k), \tag{11.160}$$

where we used $\pi_i = -P' q_i^2$ from (11.155). For a CS-neutral merger, outputs of nonmerging firms are unchanged, so the actual post-merger index equals the naive one, $HHI(M_k) = HHI^{naive}(M_k)$. Among CS-neutral mergers, the one with the higher naive post-merger Herfindahl index therefore raises aggregate profit more. Under conditions that make merger curves upward sloping and non-crossing, the authority should discriminate by the naive post-merger index. This is the statistic that concentration screens in merger guidelines use (Table 11.4).

Differentiated products. With CES or logit demand and price competition, profits can be written as functions of a firm's own strategic variable and an aggregator $\Psi = \sum_j \psi_j$. Its terms are unrelated to the curvature ψ of Section 11.4.4, and consumer surplus increases with Ψ. For logit demand $\psi_j = \exp\left(\alpha(\bar{v} - p_j)\right)$ and consumer surplus is $\frac{1}{\alpha} \ln \Psi$ plus a constant, as in Chapter 7. For CES demand with elasticity of substitution $\varsigma > 1$, $\psi_j = p_j^{1-\varsigma}$. These aggregative games share the properties of the Cournot model that Lemmas 11.64 to 11.66 use, so Proposition 11.68 carries over. Nocke and Schutz (2018) develop the aggregative-games approach for multiproduct firms, which Section 11.3.3 used to extend the synergy condition beyond Cournot.

Other welfare standards. If the authority maximizes $W = CS + \omega \Pi$ with $\omega \in [0, 1]$, where $\omega = 1$ is the total surplus standard, the analogue of Proposition 11.68 holds under efficient bargaining. The minimum acceptable welfare gain is zero for the smallest merger and rises with size. For the offer game, the result holds when ω is small.

Fixed-cost synergies. If mergers also save fixed costs, merger curves become bands. The main result holds when the idiosyncratic fixed-cost savings are small enough that bands of different mergers do not overlap. Common fixed-cost savings shift all bands equally and leave the optimal policy unchanged.

11.10.6 Lessons and limits

Two lessons stand out. First, a merger-by-merger consumer surplus test is not the best policy when firms choose among mutually exclusive mergers. The authority should ask what the alternative merger would have been, not only what the proposed merger does. Second, naive concentration statistics carry information about firms' proposal incentives, which gives screens based on $2s_0s_k$ and the naive post-merger index a rationale beyond their role as predictors of price effects.

Later work gives the naive change a second rationale, which Section 11.2.3 reports. With price competition under logit, nested logit or CES demand, the consumer surplus lost in a merger without synergies is approximately proportional to the naive ΔHHI (Nocke and Schutz, 2019). The efficiencies needed to leave consumers unharmed rise with the naive change and, holding it fixed, do not depend on the level of the index (Nocke and Whinston, 2020). The Cournot version of this result is (11.26). Both rationales point to naively computed concentration statistics, and the second singles out the change. Nocke and Whinston (2020) also conclude that the presumptions of the 2010 Guidelines are likely too lax (Asker and Nocke, 2021, p. 227, n. 124).

The model's limits are also clear. The authority commits to a policy and observes everything about the proposed merger, including post-merger costs, which in practice must be predicted.

Only one merger can be proposed, and the setting is static. In a dynamic world, mergers rejected today may be replaced by others tomorrow, and approved mergers change the pool of future mergers. Nocke and Whinston (2010) show that when possible mergers are disjoint, a myopic consumer surplus standard is optimal, so the force identified here comes from overlap among possible mergers. The next subsection explains why.

11.10.7 Merger review over time, investment and innovation

Mergers are not one-time events. When merger opportunities arise over time, approving a merger today changes the profitability and the welfare effects of the mergers that rivals may propose later (Asker and Nocke, 2021, p. 232). A policy that looks only at current market conditions may then be wrong. This subsection shows when it is not, and what changes once firms invest and innovate.

A complementarity between disjoint mergers. Two mergers are *disjoint* if no firm takes part in both. In the Cournot model of Section 11.10.1, the consumer surplus effects of disjoint mergers have a simple structure.

Proposition 11.70 (Sign-preserving complementarity, Nocke and Whinston, 2010)**.** *Let inverse demand satisfy* (11.150)*, let marginal costs be constant, and let all firms be active in every market structure considered. Let $\mathcal{M}_A$ and $\mathcal{M}_B$ be disjoint mergers with post-merger costs c_A and c_B.*

(i) If each merger is CS-nondecreasing at the current market structure, each remains CS-nondecreasing once the other has taken place.

(ii) If each merger is CS-decreasing at the current market structure, each remains CS-decreasing once the other has taken place.

Proof. With constant marginal costs, Proposition 11.15 says that a merger $\mathcal{M}$ with post-merger cost $c_{\mathcal{M}}$ is CS-nondecreasing at a market structure with price P if and only if

$$P - c_{\mathcal{M}} \geq \sum_{i \in \mathcal{M}} (P - c_i) = |\mathcal{M}|\, P - \sum_{i \in \mathcal{M}} c_i.$$

Rearranging,

$$c_{\mathcal{M}} \leq \sum_{i \in \mathcal{M}} c_i - \big(|\mathcal{M}| - 1\big) P. \tag{11.161}$$

The right side falls in P, because $|\mathcal{M}| \geq 2$. Let P^0 be the current price and P^B the price after $\mathcal{M}_B$. The good is homogeneous, so $P^B \leq P^0$ if $\mathcal{M}_B$ is CS-nondecreasing and $P^B > P^0$ if it is CS-decreasing. The partners of $\mathcal{M}_A$ are not in $\mathcal{M}_B$, so their costs and c_A do not change. Only the price in (11.161) moves. In case (i), (11.161) holds for $\mathcal{M}_A$ at P^0, and its right side weakly rises when the price falls to P^B. So it still holds. In case (ii), (11.161) fails for $\mathcal{M}_A$ at P^0, and its right side falls when the price rises to P^B. So it still fails. Exchanging the roles of the two mergers completes the proof. □

The intuition is that a merger is more likely to help consumers the more intense competition is, because intense competition weakens its market-power effect. A CS-increasing merger intensifies competition. It can even turn a second, CS-decreasing merger into a CS-increasing one, and the first merger then stays CS-increasing once the second has taken place (Asker and Nocke, 2021, p. 233).

Myopic review can be optimal. Proposition 11.70 underlies the dynamic result of Nocke and Whinston (2010). Suppose merger opportunities arrive over time, a merger that is not proposed or is blocked today can be proposed again later, and possible mergers are disjoint. An authority that maximizes discounted consumer surplus can then adopt a completely myopic policy. In each period it approves the subset of proposed mergers that maximizes current consumer surplus and ignores future mergers. It never regrets approving a merger that is CS-nondecreasing when approved, by part (i). It never regrets blocking a CS-decreasing merger, because the opportunity remains and the merger can be approved once its effect turns positive. Firms' incentives to propose are aligned with the authority's goal, because a CS-nondecreasing merger is profitable (Corollary 11.14) and stays profitable when it induces other mergers. The myopic policy is optimal in a strong sense. The authority could not do better even with perfect foresight of future merger opportunities and the power to undo past approvals (Asker and Nocke, 2021, p. 233). The result extends to price competition with logit or CES demand (Nocke and Schutz, 2019).

Both assumptions matter. When firms choose among alternative partners, as in Section 11.10.1, possible mergers overlap and are not disjoint. That is why approving every CS-nondecreasing merger is optimal in Nocke and Whinston (2010) but not in Nocke and Whinston (2013) (Asker and Nocke, 2021, p. 234, n. 141).

Investment, entry and buyouts. Mermelstein et al. (2020) compute optimal merger policy in a dynamic model with scale economies. Firms lower their unit costs by accumulating capital, and mergers lower them by combining capital stocks. Firms choose investment and whether to propose a merger, and the authority decides whether to block it. After an approved merger, a potential entrant without capital appears and decides how much to invest. Three findings stand out (Asker and Nocke, 2021, pp. 235–236). First, the optimal dynamic policy differs markedly from the static policy that evaluates each merger at the current state. Second, commitment matters. If society values discounted aggregate surplus but the authority cannot commit to its future policy, giving it a tougher consumer surplus standard can be better. Third, in their baseline a permissive policy raises firms' incentives to invest in almost every state, yet it lowers investment on average. Once mergers are allowed, the industry spends more time in concentrated states, where incentives to invest are weak. A permissive policy also induces entry for buyout, in which entrants overinvest in capital only to be bought by an incumbent (Rasmusen, 1988).

A static model gives a sharper result for process innovation. Motta and Tarantino (2019) let each firm choose its price and an investment that lowers its marginal cost, with demand that has the independence of irrelevant alternatives property. Suppose the merger's synergies affect production costs and not the cost of investment. If the merging partners want to raise their prices at the pre-merger investments, they also want to invest less, because the return to a lower marginal cost grows with output. A merger that leaves consumers unharmed therefore requires the same production cost synergies as when investment is ignored (Asker and Nocke, 2021, pp. 234–235).

Innovation. Acquisitions of innovative rivals raise a different question. Cabral (2018) studies a dominant firm and a fringe firm that invest in innovation over time. An acquisition transfers the leader's technology to the laggard. In equilibrium the dominant firm acquires the fringe firm's innovations, and allowing such acquisitions raises the rate of incremental innovation, an *innovation for buyout* effect. When firms can also invest in radical innovation, which would make the fringe firm dominant, acquisitions lower the radical innovation rate (Asker and Nocke, 2021, p. 236). Igami and Uetake (2020) provide rare empirical evidence. They estimate

a dynamic model of the hard disk drive industry with endogenous innovation, entry and exit. In their model, the rule of thumb that blocks mergers when three or fewer firms exist comes reasonably close to maximizing the discounted value of social welfare (Asker and Nocke, 2021, p. 264). Section 11.11.5 returns to acquisitions that end innovation projects.

11.11 Assessment and open issues

11.11.1 What the approaches deliver

This chapter has studied three families of tools. Retrospective studies compare prices before and after consummated mergers with a control group, using difference-in-differences or stock-market event studies (Section 11.6). Simple theory, through upward pricing pressure and its relatives, turns diversion ratios and margins into a screen (Section 11.4). Prospective econometric models estimate demand, recover costs from first-order conditions and solve for the post-merger equilibrium (Section 11.5). Table 11.41 summarizes what each requires and where the evidence of this chapter shows its weaknesses.

Table 11.41: Approaches to evaluating horizontal mergers

Approach	What it needs	What it delivers	Weaknesses seen in this chapter
Retrospective difference-in-differences	Prices of merging firms and a control group before and after a consummated merger	Transparent estimate of the realized price effect	Controls react strategically (Houde, Analgesics). Samples and price measures matter (Hastings versus Taylor et al.). Only cleared mergers are observed
Stock-market event studies	Abnormal returns of merging firms and rivals	Market expectations of profits	Profits, not consumer effects. Confounding news
Upward pricing pressure and GUPPI	Diversion ratios, margins, an efficiency credit	Sign of the price pressure without market definition	Magnitudes require pass-through and hence demand curvature
Merger simulation	Estimated demand, a conduct assumption and equilibrium computation	Price, quantity and welfare predictions for any counterfactual	Functional form drives pass-through (Analgesics). Logit shocks dampen rival responses (Houde). Conduct may change (MillerCoors). Products and capacity held fixed
Models of repositioning, investment and merger choice	Product or capacity choices before and after mergers	Effects beyond short-run prices	Mostly descriptive (Sweeting). Costs inferred as residuals (Pesendorfer). Policy models assume commitment and observability (Nocke and Whinston)

Notes: Our summary. Analgesics refers to Björnerstedt and Verboven (2016), MillerCoors to Miller and Weinberg (2017), and Taylor et al. to Taylor et al. (2010).

The approaches are complements. Retrospective estimates validate or reject the assumptions of structural models, as in Houde (2012) and Björnerstedt and Verboven (2016). Structural

models explain what retrospective designs can and cannot identify, such as the bias from contaminated controls. Simple screens are cheap and robust in sign but say little about magnitudes. The validation record is mixed. Houde's simulation matches the retrospective magnitude, while analgesics simulations with unit demand under-predict the price increase, and simulations of airline mergers show large prediction errors (Peters, 2006). The MillerCoors evidence suggests that post-merger conduct may change in ways a unilateral-effects simulation misses.

11.11.2 Limitations of current practice

Three limitations recur. The first is the focus on price. Mergers also change quality, branding and variety. Merging radio stations repositioned their playlists without changing their commercial loads (Section 11.9.2). After Maytag-Whirlpool the merged firm cut the number of models it offered (Section 11.6.8). Price-only evaluations miss these margins, and their welfare effects are hard to sign (Chapter 10).

The second is the static framing. Standard analysis holds fixed entry, capacity and the pool of future mergers. Pesendorfer's model shows that investment responses can make mergers without synergies profitable and raise their price effects. Nocke and Whinston show that the optimal standard depends on the alternatives firms could have chosen. Dynamic models of mergers with entry and investment (Berry and Pakes, 1993; Gowrisankaran, 1999; Mermelstein et al., 2020) and dynamic merger review (Nocke and Whinston, 2010) address these issues, at the cost of heavy computation and many assumptions (Section 11.10.7). Free entry, the static benchmark for these concerns, is slow in practice (Section 11.3.4).

The third is the choice of industries. Most of the evidence comes from markets with good scanner or survey data and fairly simple products: cereal, beer, analgesics, gasoline and appliances. Many contested mergers involve hospitals, platforms, technology, networks or inputs sold through negotiation. In these markets prices are bargained, products are complex, or one side of the market pays nothing. Bargaining changes the analysis. Gowrisankaran et al. (2015) show that insurers' bargaining power can substantially counteract the market power of merging hospitals (Section 11.6.9). Loertscher and Marx (2019) study bidding markets in which a powerful buyer runs a procurement auction. As in Farrell and Shapiro (1990), a merger of suppliers without cost synergies harms the buyer, although buyer power mitigates the harm. Strong synergies can remove the harm, but they can also make an otherwise profitable merger unprofitable (Asker and Nocke, 2021, p. 238).

11.11.3 Remedies

Authorities approve mergers subject to remedies far more often than they block them. From 1990 to 2014 the European Commission approved about 15 times as many mergers with remedies as it prohibited. In the United States, 60 percent of the mergers that the agencies challenged between 2003 and 2012 were later approved with remedial commitments (Asker and Nocke, 2021, p. 253). A *behavioral remedy* constrains the merged firm's conduct, for example through a licensing agreement. A *structural remedy*, or *divestiture*, transfers physical assets or intellectual property to another firm. Given how common remedies are, surprisingly little is known about them. Whether a divestiture eliminates the harm of a merger depends on how the transferred assets change the costs of the buyer and of the merged firm. It also depends on how the divestiture interacts with any synergies.

When divestitures help. Vergé (2010) studies a Cournot model in which every firm has the same cost function $C(q, k)$, homogeneous of degree one in output and capital. A merger without synergies pools the partners' capital and is CS-decreasing. A divestiture moves some of the merged firm's capital to outsiders. Vergé shows that divestitures mitigate the harm to consumers if and only if the reallocation makes the industry more symmetric. He also shows when no divestiture can restore pre-merger consumer surplus, which depends on the number of outsiders and on the pre-merger asymmetries in capital (Asker and Nocke, 2021, pp. 253–254). The physical-capital technology of Example 11.8, $C(q, k) = \frac{q^2}{2k}$, is homogeneous of degree one and shows the mechanism. Industry output is $Q = \frac{a\tilde{K}}{1+\tilde{K}}$, which rises with

$$\tilde{K} = \sum_i g(k_i), \qquad g(k) = \frac{k}{1+k}.$$

The function g is strictly concave with $g(0) = 0$, so consumer surplus is a concave function of the distribution of capital. Without a divestiture, the merger of firms 1 and 2 changes $\tilde{K}$ by $g(k_1 + k_2) - g(k_1) - g(k_2) < 0$, since a strictly concave function with $g(0) = 0$ is strictly subadditive. Now let the merged firm, with capital $k_M = k_1 + k_2$, transfer an amount d to an outsider o. The change in $\tilde{K}$ relative to the merger without divestiture is

$$\Gamma(d) = g(k_M - d) + g(k_o + d) - g(k_M) - g(k_o), \qquad \Gamma'(0) = g'(k_o) - g'(k_M).$$

Because g' is decreasing, $\Gamma'(0) > 0$ if and only if $k_o < k_M$. A small divestiture therefore raises consumer surplus if and only if it goes to a firm smaller than the merged firm. In other words, it must make the two firms more alike. Since Γ is concave, the best divestiture to a single smaller outsider equalizes the two capital stocks. With three firms of capital 1, for instance, $\tilde{K} = 1.5$ before the merger. The merged firm has capital 2, and the best divestiture of $\frac{1}{2}$ leaves two firms with capital 1.5 each and $\tilde{K} = 2 \times 0.6 = 1.2$. This is above the 1.17 of the merger without remedy, $g(2) + g(1) = \frac{2}{3} + \frac{1}{2}$, and below the pre-merger 1.5. The divestiture mitigates the harm without removing it. These results concern unilateral effects. With coordinated effects they may reverse, since asymmetries hinder collusion (Proposition 11.49).

Nocke and Rhodes (2019) study remedies for mergers that span many markets. In each market the partners hold assets that can be divested to outsiders, including firms not yet active. The set of divestitures is the outcome of efficient bargaining between an authority that cares about consumer surplus and the profit-maximizing partners. It is subject to a consumer surplus constraint in each market and to the partners' participation constraint. More competitive markets need fewer divestitures. The key concept is the *remedies exchange rate*, the profit the merged firm must give up for an extra dollar of consumer surplus. Under conditions on the curvature of demand, the rate improves in a market as more assets are divested there. The efficient bargain is then bang-bang: maximum divestitures in some markets and only the minimum needed to meet the constraint in the others. Perhaps surprisingly, the efficient bargain places the maximum divestitures in the markets where the partners face more efficient rivals. The reason is that the average remedies exchange rate tends to be worse in those markets (Asker and Nocke, 2021, p. 254).

Evidence. Friberg and Romahn (2015) study the 2001 merger of Carlsberg and Pripps in the Swedish beer market. The authority approved it on condition that the partners divest 18 beer varieties to a small rival, Galatea. A difference-in-differences comparison with the non-merging brewers as controls shows that the merger with remedies lowered the prices both of the partners' retained varieties and of the divested ones. The first result suggests

synergies large enough to outweigh market power. The second fits a buyer with less market power than the partners had before the merger. A random-coefficients logit simulation on pre-merger data predicts that, without cost changes, the divestitures would have reduced the price increases of the retained products without eliminating them. Post-merger prices imply marginal cost savings of 5 percent for Carlsberg and 10 percent for Pripps (Asker and Nocke, 2021, p. 255). Two caveats apply. The non-merging brewers may be invalid controls, and the merger was anticipated long before it was consummated, so there is no sharp break between the periods (n. 197). Lagos (2018) studies station divestitures after a 2013 merger in Chilean retail gasoline. Where the merger raised concentration, retail margins rose by between 0 and 4 percent depending on the specification. Stations within 1 kilometer of a divested station saw margins fall by about 2 percent, but only in municipalities with few affected stations (Asker and Nocke, 2021, p. 263). In their conclusion, Asker and Nocke (2021, p. 261) single out the effects of divestitures and their optimal design as an area where little is known.

11.11.4 Recent controversial mergers

Table 11.42 lists proposed mergers that drew public controversy in the decade and a half before this edition. They span health care, telecommunications and media, retail, airlines, technology, finance and rail. Several raise issues that the tools of this chapter address only partly.

Table 11.42: Selected controversial proposed mergers in the United States

Sector	Proposed merger	Outcome
Health care	Aetna and Humana	Blocked, 2017
	Anthem and Cigna	Blocked, 2017
	UnitedHealth and Amedisys	Allowed with divestitures, 2025
	Edwards Lifesciences and JenaValve	Blocked by preliminary injunction, 2026
Telecom and media	AT&T and T-Mobile	Abandoned, 2011
	Comcast and Time Warner Cable	Abandoned, 2015
	T-Mobile and Sprint	Allowed, 2020
	Paramount and Warner Bros. Discovery	Cleared by the DOJ, then challenged by 12 states and settled by consent decree, 2026
Retail and airlines	Kroger and Albertsons	Blocked, 2024
	Tapestry and Capri	Blocked, 2024
	JetBlue and Spirit	Blocked, 2024
Technology and finance	Microsoft and Activision Blizzard	FTC challenge failed, 2023
	Capital One and Discover	Allowed, 2025
	Hewlett Packard Enterprise and Juniper	DOJ settlement, entered by the court in 2026 after a contested Tunney Act review
Rail	Union Pacific and Norfolk Southern	Under Surface Transportation Board review, final briefs due May 2027

Notes: Status as of autumn 2026. The Tunney Act (Antitrust Procedures and Penalties Act) requires a court to find that a consent decree negotiated by the Department of Justice is in the public interest. The Surface Transportation Board has exclusive jurisdiction over railroad mergers. Outcomes from 2025 on follow the agencies' orders and settlements and the courts' opinions and orders.

11.11.5 Open issues

The cases in Table 11.42 point to several issues that a complete merger analysis must handle.

Two-sided platforms and media. Media and payment networks serve two groups whose participation affects each other. A merger can raise the price to one side and lower it to the other, and the relevant welfare measure combines both. Radio is an example, where Sweeting (2010) studied listeners while the Department of Justice examined advertising prices. Structural analyzes of media mergers with two-sided demand include Chandra and Collard-Wexler (2009) and Jeziorski (2014). Platform economics lies outside the scope of this edition.

Labor-market power. Mergers of employers can lower wages where workers have few alternative employers, as in hospitals or grocery chains. Prager and Schmitt (2021) find slower wage growth for skilled hospital workers after mergers that substantially raised employer concentration. The tools of this chapter carry over with labor supply in place of product demand, and the 2023 Merger Guidelines discuss labor markets explicitly (U.S. Department of Justice and Federal Trade Commission, 2023).

Innovation and nascent competition. In technology and pharmaceuticals, a target may be a small firm whose future products could challenge the acquirer. Cunningham et al. (2021) show that incumbent drug firms acquire projects that overlap with their own and then discontinue them more often than other projects. Current prices say little about such losses, and predicting the counterfactual development path is hard.

Failing firms, capacity and networks. Airline mergers combine networks and capacity, and their effects depend on route-level overlap, hub dominance and entry (Chapter 9). Arguments that a target would exit without the merger, raised for example in airline cases, require a counterfactual in which the target's assets leave the market.

Vertical and complementary effects. Several cases combine horizontal overlaps with vertical relations, such as content and distribution in media or devices and network equipment. Foreclosure and the elimination of double marginalization then enter alongside unilateral effects. Houde (2012) illustrates how vertical control of retail prices can turn a supply agreement into a horizontal merger in effect.

Remedies. Divestitures and behavioral commitments aim to preserve competition while allowing efficiencies. Section 11.11.3 shows that their theory is young and their evidence thin. The Tunney Act review of Department of Justice settlements makes the design of remedies a legal issue as well.

Rising markups and common ownership. Two aggregate literatures form a backdrop to merger policy (Asker and Nocke, 2021, pp. 257–261). De Loecker et al. (2020) estimate the markups of US publicly listed firms from 1955 to 2016, following the production approach of De Loecker and Warzynski (2012). The revenue-weighted average rises, but most firms see no increase and the median is flat. The rise comes from the upper tail. Between 1980 and 2016 the 90th-percentile markup rose from 1.5 to 2.5. The second literature measures *common ownership*, the holding of equity in competing firms by the same institutional investors. Backus et al. (2021b) compute the weight that each S&P 500 firm would place on every other firm's profit if managers served their common owners. The mean weight across pairs rose from about 0.2 in 1980 to almost 0.7 in 2017. These weights are the off-diagonal κ_{fg} of the objective (11.97) and the matrix $\Omega(\kappa)$ of Proposition 11.51, read literally as ownership shares in the sense of O'Brien and Salop (2000). A rise in common ownership thus acts like a partial merger among the firms' owners, without a filing or a review. Whether it changes conduct in product markets is still debated.

Regulated industries and political economy. Rail mergers are reviewed by the Surface Trans-

portation Board under a public-interest standard, outside the Clayton Act framework of Section 11.1.2. State attorneys general can sue to block mergers that federal agencies cleared. These institutions change which mergers are proposed and how they are judged. In the spirit of Section 11.10, they also change firms' incentives over which merger to propose.

11.12 Bibliographic notes

Whinston (2006, ch. 3) gives a graduate treatment of horizontal mergers that covers most of the theory of Sections 11.3 and 11.4. Asker and Nocke (2021) survey mergers and collusion for the most recent Handbook of Industrial Organization. Their survey is the source of much of the newer material here, from the evidence on efficiencies and screens to coordinated effects, remedies and the table of retrospectives. The merger paradox goes back to Salant et al. (1983). Its two classic responses are the capital model of Perry and Porter (1985) and the Bertrand analysis of Deneckere and Davidson (1985). Farrell and Shapiro (1990) replaced these examples with a general analysis of Cournot mergers in equilibrium, and Nocke and Whinston (2013) built their analysis of policy on its synergy condition. The agencies' own statements of method are the Horizontal Merger Guidelines of 1992 and 2010 and the Merger Guidelines of 2023 (U.S. Department of Justice and Federal Trade Commission, 1992, 2010, 2023).

Recent theory refines these classic results. Nocke and Schutz (2018, 2019) carry the synergy condition and the link between consumer surplus and the naive change in concentration over to multiproduct price competition. Nocke and Whinston (2020) derive concentration screens from the efficiencies a merger needs. Spector (2003) and Davidson and Mukherjee (2007) analyze mergers under free entry, and Collard-Wexler (2014) measures how slowly entry comes. Compte et al. (2002) show that capacity asymmetries can make a merger hinder collusion. Vergé (2010) and Nocke and Rhodes (2019) study divestiture remedies, and Friberg and Romahn (2015) evaluate one. Besanko and Spulber (1993) and Wollmann (2019) show how notification rules shape which mergers are proposed.

The economics of unilateral effects with differentiated products developed alongside merger practice. Werden (1996) derived compensating marginal cost reductions, and O'Brien and Salop (2000) extended the ownership matrix to partial ownership. Farrell and Shapiro (2010) reframed the analysis as upward pricing pressure, and Jaffe and Weyl (2013) connected pressure to predicted price changes through pass-through. Werden and Froeb (2008) review unilateral effects and merger simulation as practiced at the agencies. Miller et al. (2017b) ask how well pricing-pressure measures predict the price effects of full simulations. The simulation approach itself rests on the demand models of Hausman et al. (1994), Werden and Froeb (1994) and Nevo (2000b). Crooke et al. (1999) showed early how much its predictions depend on functional form.

Retrospective evaluation has grown into a literature of its own. Ashenfelter et al. (2014) and Kwoka (2015) collect the evidence from consummated mergers and draw lessons for enforcement. Validation studies that set simulations against retrospective estimates include Peters (2006) for airlines, Weinberg and Hosken (2013) for consumer products, Houde (2012) for gasoline and Björnerstedt and Verboven (2016) for painkillers. The beer industry has become a laboratory for both approaches. Ashenfelter et al. (2015) estimate the efficiency and concentration effects of the MillerCoors joint venture from regional variation, and Miller et al. (2021) model price leadership in the same industry.

Static merger analysis holds fixed the set of products, the capacities of firms and the pool of future mergers. Sweeting (2010) and Pesendorfer (2003) show empirically that the first two

respond to mergers. Dynamic models of mergers with entry and investment begin with Berry and Pakes (1993) and Gowrisankaran (1999). Nocke and Whinston (2010) study merger review when mergers arrive over time, and Mermelstein et al. (2020) compute optimal merger policy in a dynamic model with investment and entry. The links between mergers and collusion, which Section 11.8 measures, are developed in Chapters 12 and 13.

11.13 Exercises

1. *Critical loss and aggregate diversion.* A hypothetical monopolist of a candidate market sets price p and has constant marginal cost c, so its margin is $L = \frac{p-c}{p}$. It considers a price increase of a fraction X.

   (a) Derive the critical loss $CL = \frac{X}{X+L}$. For linear demand, derive the breakeven threshold elasticity $\frac{1}{X+L}$ and the profit-maximizing threshold elasticity $\frac{1}{2X+L}$. Evaluate all three with $X = 0.05$ and $L = 0.4$.

   (b) The candidate market contains four symmetric single-product firms. Each product's aggregate diversion ratio to the other three is 0.15. Use Proposition 11.2 to decide whether the candidate market passes the breakeven test.

   (c) A consultant measures the actual loss as $\frac{X}{L}$, the loss of one firm that raises its price alone. Show that this loss always exceeds CL, and explain what the calculation leaves out.

2. *The Williamson trade-off.* Normalize the pre-merger price and quantity to $p_0 = 1$ and $q_0 = 1$. Demand is linear with elasticity one at p_0.

   (a) The industry is competitive before the merger, so $c_0 = p_0$. Use (11.9) to compute the cost saving, in percent of c_0, that leaves total surplus unchanged after price increases of 5 and 10 percent. Compare the exact values with the approximation $\frac{1}{2}\varepsilon\left(\frac{\Delta p}{p_0}\right)^2$.

   (b) Now let $c_0 = 0.8$ before the merger. Use (11.10) to compute the saving needed to offset a 10 percent price increase. Explain why it is several times larger than in part (a).

   (c) Explain why a consumer surplus standard requires a model of how the cost saving affects the price. Suppose a monopolist facing $P(Q) = a - bQ$ replaces a competitive industry with cost $c_0 < a$. Find the largest post-merger cost c_1 that does not raise the price.

3. *The merger paradox and the synergies it requires.* Use the linear Cournot model of Section 11.3.2.

   (a) Derive the profitability condition (11.11). Find the smallest profitable merger for $N = 10$ and for $N = 20$.

   (b) Let demand be $P = 10 - Q$ with three firms of cost 4, and let firms 1 and 2 merge with marginal cost c_M. Show that the price-neutral cost of Proposition 11.12 is $c_M = 2.5$.

   (c) Find the range of c_M for which the merger is profitable. Show that every c_M between 2.5 and about 3.82 gives a merger that is profitable and raises the price. Explain why the agency cannot rely on profitability to screen out such mergers.

   (d) Now let entry be free. Every incumbent and potential entrant has marginal cost 1 and must sink an entry cost $F = 4$, and demand is $P = 10 - Q$. Find the number of firms in a

free-entry equilibrium when the number of firms must be an integer. Two incumbents merge without synergies. Show that the merger triggers entry and is unprofitable, and relate the result to Proposition 11.22.

4. *The external effect of a Cournot merger.* Three Cournot firms have market shares $(0.6, 0.25, 0.15)$. Consider a small transfer of capital between two of them that raises the price.

   (a) With constant marginal costs and linear demand, use Corollary 11.18 to find the pairs for which the external effect is positive.

   (b) With linear demand and costs $\frac{q^2}{2k}$, show first that every firm's share is below the market elasticity ε. With $\varepsilon = 0.8$, use (11.31) to sign the external effect for the pair $(2, 3)$ and for the pair $(1, 3)$.

   (c) Explain, using the decomposition in the proof of Proposition 11.17, why mergers of small firms tend to have positive external effects. What does this imply for a policy that treats every increase in the Herfindahl index as harmful?

5. *Pricing pressure and simulation in a logit duopoly.* Two single-product firms face logit demand with an outside good. Before their merger, both charge $p = 1$, both have marginal cost $c = 0.6$, each has share 0.25 and the outside share is 0.5.

   (a) Calibrate the price coefficient from the logit Lerner condition and show that $\alpha = \frac{10}{3}$. Compute the diversion ratio, UPP, GUPPI and the compensating marginal cost reduction of Proposition 11.27. Show that the reduction equals one third of marginal cost.

   (b) By Proposition 11.33, the first iteration of the merger simulation predicts a price of 1.2 for both products. Solve the post-merger Bertrand-Nash equilibrium numerically, and compare the two predictions.

   (c) Explain the gap between them with the pass-through results of Section 11.4.4. Compute the change in consumer surplus from (11.69).

6. *Pass-through and the shape of demand.*

   (a) Derive the single-product pass-through rate of Lemma 11.31 for linear demand, constant-elasticity demand and logit demand with rivals' prices fixed.

   (b) Using (11.93) and (11.94), explain why own elasticities rise with price under unit demand and stay roughly constant under constant expenditures.

   (c) Use parts (a) and (b) to explain why the constant-expenditure models of Table 11.27 predict larger price increases than the unit-demand models. Then explain why the calibration of Table 11.29, which matches elasticities, diversion and margins, still produces different predictions.

7. *Retrospective designs.*

   (a) In the linear Bertrand model of Assumption 11.23 with $N = 4$, $b = 1$ and $d = 0.2$, compute λ in (11.79). What share of the insiders' price increase does a DiD estimator with an outsider as control recover? Explain why the bias is largest when the merger matters most.

   (b) Using the estimates with state fixed effects in Table 11.22, compute the Wald ratio (11.89) and compare it with the reported IV estimate. Interpret the result as a percentage effect of one rival merger.

(c) State the exclusion restriction behind Dafny's instrument. Propose one falsification test beyond those in the paper, and say which violation it would detect.

8. *Coordinated effects in beer.*

(a) Three single-product firms face demand $s(p)$. Firms 1 and 2 merge, and the merged firm and firm 3 put weight κ on each other's profits. Write the three first-order conditions in the form (11.98), and verify that $\kappa = 0$ and $\kappa = 1$ give the unilateral-effects and the monopoly benchmarks.

(b) Using Proposition 11.57, explain what variation in the data identifies κ and which assumption makes the importers a valid control group.

(c) Suppose domestic light beers are closer substitutes for one another than Table 11.32 implies. In which direction would $\hat{\kappa}$ move? Use Proposition 11.53 to explain your answer.

(d) Use Table 11.34 to compute the change in each brewer's flagship price caused by coordination, with and without efficiencies. Explain why the merger can be defended under a total surplus standard but not under a consumer surplus standard.

(e) In the capacity model of Proposition 11.49, four firms have capacities $(0.6, 0.6, 0.6, 0.6)$. Compute the critical discount factor before and after a merger of two of them. Repeat with capacities $(0.2, 0.3, 0.4, 1.0)$, first for a merger of the two largest firms and then for a merger of the two smallest. Explain why the symmetric supergame of Section 11.8.1 misses the second set of answers.

Chapter 12

Collusion: Theory

Firms that compete in the same market every period can do better than the static equilibrium of Chapter 2. If each firm expects that a price cut today will provoke a price war tomorrow, high prices can persist without any enforceable contract. This possibility matters for understanding how imperfectly competitive markets work, and it is a central concern of antitrust policy. Four questions organize the economics of collusion. How often do firms collude? Can we detect collusion in data? How does collusion occur, that is, how do firms reach an agreement, monitor it and respond to cheating? And which practices and institutions make it easier? This chapter answers the last two questions with theory. Chapter 13 takes the first two to data.

One comparison runs through the whole chapter. A firm that undercuts its rivals gains profit in the current period. It loses the profit that collusion would have earned during the punishment that follows. Collusion is sustainable when the discounted loss exceeds the gain. Every model in the chapter is a variation on this incentive constraint. The models differ in what firms observe, in how demand moves over time, in what information is private, and in what institutions a cartel can build. These differences lead to different predictions about when collusive prices are high or low and whether price wars occur on the equilibrium path. The differences in predictions are what make the evidence of Chapter 13 informative.

The chapter proceeds from the simplest environment to the richest. Section 12.1 defines collusion and its forms, explains with the examples of Marshall and Marx (2012) when tacit collusion fails, sketches its legal treatment and summarizes facts from enforcement. Section 12.2 develops the theory of repeated games, with full proofs of the one-shot deviation principle, of a folk theorem and of the unraveling of collusion when the horizon is finite. Section 12.3 studies collusion when firms observe one another's actions: the Bertrand and Cournot supergames, capacity constraints, optimal punishments, asymmetries, differentiated products and coordinated effects of mergers. Section 12.4 lets demand fluctuate and works through Rotemberg and Saloner (1986), Haltiwanger and Harrington (1991) and Bagwell and Staiger (1997). Section 12.5 turns to imperfect public monitoring and to the price wars of Green and Porter (1984). It includes an N-firm model, due to Asker and Nocke (2021), that measures the value of transparency. Section 12.6 studies private information about costs and the case for rigid prices made by Athey et al. (2004a). Section 12.7 asks how explicit cartels organize themselves. It treats participation, price agreements, monitoring and plus factors, facilitating practices, multimarket contact and entry, and the quota, report and transfer schemes explained by Harrington and Skrzypacz (2011). Section 12.8 adds antitrust enforcement, with the model of leniency of Chen and Rey (2013) and the critique of the agreement requirement by Kaplow (2013). Section 12.9 reviews the evidence on what makes cartels succeed (Levenstein and

Suslow, 2006). Section 12.10 collects the predictions of all the models in one table and draws lessons for empirical work.

The chapter draws on and feeds into much of the book. Chapter 2 develops the static Bertrand and Cournot models that serve as stage games, treats Stigler (1964) in full and states the supergame thresholds that this chapter proves. The conduct parameter of Chapter 3 reappears here as a summary of the equilibrium of a dynamic game, and the critique of Corts (1999) becomes a statement about time-varying collusion. Full collusion among sellers of differentiated products corresponds to an ownership matrix of ones in the pricing model of Chapter 4. The 1955 automobile price war of Chapter 6 is a piece of evidence for Rotemberg and Saloner (1986). The coordinated effects of mergers in Chapter 11 rest on the theory of Section 12.3. The analysis of private costs in Section 12.6 is a mechanism design problem that shares its tools with the procurement auctions of Chapter 14. Appendix B collects the envelope theorem, log-concavity and the fixed-point arguments used here, and Appendix C works through collusion in a Cournot industry with free entry.

Notation and sources. Throughout the chapter δ is the discount factor. It has nothing to do with the mean utility δ_{jt} of the demand chapters. There are N firms, p^m and π^m are the monopoly price and profit, and $\underline{\delta}$ or δ^* denotes a threshold discount factor. When we quote a paper we translate its equations into this notation and say so at first use. Several papers are available to us only in working-paper versions, whose page, equation and theorem numbers can differ from the published articles. We say so whenever we cite such a number. Numbers that are our own computations, and not the authors', are labeled as such. The scripts that produce them are named in the text and kept with the figures of the chapter.

12.1 Collusion: Forms, Law, and Facts

Firms that sell substitutes can earn more by acting together than by competing. When they succeed, prices rise above the competitive level and buyers pay the difference. This section fixes the vocabulary and explains how economists model collusion. It then asks when tacit collusion fails, describes how the law treats collusion, and summarizes what the records of enforcement agencies show. Section 12.2 then develops the theory of repeated games. Section 12.3 applies it to the simplest environment, in which every firm observes what its rivals did.

12.1.1 Forms of collusion

Definition 12.1 (Collusion)**.** *Collusion* is coordination among competing firms that raises prices, restricts output, or divides markets relative to the non-cooperative outcome of their market game. A *cartel* is an organized group of firms that colludes.

The non-cooperative outcome in the definition is the static Nash equilibrium of the game that the firms play in a single period. It is an equilibrium in prices when firms set prices, in quantities when they set quantities, and in bids when they compete in an auction. Collusion is always measured against this benchmark. In the homogeneous Bertrand model of Section 2.6 the benchmark price is marginal cost, so any price above marginal cost is collusive.

Collusion takes several forms. *Price fixing* is an agreement on prices, on price increases, or on minimum prices. *Bid rigging* is collusion in auctions and procurement, where the colluders decide in advance who will win and at what bid. *Market division* allocates customers, territories, or sales quotas among the firms, so that each firm faces less competition for its share. The

forms are often combined. Most documented cartels agree on prices and also allocate sales among their members, as Section 12.7 shows.

Economists distinguish two ways of reaching a collusive outcome. *Explicit collusion* uses direct communication and agreement among the firms, such as meetings to set prices, exchanges of sales data, and payments between cartel members. Marshall and Marx (2012, p. ix) define it as an agreement among competitors that relies on interfirm communication or transfers to suppress rivalry. *Tacit collusion* sustains prices above the static Nash level as a non-cooperative equilibrium of a repeated game, without any explicit agreement. In the words of Marshall and Marx (2012, p. 9), tacit collusive equilibria are those that need no direct interaction between the firms, such as communication or transfers. The distinction concerns the means of coordination. The logic of enforcement is the same in both cases: a firm refrains from undercutting because undercutting would provoke a costly response from its rivals. Section 12.3 shows that this logic needs no communication at all when firms observe each other's prices. Communication becomes valuable when firms hold private information about costs, demand, or their own sales (Sections 12.6 and 12.7).

Collusion can also occur on the buying side of a market. A *buyer cartel* colludes to depress the prices its members pay for an input, which is collusion among buyers with monopsony power. A *no-poach agreement* is a pledge among employers not to hire each other's workers, which is collusion in a labor market. The theory of this chapter applies to both, with the direction of the price distortion reversed.

12.1.2 How economists model collusion

The modern theory of collusion starts from non-cooperative behavior. It takes the static Nash equilibrium as the outcome that firms would reach if they met only once. It then takes seriously that the same firms meet again and again. A firm that cuts its price today gains sales today, but it may provoke a price war that lowers its profit for many periods. If the future matters enough, the threat of such a war can sustain high margins today, even though every firm could gain in the short run by cutting its price (Friedman, 1971).

The workhorse model is an infinitely repeated game. A fixed set of firms plays the same stage game in every period and discounts future profits. The model abstracts from entry and exit, from investment, and from the evolution of demand and technology. Later sections relax some of these simplifications. Demand fluctuates in Section 12.4, and firms observe their rivals imperfectly in Sections 12.5 to 12.7.

Two consequences of this approach shape the whole chapter. First, collusion is a property of an equilibrium, so it requires neither a contract nor even a conversation. Second, repeated games have many equilibria. The theory tells us which outcomes can be sustained, but it does not tell us which outcome firms will reach. This multiplicity is a central difficulty for empirical work on collusion, to which Chapter 13 returns.

Game theory draws a line that is easy to misread in legal debates. *Cooperative games* allow binding agreements, whose enforcement lies outside the analysis. *Noncooperative games* allow none (Kaplow, 2013, p. 177). Competition law makes every price-fixing agreement unenforceable in court, so the oligopoly problem belongs to noncooperative theory. That theory covers express cartels with detailed negotiated agreements, the pure interdependence of two gas stations that watch each other's signs, and everything in between (p. 178). Economists also call the outcomes of a noncooperative game cooperative or noncooperative, and the double use invites confusion. Friedman (1986, p. 20), quoted by Kaplow (2013, p. 179), keeps the two apart: "The presence or absence of binding agreements is the definitive element for cooperative versus

noncooperative games." A collusive outcome of a repeated game is therefore cooperative in its payoffs and noncooperative in its structure. When an economist says that a cartel in a repeated game has no agreement, the word means a binding contract. The legal notion of agreement is broader and covers at least classic cartels (pp. 180–181). Section 12.8.4 asks whether game theory offers any narrower notion that could separate legal from illegal coordination.

12.1.3 When tacit collusion fails

If repeated interaction can sustain the monopoly price without a conversation, why do firms ever take the legal risk of explicit collusion? Marshall and Marx (2012, pp. 9–17) answer with a sequence of examples in which they remove or restore communication and transfers. Table 12.1 summarizes them and names the model of this chapter that formalizes each one.

The first two examples concern two gas stations on opposite corners of a small town. The nearest rival vendor is at least 150 miles away. Each station buys gasoline at \$2 per gallon, and a common price of \$3 maximizes joint profit. Prices are posted at 6 AM and cannot change until the next morning (p. 10). In a static setting each station undercuts any common price above cost by one cent, and the only equilibrium price is \$2.01. When the future matters, each station expects that an undercut will lead its rival to give up on high prices, and both post \$3 (p. 11). The outcome is the one that private communication could achieve, but it is reached without any. This is the Bertrand supergame of Section 12.3.1.

The remaining examples replace the stations by two plants that sell corrugated boxes through procurements (pp. 12–16). A plant learns only whether it won a procurement, never the rival's bid. With many small buyers, each plant expects 500 solicitations per quarter and wins about 250 of them at the joint-profit price. A short run of lost bids then carries little information and does little harm, so the fear of a slide in prices sustains collusion tacitly (p. 13). Three changes break this outcome. With few large buyers, each plant receives about one solicitation per quarter, and there are only four awards a year. A plant that loses two awards in a row has gone six months without a contract, and a run of five lost awards would be a financial disaster. Bids therefore drift toward marginal cost (p. 14). With many buyers whose demand moves with a common shock that the plants cannot observe, a plant that wins 125 of 500 solicitations cannot tell a slump from undercutting (pp. 14–15). With strategic buyers, a buyer can tell each plant that its rival bid lower, or promise the whole award in exchange for a cut of 10 percent. The buyer thus manufactures the appearance of cheating (pp. 15–16).

In the last three scenarios repeated play cannot discipline the rivals, and joint profits fall short of the monopoly level (p. 16). Explicit collusion adds two tools, communication and interfirm transfers. With lumpy awards, the plants can agree on the bids each submits and share the work through subcontracts. A temporary imbalance in profits can be settled with cash or an equivalent transaction, arranged before the procurement if needed. With uncertain demand, the plants can monitor each other's production and learn that a shortfall came from demand. With strategic buyers, they can monitor bids, sales and production, and transfers can correct an unequal division of the gain (pp. 16–17). Marshall and Marx note that the exposition of the Green-Porter model by Tirole (1988) formalizes the difficulties of infrequent purchases and uncertain demand (p. 16, note 27). We develop that model in Section 12.5.2.

The vitamin cartels of the 1990s fit this account. Even duopolies, in methylglucamine, vitamin A500 USP and beta-carotene, needed explicit collusion to raise prices and profits substantially (Marshall and Marx, 2012, p. 3). After the cartels ended, prices fell at different speeds. Marshall and Marx report a study of thirty vitamin products by Kovacic and coauthors (p. 18). On average, prices before the plea period were about 25 to 30 percent below their

Table 12.1: When tacit collusion fails: the scenarios of Marshall and Marx

Scenario	Outcome without communication or transfers	What explicit collusion adds	Model in this book
1. Gas stations, one period	Price \$2.01, one cent above cost	Nothing self-enforcing in a single period	Static Bertrand (Section 2.6)
2. Gas stations, repeated play	Price \$3, the joint-profit price, reached tacitly	Nothing	Bertrand supergame (Proposition 12.14)
3. Box plants, many small buyers	Bids near the joint-profit price, tacitly	Nothing	Stigler's many small buyers (Section 12.5.1)
4. Box plants, few large buyers	Bids drift toward cost	Agreed bids, subcontracts, cash transfers	Lumpy orders and detection lags (Proposition 12.16 and Section 12.5.2)
5. Many buyers, unobserved common demand shock	Bids drift toward cost	Mutual monitoring of production	Green and Porter (Section 12.5)
6. Strategic buyers	Tacit coordination harder, more so with three or more plants	Monitoring of bids, sales and production, and transfers	Private monitoring with reports (Section 12.7.3)

Notes: Scenarios and outcomes from Marshall and Marx (2012, pp. 9–17). The entry for scenario 1 in the third column and the whole last column are our reading.

plea-period maximum. Where the cartel had three or four members, prices typically fell back to pre-cartel levels within two years after the plea period. Where only two firms produced, prices stayed close to their maximum collusive levels for several years. Without communication and transfers, high prices were hard to sustain except among two producers. This is the comparative static of Proposition 12.14, in which the threshold $1 - \frac{1}{N}$ is lowest for $N = 2$.

12.1.4 Legal treatment

Competition law in the United States and the European Union treats explicit collusion as one of its most serious offenses. In the United States, Section 1 of the Sherman Act of 1890 prohibits contracts, combinations and conspiracies in restraint of trade. Courts treat price fixing, bid rigging and market division among competitors as illegal *per se*, a point of blackletter law (Kaplow, 2013, p. 61). A per se offense is established by proof of the agreement itself, without an inquiry into its effects on competition. No defense based on the reasonableness of the price is allowed. Since the *Trenton Potteries* decision of 1927 and the *Socony-Vacuum* decision of 1940, it is illegal to fix any price, even a competitive one (Kaplow, 2013, p. 197, note 46). Policy toward such hard-core collusion invites criminal sanctions in many jurisdictions (Asker and Nocke, 2021, p. 180). The Department of Justice prosecutes these cartels as crimes, and persons convicted of cartel conduct are incarcerated every year (Asker and Nocke, 2021, pp. 182–183, Figure 1). In the European Union, Article 101 of the Treaty on the Functioning of the European Union prohibits agreements and concerted practices that restrict competition. The European Commission enforces it with administrative fines on firms. Both jurisdictions also run *leniency programs*, which reduce or waive the fine of a cartel member that reports the cartel and supplies evidence. Section 12.8.1 describes the sanctions and the leniency programs in detail, and Sections 12.8.2 and 12.8.3 study how they change the incentive to collude.

Legal liability turns on proof of an agreement. On the conventional view, prices that move in parallel do not establish an agreement by themselves, and firms that reach high prices through pure interdependence, without communicating, escape liability (Kaplow, 2013, pp. 4 and 110). Kaplow (2013) argues that this focus on agreements is misplaced. The harm from collusion depends on the extent and duration of supracompetitive prices, not on the means by which firms reach them (Kaplow, 2013, pp. 9–10).

Kaplow (2013, pp. 22–26) shows with one example how hard it is to say what an agreement is. Two competitors have charged the competitive price of $3.00 for months. In a meeting, the Initiator announces that until further notice it will charge all customers $3.25 and that there will never be secret price cuts. The Responder answers that it will charge $3.35, the Initiator moves to $3.40, and the Responder matches. Most readers would call this an agreement, although no binding contract, promise or magic word was used (pp. 22–24). Now let the same moves be posted prices at two gas stations on adjacent corners of an isolated area, with no words spoken. It is almost universally accepted that this second story depicts no agreement (p. 25). Kaplow then observes that the second story is only a retelling of the first. Each price sign proclaims a price, and the rival sees every change at once, so a secret cut is impossible. One scenario is thus both a classic agreement and a clear case of no agreement. Any rule that claims to separate the two stories must therefore be mistaken (p. 26).

The legal vocabulary is unsettled as well, and Kaplow examines it term by term (pp. 29–42). Section 1 of the Sherman Act never uses the word *agreement*. The word summarizes the statute's language of contract, combination and conspiracy, while Article 101 uses it explicitly (pp. 30–31). Article 101 also prohibits *concerted practices*, a term that in its relevant sense means what is mutually contrived or agreed on (p. 33). Economists use *collusion* to describe

the economic nature of coordinated behavior. Its ordinary meaning is an agreement, often a secret one (pp. 33–34). A *meeting of the minds* is a metaphor for the parties' subjective states. It covers oligopolists who coordinate prices by understanding each other's thought processes, and economists use it to explain equilibrium (p. 34). An agreement is *express* if it is directly and explicitly stated, and *tacit* if it is not express. The two words alone say little about where the boundary lies (pp. 34–36). The basic distinction is between *independent* behavior, which does not depend on how others react, and *interdependent* behavior, which involves coordination with others (pp. 37–38). Gas stations that all raise prices after the wholesale price rises act independently. Stations that hold $3.40 because each expects the other to match any cut act interdependently (pp. 30 and 39–40). Turner (1962) opposed liability for mere interdependence as a matter of policy. Even he wrote that "there are far better grounds for saying that though there may be 'agreement' it is not unlawful agreement" (Turner, 1962, p. 671, quoted by Kaplow, 2013, p. 32).

Section 12.8.4 returns to this debate. The theory of Section 12.3 bears on one part of it: with perfect monitoring, tacit and explicit collusion are the same equilibrium.

12.1.5 Facts from enforcement

Cartel enforcement produces a steady flow of documented cases. Table 12.2 lists the ten largest fines per case that the European Commission has imposed since 1969. The largest is the trucks cartel of 2016 and 2017, at 3.8 billion euros. The list spans vehicles and their parts (trucks, car glass, bearings, emissions technology), financial markets (foreign exchange, interest rate derivatives), electronics, elevators, vitamins and air freight.

Table 12.2: Ten highest cartel fines per case imposed by the European Commission since 1969

Year(s)	Case	Fine (euros)
2016/2017	Trucks	3,807,022,000
2012	TV and computer monitor tubes	1,409,588,000
2019/2021	Forex	1,358,900,000
2013/2016/2021	Euro interest rate derivatives	1,303,518,000
2008	Carglass	1,185,500,000
2014	Automotive bearings	953,306,000
2021	Car emissions	875,189,000
2007	Elevators and escalators	832,422,250
2001	Vitamins	790,515,000
2010/2017	Airfreight (including re-adoption)	723,631,224

Notes: Amounts are adjusted for judgments of the EU courts (General Court and Court of Justice) and for amendment decisions. Statistics as of their last change on 26 February 2026. Rows are ordered by amount. The source lists Forex above TV and computer monitor tubes. Source: European Commission (2026, Table 5).

Many other markets appear in the Commission's decisions. Examples include LIBOR, steel abrasives, paper envelopes, smart cards, canned mushrooms, power cables, mattresses, North Sea shrimp, wire harnesses, computer monitor tubes, window mountings, refrigeration compressors, washing powder and bananas. Three decisions of 2025 show the reach of the law. Car recycling (458 million euros) included a buyer cartel. Sixteen carmakers and their trade association agreed not to pay car dismantlers for processing end-of-life vehicles. They also

agreed not to promote how much of a car can be recycled or how much recycled material new cars use (European Commission, 2025a). Delivery Hero and Glovo (329 million euros) agreed not to poach each other's employees, exchanged sensitive information and divided national markets. It was the first decision in which the Commission found a cartel in the labor market (European Commission, 2025b). The third decision, on starter batteries, imposed 72 million euros (European Commission, 2025c).

Annual totals are volatile. Cartel fines imposed by the Commission, before adjustment for court judgments, were 1.75 billion euros in 2021, 49 million euros in 2024 and 859 million euros in 2025 (European Commission, 2026, Table 1). Totals this volatile mostly reflect when large cases happen to close. Annual fines are therefore a poor measure of how much collusion takes place.

The record in the United States shows the same difficulty. Criminal cartel cases filed by the Antitrust Division of the Department of Justice peaked in the early 1980s at over 90 a year (Asker and Nocke, 2021, p. 182). In 1982, 92 cases were filed and fines totaled 36.8 million dollars, about 400,000 dollars per case. In 2017, 21 cases were filed and fines totaled 2.79 billion dollars, over 100 million dollars per case (p. 182). Fewer cases need not mean less collusion. The economy has grown, enforcement resources and policies have changed, and the cost of being caught has risen. Miller (2009) uses the time series of cases from 1985 to 2005 to separate detection from deterrence. In his model industries move between competition and collusion through rates of formation, detection and dissolution. He finds that the 1993 revision of the U.S. leniency program raised cartel discoveries by 60 percent, which indicates better detection. The later path of discoveries also implies greater deterrence (Asker and Nocke, 2021, pp. 186–187).

More direct evidence suggests that collusion is common. Kawai and Nakabayashi (2020) study construction projects procured by the Japanese national government between April 2003 and December 2006. When an auction goes to a second round, the lowest first-round bidder almost always wins again, while the second and third bidders often switch places. The pattern indicates that the winner was chosen before the auction. About 970 firms appear to collude. Scaling up by public construction spending, the authors estimate that collusion among construction firms affects about 0.85 percent of Japan's GDP (Asker and Nocke, 2021, pp. 184–185). Conley and Decarolis (2016) conclude that more than 30 percent of the construction projects procured by Italian regional governments from 2005 to 2010 were affected by coordination among bidders. Hyytinen et al. (2018) study Finnish cartels from 1951 to 1990, when cartels were legal and many had to register. They document 900 registered cartels, 364 of them in manufacturing and 534 in other industries. They conclude that by the end of the 1980s almost all Finnish manufacturing was cartelized (Asker and Nocke, 2021, p. 186). Enforcers thus catch only a subset of the cartels that exist.

Prosecuted cartels also reveal how explicit collusion is organized. In the early 1990s the main producers of lysine, an additive in animal feed, and of citric acid formed global cartels that lasted until mid-1995. Both agreed on prices and allocated sales quotas. Members reported their sales to the cartel, and a firm that sold more than its quota had to buy output from firms below quota (Harrington and Skrzypacz, 2011, pp. 2425–2426). The International Steel Agreement of 1926 used the same design, with payments into and out of a common fund. Sales quotas, self-reported sales and transfers between members recur across many cartels. Section 12.7.3 documents these cases and explains why the design works.

The cases above share further features. Many involve intermediate goods sold to industrial buyers, and many involve firms from several countries. The duration and success of cartels vary widely, as the evidence collected by Levenstein and Suslow (2006) shows (Section 12.9). Every such sample is selected, because we observe only cartels that were legal or that were

caught. Section 12.8 and Chapter 13 discuss what this selection implies for inference.

12.2 Repeated Games

This section collects the tools from the theory of repeated games that the rest of the chapter uses. Throughout the chapter δ denotes the discount factor. It is unrelated to the mean utility δ_{jt} of the demand chapters. We follow the standard treatments of Fudenberg and Tirole (1991) and Mailath and Samuelson (2006), and Tirole (1988, ch. 6) covers the applications to oligopoly. We prove the results that the chapter relies on.

12.2.1 The stage game and the repeated game

Definition 12.2 (Stage game and repeated game)**.** A *stage game* is $G = (\mathcal{N}, (A_i)_{i\in\mathcal{N}}, (u_i)_{i\in\mathcal{N}})$. Here $\mathcal{N} = \{1, \dots, N\}$ is the set of players, A_i is player i's set of actions, and $u_i : A \to \mathbb{R}$ is player i's stage payoff, defined on the set of action profiles $A = A_1 \times \cdots \times A_N$. In the *infinitely repeated game* $G^\infty(\delta)$, the players play G in periods $t = 0, 1, 2, \dots$ and observe the action profile $a^t \in A$ at the end of each period.

(i) A *history* of length t is $h^t = (a^0, \dots, a^{t-1}) \in H^t = A^t$, with $H^0 = \{\varnothing\}$. The set of all histories is $\mathcal{H} = \bigcup_{t\geq 0} H^t$.

(ii) A (pure) *strategy* of player i is a function $s_i : \mathcal{H} \to A_i$. A profile $s = (s_1, \dots, s_N)$ generates the *outcome path* $a^0(s) = s(\varnothing)$ and $a^t(s) = s\big(a^0(s), \dots, a^{t-1}(s)\big)$ for $t \geq 1$.

(iii) Player i's payoff is the normalized discounted sum

$$U_i(s) = (1-\delta)\sum_{t=0}^{\infty} \delta^t u_i\big(a^t(s)\big), \qquad \delta \in (0,1). \tag{12.1}$$

Several features of the definition deserve comment. Observing a^t at the end of each period is called *perfect monitoring*: every player sees every action. Later sections relax it. A strategy specifies an action after every history, including histories that do not occur when everyone follows the strategy. These off-path prescriptions describe how players would respond to deviations, and the whole theory of collusion rests on them. The factor $1-\delta$ in (12.1) expresses payoffs in per-period units. A player who receives u in every period has $U_i = u$, by the first of the three geometric sums

$$\sum_{t=0}^{\infty} \delta^t = \frac{1}{1-\delta}, \qquad \sum_{t=1}^{\infty} \delta^t = \frac{\delta}{1-\delta}, \qquad \sum_{t=0}^{T-1} \delta^t = \frac{1-\delta^T}{1-\delta}. \tag{12.2}$$

In applications we often work with the unnormalized sum $\sum_t \delta^t u_i(a^t)$, which equals (12.1) divided by $1-\delta$. Comparisons between strategies are unaffected, and we always say which form we use.

The discount factor has two interpretations that can be combined. If firms discount profits at the interest rate r per period, a profit received one period ahead is worth $\frac{1}{1+r}$ of a profit received today. Suppose in addition that the market survives into the next period only with probability $\beta \in (0,1]$, because demand may vanish or the product may become obsolete. The expected present value of next period's profit π is then

$$\frac{\beta\pi + (1-\beta)\cdot 0}{1+r} = \frac{\beta}{1+r}\,\pi,$$

so the relevant discount factor is $\delta = \frac{\beta}{1+r}$. With continuous discounting at rate r per unit of time and periods of length Δ (a length of time here, unrelated to the matrix of share derivatives), the discount factor is $\delta = e^{-r\Delta}$. Shorter periods, which mean more frequent interaction, raise δ toward one.

12.2.2 Subgame perfection

After any history h^t, the remaining game is again an infinitely repeated game, which we call the *continuation game* after h^t. A profile s induces a *continuation profile* $s|_{h^t}$ in it, defined by $s|_{h^t}(h) = s(h^t, h)$ for every history h, where (h^t, h) is the history h^t followed by h. The stage game and the discount factor are the same in every period, so every continuation game has the same structure as the original game. Player i's continuation payoff after h^t is $U_i(s|_{h^t})$. Definition 2.16 defines subgame perfection for general extensive-form games. In a repeated game with observed actions every history starts a subgame, so the general definition takes the following form.

Definition 12.3 (Subgame perfect equilibrium)**.** A profile s is a *Nash equilibrium* of $G^\infty(\delta)$ if $U_i(s) \geq U_i(s_i', s_{-i})$ for every player i and every strategy s_i'. It is a *subgame perfect equilibrium* (SPE) if, for every history $h^t \in \mathcal{H}$, the continuation profile $s|_{h^t}$ is a Nash equilibrium of the continuation game after h^t.

Subgame perfection requires optimal behavior after every history, on and off the equilibrium path. This is what makes threats credible. Suppose a strategy threatens a price war after any price cut, but fighting the war would not be optimal once the cut has occurred. A Nash equilibrium can rest on such a threat, because the threat is never tested on the equilibrium path. In an SPE the war must itself be an equilibrium of the continuation game. A firm that contemplates a deviation can therefore expect its rivals to carry out the punishment.

12.2.3 The one-shot deviation principle

Checking subgame perfection directly requires ruling out every alternative strategy after every history. The one-shot deviation principle reduces this infinite-dimensional problem to a family of one-period problems.

Definition 12.4 (One-shot deviation)**.** A *one-shot deviation* of player i from s_i at history h^t is a strategy $\hat{s}_i$ with $\hat{s}_i(h^t) \neq s_i(h^t)$ and $\hat{s}_i(h) = s_i(h)$ for every other history h. It is *profitable* if $U_i(\hat{s}_i|_{h^t}, s_{-i}|_{h^t}) > U_i(s|_{h^t})$.

A one-shot deviation takes a different action today and returns to the strategy from tomorrow on, while everyone else follows s. Its value can be written with continuation payoffs. If player i plays a_i at h^t while the others play $s_{-i}(h^t)$, the realized profile is $(a_i, s_{-i}(h^t))$. The next history is $\big(h^t, (a_i, s_{-i}(h^t))\big)$, and the deviation is worth $(1-\delta)u_i(a_i, s_{-i}(h^t)) + \delta U_i\big(s|_{(h^t,(a_i,s_{-i}(h^t)))}\big)$.

Proposition 12.5 (One-shot deviation principle)**.** *Suppose stage payoffs are bounded, with $|u_i(a)| \leq M$ for all i and all $a \in A$. A profile s is a subgame perfect equilibrium of $G^\infty(\delta)$ if and only if no player has a profitable one-shot deviation at any history. Equivalently, for every player i, every history h^t and every action $a_i \in A_i$,*

$$(1-\delta)\, u_i\big(s(h^t)\big) + \delta\, U_i\big(s|_{(h^t,s(h^t))}\big) \;\geq\; (1-\delta)\, u_i\big(a_i, s_{-i}(h^t)\big) + \delta\, U_i\big(s|_{(h^t,(a_i,s_{-i}(h^t)))}\big). \tag{12.3}$$

Proof. Necessity is immediate. A one-shot deviation at h^t is a strategy in the continuation game after h^t. If it were profitable, $s|_{h^t}$ would not be a Nash equilibrium of that continuation game.

For sufficiency, suppose that no one-shot deviation is profitable but that s is not an SPE. Then there are a player i, a history h^t and a strategy $\hat{s}_i$ such that

$$U_i(\hat{s}_i|_{h^t}, s_{-i}|_{h^t}) - U_i(s|_{h^t}) = \zeta > 0.$$

We first show that a profitable deviation can be chosen to differ from s_i in finitely many periods only. Pick an integer $T \geq 1$ with $2M\delta^T < \zeta$. Let $\tilde{s}_i$ agree with $\hat{s}_i$ at histories of length less than $t+T$ and with s_i at all longer histories. Starting from h^t, the profiles $(\tilde{s}_i, s_{-i})$ and $(\hat{s}_i, s_{-i})$ generate the same actions in periods $t, \ldots, t+T-1$. Their continuation payoffs therefore differ only through later periods, and by at most

$$(1-\delta)\sum_{\tau=T}^{\infty} \delta^\tau 2M = 2M\delta^T < \zeta.$$

Hence $U_i(\tilde{s}_i|_{h^t}, s_{-i}|_{h^t}) > U_i(s|_{h^t})$. The deviation $\tilde{s}_i$ is profitable, and it departs from s_i only in periods $t, \ldots, t+T-1$.

We next remove the deviating periods one at a time, starting with the last. Let h^{t+T-1} be the history of length $t+T-1$ that is reached from h^t when player i follows $\tilde{s}_i$ and the others follow s_{-i}. At h^{t+T-1}, the strategy $\tilde{s}_i$ prescribes some action and follows s_i afterwards. This is either no deviation at all or a one-shot deviation from s_i at h^{t+T-1}. By hypothesis it is not profitable:

$$U_i\big(s|_{h^{t+T-1}}\big) \geq U_i\big(\tilde{s}_i|_{h^{t+T-1}}, s_{-i}|_{h^{t+T-1}}\big).$$

Let s_i' agree with $\tilde{s}_i$ except at histories of length $t+T-1$, where it follows s_i. Starting from h^t, the profiles (s_i', s_{-i}) and $(\tilde{s}_i, s_{-i})$ generate the same actions up to period $t+T-2$, and both reach h^{t+T-1}. From there the first earns the left side of the last inequality and the second earns the right side. So s_i' is at least as profitable as $\tilde{s}_i$, and it departs from s_i only in periods $t, \ldots, t+T-2$. Applying the same step to periods $t+T-2, \ldots, t+1$ in turn yields a profitable deviation that departs from s_i only at the history h^t. That is a profitable one-shot deviation, which contradicts the hypothesis. □

The principle needs bounded payoffs, or more generally *continuity at infinity*: payoffs far in the future must matter little. Discounting with bounded stage payoffs provides it. A deviation that pays off only in the distant future is then worth little today, so every profitable deviation can be approximated by a finite one. In applications we use (12.3) in a simple form. At every history we compare following the strategy with deviating once and then following the strategy. When strategies depend on the history only through a few states, such as a collusive phase and a punishment phase, a handful of inequalities suffices.

12.2.4 Nash reversion, minmax payoffs and individual rationality

Proposition 12.6 (Repeated static Nash play)**.** *Let a^N be a Nash equilibrium of the stage game G. The profile in which every player i plays a_i^N after every history is a subgame perfect equilibrium of $G^\infty(\delta)$ for every $\delta \in (0,1)$.*

Proof. We apply Proposition 12.5. Fix a history h^t and a player i. Under the profile, continuation play is a^N forever whatever happens at h^t, so both continuation payoffs in (12.3) equal $u_i(a^N)$. The condition reduces to $u_i(a^N) \geq u_i(a_i, a_{-i}^N)$ for every a_i, which is the definition of a stage Nash equilibrium. □

The same argument shows that any sequence of stage Nash equilibria that depends only on calendar time is an SPE. Repeated static Nash play is the natural punishment in collusive strategies. A *grim-trigger strategy*, also called *Nash reversion*, prescribes a collusive action as long as nobody has deviated and a stage Nash equilibrium forever after any deviation (Friedman, 1971). Proposition 12.6 guarantees that the punishment phase is subgame perfect. Whether Nash reversion is the harshest available punishment depends on how it compares with the following benchmark.

Definition 12.7 (Minmax payoff)**.** Player i's *minmax payoff* is

$$\underline{v}_i = \min_{a_{-i} \in A_{-i}} \max_{a_i \in A_i} u_i(a_i, a_{-i}). \tag{12.4}$$

A payoff vector v is *individually rational* if $v_i \geq \underline{v}_i$ for every i, and *strictly* individually rational if all these inequalities are strict.

The minmax payoff is the lowest stage payoff to which the other players can hold player i when i best responds. We assume that the minimum and the maximum exist, as they do in all our applications.

Lemma 12.8 (Individual rationality)**.** *In every Nash equilibrium of $G^\infty(\delta)$, each player's payoff is at least $\underline{v}_i$. Hence, after every history of a subgame perfect equilibrium, each player's continuation payoff is at least $\underline{v}_i$.*

Proof. Let s be a Nash equilibrium. Consider the strategy s_i' that, after every history h, plays a best response to the actions $s_{-i}(h)$ that the opponents' strategies prescribe at h. In every period player i then earns $\max_{a_i} u_i(a_i, s_{-i}(h)) \geq \underline{v}_i$, so $U_i(s_i', s_{-i}) \geq \underline{v}_i$. Since s is a Nash equilibrium, $U_i(s) \geq U_i(s_i', s_{-i}) \geq \underline{v}_i$. The second statement applies the first to each continuation game. □

In the homogeneous Bertrand game with constant marginal cost c, both the static Nash payoff and the minmax payoff are zero. Rivals who price at c leave firm i at most zero profit, and firm i can always guarantee zero by pricing above its rivals. Nash reversion therefore delivers the harshest punishment that any equilibrium can impose. In the Cournot game the minmax payoff is also zero, because rivals can flood the market, but the static Nash profit is positive. Nash reversion is then a mild punishment, and Section 12.3.4 constructs harsher ones.

12.2.5 Folk theorems

The payoff vectors that can be generated in a single period are the vectors $u(a)$ with $a \in A$. By alternating action profiles over time, players can approximate convex combinations of them. It is simpler to let them randomize publicly. A *public randomization device* is a sequence of random variables ω_t, independent and uniformly distributed on $[0, 1]$, with ω_t observed by all players at the start of period t. Strategies may condition on current and past realizations. The set of *feasible payoffs* is the convex hull $V = \text{co}\{u(a) : a \in A\}$.

Theorem 12.9 (Nash-threat folk theorem)**.** *Let a^N be a stage Nash equilibrium with payoffs $u^N = u(a^N)$, and let $M_i = \max_a u_i(a)$ and $m_i = \min_a u_i(a)$ be finite.*

(i) Let a^* be an action profile with $u_i(a^*) > u_i^N$ for every i, and let $d_i = \max_{a_i} u_i(a_i, a^*_{-i})$ be player i's best deviation payoff against it. Grim-trigger strategies that play a^* until someone deviates and a^N forever after form an SPE if and only if

$$\delta \geq \delta_i^* \equiv \frac{d_i - u_i(a^*)}{d_i - u_i^N} \qquad \text{for every } i \text{ with } d_i > u_i(a^*). \tag{12.5}$$

(ii) With a public randomization device, for every feasible $v \in V$ with $v_i > u_i^N$ for every i there is $\underline{\delta} < 1$ such that, for every $\delta \in [\underline{\delta}, 1)$, some SPE has payoffs v.

Proof. (i) After a deviation, play is a^N forever, which is subgame perfect by Proposition 12.6. On the collusive path, conforming yields $u_i(a^*)$ in every period, and the best one-shot deviation yields d_i today and u_i^N in every later period. In normalized payoffs, Proposition 12.5 requires

$$u_i(a^*) \geq (1-\delta)\, d_i + \delta\, u_i^N \quad \Longleftrightarrow \quad \delta\,(d_i - u_i^N) \geq d_i - u_i(a^*).$$

If $d_i \leq u_i(a^*)$, the condition holds for every δ. Otherwise $d_i > u_i(a^*) > u_i^N$, and dividing by $d_i - u_i^N > 0$ gives (12.5). Each δ_i^* is below one because $u_i(a^*) > u_i^N$.

(ii) Write $v = \sum_{k=1}^{K} \lambda_k u(a^k)$ with weights $\lambda_k \geq 0$ that sum to one. Partition $[0,1]$ into intervals $I_1, \ldots, I_K$ of lengths $\lambda_1, \ldots, \lambda_K$. On the collusive path, the players play a^k in every period with $\omega_t \in I_k$. After any deviation, they play a^N forever. The expected payoff of each period on the path is v_i, so player i's continuation value at the start of every period on the path is v_i. Suppose $\omega_t \in I_k$. Conforming yields $(1-\delta)u_i(a^k) + \delta v_i \geq (1-\delta)m_i + \delta v_i$, and any deviation yields at most $(1-\delta)M_i + \delta u_i^N$. Conforming is therefore optimal whenever

$$\delta\,(v_i - u_i^N) \geq (1-\delta)(M_i - m_i) \quad \Longleftrightarrow \quad \delta \geq \frac{M_i - m_i}{M_i - m_i + v_i - u_i^N}.$$

The right side is below one because $v_i > u_i^N$. Let $\underline{\delta}$ be the largest of these N bounds. □

The threshold in part (i) has a structure that recurs throughout the chapter. Its numerator is the one-period gain from deviating. Its denominator is the gain from deviating measured against the punishment payoff. A larger temptation $d_i - u_i(a^*)$ or a milder punishment (a higher u_i^N) raises the threshold. Part (ii) shows that patient players can sustain any feasible payoff that beats static Nash play. The next theorem replaces the static Nash payoff by the minmax payoff.

Theorem 12.10 (Folk theorem with minmax punishments)**.** *Suppose that $N = 2$, or that $N \geq 3$ and the feasible set V has dimension N. With a public randomization device, for every feasible $v \in V$ with $v_i > \underline{v}_i$ for every i there is $\underline{\delta} < 1$ such that, for every $\delta \in [\underline{\delta}, 1)$, some SPE of $G^\infty(\delta)$ has payoffs v.*

We state this result of Fudenberg and Maskin (1986) without proof. The construction punishes a deviator by holding it to its minmax payoff for a fixed number of periods. Minmaxing may be costly for the punishers, so they must be rewarded afterwards for carrying out the punishment. With three or more players, full dimensionality makes it possible to reward the punishers without also rewarding the deviator. Versions of the theorem hold with mixed-strategy minmax payoffs and without public randomization.

Figure 12.1 illustrates both theorems in the homogeneous Bertrand duopoly. Industry profit at a common price p is $\pi(p) = (p-c)D(p)$, which is at most the monopoly profit π^m. The feasible and individually rational payoffs therefore form the triangle with vertices $(0,0)$, $(\pi^m, 0)$ and $(0, \pi^m)$. The origin is both the static Nash payoff and the minmax payoff, so the two theorems coincide here. Consider *stationary market sharing*: both firms charge p in every period, firm i serves a fraction α_i of the customers, and $\alpha_1 + \alpha_2 = 1$. Bertrand reversion follows any deviation. Firm i's normalized payoff is $\alpha_i \pi(p)$, and its best deviation serves the whole market for one period. The incentive constraint is

$$\alpha_i\, \pi(p) \geq (1-\delta)\, \pi(p) + \delta \cdot 0 \quad \Longleftrightarrow \quad \alpha_i \geq 1 - \delta.$$

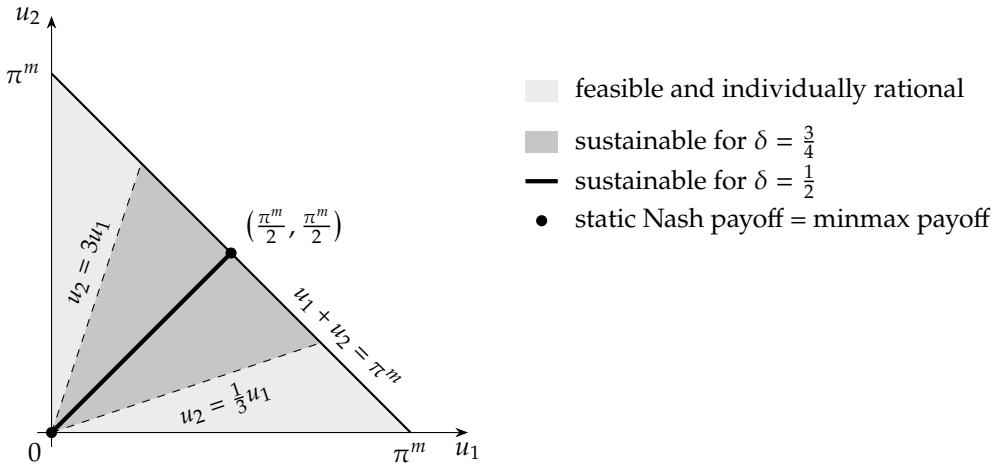

Figure 12.1: Normalized payoffs in the homogeneous Bertrand duopoly. Under stationary market sharing with Bertrand reversion, firm i needs a share $\alpha_i \geq 1 - \delta$. For $\delta = \frac{1}{2}$ only the diagonal is sustainable. For $\delta = \frac{3}{4}$ the dark region between the rays $u_2 = \frac{1}{3}u_1$ and $u_2 = 3u_1$ is sustainable. As $\delta \to 1$ the sustainable set approaches the whole triangle.

For $\delta = \frac{1}{2}$ only equal sharing works. As δ rises, the set of sustainable divisions widens and approaches the whole triangle.

The folk theorems tell us what repeated interaction makes possible. They do not predict which equilibrium firms will play. When firms are patient, collusion at the monopoly price, competition at marginal cost and everything in between are all equilibrium outcomes. Like most of the literature, the rest of this chapter studies the *most collusive equilibrium*, the SPE that maximizes the firms' joint payoff, usually within the class of symmetric equilibria. Rotemberg and Saloner (1986), Bagwell and Staiger (1997) and Athey et al. (2004a) all follow this convention. It is a natural benchmark for a cartel that can coordinate on its preferred equilibrium, and it yields sharp predictions about how collusive prices respond to the environment. Its weakness is that it assumes away the coordination problem on which explicit cartels spend much effort (Section 12.7). An equilibrium is a shared understanding of what each firm will do and how rivals will respond. Kaplow (2013, pp. 196–199) argues that this is the economic counterpart of the legal notion of a meeting of the minds, a point that Section 12.8.4 develops.

12.2.6 Finite horizons, reputation and bootstrap strategies

The folk theorems need an infinite horizon. When the last period is known and the stage game has a single equilibrium, collusion unravels from the end (Tirole, 1988, section 6.3.1).

Proposition 12.11 (Unraveling with a known finite horizon)**.** *Suppose that the stage game G has a unique Nash equilibrium a^N, and that the players play G in periods $t = 0, 1, \ldots, T$, with T finite and known. Then every subgame perfect equilibrium prescribes a^N in every period after every history.*

Proof. We argue by backward induction on the period. After any history of length T, the continuation game is a single play of G. Its only Nash equilibrium is a^N, so subgame perfection requires a^N in period T. Now suppose that a^N is played in periods $t+1, \ldots, T$ after every history. Then play from period $t+1$ on does not depend on the actions of period t. Each player's continuation payoff is the same whatever happens in period t, so the profile played in

period t must be a Nash equilibrium of G. It is therefore a^N. Induction on t from T down to 0 completes the proof. □

In the Bertrand duopoly of Section 12.3.1, the unique pure-strategy equilibrium of the stage game has both firms pricing at marginal cost. A known last period therefore destroys collusion however long the horizon is. The result is fragile in three ways, and each one corresponds to a model used in practice.

The horizon may be uncertain. The survival interpretation of Section 12.2.1 turns a market that ends at a random date into an infinitely repeated game with discount factor $\delta = \frac{\beta}{1+r}$. Tirole (1988, section 6.3.4.2) stresses that this argument assumes a survival probability that is constant over time. Little is known about equilibria when the survival probability falls sharply at some date, and collusion is then likely to be hard to sustain.

The stage game may have several equilibria. The threat to play a bad equilibrium later can then discipline play earlier. Let a^G and a^B be stage equilibria with $u_i(a^G) > u_i(a^B)$ for every i. Let a^* be any action profile, with best deviation payoffs $d_i = \max_{a_i} u_i(a_i, a^*_{-i})$. In a game of two periods, consider the profile that plays a^* in period 0, then a^G if nobody deviated and a^B otherwise. Play in period 1 is a stage equilibrium after every history. The one-shot deviation condition in period 0 is therefore the only one to check, and it reads

$$u_i(a^*) + \delta\, u_i(a^G) \;\geq\; d_i + \delta\, u_i(a^B) \qquad \text{for every } i. \tag{12.6}$$

A large enough gap between the two continuation equilibria sustains profiles that are not stage equilibria. In the three-period example of Tirole (1988, section 6.7.3.2), played without discounting, a first-period profile that pays zero to both players is sustained: conforming yields $0 + 5 + 5$, while deviating yields $5 + 1 + 1$. Benoit and Krishna (1985) show that, under some conditions, the equilibrium set of such a finitely repeated game converges to the feasible and individually rational payoffs as the horizon grows.

Finally, firms may be unsure of their rivals' payoffs. Kreps et al. (1982) show that a small doubt of this kind can sustain cooperation for most of a long finite game. Tirole (1988, section 6.5.1) illustrates the logic with a repeated prisoner's dilemma without discounting. Mutual cooperation pays 3 to each player and mutual finking pays 0. A player who finks against a cooperator gets 4, and the cooperator gets -1. With probability ε player 2 is "crazy": it cooperates until the first fink and finks forever after. A sane player 1 who finks at date 0 earns at most 4 over the whole game, because play from date 1 on is mutual finking. Suppose instead that player 1 cooperates until player 2 finks and finks forever after. It earns $3(T+1)$ against the crazy type and at least -1 against the sane type. Finking at date 0 is therefore worse whenever

$$3\varepsilon(T+1) - (1-\varepsilon) > 4 \quad\Longleftrightarrow\quad T + 1 > \frac{5-\varepsilon}{3\varepsilon}.$$

However small ε is, a long enough horizon makes even a sane player cooperate at the start. Sane players cooperate to preserve a reputation for being cooperative, and they start to exploit it only near the end.

These results also clarify what holds supergame collusion together. In the stage games of this chapter, past prices do not affect current or future profits. A firm conditions its price on past prices only because its rivals do the same. Tirole (1988, section 6.3.4.1) calls such strategies *bootstrap strategies*. Collusion rests on a self-fulfilling expectation. If we allowed only strategies that condition on payoff-relevant variables, only repeated static play (Proposition 12.6) would remain. Models in which past prices do affect current profits give retaliation a tangible motive. The alternating-move model of Maskin and Tirole (1988), discussed in Section 12.6.1, is the leading example.

12.2.7 Recursive structure and self-generation

Simple strategies such as grim trigger are easy to analyze, but the most collusive equilibrium may require more complex behavior. Abreu et al. (1990) provide a recursive characterization of the whole set of equilibrium payoffs. Every equilibrium payoff splits into a current payoff and a continuation payoff that is itself an equilibrium payoff. Formally, a payoff vector v is *enforceable* on a set $W \subseteq \mathbb{R}^N$ if there are an action profile a and a continuation function $w : A \to W$ such that, for every i and every $a_i' \in A_i$,

$$v_i = (1-\delta)\, u_i(a) + \delta\, w_i(a) \;\geq\; (1-\delta)\, u_i(a_i', a_{-i}) + \delta\, w_i(a_i', a_{-i}). \tag{12.7}$$

Let $B(W)$ be the set of payoffs enforceable on W. A set W is *self-generating* if $W \subseteq B(W)$. The main results are that every bounded self-generating set consists of SPE payoffs, and that the set of SPE payoffs is the largest bounded fixed point of the operator B. The equality in (12.7) is a promise-keeping condition, and the inequality is the one-shot deviation condition of Proposition 12.5. The authors develop the method for games with imperfect public monitoring, which include perfect monitoring as a special case. It turns the search for optimal strategies into a search over current actions and continuation values. Abreu's optimal punishments (Section 12.3.4) and the analysis of collusion with private costs (Section 12.6) rest on this logic.

12.3 Collusion under Perfect Monitoring

We now apply the tools to oligopoly. Firms observe all past prices or quantities, so any deviation is detected at once and can be punished. This is the most favorable environment for collusion. It isolates the basic trade-off between the short-run gain from cheating and the long-run loss from punishment. Section 2.10.3 stated the Bertrand and Cournot thresholds without proof. Here we prove them, extend them, and study the structure of punishments.

12.3.1 The Bertrand supergame

Assumption 12.12 (Bertrand supergame)**.** (i) There are $N \geq 2$ identical firms. They produce a homogeneous good at constant marginal cost c, with no capacity limits.

(ii) Market demand $D(p)$ is continuous and nonincreasing. Industry profit $\pi(p) = (p-c)D(p)$ is strictly increasing on $[c, p^m]$ and has a unique maximum at the *monopoly price* $p^m > c$. The *monopoly profit* is $\pi^m = \pi(p^m) > 0$.

(iii) In each period $t = 0, 1, 2, \ldots$ the firms choose prices simultaneously from a compact interval $[0, \bar{p}]$ that contains p^m. All prices are observed at the end of the period.

(iv) The firm with the lowest price serves the whole market. If k firms tie at the lowest price, each sells $\frac{1}{k} D(p)$.

(v) Firms maximize the discounted sum of profits with a common discount factor $\delta \in (0,1)$.

Firm i's stage profit is $(p_i - c)\, q_i(p)$, where $p = (p_1, \ldots, p_N)$ and its sales are

$$q_i(p) = \begin{cases} D(p_i) & \text{if } p_i < p_j \text{ for every } j \neq i, \\ \frac{1}{k}\, D(p_i) & \text{if } p_i = \min_j p_j \text{ and } k \text{ firms charge this price}, \\ 0 & \text{if } p_i > \min_j p_j. \end{cases} \tag{12.8}$$

Stage payoffs are bounded because prices lie in a compact set. We use unnormalized discounted sums in this section.

Example 12.13 (Bertrand reversion is an equilibrium)**.** The profile in which every firm charges $p_{it}(h^t) = c$ after every history is an SPE. Fix a history and a firm i, and let all rivals price at c. Conforming earns zero today. A deviation to $p > c$ sells nothing and earns zero. A deviation to $p < c$ serves the whole market at a loss, $(p - c)D(p) \leq 0$. The strategies do not depend on the history, so continuation payoffs are zero after every choice. No one-shot deviation is profitable, and Proposition 12.5 gives the result. The same conclusion follows from Proposition 12.6, because $p = c$ for all firms is a stage Nash equilibrium (Proposition 2.48). Each firm earns zero, which is its minmax payoff.

The collusive profile uses grim-trigger strategies. Every firm charges

$$p_{it}(h^t) = \begin{cases} p^m & \text{if } t = 0, \text{ or every firm charged } p^m \text{ in every period before } t, \\ c & \text{otherwise.} \end{cases} \tag{12.9}$$

Proposition 12.14 (Collusion in the Bertrand supergame)**.** *Under Assumption 12.12, the grim-trigger profile* (12.9) *is an SPE if and only if*

$$\delta \geq \underline{\delta}(N) \equiv 1 - \frac{1}{N}. \tag{12.10}$$

Proof. There are two kinds of histories. After a history with a past deviation, the profile prescribes $p = c$ forever, whatever happens next. This continuation is an SPE by Example 12.13. After a history without past deviations, firm i compares conforming with a one-shot deviation. Conforming yields $\frac{\pi^m}{N}$ in every period:

$$\frac{\pi^m}{N} + \delta \frac{\pi^m}{N} + \delta^2 \frac{\pi^m}{N} + \cdots = \frac{\pi^m}{N(1-\delta)}.$$

A deviation to a price above p^m sells nothing today and triggers reversion, so it earns zero. A deviation to a price $p < p^m$ serves the whole market today and earns $\pi(p)$, followed by zero forever. Since π is continuous and π^m is its maximum,

$$\sup_{p<p^m} \pi(p) = \pi^m.$$

The supremum is approached by small price cuts but not attained. No deviation is profitable if and only if

$$\begin{aligned} \frac{\pi^m}{N(1-\delta)} &\geq \pi^m, \\ \frac{1}{1-\delta} &\geq N, \\ 1 - \delta &\leq \frac{1}{N}, \\ \delta &\geq 1 - \frac{1}{N}. \end{aligned}$$

If $\delta < 1 - \frac{1}{N}$, the first inequality fails strictly. Some price cut close enough to p^m is then a profitable deviation. □

The threshold has a transparent meaning. A firm that conforms earns the share $\frac{1}{N}$ of monopoly profit forever. A firm that deviates earns the whole monopoly profit once and then nothing. The firm conforms if its share of the infinite stream is worth more than one period of the whole profit. With more firms each share shrinks while the deviation gain does not, so collusion requires more patience. The threshold depends neither on demand nor on cost.

Corollary 12.15 (Multiplicity and the bang-bang property)**.** *Under Assumption 12.12:*

(i) If $\delta \geq 1 - \frac{1}{N}$, then for every $\hat{p} \in [c, p^m]$ the grim-trigger profile with collusive price $\hat{p}$ in place of p^m is an SPE.

(ii) If $\delta < 1 - \frac{1}{N}$, every SPE gives every firm a payoff of zero.

Proof. (i) Replace p^m by $\hat{p}$ in the proof of Proposition 12.14. Conforming yields $\frac{\pi(\hat{p})}{N(1-\delta)}$. A deviation above $\hat{p}$ sells nothing. Because π is increasing on $[c, \hat{p}]$ and negative below c, the supremum of the profits from deviations below $\hat{p}$ is $\pi(\hat{p})$. The condition $\frac{\pi(\hat{p})}{N(1-\delta)} \geq \pi(\hat{p})$ is again $\delta \geq 1 - \frac{1}{N}$, whatever the value of $\hat{p}$. For $\hat{p} = c$ it holds trivially.

(ii) Let $\bar{\Pi}$ be the supremum, over all SPE and all histories, of the sum of the firms' continuation values. Industry profit never exceeds π^m, and each firm's continuation value is nonnegative by Lemma 12.8, so $0 \leq \bar{\Pi} \leq \frac{\pi^m}{1-\delta}$. Take any SPE and any history. Let p_t be the lowest price that the equilibrium prescribes in the current period and $\pi_t = \pi(p_t)$ the industry profit it generates. Let V_i be firm i's continuation value and V_i' its value from the next period on, so that

$$\sum_{i=1}^{N} V_i = \pi_t + \delta \sum_{i=1}^{N} V_i'.$$

Suppose $\pi_t > 0$, so that $p_t > c$. Any firm can undercut p_t slightly, earn almost π_t today, and receive at least zero afterwards. Equilibrium therefore requires $V_i \geq \pi_t$ for every i. Summing over the N firms,

$$N\pi_t \leq \sum_{i=1}^{N} V_i = \pi_t + \delta \sum_{i=1}^{N} V_i' \leq \pi_t + \delta\bar{\Pi},$$

so $\pi_t \leq \frac{\delta\bar{\Pi}}{N-1}$. This bound also holds when $\pi_t \leq 0$. Substituting it back,

$$\sum_{i=1}^{N} V_i \leq \frac{\delta\bar{\Pi}}{N-1} + \delta\bar{\Pi} = \frac{N\delta}{N-1}\,\bar{\Pi}.$$

Taking the supremum of the left side over all SPE and histories gives $\bar{\Pi} \leq \frac{N\delta}{N-1}\,\bar{\Pi}$. When $\delta < 1 - \frac{1}{N}$ the factor $\frac{N\delta}{N-1}$ is below one, so $\bar{\Pi} = 0$. Each firm's value is nonnegative, so each is zero. □

The corollary carries two lessons. First, the theory does not pin down the collusive price. Once collusion at the monopoly price is possible, so is collusion at any lower price above cost, and so is competition. Empirical work cannot infer conduct from the primitives alone, which is one reason Chapter 3 estimates conduct from data. Second, collusion in this model is all or nothing in the discount factor. Below the threshold, no strategy sustains positive profits. Above it, even the monopoly price can be sustained. Models with smoother payoffs, such as the Cournot supergame of Section 12.3.3, allow partial collusion.

12.3.2 Comparative statics: firms, detection, growth and capacity

The threshold (12.10) rises with the number of firms. It equals $\frac{1}{2}$, $\frac{2}{3}$ and $\frac{9}{10}$ for $N = 2$, 3 and 10, so collusion is easier in concentrated markets. The comparative statics in the discount factor are richer than they first appear, because several features of a market act like changes in δ. We take up detection lags, demand growth and capacity constraints.

Proposition 12.16 (Detection lags and demand growth)**.** *Modify Assumption 12.12 in two ways. First, a deviation in period t is observed by the rivals only at the end of period $t + k - 1$, for an integer $k \geq 1$, so the punishment starts in period $t + k$. Second, demand in period t is $(1 + g)^t D(p)$ for a growth rate g with $\delta(1 + g) < 1$. Then grim trigger at p^m is an SPE if and only if*

$$\left[\delta(1+g)\right]^k \geq 1 - \frac{1}{N}. \tag{12.11}$$

In particular, the condition is $\delta^k \geq 1 - \frac{1}{N}$ when demand is constant, and $\delta(1 + g) \geq 1 - \frac{1}{N}$ when detection is immediate.

Proof. Demand growth scales profits in period τ by $(1+g)^\tau$ without changing their shape, so the monopoly price is still p^m and monopoly profit in period τ is $(1+g)^\tau \pi^m$. Write $\tilde{\delta} = \delta(1+g) < 1$. Conforming from period t on yields

$$\sum_{\tau=t}^{\infty} \delta^{\tau-t}(1+g)^\tau \frac{\pi^m}{N} = (1+g)^t \frac{\pi^m}{N} \sum_{n=0}^{\infty} \tilde{\delta}^n = \frac{(1+g)^t \pi^m}{N(1-\tilde{\delta})}.$$

A firm that undercuts in period t will be punished from period $t + k$ on, whatever it does in between. Its best plan is therefore to undercut in each of the k periods before detection, earning almost the whole monopoly profit in each of them. Its payoff approaches

$$\sum_{\tau=t}^{t+k-1} \delta^{\tau-t}(1+g)^\tau \pi^m = (1+g)^t \pi^m \sum_{n=0}^{k-1} \tilde{\delta}^n = (1+g)^t \pi^m \frac{1-\tilde{\delta}^k}{1-\tilde{\delta}},$$

followed by zero. Conforming is optimal if and only if

$$\begin{aligned} \frac{(1+g)^t \pi^m}{N(1-\tilde{\delta})} &\geq (1+g)^t \pi^m \frac{1-\tilde{\delta}^k}{1-\tilde{\delta}}, \\ \frac{1}{N} &\geq 1 - \tilde{\delta}^k, \\ \tilde{\delta}^k &\geq 1 - \frac{1}{N}. \end{aligned}$$

The punishment phase is an SPE as before. □

A detection lag of k periods acts like replacing δ by δ^k, so slow detection makes collusion harder. This is the formal content of Stigler's view that the main threat to a cartel is the secret price cut (Section 2.10.2). Demand growth acts like a higher discount factor, because the future markets that a deviator puts at risk are larger than today's. The proposition also clarifies the role of frequent interaction. Suppose prices are set every Δ units of time and $\delta = e^{-r\Delta}$. If a deviation is detected at the end of the period in which it occurs, more frequent price setting raises δ and helps collusion. If detection instead takes a fixed length of real time $L = k\Delta$, then

$\delta^k = e^{-rL}$ does not depend on Δ. What matters is the real time it takes to detect and punish a deviation. Example 2.94 and Proposition 13.19 treat detection that occurs with a probability in each period. In Section 12.4 we write growth in gross terms, as Bagwell and Staiger (1997) do. Their stationary-growth condition is (12.11) with $k = 1$ and $1 + g$ replaced by their gross growth factor.

Example 12.17 (Capacity constraints)**.** Suppose each of the N firms can produce at most K units per period, with $K < D(p^m) \leq NK$. The cartel can then serve the monopoly output, but no single firm can. Demand is rationed efficiently (Definition 2.51): consumers with the highest valuations buy from the cheapest firm first. Two things change.

The gain from cheating falls. A firm that undercuts p^m sells at most K units, and $D(p) > K$ for every $p < p^m$. Its best deviation profit approaches $(p^m - c)K$, and its gain over its collusive share is

$$(p^m - c)K - \frac{\pi^m}{N} = (p^m - c)\left[K - \frac{D(p^m)}{N}\right] < \frac{N-1}{N}\,\pi^m.$$

The punishment weakens. Suppose the rivals' joint capacity is below demand at marginal cost, $(N-1)K < D(c)$. Rivals who price at c then cannot serve the whole market, and firm i can sell to the residual demand. Each rival sells at most K whatever its price, so no rival pricing can leave firm i less than

$$\underline{v}(K) = \max_p\,(p - c)\min\bigl\{K,\ D(p) - (N-1)K\bigr\} > 0. \tag{12.12}$$

This is firm i's minmax payoff. In particular, all firms pricing at c is no longer a stage equilibrium, and by Lemma 12.8 no punishment can hold a firm below $\underline{v}(K)$ per period. Even with the harshest conceivable punishment, collusion at p^m requires

$$\frac{\pi^m}{N(1-\delta)} \geq (p^m - c)K + \frac{\delta\,\underline{v}(K)}{1-\delta}.$$

Multiplying by $1 - \delta$ and collecting the terms in δ gives, whenever $(p^m - c)K > \underline{v}(K)$,

$$\delta \geq \frac{(p^m - c)K - \frac{\pi^m}{N}}{(p^m - c)K - \underline{v}(K)}.$$

Smaller capacities lower the numerator, because cheating pays less. They also raise $\underline{v}(K)$ and so lower the denominator, because punishment bites less. The net effect on the threshold is ambiguous. The bound is attained if some subgame perfect punishment holds the deviator to $\underline{v}(K)$.

Brock and Scheinkman (1985) analyze a price-setting supergame in which every firm has the same exogenous capacity. For the equilibrium they select, the collusive price is not necessarily a monotonic function of industry capacity (Tirole, 1988, ch. 6, note 10). Each firm's capacity is fixed, so industry capacity grows with the number of firms. Adding firms therefore need not lower the highest collusive price.

Compte et al. (2002) study asymmetric capacities in a stark version of the example. We follow the summary of Asker and Nocke (2021, pp. 239–240). Demand is one unit at any price up to the monopoly price of one, and zero above it. Firm i produces at zero cost up to its capacity k_i, and firms are ordered so that $k_1 \leq \cdots \leq k_N$. Firm i's *effective capacity* is $\hat{k}_i = \min\{k_i, 1\}$, the most it can sell. Write $\hat{K} = \sum_i \hat{k}_i$ for the sum of effective capacities and

$K_{-N} = \sum_{i<N} k_i$ for the capacity of all firms but the largest. The authors study equilibria in which each firm keeps the same market share α_i along every continuation path.

Suppose first that $K_{-N} \geq 1$. Any $N-1$ firms can then serve the whole market, so all firms pricing at zero is a stage equilibrium with zero profits, the harshest punishment. Firm i earns α_i per period on the collusive path. A deviator prices just below one and sells its effective capacity, so its best deviation earns almost $\hat{k}_i$. With Nash reversion, its incentive constraint is

$$\frac{\alpha_i}{1-\delta} \geq \hat{k}_i \quad \Longleftrightarrow \quad \alpha_i \geq (1-\delta)\,\hat{k}_i.$$

Summing over firms and using $\sum_i \alpha_i = 1$ gives $1 \geq (1-\delta)\hat{K}$, that is,

$$\delta \;\geq\; \underline{\delta} = \frac{\hat{K}-1}{\hat{K}}. \tag{12.13}$$

At this threshold the shares $\alpha_i = \frac{\hat{k}_i}{\hat{K}}$ satisfy every constraint with equality, so shares proportional to effective capacities attain it. A merger of firms l and m pools their capacities and has no other effect. It cannot raise $\hat{K}$, and it lowers $\hat{K}$ when $k_l + k_m > 1$. In this case mergers can only make collusion easier.

Suppose instead that $K_{-N} < 1$. The smaller firms can no longer serve the market. The static Nash equilibrium then fails to hold firms to their minmax payoffs. The harshest subgame perfect punishment has two phases, with a low price in its first period and a higher price afterward. Compte, Jenny and Rey show that, with the optimal shares, the largest firm's constraint is the one that binds. The threshold becomes

$$\underline{\delta} = \frac{\hat{k}_N}{\hat{K}}. \tag{12.14}$$

A merger that involves the largest firm raises the threshold and hurts collusion. A merger that neither involves the largest firm nor creates a new largest firm leaves the threshold unchanged (Asker and Nocke, 2021, p. 240). The largest firm gains most from undercutting and is the hardest to punish, so asymmetric capacities make collusion harder. Section 12.3.7 returns to these results in the context of mergers.

12.3.3 The Cournot supergame

Now let the N identical firms choose quantities. Each has constant marginal cost c, inverse demand is $P(Q)$, and outputs lie in a compact interval $[0, \bar{q}]$. Let $\pi(q)$ be each firm's profit when all firms produce q, and let

$$\pi^d(q) = \max_{q_i \in [0,\bar{q}]} \big[P\big(q_i + (N-1)q\big) - c\big]q_i \tag{12.15}$$

be the best one-shot deviation profit when the rivals produce q each. Write $q^m = \frac{Q^m}{N}$ for the collusive output, with Q^m the monopoly output, and let $\pi^c = \pi(q^m) = \frac{\pi^m}{N}$, $\pi^d = \pi^d(q^m)$, and π^N for the Cournot profit. Grim trigger prescribes q^m until someone deviates and the Cournot output forever after. The collusive phase satisfies Proposition 12.5 if and only if, in

unnormalized payoffs,

$$\begin{aligned} \frac{\pi^c}{1-\delta} &\geq \pi^d + \frac{\delta\,\pi^N}{1-\delta}, \\ \pi^c &\geq (1-\delta)\,\pi^d + \delta\,\pi^N, \\ \delta\,(\pi^d - \pi^N) &\geq \pi^d - \pi^c, \\ \delta &\geq \frac{\pi^d - \pi^c}{\pi^d - \pi^N}. \end{aligned} \tag{12.16}$$

The last step uses $\pi^d > \pi^c > \pi^N$. The first inequality holds because collusion is not a static equilibrium (Proposition 2.92), and the second because monopoly sharing yields more than Cournot competition. The threshold (12.16) has the structure of (12.5).

Proposition 12.18 (Collusion in the linear Cournot supergame)**.** *Let inverse demand be $P(Q) = a - bQ$ with $a > c \geq 0$ and $b > 0$, and write $k = \frac{(a-c)^2}{b}$. Then*

$$\pi^c = \frac{k}{4N}, \qquad \pi^N = \frac{k}{(N+1)^2}, \qquad q^d = \frac{(N+1)(a-c)}{4bN}, \qquad \pi^d = \frac{k(N+1)^2}{16N^2}, \tag{12.17}$$

where q^d is the best deviation output. Grim trigger with Cournot reversion sustains the collusive output if and only if

$$\delta \geq \delta^*(N) \equiv \frac{(N+1)^2}{N^2 + 6N + 1}. \tag{12.18}$$

The threshold rises with N and tends to one as $N \to \infty$.

Proof. Joint profit $(a - bQ - c)Q$ is maximized at $Q^m = \frac{a-c}{2b}$, with price $P^m = \frac{a+c}{2}$. Each firm earns

$$\pi^c = (P^m - c)\,\frac{Q^m}{N} = \frac{a-c}{2} \cdot \frac{a-c}{2bN} = \frac{k}{4N}.$$

The Cournot equilibrium has $q^N = \frac{a-c}{b(N+1)}$ and $P^N - c = \frac{a-c}{N+1}$ (Example 2.31), so $\pi^N = \frac{k}{(N+1)^2}$. A deviator faces rivals producing $(N-1)q^m = \frac{(N-1)(a-c)}{2bN}$ in total. Its first-order condition is $a - c - b(N-1)q^m - 2bq = 0$, so

$$q^d = \frac{a - c - b(N-1)q^m}{2b} = \frac{a-c}{2b}\left[1 - \frac{N-1}{2N}\right] = \frac{(N+1)(a-c)}{4bN}.$$

The first-order condition also gives $P - c = bq^d$ at the deviation, so $\pi^d = b(q^d)^2 = \frac{k(N+1)^2}{16N^2}$. The two differences in (12.16) are

$$\begin{aligned} \pi^d - \pi^c &= \frac{k}{16N^2}\left[(N+1)^2 - 4N\right] = \frac{k(N-1)^2}{16N^2}, \\ \pi^d - \pi^N &= \frac{k\left[(N+1)^4 - 16N^2\right]}{16N^2(N+1)^2} = \frac{k(N-1)^2(N^2+6N+1)}{16N^2(N+1)^2}. \end{aligned}$$

The last step uses the factorization

$$(N+1)^4 - 16N^2 = \left[(N+1)^2 - 4N\right]\left[(N+1)^2 + 4N\right] = (N-1)^2\,(N^2+6N+1).$$

The ratio of the two differences is (12.18). Differentiating,

$$\frac{d\delta^*}{dN} = \frac{2(N+1)(N^2+6N+1) - (N+1)^2(2N+6)}{(N^2+6N+1)^2} = \frac{4(N-1)(N+1)}{(N^2+6N+1)^2} > 0$$

for $N \geq 2$. Numerator and denominator of $\delta^*(N)$ are both quadratics in N with leading coefficient one, so $\delta^*(N) \to 1$. □

The threshold is $\delta^*(2) = \frac{9}{17} \approx 0.529$, and it rises to $\frac{4}{7} \approx 0.571$, $\frac{9}{14} \approx 0.643$ and $\frac{121}{161} \approx 0.752$ for $N = 3$, 5 and 10. Figure 12.2 compares it with the Bertrand threshold. Cournot collusion needs more patience than Bertrand collusion for $N = 2$, since $\frac{9}{17} > \frac{1}{2}$. It needs less for $N \geq 3$, for example $\frac{4}{7} < \frac{2}{3}$ at $N = 3$. Setting $\frac{(N+1)^2}{N^2+6N+1} = \frac{N-1}{N}$ and simplifying gives $3N^2 - 6N - 1 = 0$, so the two curves cross at $N = 1 + \frac{2}{\sqrt{3}} \approx 2.15$. Two forces work in opposite directions. Cournot reversion is a milder punishment than Bertrand reversion, because Cournot profits are positive. But the temptation is also weaker, because a Cournot deviator takes rivals' outputs as given and cannot capture the whole market. With three or more firms the second force dominates.

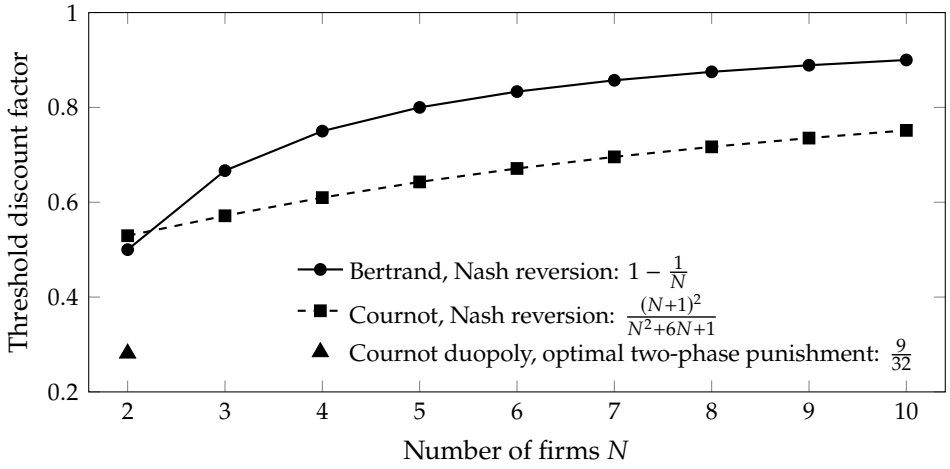

Figure 12.2: Minimum discount factors for collusion at the monopoly outcome. The Bertrand threshold is from Proposition 12.14 and the Cournot threshold, for linear demand, from Proposition 12.18. The triangle is the threshold for the linear Cournot duopoly with the optimal stick-and-carrot punishment of Example 12.22.

Unlike the Bertrand supergame, the Cournot supergame allows partial collusion. When firms are too impatient to sustain the monopoly output, they can still sustain outputs between the monopoly and Cournot levels.

Proposition 12.19 (Partial collusion in linear Cournot)**.** *In the setting of Proposition 12.18, let $\delta < \delta^*(N)$ and consider grim trigger with a symmetric collusive output q between q^m and the Cournot output q^N. The profile is an SPE if and only if $q \geq q(\delta)$, where*

$$q(\delta) = \frac{a-c}{b(N+1)} \cdot \frac{(N+1)^2(1-\delta) + 4\delta}{(N+1)^2(1-\delta) + 4N\delta}. \tag{12.19}$$

The output $q(\delta)$ falls continuously from q^N at $\delta = 0$ to q^m at $\delta = \delta^*(N)$. The most profitable sustainable symmetric output is $q(\delta)$, and the corresponding profit rises continuously from π^N to π^c as δ rises from 0 to $\delta^*(N)$.

Proof. Outputs scale with $\frac{a-c}{b}$ and profits with k, while the incentive constraint is homogeneous in profits. We may therefore set $a - c = 1$ and $b = 1$ and restore the scale at the end. Then

$$\pi(q) = q(1 - Nq), \qquad \pi^d(q) = \frac{\left[1 - (N-1)q\right]^2}{4}, \qquad \pi^N = \frac{1}{(N+1)^2},$$

where $\pi^d(q)$ follows from the best response $\frac{1-(N-1)q}{2}$, as in the proof of Proposition 12.18. The incentive constraint is $\pi^d(q) - \pi(q) \le \frac{\delta}{1-\delta}\left[\pi(q) - \pi^N\right]$. Its left side is

$$\begin{aligned}\pi^d(q) - \pi(q) &= \frac{1 - 2(N-1)q + (N-1)^2q^2 - 4q + 4Nq^2}{4} \\ &= \frac{1 - 2(N+1)q + (N+1)^2q^2}{4} = \frac{\left[1 - (N+1)q\right]^2}{4}.\end{aligned}$$

The profit difference on the right side factors as

$$\pi(q) - \pi^N = q - Nq^2 - \frac{1}{(N+1)^2} = N\left(\frac{1}{N+1} - q\right)\left(q - \frac{1}{N(N+1)}\right),$$

as expanding the product confirms. Now substitute $u = 1 - (N+1)q$, which runs from 0 at $q = q^N$ to $u^m = \frac{N-1}{2N}$ at $q = q^m = \frac{1}{2N}$. Then $\frac{1}{N+1} - q = \frac{u}{N+1}$ and $q - \frac{1}{N(N+1)} = \frac{N-1-Nu}{N(N+1)}$, so

$$\pi(q) - \pi^N = \frac{u\,(N - 1 - Nu)}{(N+1)^2}.$$

The incentive constraint becomes

$$\frac{u^2}{4} \le \frac{\delta}{1-\delta} \cdot \frac{u\,(N - 1 - Nu)}{(N+1)^2}.$$

At $u = 0$ both sides vanish. For $u > 0$, multiply both sides by $\frac{4(1-\delta)(N+1)^2}{u} > 0$:

$$\begin{aligned}(1-\delta)(N+1)^2\,u &\le 4\delta\,(N - 1 - Nu), \\ u\left[(1-\delta)(N+1)^2 + 4N\delta\right] &\le 4\delta(N-1), \\ u \le \bar{u}(\delta) &\equiv \frac{4\delta(N-1)}{(1-\delta)(N+1)^2 + 4N\delta}.\end{aligned}$$

The constraint is linear in u, so the sustainable outputs form the interval $u \in [0, \bar{u}(\delta)]$, that is, $q \ge \frac{1-\bar{u}(\delta)}{N+1}$. Since

$$1 - \bar{u}(\delta) = \frac{(1-\delta)(N+1)^2 + 4N\delta - 4\delta(N-1)}{(1-\delta)(N+1)^2 + 4N\delta} = \frac{(1-\delta)(N+1)^2 + 4\delta}{(1-\delta)(N+1)^2 + 4N\delta},$$

restoring the scale gives (12.19). Writing $\bar{u}(\delta) = \frac{4(N-1)}{(N+1)^2\frac{1-\delta}{\delta} + 4N}$ shows that $\bar{u}$ is continuous and increasing, with $\bar{u}(0) = 0$. It reaches u^m where $8N\delta = (1-\delta)(N+1)^2 + 4N\delta$, that is, at $\delta = \frac{(N+1)^2}{(N+1)^2+4N} = \delta^*(N)$. Finally, $\pi(q)$ decreases in q on $[q^m, q^N]$, so the most profitable sustainable output is the smallest one, $q(\delta)$. □

A numerical example shows how much collusion impatient firms can sustain. Take $N = 2$ and $\delta = 0.4$, below the threshold $\frac{9}{17}$, in units with $a - c = 1$ and $b = 1$. Then $\bar{u} = \frac{1.6}{5.4+3.2} = \frac{8}{43}$, and the most collusive output is $q(0.4) = \frac{1-\frac{8}{43}}{3} = \frac{35}{129} \approx 0.271$ per firm. This lies between the monopoly-sharing output 0.25 and the Cournot output 0.333. The margin is $P - c = 1 - \frac{70}{129} = \frac{59}{129} \approx 0.457$, and each firm earns $\frac{35}{129} \cdot \frac{59}{129} \approx 0.1241$. Monopoly sharing would give 0.125 and Cournot 0.1111, so the firms sustain about 93 percent of the gain from collusion over Cournot competition. The script `partial_cournot.py` confirms these values by brute force.

Remark 12.20 (Repeated play and the conduct parameter). The menu of conduct in Table 2.4 sets $\theta = 0$ for competition, $\theta = \frac{1}{N}$ for Cournot and $\theta = 1$ for monopoly. In the linear model the supply relation reads $P - c = \theta\, bQ$. Along the partial-collusion frontier of Proposition 12.19, with $u = \bar{u}(\delta)$,

$$\theta(\delta) = \frac{P - c}{bQ} = \frac{1 + N\bar{u}(\delta)}{N\left[1 - \bar{u}(\delta)\right]},$$

which rises continuously from $\frac{1}{N}$ at $\delta = 0$ to 1 at $\delta = \delta^*(N)$. In the example above, $\theta(0.4) = \frac{59}{70} \approx 0.84$. A conduct parameter estimated from data is thus a summary of the equilibrium of a dynamic game. If demand or costs change over time, the most collusive equilibrium changes too, and a constant θ averages over conduct that varies. This is the critique of Corts (1999) discussed in Section 3.6.2. With differentiated products, full collusion is joint profit maximization over all products. It corresponds to an ownership matrix of ones, $\Omega = \mathbf{1}\mathbf{1}^\top$, in the markup equation (4.4). The partial internalization weights of Remark 11.52 are a reduced form for intermediate conduct.

12.3.4 Optimal punishments

Nash reversion is a natural punishment, but in the Cournot game it is far from the harshest credible one. Cournot profits are positive, while the minmax payoff is zero. Abreu (1986, 1988) showed how to construct the harshest credible punishments, and that they can be described simply.

Abreu (1988) proves that every SPE outcome path can be supported by a *simple strategy profile*. Such a profile consists of the desired path and one punishment path for each player. Any unilateral deviation by player i, from any path, starts player i's punishment path from its beginning. Simultaneous deviations by several players are ignored. The *optimal penal code* uses, for each player, a punishment path that gives that player its lowest SPE payoff. An outcome path is then an SPE path if and only if no player gains from a one-shot deviation from it followed by that player's lowest SPE payoff. Harsher credible punishments thus enlarge the set of sustainable paths, and the worst punishments sustain the most.

For symmetric Cournot supergames, Abreu (1986) shows that, under regularity conditions, the optimal symmetric punishment has a two-phase *stick-and-carrot* form. In the first phase all firms produce a high output x for one period, which is the stick. They then return to the most collusive symmetric path, which is the carrot.

Proposition 12.21 (Two-phase punishments)**.** *Consider N identical Cournot firms, with $\pi(q)$ and $\pi^d(q)$ defined as in (12.15). Fix a collusive output q^c and a stick output x, and define a profile with two states. In state C every firm produces q^c, and in state P every firm produces x. Play starts in state C. After any period in which some firm deviated from the prescribed output, the next state is P. After any*

period without a deviation, the next state is C. The profile is an SPE if and only if

$$\pi^d(q^c) - \pi(q^c) \le \delta \left[\pi(q^c) - \pi(x)\right], \tag{12.20}$$

$$\pi^d(x) - \pi(x) \le \delta \left[\pi(q^c) - \pi(x)\right]. \tag{12.21}$$

Proof. We use unnormalized values. The value of state C is $V_C = \frac{\pi(q^c)}{1-\delta}$, since without deviations the game stays in C. The value of state P is one period of the stick followed by the carrot, $V_P = \pi(x) + \delta V_C$. By Proposition 12.5 we only need to rule out one-shot deviations in each state, and every deviation leads to P.

In state C, the best one-shot deviation earns $\pi^d(q^c)$ and moves the game to P. It is unprofitable if and only if $\pi^d(q^c) + \delta V_P \le V_C$. Using the expressions for V_C and V_P,

$$V_C - \delta V_P = \frac{\pi(q^c)}{1-\delta} - \delta\pi(x) - \frac{\delta^2\pi(q^c)}{1-\delta} = (1+\delta)\,\pi(q^c) - \delta\,\pi(x).$$

The condition $\pi^d(q^c) \le (1+\delta)\pi(q^c) - \delta\pi(x)$ is (12.20).

In state P, the best one-shot deviation earns $\pi^d(x)$ and restarts the stick, so the game is again in P. It is unprofitable if and only if $\pi^d(x) + \delta V_P \le V_P$, that is,

$$\pi^d(x) \le (1-\delta)V_P = (1-\delta)\,\pi(x) + \delta\,\pi(q^c).$$

Subtracting $\pi(x)$ from both sides gives (12.21). □

The two constraints have clear meanings. The *carrot constraint* (12.20) says that the one-period gain from cheating on the collusive output must not exceed the loss from spending one period in the stick instead of the carrot. The *stick constraint* (12.21) says that firms must be willing to carry out the punishment. During the stick each firm would like to cut its output and enjoy the higher price. It refrains because a deviation would restart the stick and delay the return to collusion. The normalized value of the punishment is $(1-\delta)\pi(x) + \delta\pi(q^c)$. The stick can impose a stage profit below the minmax payoff, even a loss. By (12.21), however, the value of the whole punishment is at least $\pi^d(x)$, which is at least the minmax payoff.

Example 12.22 (Stick and carrot in the linear Cournot duopoly)**.** Two firms with constant marginal cost $c \ge 0$ face the inverse demand $P(Q) = a - Q$ for every $Q \ge 0$, with $a > c$. Outputs scale with $a - c$ and profits with $(a-c)^2$, and the thresholds on δ do not depend on the scale, so we set $a - c = 1$. The collusive output is $q^c = q^m = \frac{1}{4}$, with

$$\pi(q^m) = \frac{1}{4}\cdot\frac{1}{2} = \frac{1}{8}, \qquad \pi^d(q^m) = \left(\frac{1-\frac{1}{4}}{2}\right)^2 = \frac{9}{64}, \qquad \pi^d(q^m) - \pi(q^m) = \frac{1}{64}.$$

For a stick output $x \le 1$, the stage profit is $\pi(x) = x(1-2x)$ and the best response to x is $\frac{1-x}{2}$, so $\pi^d(x) = \frac{(1-x)^2}{4}$. The gain from deviating during the stick and the loss from the stick are

$$\pi^d(x) - \pi(x) = \frac{1 - 2x + x^2 - 4x + 8x^2}{4} = \frac{(3x-1)^2}{4},$$

$$\pi(q^m) - \pi(x) = \frac{1 - 8x + 16x^2}{8} = \frac{(4x-1)^2}{8}.$$

For $x \neq \frac{1}{4}$, constraints (12.20) and (12.21) become $\delta \geq \delta_C(x)$ and $\delta \geq \delta_S(x)$, with

$$\delta_C(x) = \frac{\frac{1}{64}}{\frac{(4x-1)^2}{8}} = \frac{1}{8(4x-1)^2}, \qquad \delta_S(x) = \frac{\frac{(3x-1)^2}{4}}{\frac{(4x-1)^2}{8}} = \frac{2(3x-1)^2}{(4x-1)^2}.$$

For $x < \frac{1}{4}$ the stick raises the price. Then $\delta_S(x) = 2\left(\frac{1-3x}{1-4x}\right)^2 \geq 2$, because $1-3x \geq 1-4x > 0$, so no such stick works. We therefore take $x > \frac{1}{4}$. A harsher stick lowers δ_C. Beyond the Cournot output $x = \frac{1}{3}$, it raises δ_S, because the ratio $\frac{3x-1}{4x-1}$ has derivative $\frac{1}{(4x-1)^2} > 0$. On $(\frac{1}{4}, \frac{1}{3}]$ no stick works, since $\delta_C(x) \geq \delta_C(\frac{1}{3}) = \frac{9}{8} > 1$. For $x \geq 1$ the best response is zero, and $\delta_S(x) = \frac{2x^2-x}{2x^2-x+\frac{1}{8}} \geq \frac{8}{9}$. The lowest discount factor that some stick can support is therefore attained where the two curves cross on $(\frac{1}{3}, 1)$:

$$\begin{aligned} \frac{(3x-1)^2}{4} &= \frac{1}{64}, \\ (3x-1)^2 &= \frac{1}{16}, \\ 48x^2 - 32x + 5 &= 0. \end{aligned}$$

The roots are $x = \frac{1}{4}$, which is the collusive output itself, and $x = \frac{5}{12}$. At $x = \frac{5}{12}$,

$$\pi(x) = \frac{5}{12} \cdot \frac{1}{6} = \frac{5}{72}, \qquad \pi(q^m) - \pi(x) = \frac{9}{72} - \frac{5}{72} = \frac{1}{18}, \qquad \underline{\delta} = \frac{\frac{1}{64}}{\frac{1}{18}} = \frac{18}{64} = \frac{9}{32}.$$

In general units the stick output is $x = \frac{5(a-c)}{12}$ per firm. The stick price is $\frac{a+5c}{6}$, still above marginal cost, and each firm earns $\frac{5(a-c)^2}{72}$, below the Cournot profit $\frac{8(a-c)^2}{72}$. The optimal two-phase punishment sustains monopoly for $\delta \geq \frac{9}{32} \approx 0.281$, against $\frac{9}{17} \approx 0.529$ with Nash reversion. A grid search in `abreu_check.py` over stick outputs confirms the threshold and the stick output for several values of c.

Figure 12.3 draws the two constraints. A harsher stick makes cheating on the cartel less attractive, but it also makes the punishment harder to enforce. The best stick balances the two.

Remark 12.23 (The price floor and the limit of punishment). Example 12.22 treats inverse demand as linear for all outputs, so that very large outputs would drive the price below zero. The optimal stick keeps the price above marginal cost, but the assumption still matters, because it determines which sticks are available. Suppose instead that the price cannot fall below zero, $P(Q) = \max\{a - Q, 0\}$. With $c = 0$, each firm producing at least a drives the price to zero at no cost. Deviating during such a stick cannot raise the price, so the stick constraint is slack. The carrot constraint becomes $\frac{1}{64} \leq \frac{\delta}{8}$, that is, $\delta \geq \frac{1}{8}$. With $c > 0$, a stick that floods the market costs cx per period. Our computations with `abreu_check.py` show that flooding sticks beat $\frac{9}{32}$ only when $c < 0.051(a-c)$. Suppose $0 < c \leq \frac{a-c}{64}$. A flooding stick in which each firm produces $\frac{(a-c)^2}{64c}$, earning $-\frac{(a-c)^2}{64}$ per period, then reaches $\delta = \frac{1}{9}$, provided outputs this large are feasible. At $c = 0$ a stick cannot impose a loss, and the best two-phase code reaches only $\frac{1}{8}$. No equilibrium can do better than $\frac{1}{9}$. By Lemma 12.8 a deviator's continuation value is at least the minmax payoff zero, so sustaining monopoly sharing requires $\frac{\pi(q^m)}{1-\delta} \geq \pi^d(q^m)$, that is, $\delta \geq 1 - \frac{8}{9} = \frac{1}{9}$. The general lesson is that the harshness of credible punishments depends on how much damage firms can inflict on one another in a period, and at what cost to themselves.

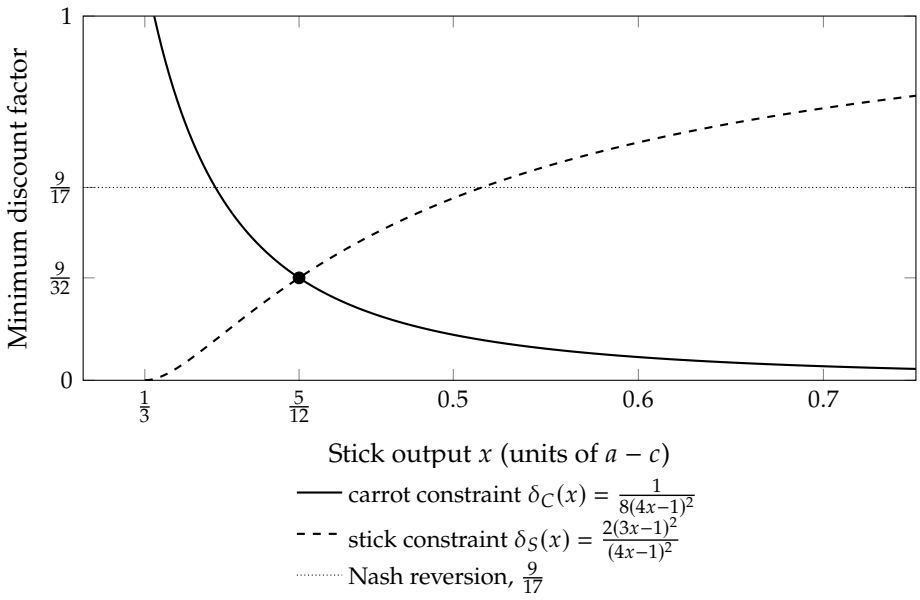

Figure 12.3: The two constraints of the stick-and-carrot punishment in the linear Cournot duopoly with inverse demand $a - Q$, from Example 12.22. A stick output x supports monopoly sharing for every δ above both curves. The best stick, $x = \frac{5(a-c)}{12}$, equates the two constraints at $\delta = \frac{9}{32}$.

In the Bertrand supergame optimal punishments add nothing. Bertrand reversion already holds every firm to its minmax payoff of zero, which no equilibrium can undercut. Two broader lessons follow from Abreu's analysis. First, the sustainability of collusion depends on the severity of credible punishments as well as on patience. Second, the most effective punishment is a short, sharp price war followed by a return to collusion. Wars of this kind reappear in the models of imperfect monitoring (Section 12.5) and in the model of imperfect cartels of Bernheim and Madsen (2017) (Section 13.7). Stick-and-carrot schemes have one weakness. Once a deviation has occurred, all firms would gain by skipping the stick and returning to collusion at once. Punishments that are immune to such renegotiation are milder, which limits how much collusion they can sustain (Farrell and Maskin, 1989).

12.3.5 Asymmetric firms

Symmetric models hide a problem that real cartels face: firms differ, and the collusive agreement must satisfy every firm's incentive constraint. Consider two Bertrand firms with marginal costs $c_1 < c_2$, and write $\pi_i(p) = (p - c_i)D(p)$ and $p^m(c_i)$ for firm i's monopoly price. Suppose $c_2 < p^m(c_1)$, so that the cost advantage is not drastic. The static Bertrand equilibrium then has firm 1 serving the market at a price equal to c_2. Firm 1 earns $\pi_1(c_2) = (c_2 - c_1)D(c_2) > 0$ and firm 2 earns nothing. Let the firms collude on a common price $p \in (c_2, p^m(c_1)]$ and divide the customers in shares α_1 and $\alpha_2 = 1 - \alpha_1$. Undercutting gives either firm the whole market for one period. With Nash reversion, the normalized incentive constraints are

$$\alpha_1 \, \pi_1(p) \geq (1 - \delta) \, \pi_1(p) + \delta \, \pi_1(c_2), \qquad \alpha_2 \, \pi_2(p) \geq (1 - \delta) \, \pi_2(p). \tag{12.22}$$

The efficient firm fears punishment less than its rival, because it keeps a positive profit in the price war. Its constraint requires $\alpha_1 \geq 1 - \delta + \delta\psi_1$, where $\psi_1 = \frac{\pi_1(c_2)}{\pi_1(p)} \in (0, 1)$, while firm 2 needs

$\alpha_2 \geq 1 - \delta$. Adding the two requirements and using $\alpha_1 + \alpha_2 = 1$ gives

$$1 \geq 2(1-\delta) + \delta\psi_1 \quad \Longleftrightarrow \quad \delta \geq \frac{1}{2 - \psi_1}.$$

The threshold exceeds the symmetric value $\frac{1}{2}$ and rises with the cost gap, which raises ψ_1. The cartel must also give the efficient firm a larger share of the market. In addition, the firms disagree about the price, since the low-cost firm prefers a lower monopoly price than the high-cost firm.

Without side payments, the firms can still trade price against market share. Tirole (1988, section 6.3.2.4, Exercises 6.1 and 6.5) characterizes the efficient trade. Fix a profit target $\bar{\pi}_2 > 0$ for firm 2. Both firms charge the price p, and firm i produces $s_i D(p)$, with $s_1 + s_2 = 1$. A *constrained-efficient market-sharing allocation* maximizes firm 1's profit given firm 2's target:

$$\max_{p,\, s_1,\, s_2} (p - c_1)\, s_1 D(p) \quad \text{subject to} \quad (p - c_2)\, s_2 D(p) \geq \bar{\pi}_2, \qquad s_1 + s_2 = 1. \tag{12.23}$$

Varying $\bar{\pi}_2$ traces the frontier of profit pairs that the firms can reach without transfers.

Proposition 12.24 (Market sharing without side payments)**.** *Let D be positive and decreasing, and let $(p - c)D(p)$ be strictly concave in p for every c. Suppose that the solution of (12.23) has $p > c_2$. Then:*

(i) The price lies between the two monopoly prices, $p^m(c_1) \leq p \leq p^m(c_2)$.

(ii) The price solves

$$\big[(p - c_1)D'(p) + D(p)\big] + \frac{(c_2 - c_1)\,\bar{\pi}_2}{(p - c_2)^2} = 0. \tag{12.24}$$

(iii) The price p and firm 2's share s_2 both rise with the target $\bar{\pi}_2$.

Proof. The constraint binds at the optimum, because otherwise moving share to firm 1 raises firm 1's profit. Hence $s_2 = \frac{\bar{\pi}_2}{(p - c_2)D(p)}$, and firm 1's profit as a function of p alone is

$$\Pi_1(p) = (p - c_1)D(p)\left[1 - \frac{\bar{\pi}_2}{(p - c_2)D(p)}\right] = (p - c_1)D(p) - \frac{(p - c_1)\,\bar{\pi}_2}{p - c_2}.$$

(i) Strict concavity implies $p^m(c_1) < p^m(c_2)$. For $p < p^m(c_1)$, both $(p - c_1)D(p)$ and $(p - c_2)D(p)$ rise with p. Both factors in the first expression for Π_1 are then positive and rising, so Π_1 rises. For $p > p^m(c_2)$, both factors fall, so Π_1 falls. The optimum therefore lies in $[p^m(c_1), p^m(c_2)]$.

(ii) The derivative of the last term uses

$$\frac{\mathrm{d}}{\mathrm{d}p}\,\frac{p - c_1}{p - c_2} = \frac{(p - c_2) - (p - c_1)}{(p - c_2)^2} = -\frac{c_2 - c_1}{(p - c_2)^2}.$$

Setting $\Pi_1'(p) = 0$ gives (12.24).

(iii) Let $\Phi(p, \bar{\pi}_2)$ be the left side of (12.24). The bracket falls with p by strict concavity, and the second term falls with p for $p > c_2$, so $\frac{\partial \Phi}{\partial p} < 0$. Also $\frac{\partial \Phi}{\partial \bar{\pi}_2} = \frac{c_2 - c_1}{(p - c_2)^2} > 0$. By the implicit function theorem,

$$\frac{\mathrm{d}p}{\mathrm{d}\bar{\pi}_2} = -\frac{\partial \Phi}{\partial \bar{\pi}_2}\left(\frac{\partial \Phi}{\partial p}\right)^{-1} > 0.$$

For the share, solve (12.24) for $\bar{\pi}_2$ and substitute it into s_2:

$$s_2 = \frac{-\left[(p-c_1)D'(p) + D(p)\right](p-c_2)}{(c_2-c_1)\,D(p)}.$$

On $[p^m(c_1), p^m(c_2)]$ the factor $-[(p-c_1)D'(p)+D(p)]$ is nonnegative and rising, $p-c_2$ is positive and rising, and $\frac{1}{D(p)}$ is positive and rising. Their product rises with p, and hence with $\bar{\pi}_2$. □

The proposition shows how a cartel without transfers compensates the high-cost firm. To give firm 2 more profit, it raises the price toward firm 2's preferred level and also gives firm 2 more of the market. Both moves sacrifice industry profit, because the efficient allocation would let firm 1 serve the market at $p^m(c_1)$. The comparison with (12.22), where the price was fixed at or below $p^m(c_1)$, shows that efficient sharing uses higher prices.

Which points of this frontier can grim trigger sustain? Let π_i^* be firm i's collusive profit at an allocation. Firm 1's best deviation charges its own monopoly price $p^m(c_1) \le p$, takes the whole market and earns $\pi_1(p^m(c_1))$. Bertrand reversion then leaves it $\pi_1(c_2)$ per period. Firm 2's best deviation undercuts p slightly and earns almost $(p-c_2)D(p)$, and reversion leaves it zero. The two constraints are

$$\pi_1\big(p^m(c_1)\big) - \pi_1^* \;\le\; \frac{\delta}{1-\delta}\big[\pi_1^* - \pi_1(c_2)\big], \qquad (p-c_2)D(p) - \pi_2^* \;\le\; \frac{\delta}{1-\delta}\,\pi_2^*. \tag{12.25}$$

The first holds only if firm 1's collusive profit is high enough, and the second only if firm 2's is. For a given δ only a middle segment of the frontier is sustainable. This is the counterpart, with a variable price, of (12.22). Tirole adds that the choice among these allocations is itself a coordination problem, which no symmetry argument can settle when costs differ (section 6.3.2.4).

Capacity asymmetries work through both sides of the constraint. A firm with spare capacity gains much from undercutting and is hard to punish, because its small rivals cannot flood the market (Example 12.17 and Compte et al., 2002). A firm whose incentive constraint is the hardest to satisfy, because of low costs, spare capacity, or a small share of the collusive profits, constrains what the whole group can sustain. Merger guidelines call a firm that plays this disruptive role a *maverick* (U.S. Department of Justice and Federal Trade Commission, 2010). Product differentiation is a further source of asymmetry, and the next subsection studies its symmetric version.

12.3.6 Differentiated products

With differentiated products, a firm that undercuts its rivals gains some of their customers but not all, and the static Nash equilibrium yields positive profits. Both the temptation and the punishment become milder. We work out a linear duopoly in which the two effects can be compared in closed form.

Proposition 12.25 (Collusion with differentiated products)**.** *Two firms with zero marginal cost face demands $q_i = 1 - p_i + s\,p_j$ for $i \neq j$, with $0 \le s \le \sqrt{3}-1 \approx 0.73$. Here s measures substitutability and is not a market share. With grim trigger and Bertrand-Nash reversion, the joint-profit price is sustainable if and only if*

$$\delta \ge \underline{\delta}(s) \equiv \frac{(2-s)^2}{s^2 - 8s + 8}. \tag{12.26}$$

The threshold increases in s, from $\frac{1}{2}$ at $s=0$ to $\frac{3}{5}$ at $s=\sqrt{3}-1$.

Proof. The model is Example 4.6 with $a = b = 1$, $d = s$ and $c = 0$. We compute the three profits.

We start with the static Nash equilibrium. Firm i maximizes $p_i(1 - p_i + sp_j)$. The first-order condition $1 - 2p_i + sp_j = 0$ gives the symmetric equilibrium price $p^N = \frac{1}{2-s}$. Each firm sells $1 - (1-s)p^N = \frac{1}{2-s}$, so $\pi^N = \frac{1}{(2-s)^2}$.

Under collusion the firms choose a common price p to maximize $2p\big[1 - (1-s)p\big]$. The first-order condition $1 - 2(1-s)p = 0$ gives $p^c = \frac{1}{2(1-s)}$. Each firm sells $\frac{1}{2}$, so $\pi^c = \frac{1}{4(1-s)}$.

A firm i that deviates against p^c maximizes $p_i(1 - p_i + sp^c)$, so

$$p^d = \frac{1 + sp^c}{2} = \frac{1}{2}\left[1 + \frac{s}{2(1-s)}\right] = \frac{2-s}{4(1-s)}.$$

Its sales equal its price, $1 - p^d + sp^c = p^d$, so $\pi^d = (p^d)^2 = \frac{(2-s)^2}{16(1-s)^2}$. At this price the rival sells

$$1 - p^c + s\,p^d = \frac{4(1-s) - 2 + s(2-s)}{4(1-s)} = \frac{2 - 2s - s^2}{4(1-s)},$$

which is nonnegative if and only if $s \le \sqrt{3} - 1$. For larger s the linear system would assign the rival negative sales, and the deviation must be computed with the rival's demand truncated at zero.

The threshold (12.16) applies with these profits. The two differences are

$$\pi^d - \pi^c = \frac{(2-s)^2 - 4(1-s)}{16(1-s)^2} = \frac{s^2}{16(1-s)^2},$$
$$\pi^d - \pi^N = \frac{(2-s)^4 - 16(1-s)^2}{16(1-s)^2(2-s)^2} = \frac{s^2\,(s^2 - 8s + 8)}{16(1-s)^2(2-s)^2},$$

where the second line uses the factorization

$$(2-s)^4 - 16(1-s)^2 = \big[(2-s)^2 - 4(1-s)\big]\big[(2-s)^2 + 4(1-s)\big] = s^2\,(s^2 - 8s + 8).$$

Their ratio is (12.26). The quadratic $s^2 - 8s + 8$ has roots $4 \pm 2\sqrt{2}$, both outside $[0, 1]$, so it is positive on $[0, 1]$. Differentiating,

$$\frac{d\underline{\delta}}{ds} = \frac{-2(2-s)(s^2 - 8s + 8) - (2-s)^2(2s - 8)}{(s^2 - 8s + 8)^2} = \frac{4s(2-s)}{(s^2 - 8s + 8)^2} > 0$$

for $s \in (0, 1)$. At $s = 0$ the threshold is $\frac{4}{8} = \frac{1}{2}$. At $s = \sqrt{3} - 1$ we have $(2-s)^2 = 12 - 6\sqrt{3}$ and $s^2 - 8s + 8 = 20 - 10\sqrt{3}$, so the threshold is $\frac{6(2-\sqrt{3})}{10(2-\sqrt{3})} = \frac{3}{5}$. □

Figure 12.4 plots the threshold. In this specification collusion is easier when products are more differentiated. Both the gain from deviating and the loss from punishment vanish as $s \to 0$, since

$$\pi^d - \pi^c = \frac{s^2}{16(1-s)^2}, \qquad \pi^c - \pi^N = \frac{s^2}{4(1-s)(2-s)^2}.$$

The threshold depends on their ratio $R(s) = \frac{(2-s)^2}{4(1-s)}$, because $\underline{\delta} = \frac{\pi^d - \pi^c}{(\pi^d - \pi^c) + (\pi^c - \pi^N)} = \frac{R}{1+R}$. The ratio equals one at $s = 0$ and rises with s, so closer substitutes raise the temptation faster than they raise the punishment. Deneckere (1983, eq. (21)) and Ross (1992, eq. (8)) derive

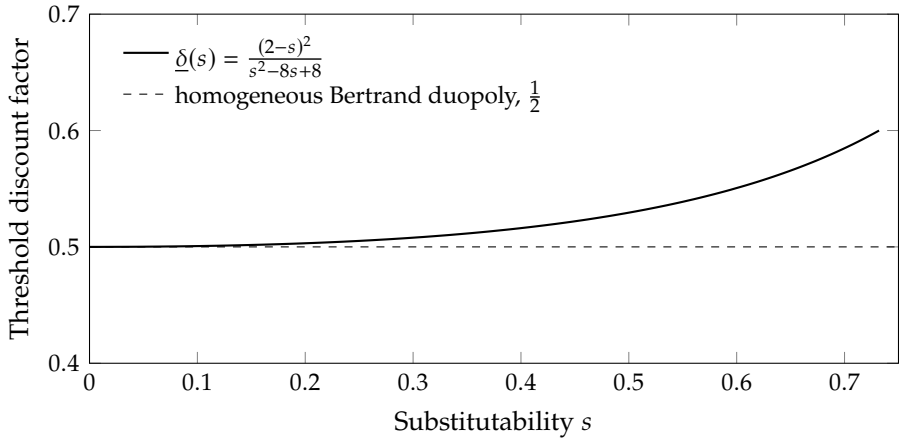

Figure 12.4: Minimum discount factor for collusion at the joint-profit price in the linear differentiated duopoly $q_i = 1 - p_i + s\, p_j$ with zero cost and Bertrand-Nash reversion (Proposition 12.25).

the same threshold. They state it as the highest interest rate at which collusion survives, $\frac{1-\underline{\delta}}{\underline{\delta}} = \frac{1}{R(s)} = \frac{4(1-s)}{(2-s)^2}$. Deneckere measures substitutability by the cross-to-own ratio in inverse demand, which equals $-s$ in our model. Substituting $-s$ for his parameter turns his eq. (21) into this expression.

Two cautions apply. First, the closed form holds only for $s \leq \sqrt{3} - 1$. Beyond that point the deviator's best price would drive the rival's linear demand below zero. The deviator can take at most the rival's whole market, so its best deviation then leaves the rival with exactly zero sales. Deneckere (1983, pp. 40–42) and Ross (1992, p. 7) show that with this cap the threshold stops rising. Ross (1992, p. 7) puts the turning point near $s = 0.77$. His eq. (9) gives a highest interest rate of 0.64 there, so the threshold is $\frac{1}{1.64} \approx 0.61$. The threshold then falls back toward the homogeneous Bertrand value $\frac{1}{2}$ as $s \to 1$, so the relation is non-monotone over the full range. Second, the answer depends on the model of differentiation. Within the linear model the threshold depends only on the ratio of the cross-price to the own-price effect, which is s here. The scale of demand does not matter (Ross, 1992, p. 7). In a spatial model with linear transport costs, where the best deviation steals only marginal customers, the threshold falls as transport costs rise. A cartel of differentiated products can then be more stable than one of identical products (Ross, 1992, pp. 8–11). The general point survives. Differentiation weakens both the temptation to cheat and the punishment, and which effect dominates depends on the specific model of differentiation (Ross, 1992, p. 5).

12.3.7 Coordinated effects of mergers

The theory of this section supplies the economics behind the *coordinated effects* of mergers (Definition 11.48). A merger can make collusion easier through three channels. It removes a firm, which lowers the threshold. In the Bertrand supergame a merger from N to $N - 1$ firms lowers it from $1 - \frac{1}{N}$ to $1 - \frac{1}{N-1}$, for example from 0.75 to 0.67 when four firms become three. In the linear Cournot supergame a merger from three firms to two lowers δ^* from $\frac{4}{7} \approx 0.571$ to $\frac{9}{17} \approx 0.529$. In the Bertrand supergame the deviation profit, which is the monopoly profit, and the punishment profit, which is zero, do not depend on the number of firms. In richer models both fall as firms are added. A merger then raises both sides of the incentive constraint, and its effect on the threshold is ambiguous in general (Asker and Nocke, 2021, p. 239). In the linear

Cournot case the net effect lowers the threshold, as the numbers above show. A merger also changes asymmetries, and the model of Compte et al. (2002) shows how. When the firms other than the largest can serve the market, the threshold (12.13) is $\frac{\hat{K}-1}{\hat{K}}$, and a merger can only lower it. When they cannot, the threshold (12.14) is $\frac{\hat{k}_N}{\hat{K}}$. A merger involving the largest firm then raises it, while a merger among smaller firms that leaves the largest firm unchanged has no effect. A merger that creates a large firm with spare capacity, or that gives the merged firm a cost advantage, can thus create a maverick and make collusion harder. Finally, a merger can eliminate a maverick, which is the case that merger guidelines emphasize (U.S. Department of Justice and Federal Trade Commission, 2010). Because the theory has many equilibria, it identifies the conditions under which coordination is feasible after a merger. It cannot tell us whether coordination will occur. Section 11.8 studies the evidence from the MillerCoors joint venture, where post-merger prices are consistent with coordination (Miller and Weinberg, 2017).

Entry interacts with collusion as well. Under perfect collusion with free entry, firms enter until the collusive profit per firm equals the fixed cost. In the linear Cournot model with a fixed cost Φ per firm and period, collusion supports $N^m = \frac{(a-c)^2}{4b\Phi}$ firms, at least as many as Cournot competition with free entry. Entry then dissipates the whole monopoly rent (Section C.1). Consumers gain nothing, because the price stays at the monopoly level. The larger number of firms also raises the discount factor that collusion requires, since $\delta^*(N^m) > \delta^*(N)$ for any smaller N. Under full collusion the Lerner index is $\frac{a-c}{a+c}$ whatever the number of firms, so concentration and margins are unrelated under collusion. Cross-industry regressions of margins on concentration therefore mix industries whose margins respond to concentration (Cournot) with industries whose margins do not (collusion), as Sections 2.5.6 and C.1 show.

12.4 Collusion When Demand Fluctuates

The supergames of Section 12.3 hold demand fixed. Real markets move with the seasons, the business cycle and shifts in tastes. This section asks how such movements change what a cartel can sustain. The answer rests on one comparison. In each period a firm weighs the gain from undercutting today against the collusive profit it loses in the punishment that follows. The gain depends on current demand. The loss depends on expected future demand. When demand fluctuates, both sides of the incentive constraint move, and they need not move together.

The models of this section differ in how today's demand predicts future demand. If demand shocks are independent over time and observed by the firms, the future loss is the same in every state, while the gain is largest when demand is high. Collusion is then hardest in booms, and collusive margins are countercyclical (Rotemberg and Saloner, 1986). If demand follows a predictable cycle, the future loss is small when demand is about to fall (Haltiwanger and Harrington, 1991). If booms and recessions are persistent phases of growth, the future loss is larger in the phase that predicts higher future demand (Bagwell and Staiger, 1997). In all three models firms observe demand, so the most collusive equilibrium has no price war on its equilibrium path. Price wars on the path appear when demand is unobserved, the case of Green and Porter (1984) in Section 12.5.

Throughout this section δ is the discount factor. The state of demand in period t is ω_t. The papers write ϵ_t for it, a symbol the book reserves for taste shocks. Market demand in state ω is $D(p, \omega)$, and industry profit at a common price p is $\pi(p, \omega) = (p - c)D(p, \omega)$. The monopoly price is $p^m(\omega)$ and monopoly profit is $\pi^m(\omega) = \pi(p^m(\omega), \omega)$. When we quote a

paper's equations we translate them into this notation.

12.4.1 A two-state model

We begin with two demand states. This version shows the logic of Rotemberg and Saloner (1986) in a few lines and produces four regimes of optimal collusion.

Assumption 12.26 (Two independent demand states)**.**

(i) $N \geq 2$ firms sell a homogeneous good at constant marginal cost c. In each period $t = 0, 1, 2, \ldots$ they set prices simultaneously. The firm with the lowest price serves the market, and firms tied at the lowest price share it equally.

(ii) Market demand is $D_H(p)$ in the high state and $D_L(p)$ in the low state. Each state occurs with probability $\frac{1}{2}$, independently across periods, and $D_H(p) > D_L(p)$ at every price.

(iii) All firms observe the state before they set prices, and all past prices are observed.

(iv) Industry profit $\pi_s(p) = (p - c)D_s(p)$ has a unique maximizer p_s^M and is strictly increasing on $[c, p_s^M]$. We write $\pi_s^M = \pi_s(p_s^M)$ for $s \in \{H, L\}$.

(v) Firms maximize expected discounted profit with discount factor $\delta \in (0, 1)$.

Since $D_H > D_L$, we have $\pi_H(p) > \pi_L(p)$ at every $p > c$. Hence $\pi_H^M \geq \pi_H(p_L^M) > \pi_L^M$. In this subsection H and L name states. They are not the Herfindahl index or a number of periods.

The firms consider the strategy profile

$$p_{it}(h^t) = \begin{cases} p_H & \text{if no firm has deviated before } t \text{ and the state is } H, \\ p_L & \text{if no firm has deviated before } t \text{ and the state is } L, \\ c & \text{if some firm has deviated before } t, \end{cases} \tag{12.27}$$

where h^t records past prices and states. The third line is Bertrand reversion. It gives every firm zero profit, which is the minmax payoff of the stage game (Lemma 12.8), so no credible punishment is harsher. We restrict attention to prices $p_s \in [c, p_s^M]$. A price above p_s^M is never useful. A deviator could then charge p_s^M and earn π_s^M. Replacing p_s by the price below p_s^M with the same profit leaves the future unchanged and lowers the deviation payoff.

The incentive constraints. Let

$$V \equiv \frac{1}{2}\pi_H(p_H) + \frac{1}{2}\pi_L(p_L) \tag{12.28}$$

be expected industry profit per period on the collusive path. Consider a period in state s with no earlier deviation. A firm that conforms earns $\frac{1}{N}\pi_s(p_s)$ today. From tomorrow on it earns $\frac{V}{N}$ per period in expectation. Because states are independent over time, this expectation does not depend on today's state. The discounted value of the future is

$$\sum_{\tau=1}^{\infty} \delta^\tau \frac{V}{N} = \frac{\delta}{1-\delta}\,\frac{V}{N}.$$

The best deviation undercuts to $p_s - \varepsilon'$ for a small $\varepsilon' > 0$. (We write ε' for the price cut because ε is an elasticity.) The deviator serves the whole market and earns $\pi_s(p_s - \varepsilon')$, which tends to $\pi_s(p_s)$ as $\varepsilon' \to 0$. Afterwards every firm prices at c, and the deviator earns zero. Conforming is optimal if

$$\pi_s(p_s) \leq \frac{1}{N}\pi_s(p_s) + \frac{\delta}{1-\delta}\,\frac{V}{N}.$$

Subtracting $\frac{1}{N}\pi_s(p_s)$ from both sides gives

$$\frac{N-1}{N}\,\pi_s(p_s) \le \frac{\delta}{1-\delta}\,\frac{1}{N}\left[\frac{1}{2}\pi_H(p_H)+\frac{1}{2}\pi_L(p_L)\right], \qquad s \in \{H,L\}. \tag{12.29}$$

Proposition 12.27 (Incentive constraints with two demand states)**.** *Under Assumption 12.26, with $p_s \in [c, p_s^M]$ for $s = H, L$, the profile (12.27) is a subgame perfect equilibrium if and only if (12.29) holds in both states.*

Proof. After a deviation the profile prescribes the static Nash equilibrium in every period, whatever happens. This is subgame perfect by Proposition 12.6. On the collusive path, the one-shot deviation principle (Proposition 12.5) lets us check single deviations. A price above p_s sells nothing today and leads to zero profit forever, so it is never better than conforming. A price $p' < p_s$ earns $\pi_s(p') < \pi_s(p_s)$ today, because π_s is strictly increasing on $[c, p_s^M]$, and zero afterwards. If (12.29) holds, every such deviation pays strictly less than conforming. If (12.29) fails in state s, then $\pi_s(p_s)$ exceeds the conforming payoff. By continuity, $\pi_s(p')$ also exceeds it for p' close enough to p_s, and that deviation is profitable. □

The left side of (12.29) is the current gain from cheating. It is larger in the high state, because a deviator steals a larger market. The right side is the future loss from the price war. It is the same in both states, because independent shocks make tomorrow's expected demand the same whatever happens today. The temptation is therefore strongest in the high state.

Optimal collusion. Define the *slack factor*

$$\kappa \equiv \frac{\delta}{(1-\delta)(N-1)}. \tag{12.30}$$

It rises with δ, falls with N, and equals one exactly when $\delta = \frac{N-1}{N}$, the patience threshold of Proposition 12.14. Multiplying (12.29) by $\frac{N}{N-1}$ gives

$$\pi_s(p_s) \le \kappa V, \qquad s = H, L. \tag{12.31}$$

Optimal collusion selects the most collusive equilibrium in the sense of Section 12.2.5: the subgame perfect equilibrium that maximizes the firms' expected profit V. It is convenient to choose profit levels $v_s = \pi_s(p_s) \in [0, \pi_s^M]$ instead of prices. Because π_s is strictly increasing on $[c, p_s^M]$, each v_s determines p_s uniquely. Substituting $V = \frac{1}{2}(v_H + v_L)$ into (12.31) and collecting terms gives

$$\left(1-\frac{\kappa}{2}\right) v_H \le \frac{\kappa}{2}\, v_L, \qquad \left(1-\frac{\kappa}{2}\right) v_L \le \frac{\kappa}{2}\, v_H.$$

If $\kappa \ge 2$ both constraints hold for all profit levels. If $\kappa < 2$ they read $v_H \le r v_L$ and $v_L \le r v_H$ with $r \equiv \frac{\kappa}{2-\kappa}$. Problems of this form recur in this section, so we solve them once.

Lemma 12.28 (Greatest point of a pair of linked constraints)**.** *Let $X_1, X_2 > 0$ and $a_1, a_2 \in (0, +\infty]$, where $a_i = +\infty$ means that the corresponding constraint is absent. Let*

$$S = \{(x_1, x_2) \in [0, X_1] \times [0, X_2] : x_1 \le a_1 x_2,\ x_2 \le a_2 x_1\}.$$

(i) If $a_1 a_2 < 1$, then $S = \{(0,0)\}$.

(ii) If $a_1 a_2 \ge 1$, then $x^* = (\min\{X_1, a_1 X_2\},\ \min\{X_2, a_2 X_1\})$ belongs to S and $x^* \ge x$ componentwise for every $x \in S$. At most one coordinate of x^* lies below its cap X_i.

Proof. (i) If $a_1 a_2 < 1$, both a_i are finite. For $x \in S$, $x_1 \le a_1 x_2 \le a_1 a_2 x_1$, so $(1 - a_1 a_2) x_1 \le 0$ and $x_1 = 0$. Then $x_2 \le a_2 x_1 = 0$.

(ii) Every $x \in S$ satisfies $x_1 \le \min\{X_1, a_1 x_2\} \le \min\{X_1, a_1 X_2\} = x_1^*$, and likewise $x_2 \le x_2^*$. It remains to show $x^* \in S$. Suppose first that both coordinates are capped, $x^* = (X_1, X_2)$. Then $X_1 \le a_1 X_2$ and $X_2 \le a_2 X_1$, so $x^* \in S$. Suppose next that $a_2 X_1 < X_2$, so $x^* = (\min\{X_1, a_1 X_2\}, a_2 X_1)$. Since $a_1 X_2 > a_1 a_2 X_1 \ge X_1$, the first coordinate equals X_1. The constraints read $X_1 \le a_1 a_2 X_1$, which holds, and $a_2 X_1 \le a_2 X_1$. The case $a_1 X_2 < X_1$ is symmetric. Both coordinates cannot fall below their caps, because $a_1 X_2 < X_1$ and $a_2 X_1 < X_2$ together imply $a_1 a_2 < 1$. □

The greatest point maximizes every coordinate at once. It therefore maximizes any objective that increases in both coordinates, such as the cartel's expected profit.

Proposition 12.29 (Four regimes of optimal collusion)**.** *Let Assumption 12.26 hold and define*

$$\bar{\kappa} \equiv \frac{2\pi_H^M}{\pi_H^M + \pi_L^M} \in (1, 2), \qquad \bar{\delta} \equiv \frac{\bar{\kappa}(N-1)}{1 + \bar{\kappa}(N-1)}. \tag{12.32}$$

The most collusive equilibrium of the form (12.27) is as follows.

(i) Regime 1 *($\kappa \ge \bar{\kappa}$, equivalently $\delta \ge \bar{\delta}$). Firms charge the monopoly price in both states.*

(ii) Regime 2 *($1 < \kappa < \bar{\kappa}$). Firms charge $p_L = p_L^M$. The boom price $p_H < p_H^M$ is the price on the increasing branch of π_H that solves*

$$\pi_H(p_H) = \frac{\kappa\, \pi_L^M}{2 - \kappa}. \tag{12.33}$$

(iii) Regime 3 *($\kappa = 1$, equivalently $\delta = \frac{N-1}{N}$). Both constraints bind, $\pi_H(p_H) = \pi_L(p_L) = \pi_L^M$, so $p_L = p_L^M$ and $p_H < p_L$.*

(iv) Regime 4 *($\kappa < 1$). Only the competitive outcome $p_H = p_L = c$ is sustainable.*

Proof. Apply Lemma 12.28 with $x_1 = v_H$, $x_2 = v_L$, $X_1 = \pi_H^M$ and $X_2 = \pi_L^M$. If $\kappa \ge 2$, set $a_1 = a_2 = +\infty$, and the greatest point is monopoly in both states. Since $\bar{\kappa} < 2$, this case belongs to regime 1. If $\kappa < 2$, set $a_1 = a_2 = r = \frac{\kappa}{2-\kappa}$. Then $r < 1$ exactly when $\kappa < 1$, and part (i) of the lemma gives regime 4. If $1 \le \kappa < 2$, then $r \ge 1$ and part (ii) gives

$$v_L^* = \min\{\pi_L^M, r\pi_H^M\} = \pi_L^M, \qquad v_H^* = \min\{\pi_H^M, r\pi_L^M\},$$

where the first equality uses $r\pi_H^M \ge \pi_H^M > \pi_L^M$. The boom profit is capped below π_H^M exactly when $r\pi_L^M < \pi_H^M$. Substituting r and rearranging,

$$\kappa\, \pi_L^M < (2 - \kappa)\, \pi_H^M \iff \kappa \left(\pi_H^M + \pi_L^M\right) < 2\pi_H^M \iff \kappa < \bar{\kappa}.$$

This yields regimes 1 and 2, with $v_H^* = r\pi_L^M$ in regime 2, which is (12.33). At $\kappa = 1$ we have $r = 1$ and $v_H^* = v_L^* = \pi_L^M$. Then $\pi_H(p_H) = \pi_L(p_L^M) < \pi_H(p_L^M)$. If $p_L^M \le p_H^M$, monotonicity of π_H on $[c, p_H^M]$ gives $p_H < p_L^M$. If $p_L^M > p_H^M$, then $p_H \le p_H^M < p_L^M$. Either way $p_H < p_L$. Finally, $\kappa \ge \bar{\kappa}$ means $\frac{\delta}{1-\delta} \ge \bar{\kappa}(N-1)$, which rearranges to $\delta \ge \bar{\delta}$. The greatest point maximizes V, so it is the most collusive equilibrium. □

Two checks are useful. Without fluctuations, $\pi_H^M = \pi_L^M$, so $\bar{\kappa} = 1$ and $\bar{\delta} = \frac{N-1}{N}$, the threshold of the constant-demand Bertrand supergame. With fluctuations, $\bar{\kappa} - 1 = \frac{\pi_H^M - \pi_L^M}{\pi_H^M + \pi_L^M}$. The range of discount factors with state-dependent pricing widens with the dispersion of monopoly profits. The next result says when the boom price lies below the recession price.

Corollary 12.30 (Countercyclical prices in regime 2)**.** *Suppose $p_L^M \le p_H^M$, so the monopoly price is weakly higher in the high state. In regime 2, $p_H < p_L$ if and only if $\frac{\kappa}{2-\kappa} < \frac{\pi_H(p_L^M)}{\pi_L^M}$. The right side exceeds one, so the boom price is below the recession price for all κ in an interval above one. If instead $p_L^M > p_H^M$, then $p_H < p_L$ throughout regimes 2 and 3.*

Proof. In regime 2, $p_L = p_L^M$, and both p_H and p_L^M lie in $[c, p_H^M]$, where π_H is strictly increasing. So $p_H < p_L^M$ if and only if $\pi_H(p_H) < \pi_H(p_L^M)$. By (12.33) this is $\frac{\kappa}{2-\kappa}\pi_L^M < \pi_H(p_L^M)$. If $p_L^M > p_H^M$, then $p_H \le p_H^M < p_L^M = p_L$. □

Example 12.31 (Multiplicative demand shocks)**.** Let $D_s(p) = A_s(1-p)$ with $A_H > A_L > 0$ and $c = 0$. Then $\pi_s(p) = A_s p(1-p)$, so $p_H^M = p_L^M = \frac{1}{2}$ and $\pi_s^M = \frac{A_s}{4}$. The threshold for full monopoly is $\bar{\kappa} = \frac{2A_H}{A_H + A_L}$. In regime 2, (12.33) becomes

$$A_H\, p_H(1-p_H) = \frac{\kappa A_L}{4(2-\kappa)}.$$

The lower root of this quadratic is

$$p_H = \frac{1}{2}\left[1 - \sqrt{1 - \frac{\kappa A_L}{(2-\kappa)A_H}}\right] < \frac{1}{2} = p_L. \tag{12.34}$$

The recession price is the monopoly price, and the boom price is strictly lower throughout regime 2. Since $c = 0$, the price is also the margin $p - c$, so margins are countercyclical. With $N = 2$, $A_H = 1.5$ and $A_L = 1$ we get $\bar{\kappa} = 1.2$ and $\bar{\delta} = \frac{6}{11} \approx 0.545$. At $\kappa = 1$ the boom price is $\frac{1}{2}\left(1 - \sqrt{1 - \frac{A_L}{A_H}}\right) \approx 0.211$. At $\delta = 0.52$, where $\kappa \approx 1.083$, it is $p_H \approx 0.270$. Figure 12.5 plots both prices against δ.

What the regimes mean. In regime 2 the cartel concedes in the boom. It lowers the boom price until the gain from undercutting no longer exceeds the future loss. It keeps the recession price at the monopoly level, because a higher recession profit raises V and relaxes the boom constraint as well. The result is a pricing pattern that Rotemberg and Saloner (1986) call a *price war during a boom*: a period of low prices and margins when demand is high. Nobody cheats. The low boom price is part of the collusive agreement, chosen so that nobody wants to cheat.

Three caveats follow from the proposition. The prediction of countercyclical margins needs optimal collusion. The competitive outcome is also an equilibrium for every δ, and so is constant pricing at any price that satisfies both constraints. The prediction also needs intermediate patience. In the example, cyclical pricing occurs only for $\delta \in [0.5, 0.545)$. Finally, it relies on independent shocks. With persistent demand the future loss depends on today's state, and the conclusion can reverse, as Sections 12.4.3 and 12.4.4 show. Regime 3 is a knife-edge case with two states. With a continuum of states, profits are capped at a common level in all high states, and this pattern holds for an interval of discount factors. We turn to that model now.

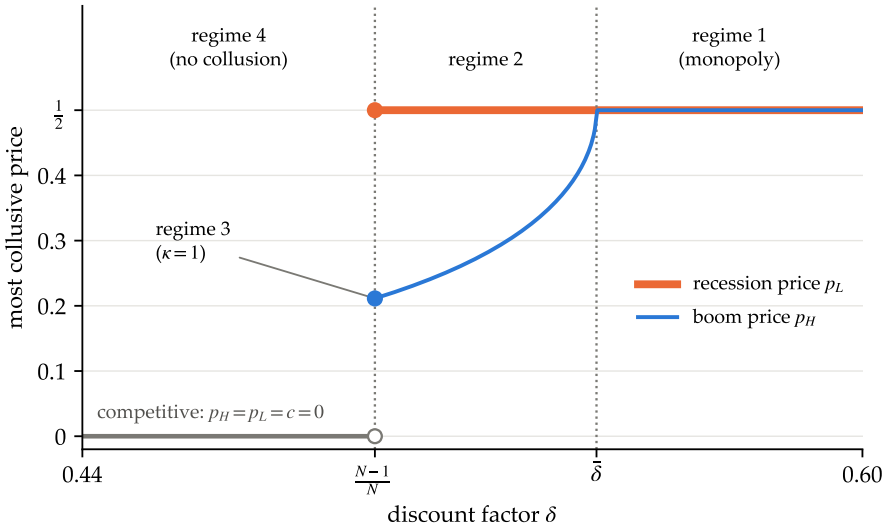

Figure 12.5: Most collusive prices in the two-state model of Example 12.31: $N = 2$, $c = 0$, $D_s(p) = A_s(1-p)$ with $A_H = 1.5$ and $A_L = 1$, each state with probability $\frac{1}{2}$. Below $\delta = \frac{N-1}{N} = \frac{1}{2}$ only competitive pricing is sustainable (regime 4). At $\delta = \frac{1}{2}$ both constraints bind (regime 3). Between $\frac{1}{2}$ and $\bar{\delta} = \frac{6}{11}$ the recession price is the monopoly price $\frac{1}{2}$ and the boom price is lower (regime 2). Above $\bar{\delta}$ both prices equal $\frac{1}{2}$ (regime 1). Script `rs_two_state.py`.

12.4.2 Rotemberg and Saloner (1986): price wars during booms

The question

Rotemberg and Saloner (1986) ask how implicitly colluding oligopolists behave when demand fluctuates. Their paper has two objectives (p. 1). The first is to describe oligopoly pricing over the business cycle. The second is to ask whether this pricing itself causes business cycles and sticky prices. Their basic point is that collusion is harder when demand is high. In a boom, "chiseling away from the collusive level of output becomes more profitable for each individual firm" (p. 1), so the oligopoly can sustain only a less collusive outcome. An oligopoly that becomes more competitive in booms expands output. If its output is an input to other sectors, their output can rise too. This produces the comovement of outputs that characterizes business cycles.

The question matters for industrial organization because it overturns a piece of folklore. Scherer (1980) wrote that price cutting "runs most rampant among oligopolists with high fixed costs" precisely when business conditions turn sour (his p. 208, quoted on p. 24). Rotemberg and Saloner concede that one can build models in which recessions cause price wars. "Our basis for rejecting this folklore is not theoretical," they write. "Instead our rejection is based on facts" (p. 4). We work from the 1984 working paper (Rotemberg and Saloner, 1984), which contains the model, the macroeconomic application and the evidence. Page and table numbers in this subsection refer to it.

The model

Assumption 12.32 (Observable independent demand shocks)**.**

(i) $N \geq 2$ symmetric firms sell a homogeneous good at constant marginal cost c and set prices simultaneously in each period. The lowest price serves the market, and ties split it equally.

(ii) Demand in period t is $D(p, \omega_t)$. The state ω_t is independent and identically distributed over time, with CDF F_ω whose support is $[\underline{\omega}, \bar{\omega}]$.

(iii) All firms learn ω_t before they set prices, and all past prices are observed.

(iv) For each ω, $\pi(p, \omega)$ is continuous, strictly increasing in p on $[c, p^m(\omega)]$, and uniquely maximized at $p^m(\omega)$, with $\pi^m(\omega) > 0$.

(v) For each $p > c$, $\pi(p, \omega)$ is strictly increasing in ω. The function π^m is continuous and $\mathbb{E}[\pi^m(\omega)] < \infty$.

(vi) Firms discount the future with factor $\delta \in (0, 1)$.

Part (v) says that a higher state shifts demand out. It implies that monopoly profit rises with the state, since for $\omega' > \omega$ we have $\pi^m(\omega') \geq \pi(p^m(\omega), \omega') > \pi^m(\omega)$. The timing in (iii) is the model's defining feature. Punishments depend on future states, so their expected size depends on the distribution of ω. The reward from cheating depends on the current state, which firms see. The authors show that "for a wide variety of interesting cases the reward for cheating from the joint profit-maximizing level is monotonically increasing in ϵ_t" (pp. 6–7). Here ϵ_t is the paper's symbol for ω_t.

A *collusive scheme* is a price schedule $p(\cdot)$ that assigns a price to each state. On the collusive path, every firm charges $p(\omega_t)$. After any deviation, all firms charge c forever. This Nash reversion holds every firm to its minmax payoff of zero, so it is the harshest credible punishment. Any outcome that some subgame perfect equilibrium sustains can therefore be sustained with Nash reversion. The authors make the same point about infinite reversion. "This length is optimal since it is the biggest credible threat and since, along the equilibrium path, firms never find themselves punishing each other" (p. 2). They also note that infinite punishments are less compelling if industry membership changes, and they use low discount factors in their numerical examples for that reason (p. 8).

As in Section 12.4.1, we may restrict attention to $p(\omega) \in [c, p^m(\omega)]$. Write $v(\omega) = \pi(p(\omega), \omega)$ for industry profit in state ω on the collusive path, and $\bar{E} = \mathbb{E}[v(\omega)]$ for its expectation. The argument that led to (12.29) applies state by state. A firm that conforms in state ω earns $\frac{1}{N} v(\omega) + \frac{\delta}{1-\delta} \frac{\bar{E}}{N}$, and the best deviation earns $v(\omega)$. The incentive constraint is

$$\frac{N-1}{N} v(\omega) \leq \frac{\delta}{1-\delta} \frac{\bar{E}}{N} \qquad \text{for all } \omega.$$

With the slack factor κ of (12.30) it reads

$$v(\omega) \leq \kappa \bar{E} \qquad \text{for all } \omega \in [\underline{\omega}, \bar{\omega}]. \tag{12.35}$$

The cap $\kappa \bar{E}$ is the same in every state, because the future does not depend on the present. The cap is also endogenous. A scheme that earns more on average can afford higher profit in each state.

The paper writes the same condition in terms of the *punishment* $K = \frac{\delta}{1-\delta}\mathbb{E}[\text{per-firm profit}]$, the expected discounted profit a deviator forfeits (eq. (1), p. 8). This K is the paper's symbol and has nothing to do with the capacity of Example 12.17. A firm deviates from joint profit maximization in state ϵ_t if $(N-1)\Pi^m > K$, where Π^m is per-firm monopoly profit (p. 7). The sustainable per-firm profit in high states is $\frac{K}{N-1}$ (eq. (2), p. 9). In our notation $K = \frac{\delta\bar{E}}{(1-\delta)N}$, so the per-firm cap $\frac{K}{N-1}$ equals $\frac{\kappa\bar{E}}{N}$, which is (12.35) divided by N.

The most collusive scheme as a fixed point

Every sustainable scheme satisfies $v(\omega) \leq \min\{\pi^m(\omega), \kappa\bar{E}\}$. This suggests the map

$$h(E) \equiv \mathbb{E}_\omega \left[\min\left\{\pi^m(\omega),\ \kappa E\right\}\right], \qquad E \geq 0, \tag{12.36}$$

which gives the expected profit of the scheme that charges monopoly prices wherever the cap κE allows it. The map h is continuous and nondecreasing, $h(0) = 0$, and $h(E) \leq \mathbb{E}[\pi^m] < \infty$. It is also concave, as the expectation of a minimum of two functions that are linear in E.

Lemma 12.33 (Sustainable profit levels)**.** *Under Assumption 12.32:*

(a) A number $E \geq 0$ is the expected profit of some sustainable scheme if and only if $E \leq h(E)$.

(b) Let E^* be the largest E with $E \leq h(E)$. Then $E^* = h(E^*)$, so E^* is the largest fixed point of h.

(c) The scheme $v^*(\omega) = \min\{\pi^m(\omega), \kappa E^*\}$ is sustainable. Every sustainable scheme satisfies $v(\omega) \leq v^*(\omega)$ in every state.

Proof. (a) If v is sustainable with mean E, then $v(\omega) \leq \min\{\pi^m(\omega), \kappa E\}$ for all ω. Taking expectations, $E \leq h(E)$. Conversely, $E = 0$ is the mean of the competitive scheme. If $0 < E \leq h(E)$, define

$$v(\omega) = \frac{E}{h(E)} \min\left\{\pi^m(\omega), \kappa E\right\}.$$

Its mean is E. Since $\frac{E}{h(E)} \leq 1$, it satisfies $v(\omega) \leq \pi^m(\omega)$ and $v(\omega) \leq \kappa E$ in every state. The second inequality is (12.35) at mean E, so v is sustainable.

(b) The set $\{E \geq 0 : E \leq h(E)\}$ is closed, by continuity, and bounded by $\mathbb{E}[\pi^m]$. So it has a largest element E^*. Suppose $E^* < h(E^*)$. Let $E' = h(E^*)$. Since h is nondecreasing, $h(E') \geq h(E^*) = E'$, so E' belongs to the set and exceeds E^*, a contradiction.

(c) Sustainability of v^* follows from (a) and $E^* = h(E^*)$. If v is sustainable with mean $\bar{E}$, then $\bar{E} \leq E^*$ by (a) and (b), so $v(\omega) \leq \min\{\pi^m(\omega), \kappa\bar{E}\} \leq v^*(\omega)$. □

Part (c) says that the most collusive scheme is the best for the firms in every state at once. There is no tradeoff between states, so "most collusive" is well defined. The paper describes the same construction as a mapping from punishments to cutoffs and back to punishments, and selects the greatest fixed point (pp. 9–10).

Proposition 12.34 (Collusion with observable independent shocks)**.** *Let Assumption 12.32 hold and let E^* be the largest fixed point of h.*

(i) If $\kappa < 1$, equivalently $\delta < \frac{N-1}{N}$, then $E^* = 0$. Only competitive pricing is sustainable.

(ii) If $\kappa = 1$, then $E^* = \pi^m(\underline{\omega})$. Industry profit is the same in every state, equal to the monopoly profit of the lowest state.

(iii) If $\kappa > 1$, then $E^* > 0$ and $\kappa E^* > \pi^m(\underline{\omega})$. Firms charge monopoly prices in every state if and only if $\kappa\,\mathbb{E}[\pi^m(\omega)] \geq \pi^m(\bar{\omega})$. Otherwise there is a cutoff $\omega^* \in (\underline{\omega}, \bar{\omega})$ with $\pi^m(\omega^*) = \kappa E^*$, and

$$v^*(\omega) = \begin{cases} \pi^m(\omega) & \text{if } \omega \leq \omega^*, \\ \kappa E^* = \pi^m(\omega^*) & \text{if } \omega > \omega^*. \end{cases} \tag{12.37}$$

The cutoff solves

$$\pi^m(\omega^*)\left[1 - \kappa\left(1 - F_\omega(\omega^*)\right)\right] = \kappa \int_{\underline{\omega}}^{\omega^*} \pi^m(\omega)\,\mathrm{d}F_\omega(\omega). \tag{12.38}$$

(iv) The values E^* and κE^* and the cutoff ω^* are nondecreasing in κ. They are therefore nondecreasing in δ and nonincreasing in N.

Proof. (i) If $\kappa < 1$ and $E > 0$, then $h(E) \leq \kappa E < E$. So the only fixed point is $E^* = 0$.

(ii) If $\kappa = 1$, then $h(E) = \mathbb{E}[\min\{\pi^m(\omega), E\}] \leq E$, with equality if and only if $\pi^m(\omega) \geq E$ with probability one. Because $\underline{\omega}$ is in the support and π^m is continuous and increasing, this holds if and only if $E \leq \pi^m(\underline{\omega})$. The fixed points form the interval $[0, \pi^m(\underline{\omega})]$, and the largest is $\pi^m(\underline{\omega})$. Then $v^*(\omega) = \min\{\pi^m(\omega), \pi^m(\underline{\omega})\} = \pi^m(\underline{\omega})$ in every state.

(iii) Let $\phi(E) = h(E) - E$. For $0 < E \leq \frac{\pi^m(\underline{\omega})}{\kappa}$, the cap κE lies below $\pi^m(\omega)$ in every state, so $h(E) = \kappa E$ and $\phi(E) = (\kappa - 1)E > 0$. As $E \to \infty$, $\phi(E) \leq \mathbb{E}[\pi^m] - E \to -\infty$. By continuity ϕ has a root above $\frac{\pi^m(\underline{\omega})}{\kappa}$, so $E^* > \frac{\pi^m(\underline{\omega})}{\kappa} > 0$.

If $\kappa\mathbb{E}[\pi^m] \geq \pi^m(\bar{\omega})$, then $h(\mathbb{E}[\pi^m]) = \mathbb{E}[\pi^m]$, because the cap never binds. No fixed point exceeds $\mathbb{E}[\pi^m]$, so $E^* = \mathbb{E}[\pi^m]$ and $v^* = \pi^m$. Conversely, if $v^* = \pi^m$ almost surely, then $E^* = \mathbb{E}[\pi^m]$ and $\pi^m(\omega) \leq \kappa\mathbb{E}[\pi^m]$ for almost every ω, hence at $\bar{\omega}$ by continuity.

Otherwise $\pi^m(\underline{\omega}) < \kappa E^* < \pi^m(\bar{\omega})$. Since π^m is continuous and strictly increasing, there is a unique ω^* with $\pi^m(\omega^*) = \kappa E^*$, and v^* takes the form (12.37). The fixed-point condition $E^* = h(E^*)$ reads

$$E^* = \int_{\underline{\omega}}^{\omega^*} \pi^m(\omega)\,\mathrm{d}F_\omega(\omega) + \left(1 - F_\omega(\omega^*)\right)\kappa E^*.$$

Substitute $E^* = \frac{\pi^m(\omega^*)}{\kappa}$ and multiply by κ:

$$\pi^m(\omega^*) = \kappa \int_{\underline{\omega}}^{\omega^*} \pi^m(\omega)\,\mathrm{d}F_\omega(\omega) + \kappa\left(1 - F_\omega(\omega^*)\right)\pi^m(\omega^*).$$

Collecting the terms in $\pi^m(\omega^*)$ gives (12.38).

(iv) Write h_κ to show the dependence on κ. For $\kappa' > \kappa$, $h_{\kappa'}(E) \geq h_\kappa(E)$ for all E. So $E^*_\kappa = h_\kappa(E^*_\kappa) \leq h_{\kappa'}(E^*_\kappa)$. By Lemma 12.33(a) and (b), $E^*_{\kappa'} \geq E^*_\kappa$. Then $\kappa' E^*_{\kappa'} \geq \kappa E^*_\kappa$, and the cutoff $\omega^* = (\pi^m)^{-1}(\kappa E^*)$ rises weakly. Finally, κ increases in δ and decreases in N. □

Part (i) says that demand fluctuations do not change the patience needed for any collusion at all. Some collusion is possible exactly when $\delta \geq \frac{N-1}{N}$, as with constant demand. Fluctuations change the form of collusion above that threshold. Part (iv) restates two claims of the paper (p. 11). The set of states with monopoly pricing shrinks as N grows, "as in Stigler's model" (Stigler, 1964). It also shrinks as the future becomes less important.

Remark 12.35 (The existence conditions in the working paper). The working paper states two sufficient conditions for an interior cutoff (pp. 9–10). Its condition (ii) says that monopoly profit in the highest state exceeds κ times its mean, which is the failure of full monopoly in Proposition 12.34(iii). Its condition (i), which should ensure that some collusion is possible, is stated in a form that appears to come from typographical sign errors in its equations (3) and (5). We have derived the conditions directly. Collusion is possible if and only if $\kappa \geq 1$, and an interior cutoff exists if and only if in addition $\kappa\,\mathbb{E}[\pi^m] < \pi^m(\bar{\omega})$.

The price schedule

The profit schedule (12.37) translates into prices. Below the cutoff the cartel charges the monopoly price. Above it, profit must stay at the cap κE^* while demand keeps rising.

Proposition 12.36 (Collusive prices fall in booms)**.** *Let Assumption 12.32 hold with $\kappa > 1$ and an interior cutoff ω^*. Suppose π is continuously differentiable, $\pi_p > 0$ on $(c, p^m(\omega))$, and $\pi_\omega > 0$ for $p > c$. Let $p^*(\omega)$ be the most collusive price schedule.*

(i) For $\omega \leq \omega^*$, $p^*(\omega) = p^m(\omega)$.

(ii) For $\omega > \omega^*$, $p^*(\omega)$ is the unique $p \in (c, p^m(\omega))$ with $\pi(p, \omega) = \kappa E^*$, and

$$\frac{\mathrm{d}p^*}{\mathrm{d}\omega} = -\frac{\pi_\omega(p^*, \omega)}{\pi_p(p^*, \omega)} < 0. \tag{12.39}$$

(iii) For $\omega > \omega^*$, industry output $D(p^*(\omega), \omega)$ increases in ω.

(iv) If p^m is nondecreasing, then p^* attains its maximum at ω^*, and the ratio $\frac{p^*(\omega)}{p^m(\omega)}$ decreases strictly on $(\omega^*, \bar{\omega}]$.

Proof. (i) is (12.37). For (ii), fix $\omega > \omega^*$. Then $\pi(c, \omega) = 0 < \kappa E^* < \pi^m(\omega)$. Since $\pi(\cdot, \omega)$ is continuous and strictly increasing on $[c, p^m(\omega)]$, there is exactly one $p \in (c, p^m(\omega))$ with $\pi(p, \omega) = \kappa E^*$. Differentiate the identity $\pi(p^*(\omega), \omega) = \kappa E^*$ with respect to ω:

$$\pi_p(p^*, \omega)\,\frac{\mathrm{d}p^*}{\mathrm{d}\omega} + \pi_\omega(p^*, \omega) = 0.$$

Solving gives (12.39). The sign follows from $\pi_\omega > 0$ and $\pi_p > 0$ below the monopoly price. The implicit function theorem justifies the differentiation because $\pi_p \neq 0$ at p^*. For (iii), write $D(p^*, \omega) = \frac{\kappa E^*}{p^* - c}$. The numerator is constant and the denominator falls. For (iv), p^* rises weakly up to ω^* and falls after it. On $(\omega^*, \bar{\omega}]$ the numerator of $\frac{p^*}{p^m}$ falls while the denominator does not. □

The intuition is in the paper (pp. 10–11). Above the cutoff, profit is held at the sustainable level. "If P is held constant at a level above c, the profits from deviating increase. Therefore P must fall. Beyond ϵ_t^*, prices fall monotonically as ϵ_t increases." Output rises in booms for two reasons: demand shifts out and the price falls. With multiplicative shocks the monopoly price does not depend on the state, so the collusive price is constant up to ω^* and decreasing after it. Prices are then countercyclical over the whole range of states. With additive shocks the monopoly price rises with demand. The collusive price then rises up to ω^* and falls after it.

A numerical illustration. Figure 12.6 computes the most collusive schedule for $N = 2$, $c = 0$ and $\omega \sim U[1, 2]$. The script finds E^* by iterating $E \leftarrow h(E)$ from $E = \mathbb{E}[\pi^m]$. The iterates decrease

and converge to the largest fixed point. In panel (a), demand is $D(p,\omega)=\omega(1-p)$, so $p^m=\frac{1}{2}$ and $\pi^m(\omega)=\frac{\omega}{4}$. Then $\mathbb{E}[\pi^m]=0.375$. Full monopoly requires $\kappa\cdot 0.375\geq\pi^m(2)=\frac{1}{2}$, that is $\kappa\geq\frac{4}{3}$, or $\delta\geq\frac{4}{7}\approx 0.571$. With the uniform distribution, (12.38) becomes

$$\frac{\omega^*}{4}\left[1-\kappa(2-\omega^*)\right]=\kappa\int_1^{\omega^*}\frac{\omega}{4}\,\mathrm{d}\omega=\frac{\kappa\left((\omega^*)^2-1\right)}{8}.$$

Multiplying by $\frac{8}{\kappa}$ and collecting terms gives the quadratic

$$(\omega^*)^2-\left(4-\frac{2}{\kappa}\right)\omega^*+1=0,$$

whose larger root is the cutoff. At $\delta=0.52$, $\kappa\approx 1.083$, $E^*\approx 0.341$, the cap is $\kappa E^*\approx 0.369$ and $\omega^*\approx 1.477$. The price falls from $\frac{1}{2}$ at the cutoff to about 0.244 in the highest state. At $\delta=0.56$ the cutoff moves up to $\omega^*\approx 1.903$, and the price in the highest state is about 0.390. In panel (b), demand is $D(p,\omega)=\omega-p$, so $p^m(\omega)=\frac{\omega}{2}$ and $\pi^m(\omega)=\frac{\omega^2}{4}$. Full monopoly requires $\delta\geq\frac{12}{19}\approx 0.632$. At $\delta=0.54$ the cutoff is $\omega^*\approx 1.50$. The price rises to 0.75 there and then falls to about 0.339 in the highest state, where the monopoly price is 1. At $\delta=0.60$ the cutoff is $\omega^*\approx 1.855$ and the price peaks at about 0.927.

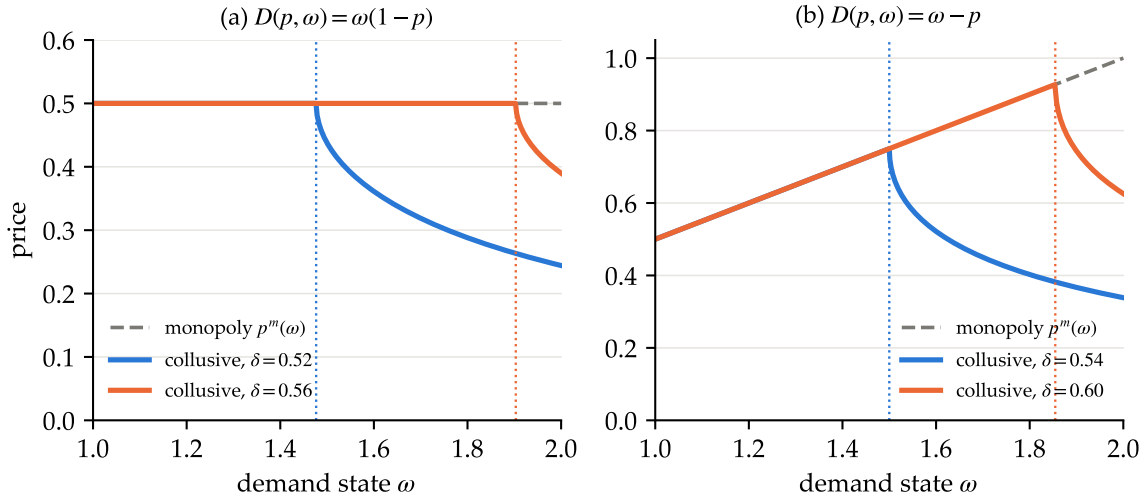

Figure 12.6: Most collusive price schedules with observable independent demand shocks: $N=2$, $c=0$, $\omega\sim U[1,2]$. Panel (a): multiplicative shocks, $D(p,\omega)=\omega(1-p)$. Panel (b): additive shocks, $D(p,\omega)=\omega-p$. Dashed: monopoly price $p^m(\omega)$. Solid: collusive price $p^*(\omega)$ for two discount factors. Dotted vertical lines mark the cutoffs ω^* of Proposition 12.34. Below the cutoff the collusive price equals the monopoly price. Above it, profit is capped at κE^* and the price falls as demand rises. Script `rs_continuum.py`.

Collude or compete

In the optimal scheme no price war is ever observed. The cartel lowers its price smoothly in booms. The paper also studies a simpler set of strategies in which the cartel can only choose between the monopoly price and the competitive price (p. 12). Such strategies are "much

simpler and less delicate." With this restriction "the firms know that when demand is high the monopoly outcome cannot be maintained. They therefore assume that the competitive outcome will emerge, which is sufficient to fulfill their prophecy."

Formally, a *collude-or-compete scheme* charges $p^m(\omega)$ in a set C of states and c outside it. In states outside C all firms charge c, a static Nash equilibrium, so nobody wants to deviate there. In a state $\omega \in C$ the incentive constraint is $\pi^m(\omega) \le \kappa E_R$, where $E_R = \mathbb{E}[\pi^m(\omega)\mathbf{1}\{\omega \in C\}]$. Including a low state in C raises E_R without raising the largest profit to be protected. So the best set is an interval $[\underline{\omega}, x]$, and the scheme is sustainable if and only if

$$\pi^m(x) \le \kappa \int_{\underline{\omega}}^{x} \pi^m(\omega)\, \mathrm{d}F_\omega(\omega). \tag{12.40}$$

A sustainable collude-or-compete scheme is also sustainable in the unrestricted problem. So $E_R \le E^*$, and when x is interior, $\pi^m(x) \le \kappa E_R \le \kappa E^* = \pi^m(\omega^*)$, so $x \le \omega^*$. The cartel colludes in fewer states than under the optimal scheme, as the paper states. Above x the price drops from $p^m(x)$ to c: an outright price war, triggered by high demand. This version is the one that connects with empirical studies that classify periods as collusive or competitive, such as Bresnahan (1987) and Porter (1983a).

Remark 12.37 (When do collude-or-compete schemes produce wars?). Condition (12.40) can fail for every interior x even when the optimal scheme sustains a lot of collusion. In the two-state model, colluding only in the low state requires $\pi_L^M \le \kappa \cdot \frac{1}{2}\pi_L^M$, that is $\kappa \ge 2$. But $\bar{\kappa} < 2$, so for $\kappa \ge 2$ the cartel can already charge monopoly prices in both states. The restricted scheme is all or nothing. The same happens in both examples of Figure 12.6. Our computation gives $E_R = 0$ at all four discount factors shown, although the optimal scheme earns between 82 and almost 100 percent of expected monopoly profit there. The right side of (12.40) is small for x near $\underline{\omega}$. A war region at the top therefore requires a distribution in which very high states are rare. Then the low states accumulate enough profit to protect collusion up to some x, and the thin upper tail adds too little to protect collusion beyond it.

The shares in the remark are $\frac{0.341}{0.375} \approx 0.91$ and $\frac{0.374}{0.375} \approx 0.997$ in panel (a), and $\frac{0.479}{0.583} \approx 0.82$ and $\frac{0.573}{0.583} \approx 0.98$ in panel (b).

Increasing marginal cost

The model so far assumes constant marginal cost. Increasing marginal cost complicates the model in three ways (p. 12). First, a price cutter may not want to supply all demand at its price, since it never produces where marginal cost exceeds price. Second, the profit that the cartel can sustain differs across states, unlike in the constant-cost case. Third, cheating can take the form of raising price, since rivals that are unwilling to supply all demand at their price leave some customers for a firm that charges more.

When deviators do not meet all demand, the paper uses the envelope theorem (p. 13). Suppose first that the cartel charges the monopoly price, which rises with demand. A deviator produces its output q^d where marginal cost equals the collusive price. By the envelope theorem its profit rises with the state at rate $q^d \frac{\partial P}{\partial \omega}$, where P is inverse demand. A conforming firm's profit rises at the smaller rate $q^m \frac{\partial P}{\partial \omega}$, because $q^m < q^d$. Deviation therefore becomes more tempting as demand rises. Suppose instead that the cartel holds its price fixed as demand rises. The deviation profit then stays fixed. The conforming profit rises, because the collusive price exceeds marginal cost, and the temptation falls.

When deviators meet all demand, the paper works with the linear example

$$P = a + \omega - bQ, \qquad C(q_i) = c\,q_i + \frac{d}{2}q_i^2, \tag{12.41}$$

where Q is industry output and C is each firm's cost (eqs. (6) and (7)). A cartel that splits output equally maximizes $(a+\omega-bQ)Q - cQ - \frac{d}{2N}Q^2$. The first-order condition $a+\omega-2bQ-c-\frac{d}{N}Q = 0$ gives monopoly output and price (eqs. (8) and (9)):

$$Q^m = \frac{a+\omega-c}{2b+\frac{d}{N}}, \qquad P^m = a+\omega-bQ^m = \frac{(a+\omega)(bN+d)+bNc}{2bN+d}.$$

A deviator charging just below P^m would like to produce where $c + dq = P^m$, that is

$$\bar{q} = \frac{P^m - c}{d} = \frac{(a+\omega-c)\left(b+\frac{d}{N}\right)}{d\left(2b+\frac{d}{N}\right)}$$

(eq. (10)). Dividing, $\frac{\bar{q}}{Q^m} = \frac{b+\frac{d}{N}}{d}$. The deviator meets all demand if and only if $\bar{q} \geq Q^m$, that is $b \geq \frac{(N-1)d}{N}$. Marginal cost must not rise too steeply and N must not be too large. When the deviator meets demand, it sells Q^m at P^m alone, so

$$\Pi^d = P^m Q^m - cQ^m - \frac{d}{2}(Q^m)^2.$$

Per-firm collusive profit is $\Pi^m = \frac{1}{N}(P^m Q^m - cQ^m) - \frac{d}{2}\left(\frac{Q^m}{N}\right)^2$. Hence

$$\Pi^d - N\Pi^m = -\frac{d}{2}(Q^m)^2 + \frac{d}{2N}(Q^m)^2 = \frac{Nd(1-N)}{2}(q^m)^2, \qquad q^m = \frac{Q^m}{N},$$

which is eq. (11). By the envelope theorem, $\frac{\mathrm{d}\Pi^m}{\mathrm{d}\omega} = q^m$. Since $\Pi^d - \Pi^m = (N-1)\Pi^m + \frac{Nd(1-N)}{2}(q^m)^2$ and $\frac{\mathrm{d}q^m}{\mathrm{d}\omega} = \frac{1}{2bN+d}$,

$$\frac{\mathrm{d}(\Pi^d - \Pi^m)}{\mathrm{d}\omega} = (N-1)q^m - Nd(N-1)\frac{q^m}{2bN+d} = \frac{(N-1)q^m\,(2bN - d(N-1))}{2bN+d}, \tag{12.42}$$

which is eq. (12). It is positive whenever the deviator meets demand, because then $2bN \geq 2d(N-1) > d(N-1)$. Cheating becomes more attractive as demand rises.

The paper computes the optimal schedule numerically. For a given punishment, the sustainable price in each state solves a quadratic equation. The punishment is then updated, starting from a large value and iterating to the first fixed point (p. 14). Its Figure 1 uses $a = 60$, $b = 1$, $c = 0$, $d = \frac{1}{3}$, $\delta = 0.7$, $N = 5$ and a state uniform on $\{0, 1, \ldots, 80\}$. By eq. (9) the monopoly price rises linearly from about 30.97 in state 0 to about 72.26 in state 80 (our computation). The collusive price equals the monopoly price only in the lowest states. It then falls, reaches a minimum in the middle of the range of states, and rises slowly at high states. The rise at the top has a simple cause (p. 15). In high states the collusive price is so low that a deviator would expand only until price equals its marginal cost. It would no longer serve the whole market. From there, higher demand at a constant price reduces the temptation, "thus the oligopoly can afford to increase its prices somewhat."

Quantity competition

With quantities as strategic variables two things change (p. 15). A deviator takes rivals' outputs as given, so its residual demand is market demand shifted left by their combined output. And the punishment is the Cournot equilibrium, which yields positive profit. The results are weaker than with prices. Higher demand need not raise the temptation to cheat. The paper gives a counterexample (p. 16 and its Figure 2). Suppose demand has constant elasticity and a shock shifts it horizontally. Then the collusive price is the same in both states, and a deviator faces the same residual demand curve in both, up to a horizontal translation. The extra sales from cheating are the same in both states, but the revenue lost on the units it would have sold anyway is smaller in the low state. So the incentive to deviate is strictly larger in the low state. The authors draw a related conclusion: if the cartel keeps its price constant when demand shifts horizontally, the incentive to cheat falls.

A short calculation makes the counterexample precise. Let marginal cost be a constant c, and let $\bar{p}$ be the collusive price in both states. In the high state ω'' demand exceeds demand in the low state ω' by a constant $k > 0$ at every price. Each firm's collusive output is $q^s(\omega) = \frac{1}{N} D(\bar{p}, \omega)$, so $q^s(\omega'') > q^s(\omega')$. Rivals keep producing $(N-1)q^s(\omega)$. A deviator that charges $p < \bar{p}$ therefore sells $D(p,\omega) - (N-1)q^s(\omega) = q^s(\omega) + y(p)$. The extra sales $y(p) = D(p,\omega) - D(\bar{p},\omega)$ are the same in both states, because the shift k cancels. The deviator's gain over its conforming profit $\Pi^s(\omega) = (\bar{p} - c)\, q^s(\omega)$ is

$$\begin{aligned}\Pi^d(p,\omega) - \Pi^s(\omega) &= (p-c)\big[q^s(\omega) + y(p)\big] - (\bar{p}-c)\, q^s(\omega) \\ &= (p-c)\, y(p) - (\bar{p}-p)\, q^s(\omega).\end{aligned}$$

The first term is the profit on the extra sales, the equal segments AB and CD of the paper's Figure 2 (p. 16). The second term is the loss on the units the firm would have sold anyway, and it rises with $q^s(\omega)$. Hence every deviation price $p < \bar{p}$ gains strictly more in the low state. If some deviation pays in the high state, the best deviation pays strictly more in the low state.

With linear demand and cost (12.41), higher demand always raises the temptation. Suppose each firm is asked to produce q^s. A deviator maximizes (eq. (13))

$$\Pi^d = q_i \left[a + \omega - c - b\left((N-1)q^s + q_i\right)\right] - \frac{d}{2} q_i^2,$$

and the first-order condition gives (eq. (14))

$$q^d = \frac{a + \omega - c - b(N-1)q^s}{2b + d}.$$

Let $X = a + \omega - c$ and evaluate at the monopoly output $q^s = q^m = \frac{X}{2bN+d}$. The term in brackets of the deviator's problem is $A \equiv X - b(N-1)q^m = \frac{X(bN+b+d)}{2bN+d}$, and the deviator earns $\Pi^d = \frac{A^2}{2(2b+d)}$. A conforming firm earns $\Pi^m = q^m(X - bNq^m) - \frac{d}{2}(q^m)^2 = \frac{X^2}{2(2bN+d)}$. Subtracting, and using $(bN+b+d)^2 - (2b+d)(2bN+d) = b^2(N-1)^2$,

$$\Pi^d - \Pi^m = \frac{b^2(N-1)^2 X^2}{2(2b+d)(2bN+d)^2}, \qquad \frac{\mathrm{d}(\Pi^d - \Pi^m)}{\mathrm{d}\omega} = \frac{[b(N-1)]^2\,(a+\omega-c)}{(d+2bN)^2(2b+d)} > 0.$$

The derivative is the expression on p. 17 of the paper. If the cartel can only collude or compete, high states produce price wars. If it can choose output freely, it raises output in high states just enough to deter deviation. The paper's Figure 3 uses $a = 60$, $b = 1$, $c = 0$, $d = \frac{1}{3}$, $\delta = 0.7$ and

$N = 5$, the parameters of its Figure 1. It plots the ratio of the collusive to the monopoly price. The ratio equals one in states up to about 61 and then falls almost linearly to about 0.92 in state 80 (values read from the figure). The figure's axis is labeled "Monopoly Price/Oligopoly Price," but the text and the plotted values below one show that it is the oligopoly price relative to the monopoly price. These quantity results hold within Nash-reversion punishments. In the Cournot supergame harsher credible punishments exist (Section 12.3), and with them the cap would be higher.

From oligopoly pricing to business cycles

The paper's Section III embeds the oligopoly in a two-sector general equilibrium model (pp. 19–23). Sector 1 is competitive and sector 2 is the oligopoly. Workers supply any amount of labor at a wage equal to the price of good 1, and both are normalized to one. Good 1 is produced from labor L_{1t} and an input Q_{21t} of good 2 (p. 19),

$$Q_{1t} = A_1 Q_{21t} - \frac{B_1}{2} Q_{21t}^2 + G_1 L_{1t} - \frac{H_1}{2} L_{1t}^2. \tag{12.43}$$

Competitive firms equate the price of each input with its marginal revenue product. For good 2 this gives the input demand

$$P_{2t} = A_1 - B_1 Q_{21t} \quad \Longleftrightarrow \quad Q_{21t} = \frac{A_1 - P_{2t}}{B_1}.$$

For labor it gives $G_1 - H_1 L_{1t} = 1$, so employment in sector 1 is constant. Consumers' inverse demand for good 2 is $P_{2t} = A_c - B_c Q_{2ct} + e_t$, where e_t is an i.i.d. taste shock. Add the two demands, $Q_{2t} = Q_{21t} + Q_{2ct}$, and solve for P_{2t}:

$$P_{2t} = a + \omega_t - b Q_{2t}, \qquad a = \frac{A_c B_1 + B_c A_1}{B_c + B_1}, \quad b = \frac{B_c B_1}{B_c + B_1}, \quad \omega_t = \frac{B_1}{B_c + B_1} e_t.$$

This is the linear demand of (12.41). Producing Q_{2t} requires $c Q_{2t} + \frac{d}{2} Q_{2t}^2$ units of labor, so marginal cost is $c + d Q_{2t}$ as in the partial-equilibrium model (p. 20).[1]

The two outputs are linked through the price of good 2. Differentiate (12.43) along the input demand:

$$\frac{\partial Q_{1t}}{\partial P_{2t}} = \left(A_1 - B_1 Q_{21t}\right) \frac{\partial Q_{21t}}{\partial P_{2t}} = P_{2t} \cdot \left(-\frac{1}{B_1}\right) < 0.$$

Output of good 2 is $Q_{2t} = \frac{a + \omega_t - P_{2t}}{b}$, which rises with ω_t and falls with P_{2t}. Suppose first that sector 2 is competitive, or always acts as a monopolist. Both the competitive and the monopoly price rise with ω_t, so a taste shift toward good 2 lowers the output of good 1 (p. 20). The two outputs move in opposite directions, and the economy moves along a production possibility frontier. Suppose instead that the oligopoly plays the optimal supergame with prices as the strategic variable. A higher ω_t can then lower P_{2t} (Section 12.4.2). Sector 1 buys more of the input and expands, and sector 2 sells more as well. Both outputs rise together, as all outputs do in a boom (p. 21). Profits can still be procyclical, because revenue minus total cost can rise

[1] Rotemberg and Saloner write $\alpha, \beta, \gamma, \xi, n, m$ and ε_t for our $A_1, B_1, G_1, H_1, A_c, B_c$ and ω_t. Their equations (14) and (16) on pp. 19–20 print the labor demand as $\frac{1+\gamma}{\xi}$ and the intercept as $\frac{n\beta + m\gamma}{m+\beta}$. The first-order conditions give $\frac{\gamma - 1}{\xi}$ and $\frac{n\beta + m\alpha}{m+\beta}$. Neither difference affects the argument. The working paper's numbers (13) and (14) for these equations repeat numbers already used on p. 17, so we cite the section by page.

with output when there are fixed costs, even as margins fall (p. 22). The authors argue that this mechanism makes sticky prices and a multiplier natural. They also argue that stabilization policy could be harmful if booms reflect shifts toward oligopolistic goods. "If demand for the goods produced by oligopolies were stable they might collude always, leaving the economy in a permanent recession" (p. 37).

The evidence

Section IV of the paper confronts the folklore with four kinds of evidence (pp. 24–36). None of them is a structural test. Each asks whether prices or margins in concentrated industries fall when demand is high.

The folklore. Scherer (1980) cites three industries in support of the folklore: rayon, cement and steel. The rayon evidence shows mainly that the nominal price of rayon fell in the Great Depression, when broad price indices also fell. That is "hardly proof of a price war" (p. 24). For steel, Scherer himself grants that the industry avoided "widespread price deterioration, even when operating at less than 65% capacity between 1958 and 1962" (p. 24). That leaves cement.

Cement: data and estimating equation. The data are yearly from 1947 to 1981. The cement price p_t^c is the average price of portland cement from the Bureau of Mines' *Minerals Yearbook*. It is deflated either by the producer price index PPI_t or by the price index of construction materials p_t^{con}, both from the Bureau of Labor Statistics. The regression relates the yearly growth rate of the real cement price to the contemporaneous growth rate of GNP. In log-difference notation,

$$\Delta \ln \left(\frac{p_t^c}{P_t} \right) = \beta_0 + \beta_1 \Delta \ln GNP_t + u_t, \qquad u_t = \phi \, u_{t-1} + e_t, \qquad P_t \in \left\{ PPI_t, \; p_t^{con} \right\}. \tag{12.44}$$

The paper describes the variables as yearly growth rates and does not say whether they are log differences or percentage changes. Columns (1) and (3) of its Table 1 are ordinary least squares with $\phi = 0$. The Durbin-Watson statistics of these regressions are low, so columns (2) and (4) re-estimate the equation with first-order autoregressive errors, "quasi-differenced" in the paper's words (p. 25). The paper does not say which feasible generalized least squares procedure it uses.

The identifying assumption is that GNP growth shifts the demand for cement and is unrelated to the cost and capacity shocks of the cement industry. The theory predicts $\beta_1 < 0$: when demand grows faster, the collusive price falls relative to other prices. A competitive industry with rising marginal cost, or a monopoly with procyclical monopoly prices, would instead show $\beta_1 \geq 0$.

Cement: results. Table 12.3 shows a negative coefficient on GNP growth in all four columns. "A 1% increase in the rate of growth of GNP leads to a 0.5–1.0% fall in the price of cement" (p. 25). After the correction for autocorrelation the coefficients are significant at the 5 percent level. The t-ratios are $\frac{-0.456}{0.197} \approx -2.3$ in column (2) and $\frac{-0.876}{0.149} \approx -5.9$ in column (4). The ordinary least squares standard errors in columns (1) and (3) are not reliable given the low Durbin-Watson statistics. The anecdotes agree. The real price of cement rose in the recession years 1954 and 1958 and fell in the boom years 1955 and 1959 (p. 25).

Cement: caveats. The authors raise two objections themselves (pp. 25–26). First, the demand for cement might be only weakly related to GNP. Cement output growth has a correlation of 0.69 with GNP growth and 0.77 with the growth of construction, which is procyclical. These correlations do not show that cement is more cyclical than the typical sector in GNP. Without

Table 12.3: The cyclical behavior of real cement prices, yearly data 1947–1981

Dependent variable: growth of	(1) $\frac{p^c}{PPI}$	(2) $\frac{p^c}{PPI}$	(3) $\frac{p^c}{p^{con}}$	(4) $\frac{p^c}{p^{con}}$

Durbin-Watson	1.03	1.73	1.28	1.92

Notes: Estimates of (12.44). p^c is the price of cement, *PPI* the producer price index and p^{con} the price index of construction materials. Columns (1) and (3) are ordinary least squares. Columns (2) and (4) allow first-order autocorrelated errors and are estimated on quasi-differenced data. Standard errors in parentheses. The paper reports no sample size. Yearly data for 1947–1981 give at most 35 growth rates. Source: Rotemberg and Saloner (1984), Table 1.

a structural model the question cannot be settled. Second, the regression omits variables a reduced form should contain, such as the capacity of cement plants. The authors reply that capacity is endogenous and that adjustment costs make it unresponsive to GNP in the short run. Three further concerns are worth stating. Input costs, such as energy prices in the 1970s, may move against GNP and enter the cement price directly. If the construction-materials index in columns (3) and (4) is procyclical, the deflated price is mechanically more countercyclical, which may explain why those coefficients are larger. And a negative β_1 is consistent with any model in which margins fall in booms, including models with capacity constraints or countercyclical demand elasticities. The regression supports the prediction without isolating the mechanism.

Railroads in the 1880s. Porter (1983a) estimated when the railroad cartel on the route from Chicago to New York, the Joint Executive Committee, was colluding and when it was in a price war. Green and Porter's theory predicts wars after unexpectedly low demand. Rotemberg and Saloner say that Porter "finds no support for this theory from the residuals of his estimated equations" and argue that his results support their theory instead (p. 26). Table 12.4 reproduces their evidence. The first three columns come from Porter's paper. The first is Porter's estimated index of cartel nonadherence, which parallels closely the contemporary reports in the *Railway Review* and the *Chicago Tribune*. The second gives rail shipments of wheat from Chicago to New York. The third gives the share of wheat shipped from Chicago by rail rather than by lake. The last two columns are from the Chicago Board of Trade annual reports. National grain production adds wheat, corn, rye, oats and barley in tons. The last column counts the days between April 1 and December 31 on which the Straits of Mackinac were closed to navigation, which prevented shipment by lake.

The most severe price wars occurred in 1881, 1884 and 1885. These are the years with the largest rail shipments, in absolute terms and relative to lake shipments (p. 27). This alone does not show high demand, since shipments may be high because railroads compete. The authors therefore look at two determinants of demand for rail transport. The lakes stayed closed longest in 1881 and 1885, the years with the highest nonadherence. In 1883 and 1884 the lakes were closed only slightly less than in 1885, yet there was a war only in 1884. Grain

Table 12.4: The railroad cartel, 1880–1886

Year	Estimated nonadherence	Rail shipments (million bushels)	Fraction shipped by rail (%)	Total grain production (billion tons)	Days lakes closed (April 1 to Dec. 31)
1880	0.00	4.73	22.1	2.70	35
1881	0.44	7.68	50.0	2.05	69
1882	0.21	2.39	13.8	2.69	35
1883	0.00	2.59	26.8	2.62	58
1884	0.40	5.90	34.0	2.98	58
1885	0.67	5.12	48.5	3.00	61
1886	0.06	2.21	17.4	2.83	50

Notes: Columns 1 to 3 are from Porter (1983a), columns 4 and 5 from the Chicago Board of Trade annual reports, as compiled by Rotemberg and Saloner. Units as printed in the source. The lakes were always closed from January 1 to March 31. Source: Rotemberg and Saloner (1984), Table 2.

production explains 1883. It was the second lowest of the period and 12 percent below 1884 (p. 28). In the authors' words, this "must have depressed demand so much that, in spite of the lake closings, total demand for rail transport was low enough to warrant cooperation."

The authors anticipate two objections (pp. 28–29). Porter used weekly data, while their table is annual. They reply that the wars followed a seasonal pattern. The first began around January 1881 and lasted the whole year. The second began around January 1884 and ended at the end of 1885. Agents could predict the opening of the lakes in midwinter by studying the thickness of the ice. A railroad that expected a war in the future had two reasons to cut its price at once. The penalty for deviating was smaller, since the future would be competitive anyway. And shippers who could store grain would postpone shipments ahead of an expected war, which lowered even the monopoly price. The second objection is that national grain production is a poor proxy for production in the Chicago region. They reply that national movements mostly reflect the grain belt, which includes Illinois. The weekly analysis belongs to Porter's own paper and to Ellison (1994), who tests Green-Porter against Rotemberg-Saloner with the same data. Section 13.3 treats both.

Automobiles in 1955. Bresnahan (1987) studies the American automobile industry in the model years 1954 to 1956 (Section 6.6). Production in 1955 was 44 percent above its 1954 level, and it fell by about 27 percent in 1956 (Table 6.3). The working paper of Rotemberg and Saloner (1984) reports a 45 percent rise and a 44 percent fall (p. 26). The second figure does not match Bresnahan's Table I. Bresnahan finds that a model of competitive pricing fits the 1955 data, while a collusive model fits 1954 and 1956. Rotemberg and Saloner add that GNP fell 1 percent in 1954, rose 7 percent in 1955 and rose 2 percent in 1956 (p. 26). In their words, "Insofar as cartels can only sustain either competitive or collusive outcomes, this is what our theory predicts" (p. 26). The competitive year was the boom year.

Price-cost margins. A direct test would compare prices with marginal costs in booms and recessions. Marginal cost data are scarce, so industrial organization economists use the *price-cost margin*, sales minus payroll and material costs, divided by sales. Scherer (1980) summarizes the studies of its cyclical behavior (his p. 357, quoted on p. 29). Concentrated industries reduce prices, and above all price-cost margins, "by less in response to a demand slump and increase them by less in the boom phase." The folklore predicts the opposite. Rotemberg and Saloner argue that the fact favors their theory (p. 30). If part of payroll is a fixed cost, measured margins rise in booms even when price and marginal cost do not change. Measured margins

in concentrated industries rise by less. Either fixed costs matter less in concentrated industries, which they find unlikely, or concentrated industries cut prices relative to marginal cost in booms.

Product wages and concentration. The last piece of evidence uses correlations between employment and the *real product wage*. This is the average hourly wage divided by the industry's value-added deflator. Burda (1984) computed the correlations from detrended yearly data for 1947–1978. To see why it measures margins, let marginal cost be $mc = \frac{w}{MPL}$, where w is the wage and MPL the marginal product of labor. Then

$$\frac{w}{p} = MPL \cdot \frac{mc}{p} = MPL\,(1 - L),$$

with L the Lerner index. With constant marginal product, a product wage that rises with employment means a Lerner index that falls in booms. With diminishing returns, MPL falls in booms, which strengthens the inference (p. 31). The measure remains valid when part of payroll is fixed. Its weakness is that materials must be proportional to output and passed through as in a competitive industry (p. 30). The concentration ratio of each two-digit industry is a 1967 sales-weighted average of four-digit four-firm ratios.

Panel A of Table 12.5 shows that concentrated industries such as motor vehicles and electrical equipment tend to have positive correlations. Unconcentrated ones such as leather, food and wood products tend to have negative correlations (p. 32). The theory does not say that a slightly more concentrated industry cuts prices more in booms. A pure monopoly charges the monopoly price, which usually rises with demand. So the authors split the sample at the median concentration ratio of 35.4, which lies between food and nonelectrical machinery. Panel B gives the resulting 2×2 table. Dropping the three industries whose correlations are close to zero (SIC 22, 28 and 372–9) turns the counts 7:3:3:7 into 7:2:2:6. A χ^2 test rejects independence with 92 percent confidence for Panel B and 97 percent for the reduced table. Fisher's exact test against the alternative that concentrated industries have more positive correlations rejects with 91 and 96 percent confidence (pp. 33–34). We recomputed these numbers. The Pearson statistic without continuity correction is 3.20 ($p = 0.074$) for Panel B and 4.74 ($p = 0.030$) for the reduced table. The one-sided Fisher p-values are 0.089 and 0.045.

Alternative explanations. The authors discuss two (p. 34). Positive correlations could come from monopoly pricing with short-run increasing returns to labor. They find this unlikely, because firms cut production by closing their least efficient plants first. Positive correlations could also come from technology shocks that raise labor demand in a sector with upward sloping labor supply. But the sectors with positive correlations, such as stone, clay and glass, printing and publishing, and rubber, "appear to be sectors with fairly stagnant technologies" (p. 35).

Critiques and limitations

The theory and the evidence have limits that later work addressed.

(1) *Selection and patience.* Countercyclical pricing describes the most collusive equilibrium for intermediate discount factors. The competitive equilibrium and many constant-price equilibria exist as well. The theory restricts what can be sustained, and the prediction rests on the selection.

(2) *Independent shocks.* Business cycles are persistent. A boom today predicts high demand tomorrow, which raises the future loss from a price war exactly when the current gain is

Table 12.5: Concentration and the correlation between real product wages and employment

Panel A: two-digit manufacturing industries

SIC	Industry	Correlation	CR4	Group	Sign
Durables					
24	Lumber and wood products	−0.33	17.6	U	−
25	Furniture and fixtures	−0.18	21.6	U	−
32	Stone, clay and glass	0.39	37.4	C	+
33	Primary metals	0.32	42.9	C	+
34	Fabricated metal industries	0.23	29.1	U	+
35	Machinery except electrical	0.12	36.3	C	+
36	Electrical and electronic equipment	0.34	45.0	C	+
371	Motor vehicles and equipment	0.19	80.8	C	+
372–9	Other transportation equipment	0.02	50.1	C	+
38	Instruments and related products	−0.36	47.8	C	−
Nondurables					
20	Food and kindred products	−0.30	34.5	U	−
21	Tobacco manufactures	−0.64	73.6	C	−
22	Textile mill products	0.04	34.1	U	+
23	Apparel and related products	−0.53	19.7	U	−
26	Paper and allied products	−0.42	31.2	U	−
27	Printing and publishing	0.40	18.9	U	+
28	Chemical and allied products	−0.03	49.9	C	−
29	Petroleum and coal products	−0.48	32.9	U	−

Panel B: contingency table

	Unconcentrated (U)	Concentrated (C)	Total
Negatively correlated	7	3	10
Positively correlated	3	7	10
Total	10	10	20

Notes: "Correlation" is the correlation between the real product wage and employment, detrended yearly data 1947–1978, from Burda (1984). CR4 is the 1967 four-firm concentration ratio, a sales-weighted average over four-digit industries (excluding those ending in 99). The groups split the sample at the median concentration of 35.4. The Group and Sign columns are our classification, and they reproduce Panel B. Source: Rotemberg and Saloner (1984), Tables 3 and 4.

large. Sections 12.4.3 and 12.4.4 show that persistence can reverse the prediction. Kandori (1991) shows that countercyclical pricing survives a family of correlated shocks when the discount factor is close to a specific value determined by N, as summarized by Bagwell and Staiger (1995, p. 2).

(3) *No wars on the path.* With observable demand the optimal scheme lowers prices smoothly. Actual breakdowns need restricted strategies, and Remark 12.37 shows that even then wars at the top require special distributions. Wars that follow unobserved shocks belong to the theory of Section 12.5.

(4) *Other forces.* Staiger and Wolak (1992) add capacity constraints to the model. As Bagwell and Staiger summarize it, low prices may then be required during downturns, a conclusion analogous to Green and Porter's (Bagwell and Staiger, 1995, fn. 1). Storage and intertemporal substitution by buyers, which the authors invoke for the railroads, also change the incentive constraints.

(5) *Reduced-form evidence.* Each piece of evidence shows that margins or prices fall in booms in concentrated industries. None identifies the mechanism. Capacity, input costs, demand elasticities and fixed costs can produce the same correlations. The classification by concentration is crude, as the authors note for printing. Its concentration ratio is low, but its main components, newspapers, books and magazines, are highly concentrated once location and type are taken into account (p. 32).

The link to conduct estimation

Rotemberg-Saloner collusion makes conduct vary with demand. This matters for the conduct-parameter method of Chapter 3. Write the supply relation as

$$p_t - c_t = \theta_t m_t, \qquad m_t = \frac{Q_t}{\left|\frac{\partial Q_t}{\partial p_t}\right|},$$

where m_t is the markup term. Suppose conduct falls linearly with demand, $\theta_t = \vartheta_0 - \vartheta_1 m_t$ with constants ϑ_0 and $\vartheta_1 > 0$, as in a cartel that concedes in booms. A researcher who estimates a constant conduct parameter by instrumental variables with a demand shifter recovers a weighted average of the local slope of the supply relation (Proposition 3.31). The markup is $\theta_t m_t = \vartheta_0 m_t - \vartheta_1 m_t^2$, whose slope is $\vartheta_0 - 2\vartheta_1 m_t$. For small demand movements around $\bar{m}$ the estimate is close to $\vartheta_0 - 2\vartheta_1 \bar{m}$, while average conduct is $\vartheta_0 - \vartheta_1 \bar{m}$. The estimate understates market power and can be negative (Corts, 1999). Section 3.6.2 develops the general result.

Contribution

The paper made three lasting contributions. It gave a general logic for collusion under fluctuating demand: compare the current temptation with the expected future loss, and adjust the collusive price state by state to balance them. It derived a testable prediction about markups over the cycle, the opposite of the folklore. And it reinterpreted observed price wars, such as those of 1955 and the 1880s, as consequences of high demand. The papers in the rest of this section keep the logic and change the demand process.

12.4.3 Predictable cycles: Haltiwanger and Harrington (1991)

Haltiwanger and Harrington (1991) replace independent shocks with a deterministic demand cycle that firms know in advance. The original paper is not available to us. We describe its results as Bagwell and Staiger (1995, pp. 1–3) summarize them and develop the logic in our own example. In their framework both the temptation to cheat and the expected cost of a price war change as the cycle is traversed. They define a boom as a sequence of periods in which demand rises and a recession as a sequence in which it falls.

The incentive constraint. Let demand in period t be $D_t(p) = A_t d(p)$, where the path $\{A_t\}$ is known to all firms. Let $\pi_t(p) = (p - c)D_t(p)$ and let p_t be the collusive price at date t, with Bertrand reversion forever after a deviation. A firm that conforms at date t earns $\frac{1}{N}\pi_t(p_t) + \frac{1}{N}\sum_{\tau>t}\delta^{\tau-t}\pi_\tau(p_\tau)$. The best deviation earns $\pi_t(p_t)$ and then zero. The incentive constraint is

$$\frac{N-1}{N}\,\pi_t(p_t) \le \frac{1}{N}\sum_{\tau>t}\delta^{\tau-t}\pi_\tau(p_\tau). \tag{12.45}$$

The right side now depends on the date. Two dates with the same current demand can have very different futures. On the rising side of the cycle the near future brings higher demand. On the falling side it brings lower demand. The most collusive path is the greatest solution of $v_t = \min\left\{\pi_t^m, \frac{1}{N-1}\sum_{s\ge1}\delta^s v_{t+s}\right\}$, where $v_t = \pi_t(p_t)$ and π_t^m is monopoly profit at date t. Lemma 13.24 in Chapter 13 proves that this greatest solution exists, for punishments of any length.

Example 12.38 (A four-period cycle)**.** Let $D_t(p) = A_t(1-p)$ with $c = 0$, and let A_t cycle through $(4, 8, 12, 8)$. Call the four dates L (low), M^+ (middle, rising), H (high) and M^- (middle, falling). Monopoly profits are $\pi_t^m = \frac{A_t}{4}$, so they cycle through $(\pi_L, \pi_M, \pi_H, \pi_M) = (1, 2, 3, 2)$. Suppose all future dates earn monopoly profits. From M^+ the next four dates bring $(\pi_H, \pi_M, \pi_L, \pi_M)$, and from M^- they bring $(\pi_L, \pi_M, \pi_H, \pi_M)$. The cycle repeats every four periods, so the future values are

$$R_{M^+} = \frac{\delta\pi_H + \delta^2\pi_M + \delta^3\pi_L + \delta^4\pi_M}{1-\delta^4}, \qquad R_{M^-} = \frac{\delta\pi_L + \delta^2\pi_M + \delta^3\pi_H + \delta^4\pi_M}{1-\delta^4}.$$

Subtracting,

$$R_{M^+} - R_{M^-} = \frac{(\delta - \delta^3)(\pi_H - \pi_L)}{1-\delta^4} = \frac{\delta(\pi_H - \pi_L)}{1+\delta^2} > 0.$$

At the same current demand, the future loss from a war is smaller on the falling side. With $N = 2$, monopoly pricing at each date, holding the others at monopoly, requires δ of at least 0.313 at L, 0.449 at M^+, 0.621 at H and 0.548 at M^- (our computation). At $\delta = 0.58$ only the peak price is cut, to about 0.284. At $\delta = 0.52$ the most collusive prices at (L, M^+, H, M^-) are about $(0.500, 0.216, 0.124, 0.194)$. At the middle demand level the price is higher on the rising side, 0.216, than on the falling side, 0.194. The script `hh_cycle.py` computes these numbers.

The example shows both forces at work. The peak has the lowest price, which is the Rotemberg-Saloner effect of current demand. Among dates with equal demand, the price is lower where demand is about to fall, which is the effect that Haltiwanger and Harrington emphasize. Section 13.6.1 computes a longer smooth cycle with finite punishments and reaches the same conclusion.

Results. According to Bagwell and Staiger's summary, Haltiwanger and Harrington show that collusion is most difficult in recessions, when the cost of a future price war is smallest. They

demonstrate that collusive prices are higher in booms, holding all else equal. The relation between the collusive price and the level of current demand is less clear, and they cannot give complete analytic results on it. Their simulations show that collusive prices are often procyclical. As the discount factor drops relative to the number of firms, collusive prices become increasingly countercyclical, much as Rotemberg and Saloner predicted (Bagwell and Staiger, 1995, p. 2).

Deterministic cycles suit seasonal demand better than business cycles, whose turning points are hard to predict. Bagwell and Staiger note this and point to evidence for the Haltiwanger-Harrington model in retail gasoline, where demand fluctuations are mainly seasonal (Bagwell and Staiger, 1995, fn. 5). That evidence, Borenstein and Shepard (1996), is a deep dive in Section 13.6.2.

12.4.4 Bagwell and Staiger (1997): collusion over the business cycle

The question

Bagwell and Staiger (1997) ask whether collusive prices are procyclical or countercyclical when booms and recessions are persistent but unpredictable phases. They follow Hamilton (1989) and model the business cycle as a Markov process that switches between a fast-growth state and a slow-growth state. A *boom* is a period of fast growth in the level of demand, and a *recession* a period of slow growth. Recessions may, but need not, have negative growth. Prices are *procyclical* if they are higher in booms and *countercyclical* if they are higher in recessions. The paper has two main results (WP abstract). Collusive prices may be procyclical (countercyclical) when growth rates are positively (negatively) correlated over time. And the amplitude of the collusive price cycle is larger when booms are expected to be shorter and recessions longer. We work from the 1995 working paper (Bagwell and Staiger, 1995) and cite its theorem and equation numbers. We change its notation: n becomes N, the growth rates b and r become g_b and g_r, and its value functions Ω, ω, $\tilde{\omega}_b$, $\tilde{\omega}_r$ become Γ, w, W_b, W_r.

Assumptions and the stationary-growth benchmark

Assumption 12.39 (Bertrand supergame with a growing market)**.**

(i) $N \geq 2$ firms sell a nondurable homogeneous good in periods $t = 1, 2, \ldots$ and set prices simultaneously. Consumers divide evenly among the lowest-priced firms.

(ii) The number of consumers in period t is $G_t > 0$, the *level of market demand*. Each consumer has demand $D(p)$. A lowest-priced firm earns $\pi(p) = (p - c)D(p)$ per consumer it serves. The function π has a unique maximizer p^m and is strictly increasing on $[c, p^m]$. Prices are chosen from $[0, p^m]$.

(iii) Firms observe all past prices and the current and past levels of demand.

(iv) Firms use symmetric strategies. The *most collusive prices* are the highest prices supported by a symmetric subgame perfect equilibrium. Following Abreu (1986), a deviation is punished by competitive pricing, $p = c$, in every later period.

Here G_t is a level, not a distribution function. The monopoly price is acyclic because it does not depend on the number of consumers. Any cyclical movement in collusive prices therefore comes from the incentive constraints. Two per-consumer quantities organize the analysis. A

firm that undercuts a common price p captures the whole market, so its *per-consumer gain from cheating* is

$$\Gamma(p) = \pi(p) - \frac{\pi(p)}{N} = \frac{N-1}{N}\,\pi(p). \tag{12.46}$$

In a war each firm earns $\frac{\pi(c)}{N} = 0$ instead of $\frac{\pi(p)}{N}$. So the *per-consumer, per-period cost of a war* is

$$w(p) = \frac{\pi(p)}{N} - \frac{\pi(c)}{N} = \frac{\pi(p)}{N}. \tag{12.47}$$

In the *stationary-growth game*, $G_{t+1} = g\,G_t$ with $0 < \delta g < 1$. Demand expands if $g > 1$ and contracts if $g < 1$. The condition $\delta g < 1$ keeps discounted demand finite. The tradeoff is the same at every date, so a single most collusive price p^* is charged in every period.

Proposition 12.40 (Stationary growth)**.** *In the stationary-growth game, the most collusive price is $p^* = p^m$ if $\delta g \geq \frac{N-1}{N}$ and $p^* = c$ otherwise.*

Proof. At date t, cheating on a common price p gains $G_t\Gamma(p)$. It costs $G_\tau w(p)$ at every later date τ, and $G_\tau = g^{\tau-t}G_t$. The incentive constraint is

$$G_t\,\Gamma(p) \leq \sum_{\tau=t+1}^{\infty} \delta^{\tau-t} G_\tau\, w(p) = G_t \sum_{\tau=t+1}^{\infty} (\delta g)^{\tau-t} w(p) = G_t\,\frac{\delta g}{1-\delta g}\,w(p).$$

Cancel G_t and substitute (12.46) and (12.47):

$$\frac{N-1}{N}\,\pi(p) \leq \frac{\delta g}{1-\delta g}\,\frac{\pi(p)}{N}.$$

For $p > c$ we may divide by $\frac{\pi(p)}{N} > 0$, which gives $(N-1)(1-\delta g) \leq \delta g$, or $N - 1 \leq N\delta g$. This is $\delta g \geq \frac{N-1}{N}$, and it does not depend on p. If it holds, every $p \in (c, p^m]$ is sustainable and the most collusive price is p^m. If it fails, no $p > c$ is sustainable. □

Collusion is easier with more patient firms, fewer firms and faster growth. The ability to collude jumps at $\delta g = \frac{N-1}{N}$ (WP p. 9). The result matches Proposition 12.16. There demand grows at the net rate g, so the effective discount factor is $\delta(1+g)$. Here g is the gross growth factor, so it is δg.

The Markov-growth game

Demand grows at one of two rates. Period t is a *boom period* if $G_t = g_b G_{t-1}$ and a *recession period* if $G_t = g_r G_{t-1}$, where $1 > \delta g_b > \delta g_r > 0$. The growth rate $g_t \in \{g_b, g_r\}$ follows a Markov chain with

$$\rho \equiv \mathbb{P}(g_t = g_r \mid g_{t-1} = g_b), \qquad \lambda \equiv \mathbb{P}(g_t = g_b \mid g_{t-1} = g_r). \tag{12.48}$$

So ρ is the probability that a boom turns into a recession and λ the probability that a recession turns into a boom. In this subsection ρ is a transition probability, not pass-through. These parameters fix the expected durations of the phases. A boom phase that starts in period t lasts exactly z periods with probability $\rho(1-\rho)^{z-1}$, since it continues $z-1$ times and then ends. Using $\sum_{z\geq 1} z x^{z-1} = \frac{1}{(1-x)^2}$ with $x = 1-\rho$, the expected duration is

$$\sum_{z=1}^{\infty} z\,\rho(1-\rho)^{z-1} = \frac{\rho}{\rho^2} = \frac{1}{\rho}.$$

By the same argument a recession lasts $\frac{1}{\lambda}$ periods on average. The stationary-growth game is the special case in which booms never end.

The incentive constraints

The Markov structure makes the incentives the same in every boom period, whatever the date, and the same in every recession period. The most collusive prices are therefore a pair, p_b in booms and p_r in recessions. Suppose the pair (p_b, p_r) is charged forever. Let W_b be a firm's expected discounted profit from period $t+1$ on, per consumer of period $t+1$, when period $t+1$ is a boom. Define W_r in the same way for a recession. Since profits fall to zero in a war, W_b and W_r also measure the cost of a war.

Suppose period t is a boom. Next period demand is $g_r G_t$ with probability ρ and $g_b G_t$ with probability $1-\rho$. The boom incentive constraint is

$$G_t\,\Gamma(p_b) \le \delta\left[\rho\,(g_r G_t)\,W_r + (1-\rho)\,(g_b G_t)\,W_b\right].$$

The level G_t cancels. Future demand is always proportional to current demand, so the current level is a scaling factor that does not affect the incentive to collude. The full system is (WP (1)–(4))

$$\Gamma(p_b) \le \delta\left[\rho\, g_r W_r + (1-\rho)\, g_b W_b\right], \tag{12.49}$$

$$\Gamma(p_r) \le \delta\left[\lambda\, g_b W_b + (1-\lambda)\, g_r W_r\right], \tag{12.50}$$

$$W_b = w(p_b) + \delta\left[\rho\, g_r W_r + (1-\rho)\, g_b W_b\right], \tag{12.51}$$

$$W_r = w(p_r) + \delta\left[\lambda\, g_b W_b + (1-\lambda)\, g_r W_r\right]. \tag{12.52}$$

The first two lines compare today's temptation with the discounted future profit that cheating destroys. The last two are recursions for that future profit. Write them as a linear system:

$$\left[1-(1-\rho)\delta g_b\right] W_b - \rho\,\delta g_r W_r = w(p_b), \qquad -\lambda\,\delta g_b W_b + \left[1-(1-\lambda)\delta g_r\right] W_r = w(p_r).$$

Its determinant is $\left[1-(1-\lambda)\delta g_r\right]\left[1-(1-\rho)\delta g_b\right] - \delta^2\lambda g_b \rho g_r$. Define

$$\Delta \equiv \frac{\delta}{\left[1-(1-\lambda)\delta g_r\right]\left[1-(1-\rho)\delta g_b\right] - \delta^2\lambda g_b \rho g_r}. \tag{12.53}$$

In this subsection Δ is a scalar, unrelated to the matrix of share derivatives or to the difference operator of (12.44). The paper shows that $\Delta > 0$ and that Δ increases in δ on $(0, \frac{1}{g_b})$ (WP fn. 7). Cramer's rule gives (WP (5) and (6))

$$\begin{aligned} W_b &= \left\{\frac{w(p_b)\left[1-(1-\lambda)\delta g_r\right]}{\delta} + w(p_r)\rho g_r\right\}\Delta, \\ W_r &= \left\{\frac{w(p_r)\left[1-(1-\rho)\delta g_b\right]}{\delta} + w(p_b)\lambda g_b\right\}\Delta. \end{aligned} \tag{12.54}$$

Substitute into the right side of (12.49), which is $\delta\rho g_r W_r + \delta(1-\rho) g_b W_b$. The coefficient on $w(p_r)$ is

$$\rho g_r \Delta\left[1-(1-\rho)\delta g_b\right] + (1-\rho) g_b \Delta\,\delta\rho g_r = \rho g_r \Delta.$$

The coefficient on $w(p_b)$ is

$$g_b\Delta\left[\delta\rho g_r\lambda + (1-\rho)\left(1-(1-\lambda)\delta g_r\right)\right] = g_b\Delta\left[1-\rho-\delta g_r(1-\lambda-\rho)\right],$$

where the equality uses $(1-\rho)(1-\lambda)-\rho\lambda = 1-\lambda-\rho$. The recession constraint works the same way. The two constraints become (WP (8) and (9))

$$\Gamma(p_b) \leq \left\{ w(p_r)\rho g_r + w(p_b) g_b \left[1-\rho-\delta g_r(1-\lambda-\rho)\right] \right\} \Delta, \tag{12.55}$$

$$\Gamma(p_r) \leq \left\{ w(p_b)\lambda g_b + w(p_r) g_r \left[1-\lambda-\delta g_b(1-\lambda-\rho)\right] \right\} \Delta. \tag{12.56}$$

The future loss is a weighted average of the profit lost in future booms and recessions, with weights that reflect the expected time spent in each. Substitute $\Gamma = \frac{N-1}{N}\pi$ and $w = \frac{\pi}{N}$, multiply by N, and move the own-state term to the left. The constraints take the form (WP (10)–(13))

$$\pi(p_b)\,\mathcal{B} \leq \pi(p_r)\,\rho g_r \Delta, \qquad \pi(p_r)\,\mathcal{R} \leq \pi(p_b)\,\lambda g_b \Delta, \tag{12.57}$$

with

$$\mathcal{B} = N\!-\!1\!-\!g_b\Delta\left[1-\rho-\delta g_r(1-\lambda-\rho)\right], \qquad \mathcal{R} = N\!-\!1\!-\!g_r\Delta\left[1-\lambda-\delta g_b(1-\lambda-\rho)\right]. \tag{12.58}$$

The coefficient $\mathcal{B}$ is the net temptation in a boom: the gain from cheating minus the part of the future loss that comes from future boom profits.

Correlation of growth rates

In the stationary game the growth rate decides everything. In the Markov game the relevant object is expected future growth, which may depend on the current phase. One period ahead,

$$\begin{aligned}\mathbb{E}[G_{t+1} \mid g_t = g_b] - \mathbb{E}[G_{t+1} \mid g_t = g_r] &= \left[(1-\rho)g_b + \rho g_r - \lambda g_b - (1-\lambda)g_r\right] G_t \\ &= (1-\lambda-\rho)(g_b - g_r)\, G_t.\end{aligned}$$

Expected demand next period is higher after a boom if and only if $1-\lambda-\rho > 0$. What matters for collusion is discounted demand over the whole future. Normalize $G_t = 1$ and let $\tilde{G}_b$ be expected discounted demand from period t on when t is a boom, and $\tilde{G}_r$ the same for a recession. They satisfy $\tilde{G}_b = 1 + \delta\left[\rho g_r \tilde{G}_r + (1-\rho) g_b \tilde{G}_b\right]$ and $\tilde{G}_r = 1 + \delta\left[\lambda g_b \tilde{G}_b + (1-\lambda) g_r \tilde{G}_r\right]$. Solving (WP (14)),

$$\tilde{G}_b - \tilde{G}_r = \Delta\,(g_b - g_r)(1-\lambda-\rho). \tag{12.59}$$

Growth rates are *positively correlated* if $1-\lambda-\rho > 0$, *negatively correlated* if $1-\lambda-\rho < 0$, and *uncorrelated* if $1-\lambda-\rho = 0$. Under positive correlation a boom predicts more future demand, so a war started in a boom costs more. Collusion should then be easier in booms. Under negative correlation the reverse holds.

The most collusive prices

The analysis has four parameters besides (ρ, λ): N, δ, g_b and g_r. The first result disposes of the extreme cases.

Proposition 12.41 (Extreme cases)**.** *In the Markov-growth game:*

(i) If $\delta g_r \geq \frac{N-1}{N}$, then $p_b^* = p_r^* = p^m$.

(ii) If $\delta g_b < \frac{N-1}{N}$, then $p_b^* = p_r^* = c$.

Proof. On every path, growth in each period is at least g_r and at most g_b. So discounted demand from any state satisfies $\frac{1}{1-\delta g_r} \le \tilde{G}_s \le \frac{1}{1-\delta g_b}$.

(i) At $p_b = p_r = p^m$, the recursions (12.51)–(12.52) are those of $\tilde{G}$ multiplied by $w(p^m)$, so $W_s = w(p^m)\tilde{G}_s$. The right side of each incentive constraint equals $W_s - w(p^m) = w(p^m)(\tilde{G}_s - 1)$ for the current state s. The constraint $\Gamma(p^m) = (N-1)w(p^m) \le w(p^m)(\tilde{G}_s - 1)$ holds if $\tilde{G}_s - 1 \ge N - 1$. This follows from $\tilde{G}_s - 1 \ge \frac{\delta g_r}{1-\delta g_r} \ge N - 1$, where the last step is equivalent to $\delta g_r \ge \frac{N-1}{N}$.

(ii) Take any pair (p_b, p_r) and let $\bar{w} = \max\{w(p_b), w(p_r)\}$, attained in state s. Profit per consumer never exceeds $\bar{w}$, so $W_s \le \bar{w}\,\tilde{G}_s$ and the right side of the constraint in state s is at most $\bar{w}(\tilde{G}_s - 1) \le \bar{w}\frac{\delta g_b}{1-\delta g_b}$. If $\delta g_b < \frac{N-1}{N}$, this is below $(N-1)\bar{w} = \Gamma(p_s)$ whenever $\bar{w} > 0$. So the constraint fails unless $\bar{w} = 0$, which means $p_b = p_r = c$. □

This is Theorem 1 of the working paper, with a direct proof. If collusion is perfect even under permanent slow growth, it is perfect in the Markov game. If it fails even under permanent fast growth, it fails in the Markov game. The interesting case is the maintained assumption (WP (15))

$$\delta g_b > \frac{N-1}{N} > \delta g_r. \tag{12.60}$$

Under (12.60) define

$$\rho^* = \frac{\delta g_b - \frac{N-1}{N}}{\delta(g_b - g_r)}, \qquad \lambda^* = 1 - \rho^* = \frac{\frac{N-1}{N} - \delta g_r}{\delta(g_b - g_r)}, \tag{12.61}$$

both in $(0,1)$, and the three linear boundaries (WP (19)–(21))

$$\hat{\lambda}(\rho) = \frac{1 - (1-\rho)\delta g_b}{\frac{1}{\lambda^*} - \delta g_b}, \qquad \hat{\rho}(\lambda) = \frac{g_b - g_r}{g_b}\rho^* + \frac{\rho^* g_r}{g_b \lambda^*}\lambda, \qquad \tilde{\rho}(\lambda) = \frac{1 - (1-\lambda)\delta g_r}{\frac{1}{\rho^*} - \delta g_r}. \tag{12.62}$$

They have simple meanings. On $\lambda = \hat{\lambda}(\rho)$ the recession constraint holds with equality at monopoly prices, $\lambda g_b \Delta = \mathcal{R}$. On $\rho = \tilde{\rho}(\lambda)$ the boom constraint does, $\rho g_r \Delta = \mathcal{B}$. On $\rho = \hat{\rho}(\lambda)$ the two constraints in (12.57) coincide, $\mathcal{R}\mathcal{B} = (\lambda g_b \Delta)(\rho g_r \Delta)$. All three lines pass through (ρ^*, λ^*).

Proposition 12.42 (Collusion over the business cycle)**.** *Under Assumption 12.39 and* (12.60)*:*

(i) Zero correlation *($\lambda + \rho = 1$). Firms charge p^m in both phases if $\rho \le \rho^*$, and c in both phases if $\rho > \rho^*$.*

(ii) Positive correlation *($\lambda + \rho < 1$). Pricing is monopoly in both phases if $\lambda \ge \hat{\lambda}(\rho)$. It is procyclical, $p_b^* = p^m > p_r^* > c$, if $\lambda < \hat{\lambda}(\rho)$ and $\rho \le \hat{\rho}(\lambda)$. It is competitive in both phases if $\rho > \hat{\rho}(\lambda)$. It is never countercyclical.*

(iii) Negative correlation *($\lambda + \rho > 1$). Pricing is monopoly in both phases if $\rho \le \tilde{\rho}(\lambda)$. It is countercyclical, $p_r^* = p^m > p_b^* > c$, if $\tilde{\rho}(\lambda) < \rho \le \hat{\rho}(\lambda)$. It is competitive if $\rho > \hat{\rho}(\lambda)$. It is never procyclical.*

(iv) Cyclical prices. *In the procyclical region the recession price solves $\pi(p_r^*) = \frac{\lambda g_b \Delta}{\mathcal{R}}\pi(p^m)$ on $[c, p^m]$. In the countercyclical region the boom price solves $\pi(p_b^*) = \frac{\rho g_r \Delta}{\mathcal{B}}\pi(p^m)$ on $[c, p^m]$. The depressed price is continuous, increasing in λ and decreasing in ρ. So the amplitude $|p_b^* - p_r^*|$ increases with the expected duration of recessions and decreases with the expected duration of booms.*

Proof. Work with profit levels $x_b = \pi(p_b)$ and $x_r = \pi(p_r)$ in $[0, \pi(p^m)]$. Because π is strictly increasing on $[c, p^m]$, they determine the prices. If $\mathcal{B} > 0$, the boom constraint in (12.57) reads $x_b \le a_b x_r$ with $a_b = \frac{\rho g_r \Delta}{\mathcal{B}}$. If $\mathcal{B} \le 0$, it holds for all prices, and we set $a_b = +\infty$. Define $a_r = \frac{\lambda g_b \Delta}{\mathcal{R}}$ in the same way. The most collusive pair is the greatest point of the set in Lemma 12.28 with $X_1 = X_2 = \pi(p^m)$. By the lemma there are three outcomes. If $a_b a_r < 1$, pricing is competitive. If $a_b a_r \ge 1$ and $\min\{a_b, a_r\} \ge 1$, pricing is monopoly. If $a_b a_r \ge 1$ and one coefficient is below one, the corresponding phase has profit $a\,\pi(p^m) < \pi(p^m)$ and the other phase charges p^m. This gives the formulas in (iv).

It remains to see which phase is weak. Substituting the definitions of $\mathcal{B}$ and $\mathcal{R}$, a direct computation (WP (A1)) gives

$$\big(\rho g_r \Delta - \mathcal{B}\big) - \big(\lambda g_b \Delta - \mathcal{R}\big) = \Delta(g_b - g_r)(1 - \lambda - \rho).$$

The coefficient a_r is below one exactly when $\lambda g_b \Delta - \mathcal{R} < 0$, and similarly for a_b. Under positive correlation the recession slack is the smaller of the two. If the boom slack is negative, so is the recession slack, both coefficients are below one, and pricing is competitive. So the boom is never the only weak phase, and pricing is never countercyclical. Negative correlation reverses the roles.

For (i), zero correlation means $\lambda = 1 - \rho$. Then the right sides of (12.49) and (12.50) coincide, because from either phase the next period is a boom with probability $1 - \rho$. If a pair (p_b, p_r) is sustainable, so is the pair that charges the higher price in both phases, since the common right side increases in both prices. So the most collusive prices are equal, $p_b = p_r = p$. Then (12.51)–(12.52) give $W_b = W_r = \frac{w(p)}{1 - \delta \bar{g}}$ with $\bar{g} = \rho g_r + (1 - \rho) g_b$, and both constraints reduce to $\Gamma(p) \le \frac{\delta \bar{g}}{1 - \delta \bar{g}} w(p)$. This is the stationary game with growth $\bar{g}$. By Proposition 12.40, monopoly pricing holds if and only if $\delta \left[\rho g_r + (1 - \rho) g_b\right] \ge \frac{N-1}{N}$, which is $\rho \le \rho^*$.

The region boundaries in (ii) and (iii) restate these conditions. Under positive correlation, $a_r \ge 1$ if and only if $\lambda \ge \hat{\lambda}(\rho)$. Under negative correlation, $a_b \ge 1$ if and only if $\rho \le \tilde{\rho}(\lambda)$. In both cases $a_b a_r \ge 1$ if and only if $\rho \le \hat{\rho}(\lambda)$.

To see that the boundaries are straight lines, let $D \equiv \frac{\delta}{\Delta} > 0$ be the determinant in (12.53). Expanding it with $(1 - \rho)(1 - \lambda) - \rho\lambda = 1 - \lambda - \rho$ gives

$$D = 1 - (1 - \rho)\delta g_b - (1 - \lambda)\delta g_r + \delta^2 g_b g_r (1 - \lambda - \rho),$$

which is affine in (ρ, λ). The condition $a_r \ge 1$ is $\lambda g_b \Delta \ge \mathcal{R}$. Substituting $\mathcal{R}$ from (12.58) and multiplying by D gives

$$\delta \left[\lambda g_b + (1 - \lambda) g_r - \delta g_b g_r (1 - \lambda - \rho)\right] \ge (N - 1) D.$$

Both sides are affine in (ρ, λ). Solving the equality for λ and substituting λ^* from (12.61) gives $\hat{\lambda}(\rho)$. The same steps applied to $\rho g_r \Delta \ge \mathcal{B}$ give $\tilde{\rho}(\lambda)$. For the third boundary we multiply $\mathcal{R}\mathcal{B} = (\lambda g_b \Delta)(\rho g_r \Delta)$ by D^2. Each side becomes quadratic in (ρ, λ), and their difference factors as

$$\begin{aligned}\big(\mathcal{R}\mathcal{B} - \lambda\rho g_b g_r \Delta^2\big)\, D^2 \\ = D\left\{(N-1)^2 - N(N-1)\delta\left[(1-\rho)g_b + (1-\lambda)g_r\right] + N^2\delta^2 g_b g_r (1 - \lambda - \rho)\right\}.\end{aligned}$$

Since $D > 0$, the boundary is the line on which the braces vanish. Solving for ρ and substituting ρ^* and λ^* gives $\hat{\rho}(\lambda)$. At (ρ^*, λ^*) the last term in the braces is zero and $\delta\left[(1 - \rho^*) g_b + \rho^* g_r\right] =$

$\frac{N-1}{N}$, so the braces vanish there, as they must. We checked each step symbolically with sympy. The monotonicity in (iv) follows from the paper's appendix (Lemmas 3 to 6). It uses $\frac{\partial \Delta}{\partial \rho} = -\Delta^2 g_b(1 - \delta g_r) < 0$ and $\frac{\partial \Delta}{\partial \lambda} = -\Delta^2 g_r(1 - \delta g_b) < 0$ (WP (A10) and (A11)). □

The proposition collects Theorems 2 to 4 of the working paper. Its proof in profit space mirrors the two-state model of Section 12.4.1. There, too, the most collusive scheme keeps the strong state at monopoly and depresses the weak one. The difference lies in which state is weak. With independent shocks, the weak state is the one with high current demand. With persistent growth, it is the phase that predicts lower future demand.

The results have a clear intuition (WP pp. 18–23). Under positive correlation a recession predicts more recession, so there is little to lose from a war started in a recession. To keep firms from cheating, the cartel lowers the recession price. If recessions are expected to last longer (λ smaller), the future loss shrinks further and the recession price must fall more, so the amplitude of the price cycle grows. If booms are too short relative to recessions ($\rho > \hat{\rho}(\lambda)$), even imperfect collusion is impossible. At that boundary the recession price jumps from a positive level to c. Under negative correlation the boom predicts a recession, the boom is the weak phase, and prices are countercyclical. Whatever the correlation, collusion is perfect when booms are long and recessions short, and it fails when booms are short and recessions long. In between, one phase is weak, and the sign of the correlation decides which. The relation between δ and N, central in the earlier literature, plays no role in the direction of the cycle. It enters only through ρ^* and λ^*, which move the regions. As $\delta g_r \to \frac{N-1}{N}$, $\lambda^* \to 0$ and the monopoly region fills the square. As $\delta g_b \to \frac{N-1}{N}$, $\rho^* \to 0$ and the competitive region does (WP p. 23).

Figure 12.7 draws the regions for $N = 2$, $\delta = 0.9$, $g_b = 1.05$ and $g_r = 0.30$, with $\pi(p) = p(1-p)$ and $c = 0$. These values satisfy (12.60), since $0.945 > 0.5 > 0.27$. Then $\rho^* \approx 0.659$ and $\lambda^* \approx 0.341$. The recession growth factor is extreme. It is chosen so that all four regions are clearly visible, because (12.60) with $N = 2$ requires $\delta g_r < \frac{1}{2}$. The monopoly region covers about 58 percent of the square, the competitive region about 25 percent, and the procyclical and countercyclical regions about 9 and 7 percent. We computed the most collusive pair at each grid point in two ways, from Proposition 12.42 and by iterating the best-response map on prices from (p^m, p^m). The classifications differ at 0.014 percent of the grid points, all on region boundaries.

Shocks within phases

The basic model has deterministic demand within a phase. Section V of the paper adds random shocks within phases and brackets the possibilities with two extremes (WP pp. 24–33). Firms observe the current shock before setting prices.

Permanent shocks. Let $G_t = g_t G_{t-1} \eta_t$, where η_t is a multiplicative shock with mean one that becomes part of the base for all future growth. (Bagwell and Staiger write ϵ_t.) The most collusive prices depend on the phase but not on the shock. The future is proportional to G_t, which already includes η_t, so the shock cancels from the incentive constraints, as G_t did before. Formally, the constraints (WP (22)–(25)) reduce to (12.49)–(12.52) once G_t is cancelled and $\mathbb{E}[\eta_{t+1}] = 1$ is imposed. Pricing is exactly as in the basic model (WP Theorem 5).

Transitory shocks. Let $G_t = g_t \frac{G_{t-1}}{\eta_{t-1}} \eta_t$, with η_t independent over time, mean one and support $[\underline{\eta}, \bar{\eta}]$ containing one. The base level grows without the shock, and the shock affects only the current period. This combines the Markov phases with Rotemberg-Saloner shocks. Let $p_b(\eta)$ and $p_r(\eta)$ be the prices in each phase when the current shock is η. The base level cancels again,

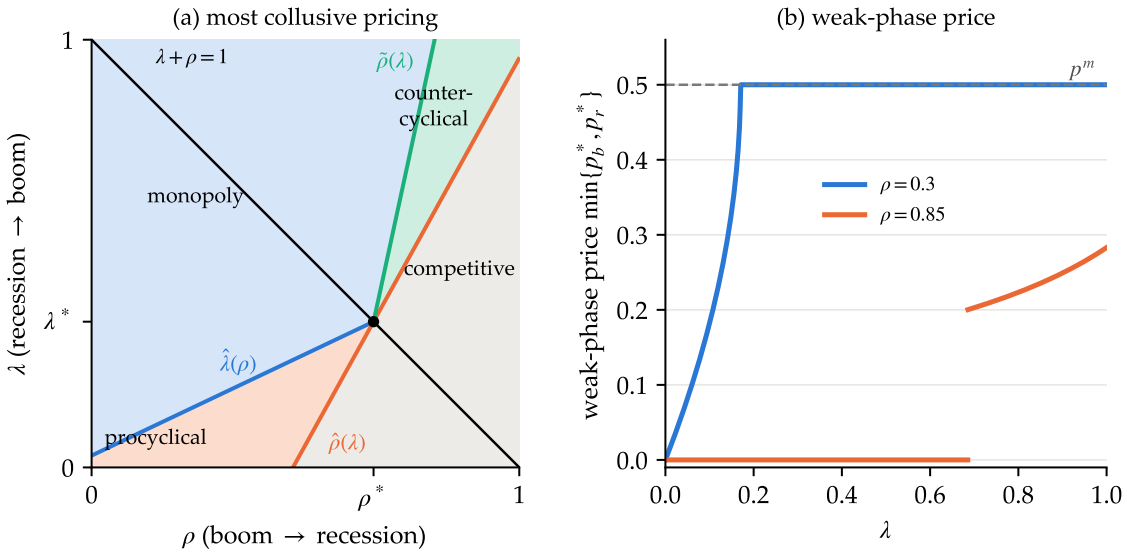

Figure 12.7: Most collusive pricing in the Markov-growth game for $N = 2$, $\delta = 0.9$, $g_b = 1.05$, $g_r = 0.30$, $\pi(p) = p(1-p)$, $c = 0$. Panel (a): regions in the space of transition probabilities (ρ, λ). Below the anti-diagonal growth rates are positively correlated, above it negatively. The boundaries $\hat{\lambda}(\rho)$, $\hat{\rho}(\lambda)$ and $\tilde{\rho}(\lambda)$ are (12.62), and they meet at $(\rho^*, \lambda^*) \approx (0.659, 0.341)$. Panel (b): the price in the weak phase as a function of λ. For $\rho = 0.3$ pricing is procyclical for $\lambda < 0.17$, and the recession price rises toward p^m as recessions become shorter. For $\rho = 0.85$ pricing is competitive for $\lambda < 0.686$, then countercyclical with a jump at the boundary. This redraws, with computed regions, Figure 1 of Bagwell and Staiger (1995). Script `bs_regions.py`.

but the current shock does not. The boom constraint becomes (WP (26))

$$\eta\,\Gamma(p_b(\eta)) \le \delta\left[\rho g_r W_r + (1-\rho) g_b W_b\right],$$

with W_b and W_r defined as before but with $\mathbb{E}[w(p(\eta))\eta]$ in place of $w(p)$ (WP (28)–(29)). The paper solves the system in two steps, following Rotemberg and Saloner. First it holds the right sides fixed at values $\tilde{W}_b$ and $\tilde{W}_r$. Each constraint then reads $\pi(p_s(\eta)) \le \frac{N}{N-1}\frac{\tilde{W}_s}{\eta}$ (WP (34)–(35)), and the most collusive price is

$$p_s(\eta) = P^*\left(\frac{\tilde{W}_s}{\eta}\right) \equiv \begin{cases} p^m & \text{if } \pi(p^m) \le \frac{N}{N-1}\frac{\tilde{W}_s}{\eta}, \\ \min\left\{p : \pi(p) = \frac{N}{N-1}\frac{\tilde{W}_s}{\eta}\right\} & \text{otherwise} \end{cases} \tag{12.63}$$

(WP (36)–(39)). Second, it requires the values $\tilde{W}_b$ and $\tilde{W}_r$ to be consistent with the prices they generate (WP (40)–(43)). It then picks the largest fixed point of the resulting pair of equations. The competitive outcome $\tilde{W}_b = \tilde{W}_r = 0$ is always a fixed point. To leave room for perfect collusion the paper assumes (WP (44))

$$\delta g_b > \frac{\bar{\eta}(N-1)}{1+\bar{\eta}(N-1)},$$

which says that even the largest shock would not disrupt perfect collusion if growth stayed at the boom rate forever. To check this, apply the argument of Proposition 12.40 with current demand scaled by $\bar{\eta}$: $\bar{\eta}(N-1) \le \frac{\delta g_b}{1-\delta g_b}$ rearranges to the displayed condition.

The results are Theorem 6 of the working paper. Both phases use the same pricing function P^* in (12.63), and P^* is nondecreasing in $\frac{\tilde{W}}{\eta}$. So a higher transitory shock lowers the most collusive price weakly, in booms and in recessions alike. This is the Rotemberg-Saloner effect, now inside each phase. The comparison between phases still follows the correlation of growth rates. Under positive correlation the boom value exceeds the recession value at the most collusive fixed point, so $p_b(\eta) \ge p_r(\eta)$ at every shock, with strict inequality for large shocks. Negative correlation reverses the ranking. The paper's Figures 6a and 6b show both price schedules flat at p^m for small shocks and falling for large ones. The boom schedule lies above the recession schedule under positive correlation and below it under negative correlation. Transitory shocks also enlarge the parameter region with cyclical pricing, because perfect collusion in both phases and at every shock now requires more. The paper concludes that its second point "provides an interpretation of the Rotemberg-Saloner (1986) theory in terms of the transitory demand shocks that occur within broader business-cycle phases" (WP p. 33).

Empirical content and limits

The theory makes the cyclicality of collusive prices an empirical question about the demand process of each industry. The direction of the cycle depends on the correlation of growth rates, and its amplitude on the expected durations of booms and recessions. Bagwell and Staiger suggest estimating these parameters industry by industry with Hamilton's methods and comparing the predictions with industry prices (WP p. 34). No such study existed when they wrote. For the aggregate economy, Hamilton (1989) finds that quarterly growth rates of U.S. real GNP are positively correlated and that booms last longer in expectation than recessions. If an industry's demand cycle shares these features, the prediction of procyclical collusive prices "appears most salient" (WP p. 34). Existing evidence points both ways, and the paper

calls it mixed and inconclusive (WP p. 2 and fn. 4). It cites cross-industry studies of margins (Domowitz et al., 1986; Rotemberg and Woodford, 1992). It cites industry studies, among them Borenstein and Shepard (1996), Ellison (1994), Porter (1983a) and Rotemberg and Saloner (1986). It also cites evidence that cartels are most likely to break down during recessions (Suslow, 1988).

The authors list three limits (WP pp. 34–35). Marginal costs are acyclic in the model, while the evidence on their cyclicality is mixed (Bils, 1987; Miron and Zeldes, 1988). Firms are assumed to tell transitory shocks from turning points. If they observe only demand, they must infer the phase, and the sharp distinction between the responses to the two kinds of movement will soften. Finally, the analysis is partial equilibrium. With entry and exit the difference between phases may matter less, and with endogenous interest rates discounting may be more severe in booms.

12.4.5 Comparing the models

Table 12.6 compares the theories of this section with the imperfect-monitoring theory of the next. The models agree on the logic of the incentive constraint. They disagree on what current demand reveals about the future and on what firms observe. These two features decide when collusive prices are lowest and whether price wars appear on the equilibrium path. The table also suggests what data would tell the theories apart. One needs the timing of low prices relative to the level, growth and predictability of demand. One also needs to know whether low prices follow observed or unobserved shocks. Chapter 13 takes these predictions to the data.

Table 12.6: Demand fluctuations and collusive pricing: four theories compared

Model	What drives the future loss	When collusive prices are lowest	Price wars on the path?	Testable implication
Rotemberg and Saloner (1986): observed independent shocks	Expected demand, the same in every state	In high-demand states, above a cutoff	No (yes only with collude-or-compete strategies)	Margins fall when current demand is high
Haltiwanger and Harrington (1991): deterministic cycle	Demand along the known future path	When demand is about to fall, and at the peak for impatient firms	No	At equal demand, prices higher when demand rises than when it falls
Bagwell and Staiger (1997): Markov growth phases	Expected future growth, which depends on the phase	In recessions under positive correlation, in booms under negative correlation	No	Direction and amplitude of the price cycle depend on correlation and phase durations
Green and Porter (1984): unobserved shocks (Section 12.5)	Probability that a low price triggers a war	After unexpectedly low demand	Yes, finite reversions	Wars follow negative demand shocks and are not caused by cheating

12.5 Imperfect Public Monitoring: Green and Porter

In the models of Sections 12.3 and 12.4, every firm sees every rival's price. A deviation is detected at once, the threat of punishment deters it, and punishments are never carried out. Prices on the equilibrium path may move with demand, but no price war is ever triggered by a suspicion of cheating. This section removes perfect observability. Firms now see only a signal that depends both on their rivals' actions and on demand shocks that nobody observes. When all firms see the same signal, we speak of *imperfect public monitoring*. The signal is an imperfect indicator of conduct, so a cartel cannot condition punishments on deviations. It must condition them on outcomes, and outcomes are sometimes bad even when nobody cheats.

The consequence is the central result of this section. Price wars occur on the equilibrium path, and they are necessary to sustain collusion. We first recall the policing problem of Stigler (1964), which motivated the theory. We then study a Bertrand version that conveys the logic in a few lines, and the original Cournot model of Green and Porter (1984). The section ends with the stochastic process of prices that the model generates, which is the basis for the empirical tests of Section 13.3.

12.5.1 Secret price cuts: Stigler's policing problem

Stigler (1964) accepted that oligopolists wish to maximize joint profits and asked why they so often fail. His answer is that a collusive agreement must be policed, and that policing is a problem of information. Any member who can cut its price secretly earns more than by conforming. Enforcement therefore consists of detecting significant deviations. Once a cut is detected, rivals match it, so it stops paying. The difficulty is detection itself. Transaction prices are private, buyers have an interest in reporting fictitious offers, and a price cut can be disguised in non-price terms of the sale. Stigler concluded that the basic evidence of a price cut is that the cutter wins business it would otherwise not obtain (Stigler, 1964, Section II). His definition of perfect collusion is accordingly that no buyer changes sellers voluntarily.

This view yields testable implications, which Section 2.10.2 develops with Stigler's statistical model and evidence. Suppose each cut offered to a single buyer reaches a rival with probability h. A cut offered to n buyers is then detected with probability $1-(1-h)^n$, which approaches one quickly as n grows. Secret cuts are therefore offered to large buyers, and collusion holds best against many small ones. Public sealed-bid purchases reveal prices and make collusion easier. Collusion is harder when the identity of buyers changes often, because a seller's loss of customers is then a noisy signal. The incentive to cut prices secretly grows roughly in proportion to the number of rivals, so collusion is harder with more sellers. The variance of firms' sales to new customers depends on the Herfindahl index, which makes it the natural measure of concentration for this problem.

Stigler's account has a gap that the rest of this section fills. It takes for granted that detected cuts are punished, and it offers no equilibrium theory of punishment when detection is noisy. In his account a price war is the sign that a cartel has broken down. Green and Porter (1984) read Stigler differently. They treat the cartel as the solution of a design problem: an institution whose members behave noncooperatively and whose incentives must be self-enforcing. With noisy signals, the best such institution must sometimes punish members who did not cheat.

12.5.2 A Bertrand version with zero-demand shocks

The logic of on-path price wars is clearest in a price-setting model with a very simple form of noise. This version is the textbook simplification of Tirole (1988, section 6.7.1.1) of the Cournot model of Green and Porter (1984), which we study in Section 12.5.3. Tirole replaces quantity competition by price competition so that firms infer rivals' prices from their own demand, as Stigler (1964) assumed. He writes α for the probability of zero demand, which we call γ. His section 6.7.1 on secret price cuts, which also treats quantity competition, spans pp. 262–265 of the print edition (Marshall and Marx, 2012, p. 16, note 27).

Assumption 12.43 (Bertrand duopoly with unobserved demand shocks)**.**

(i) Two firms sell a homogeneous good at constant marginal cost c. They set prices simultaneously in each period $t = 0, 1, 2, \dots$ and discount the future with the factor $\delta \in (0, 1)$.

(ii) In each period demand is $D(p)$ with probability $1 - \gamma$ and zero with probability $\gamma \in (0, 1)$, independently over time. The state is drawn after prices are set, and no firm ever observes it.

(iii) Industry profit $\pi(p) = (p - c)D(p)$ is continuous and has a unique maximizer p^m, with $\pi^m \equiv \pi(p^m) > 0$.

(iv) Each firm observes its own price and its own sales. It never observes the rival's price or the state.

The lowest price serves the market and ties are split equally. Firm i's sales when the rival charges p_j are therefore

$$q_i = \begin{cases} D(p_i) & \text{if } p_i < p_j \text{ and demand is } D(\cdot), \\ \tfrac{1}{2} D(p_i) & \text{if } p_i = p_j \text{ and demand is } D(\cdot), \\ 0 & \text{if } p_i > p_j \text{ or demand is zero.} \end{cases} \tag{12.64}$$

The model builds Stigler's inference problem into the payoffs. A firm that charged p^m and sold nothing cannot tell whether demand was zero or its rival undercut it. Its only signal is its own sales, and zero sales are consistent with both events.

Definition 12.44 (Trigger strategy with punishment length T)**.** Fix an integer $T \geq 1$. Each period is either collusive or a punishment period, and period 0 is collusive. In a collusive period the firm charges p^m. Suppose that in a collusive period the firm's own sales are zero, or the firm itself charged a price different from p^m. Then the next T periods are punishment periods, in which the firm charges c. The period after the last punishment period is collusive. In every other case a collusive period is followed by a collusive period.

When both firms follow this strategy, both charge p^m in collusive periods. Both then sell nothing exactly when demand is zero, so their phases always coincide. Every zero-demand period in a collusive phase starts a *price war* of T periods at marginal cost, although nobody has cheated. We say that such a war is on the *equilibrium path*.

Proposition 12.45 (Collusion with a finite price war)**.** *Under Assumption 12.43, the value of a firm at the start of a collusive period when both firms follow the trigger strategy of Definition 12.44 is*

$$V = \frac{(1 - \gamma)\frac{\pi^m}{2}}{1 - (1 - \gamma)\delta - \gamma\delta^{T+1}}. \tag{12.65}$$

The trigger profile is a Nash equilibrium if and only if

$$\Lambda(T) \equiv 2(1-\gamma)\delta + (2\gamma - 1)\delta^{T+1} \;\geq\; 1. \tag{12.66}$$

Proof. Value of collusion. Consider a collusive period. With probability $1-\gamma$ demand is positive, each firm sells $\frac{1}{2}D(p^m)$ and earns $\frac{\pi^m}{2}$, and the next period is collusive. With probability γ demand is zero, each firm earns zero, and a war fills periods $t+1$ to $t+T$. Profits in the war are zero, and collusion resumes in period $t+T+1$, whose value seen from period t is $\delta^{T+1}V$. Hence

$$V = (1-\gamma)\Big(\frac{\pi^m}{2} + \delta V\Big) + \gamma\,\delta^{T+1}V.$$

Collect the terms in V:

$$V\big[1 - (1-\gamma)\delta - \gamma\delta^{T+1}\big] = (1-\gamma)\frac{\pi^m}{2}.$$

The bracket is positive because $(1-\gamma)\delta + \gamma\delta^{T+1} < 1$. Dividing gives (12.65).

Deviations in a war. In a punishment period the rival charges c. Any price earns at most zero, so charging c is a best response, and the firm's price cannot change the length of the war. Only deviations in collusive periods need to be checked.

Deviations in a collusive period. A price above p^m earns zero today. It leaves the rival's next phase exactly as under conformity: the rival sells something when demand is positive and nothing otherwise. It is therefore dominated by charging p^m. A price $p < p^m$ wins the whole market when demand is positive and earns $(1-\gamma)(p-c)D(p) \leq (1-\gamma)\pi^m$ in expectation. The rival then sells nothing whatever the state, so a war starts for sure. The supremum of the current gain, $(1-\gamma)\pi^m$, is approached as $p \uparrow p^m$.

Best responses. Give firm i the extra information of the rival's current phase, which can only raise its best payoff. Let W be the supremum of i's payoff at the start of a rival's collusive phase. In a war the firm earns at most zero per period, and the rival returns to collusion after T periods whatever i does. Dynamic programming then gives

$$W = \max\Big\{(1-\gamma)\frac{\pi^m}{2} + \big[(1-\gamma)\delta + \gamma\delta^{T+1}\big]W,\;\; (1-\gamma)\pi^m + \delta^{T+1}W\Big\}.$$

The right side is a contraction in W, so W is its unique bounded fixed point. Define the value of the best one-shot undercut as

$$V^d \equiv (1-\gamma)\pi^m + \delta^{T+1}V.$$

If $V \geq V^d$, then V solves the fixed-point equation, because the first branch equals V by the recursion above. Hence $W = V$, and conformity is a best response. If $V < V^d$, an undercut close to p^m followed by the trigger strategy is a profitable deviation. The profile is therefore an equilibrium if and only if $V \geq V^d$.

The condition. Replace V on the left of $V \geq V^d$ by its recursion:

$$(1-\gamma)\frac{\pi^m}{2} + \big[(1-\gamma)\delta + \gamma\delta^{T+1}\big]V \;\geq\; (1-\gamma)\pi^m + \delta^{T+1}V.$$

Move the terms in V to the left and the others to the right:

$$\big[(1-\gamma)\delta - (1-\gamma)\delta^{T+1}\big]V \;\geq\; (1-\gamma)\frac{\pi^m}{2}.$$

Divide by $1-\gamma$:

$$\left(\delta - \delta^{T+1}\right)V \;\geq\; \frac{\pi^m}{2}. \tag{12.67}$$

Substitute (12.65) and cancel $\frac{\pi^m}{2}$:

$$(1-\gamma)\left(\delta - \delta^{T+1}\right) \;\geq\; 1 - (1-\gamma)\delta - \gamma\delta^{T+1}.$$

Collect terms:

$$2(1-\gamma)\delta - (1-\gamma)\delta^{T+1} + \gamma\delta^{T+1} \;\geq\; 1,$$

which is (12.66). □

The proposition reproduces Tirole's equations (6.10) to (6.16) in our notation. His (6.10) and (6.11) are the recursions for the values of the collusive and punishment phases, with $V^- = \delta^T V^+$. His (6.14) is (12.65), his incentive constraint (6.13), $\delta(V^+ - V^-) \geq \frac{\pi^m}{2}$, is (12.67), and his (6.16) is (12.66) exactly.

Condition (12.67) has a simple reading. An undercut raises current profit by $\frac{\pi^m}{2}$ when demand is positive. Its cost is that a war then starts for sure rather than with probability γ. The extra probability of a war is $1-\gamma$, and a war destroys the T collusive periods that would have followed, worth $(\delta - \delta^{T+1})V$. Both the gain and the extra probability carry the factor $1-\gamma$, which cancels. Two special cases connect the result to earlier sections. With an infinite war ($T = \infty$), $\delta^{T+1} = 0$ and the condition becomes $\delta(1-\gamma) \geq \frac{1}{2}$. Without noise ($\gamma = 0$) the condition becomes $2\delta - \delta^{T+1} \geq 1$, which is equivalent to $\delta + \delta^2 + \cdots + \delta^T \geq 1$. A long enough punishment works if and only if $\delta > \frac{1}{2}$, and permanent reversion works if and only if $\delta \geq \frac{1}{2}$. This is the duopoly threshold $1 - \frac{1}{N}$ of Proposition 12.14.

Corollary 12.46 (The optimal length of a price war)**.** *Under Assumption 12.43:*

(i) V is strictly decreasing in T and in γ.

(ii) If $\gamma \geq \frac{1}{2}$, no T satisfies (12.66). If $\gamma < \frac{1}{2}$, the function $\Lambda(T)$ is strictly increasing in T, with $\Lambda(0) = \delta$ and $\lim_{T\to\infty} \Lambda(T) = 2(1-\gamma)\delta$. Some finite T satisfies (12.66) if and only if $2(1-\gamma)\delta > 1$.

(iii) The most profitable trigger equilibrium uses the shortest war that satisfies (12.66),

$$T^* = \min\left\{T \geq 1 : \delta^{T+1} \leq x\right\}, \qquad x \equiv \frac{2(1-\gamma)\delta - 1}{1 - 2\gamma}. \tag{12.68}$$

(iv) The threshold $\frac{1}{2(1-\gamma)}$ that δ must exceed rises with γ, and T^* is weakly increasing in γ.

(v) A war of one period never suffices: $\Lambda(1) < 1$ for every $\gamma \in [0,1)$ and $\delta \in (0,1)$, so $T^* \geq 2$ whenever collusion is sustainable.

Proof. (i) Write the denominator of (12.65) as $1 - \delta + \gamma(\delta - \delta^{T+1})$. It rises with T because δ^{T+1} falls, and it rises with γ. The numerator falls with γ. (ii) If $\gamma \geq \frac{1}{2}$, then $2\gamma - 1 \geq 0$ and $\delta^{T+1} \leq \delta$, so $\Lambda(T) \leq 2(1-\gamma)\delta + (2\gamma - 1)\delta = \delta < 1$. If $\gamma < \frac{1}{2}$, the coefficient $2\gamma - 1$ is negative and δ^{T+1} falls with T, so Λ rises toward its limit. (iii) By (i) the cartel prefers the shortest admissible war. With $\gamma < \frac{1}{2}$, condition (12.66) is equivalent to $(1-2\gamma)\delta^{T+1} \leq 2(1-\gamma)\delta - 1$, that is, to $\delta^{T+1} \leq x$. (iv) The derivative of x with respect to γ is

$$\frac{\partial x}{\partial \gamma} = \frac{-2\delta(1-2\gamma) + 2\left[2(1-\gamma)\delta - 1\right]}{(1-2\gamma)^2} = \frac{2(\delta - 1)}{(1-2\gamma)^2} < 0.$$

A smaller x requires a larger $T+1$, so T^* cannot fall when γ rises. (v) Evaluate Λ at $T=1$ and subtract one:

$$\begin{aligned}\Lambda(1)-1 &= 2(1-\gamma)\delta+(2\gamma-1)\delta^2-1\\ &= -\bigl(1-2\delta+\delta^2\bigr)-2\gamma\delta(1-\delta)\\ &= -(1-\delta)\bigl[(1-\delta)+2\gamma\delta\bigr] \;<\; 0.\end{aligned}$$

Since $\Lambda(0)=\delta<1$ as well, no war shorter than two periods satisfies (12.66). □

Part (v) is the second half of Tirole's Exercise 6.8, which sets $\gamma=\frac{1}{4}$. Collusion then needs $\delta>\frac{1}{2(1-\frac{1}{4})}=\frac{2}{3}$, and at least two punishment periods are required. The result holds for every γ. It explains why neither Example 12.47 below nor Exercise 5 of Section 12.12 can have $T^*=1$. With their parameters a war of two periods already satisfies (12.66), so $T^*=2$ in both. The reason is visible in the case $\gamma=0$. A one-period war costs the deviator its share $\frac{\pi^m}{2}$ one period later, worth $\delta\frac{\pi^m}{2}$, while undercutting gains $\frac{\pi^m}{2}$ today. The loss falls short of the gain for every $\delta<1$, and noise only widens the gap.

The trade-off behind Corollary 12.46 is specific to imperfect monitoring. Under perfect monitoring a harsher punishment is free, because it is never used. Here every war is fought on the path, so a longer war lowers the value of collusion directly. The war must be long enough to deter undercutting and no longer. A war of length zero or one never works, by part (v). Noise of one half or more makes collusion impossible with these strategies. A firm that conforms then triggers a war more often than not, and a deviation raises the probability of war too little to deter it.

The long-run frequency of wars follows from a Markov chain with states "collusive" and "war, k periods elapsed" for $k=1,\dots,T$. Let ψ_0 be the stationary probability of a collusive period. A collusive period leads to a war with probability γ, and every war lasts T periods, so each war state has stationary probability $\gamma\psi_0$. The probabilities sum to one, $\psi_0(1+\gamma T)=1$, and the long-run share of periods spent in wars is

$$1-\psi_0=\frac{\gamma T}{1+\gamma T}. \tag{12.69}$$

Collusive spells last $\frac{1}{\gamma}$ periods on average, counting the period that triggers the war.

Example 12.47 (Numbers)**.** Let $\delta=0.9$ and $\gamma=0.1$. The limit of $\Lambda(T)$ is $2(0.9)(0.9)=1.62>1$, so collusion is sustainable. Condition (12.66) reads $1.62-0.8(0.9)^{T+1}\geq 1$, that is, $0.9^{T+1}\leq\frac{0.62}{0.8}=0.775$. Since $\frac{\ln 0.775}{\ln 0.9}=2.42$, we need $T+1\geq 3$. A war of one period fails ($0.9^2=0.81$), and a war of two periods works ($0.9^3=0.729$), so $T^*=2$. By (12.65), $V=\frac{0.45}{1-0.81-0.0729}\pi^m=3.84\,\pi^m$. The same strategies with an infinite war give $V=\frac{0.45}{0.19}\pi^m=2.37\,\pi^m$, and perfect monitoring gives $\frac{0.5}{0.1}\pi^m=5\,\pi^m$. By (12.69), the firms spend $\frac{0.2}{1.2}=\frac{1}{6}$ of all periods in wars. All numbers are computed by `figures/ch12/src/gp_path.py`.

Figures 12.8 and 12.9 summarize four lessons. First, price wars occur on the equilibrium path even though no firm ever cuts its price. They are necessary: if firms forgave zero sales, undercutting would go unpunished and collusion would unravel. Second, optimal collusion uses a finite war, as short as the incentive constraint allows. Third, more noise makes collusion harder. The patience required rises with γ, and both the expected collusive profit and the value of collusion fall. Fourth, wars follow unexpectedly low demand. This timing is the opposite of

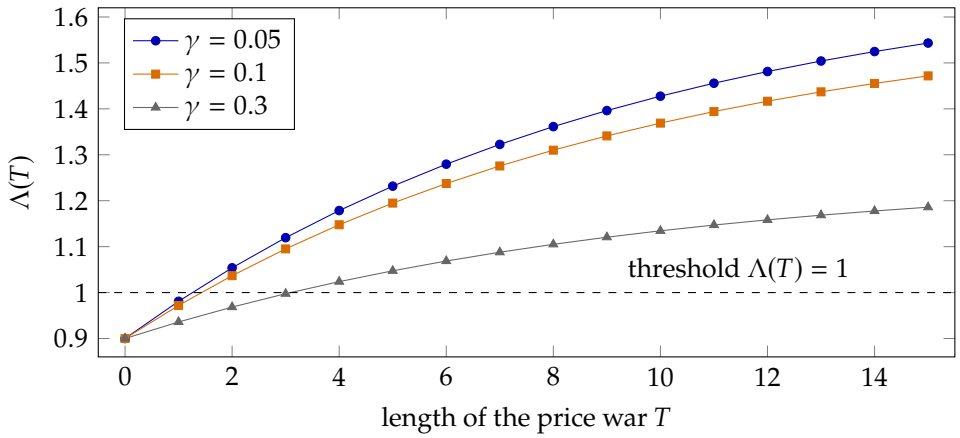

Figure 12.8: The left side of the incentive constraint (12.66) as a function of the length of the price war, for $\delta = 0.9$. Collusion is sustainable with punishment length T when $\Lambda(T) \geq 1$. The shortest admissible war is $T^* = 2$ for $\gamma = 0.05$ and $\gamma = 0.1$, and $T^* = 4$ for $\gamma = 0.3$. The curves approach $2(1-\gamma)\delta$ as T grows.

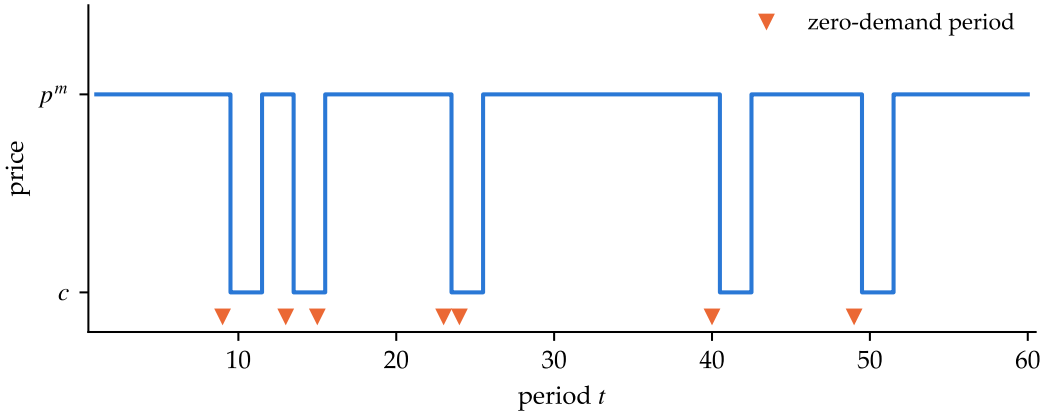

Figure 12.9: A simulated equilibrium price path in the Bertrand version of Green and Porter, with $\gamma = 0.1$ and the optimal war length $T = 2$ for $\delta = 0.9$. Triangles mark periods of zero demand. A zero-demand period in a collusive phase starts a two-period war at marginal cost. Zero-demand periods inside a war (periods 15 and 24) have no effect. Wars occupy 10 of the 60 periods, the long-run share $\frac{1}{6}$. Nobody ever cheats. Source: our simulation, `figures/ch12/src/gp_path.py`.

Section 12.4.2, where demand is observed and collusive prices are lowest in booms. Table 12.6 compares the predictions, and Section 13.3 confronts them with data.

The equilibrium has an uncomfortable feature. When a war starts, both firms know that nobody cheated, since each knows the other's strategy. Both would gain by skipping the war, yet the war is needed to keep conformity optimal in collusive periods. Equilibria of this kind are not robust to renegotiation after bad outcomes. Cartels that can talk and audit each other's sales can avoid some of these wars, which is one reason why explicit cartels organize monitoring (Section 12.7).

N firms, random punishments and the value of transparency. Asker and Nocke (2021, pp. 203–205) use a variant of this model with N firms and a noisy public signal. It yields closed forms for the threshold and for the value of collusion, and it shows why transparency matters even far above the threshold. We state it in our notation. Asker and Nocke write n for N, β for our γ, α for our λ and ρ for our ϕ, and their π^m is our expected profit $\bar{\pi}$.

Assumption 12.48 (Bertrand oligopoly with a noisy public signal)**.**

(i) N identical firms sell a homogeneous good at marginal cost c. Demand in period t is $\theta_t D(p)$, where $\theta_t = 0$ with probability γ and $\theta_t = 1$ otherwise, independently over time. Write $\bar{\pi} = (1-\gamma)\pi^m$ for the expected monopoly profit.

(ii) Firms observe neither θ_t nor rivals' prices. At the start of period t they observe a public signal $s_t \in \{0, 1\}$. It equals one if some firm priced below p^m in period $t-1$. If all firms charged at least p^m, it equals one with probability λ when $\theta_{t-1} = 0$ and zero otherwise.

(iii) A public random variable r_t, uniform on $[0, 1]$, is drawn at the start of each period. The signal is noisy, $\gamma\lambda > 0$, and satisfies $\gamma\lambda < \frac{1}{N}$.

Under the strategy profile $\sigma(\phi)$, every firm charges p^m until the first period in which $s_t = 1$ and $r_t \le \phi$. From then on every firm prices at c forever. A bad signal thus triggers Nash reversion with probability $\phi \in [0, 1]$, and the cartel chooses ϕ. The profile conditions only on public information. It is a *perfect public equilibrium* if it is optimal for every firm after every public history. Section 12.6.3 gives the formal definition.

Proposition 12.49 (Threshold and value with a noisy signal)**.** *Under Assumption 12.48, $\sigma(\phi)$ is a perfect public equilibrium if and only if*

$$\phi \;\ge\; \phi^* \equiv \frac{1-\delta}{\delta} \cdot \frac{N-1}{1-N\gamma\lambda}. \tag{12.70}$$

Collusion at p^m is therefore sustainable in this class if and only if

$$\delta \;\ge\; \underline{\delta} = \frac{N-1}{N(1-\gamma\lambda)}. \tag{12.71}$$

The best such equilibrium uses ϕ^*, and each firm's per-period value is

$$v^* = (1-\delta)V(\phi^*) = \frac{1-N\gamma\lambda}{1-\gamma\lambda} \cdot \frac{\bar{\pi}}{N}. \tag{12.72}$$

Proof. On the path, each firm earns $\frac{\bar{\pi}}{N}$ in expectation. Reversion is triggered next period with probability $\gamma\lambda\phi$, after which every firm earns zero. The value before reversion therefore solves

$$V(\phi) = \frac{\bar{\pi}}{N} + \delta(1-\gamma\lambda\phi)V(\phi) \quad\Longrightarrow\quad V(\phi) = \frac{\bar{\pi}}{N\left[1-\delta(1-\gamma\lambda\phi)\right]}.$$

A firm that undercuts slightly earns almost $\bar{\pi}$ in expectation, and the signal then equals one for sure. Reversion follows with probability ϕ, so the best one-shot deviation is worth $V^{\text{dev}}(\phi) = \bar{\pi} + \delta(1-\phi)V(\phi)$. Reversion is a stage equilibrium after every history, so by the one-shot deviation principle the profile is an equilibrium if and only if $V(\phi) \geq V^{\text{dev}}(\phi)$. Rearrange this as $V(\phi)\big[1-\delta(1-\phi)\big] \geq \bar{\pi}$ and substitute $V(\phi)$:

$$\frac{1-\delta+\delta\phi}{N\big[1-\delta+\delta\gamma\lambda\phi\big]} \geq 1 \quad \Longleftrightarrow \quad 1-\delta+\delta\phi \geq N(1-\delta)+N\delta\gamma\lambda\phi.$$

Collect the terms in ϕ:

$$\delta\phi\,(1-N\gamma\lambda) \;\geq\; (N-1)(1-\delta).$$

Since $N\gamma\lambda < 1$, dividing gives (12.70). A probability $\phi \leq 1$ satisfies it if and only if $\phi^* \leq 1$, that is, $\delta(1-N\gamma\lambda) \geq (N-1)(1-\delta)$. Collecting the terms in δ gives $\delta(N-N\gamma\lambda) \geq N-1$, which is (12.71). The value $V(\phi)$ falls with ϕ, so the best equilibrium in the class uses ϕ^*. At ϕ^*,

$$\delta\gamma\lambda\phi^* = \frac{(1-\delta)(N-1)\gamma\lambda}{1-N\gamma\lambda}, \qquad 1-\delta+\delta\gamma\lambda\phi^* = (1-\delta)\,\frac{1-\gamma\lambda}{1-N\gamma\lambda}.$$

Substituting into $(1-\delta)V(\phi^*)$ gives (12.72). □

These are equations (3) to (5) of Asker and Nocke. Two special cases connect them with the rest of the chapter. With perfect monitoring, $\lambda = 0$, the threshold is $\frac{N-1}{N}$ of Proposition 12.14 and $v^* = \frac{\bar{\pi}}{N}$. With $N = 2$ and $\lambda = 1$, zero demand always triggers the signal, as zero sales do in Assumption 12.43. The threshold (12.71) is then $\frac{1}{2(1-\gamma)}$, the threshold of Corollary 12.46 for an infinite war.

The result changes how we should read comparative statics. Under perfect monitoring the per-period value jumps from zero to $\frac{\bar{\pi}}{N}$ at the threshold and is flat above it. A small change in the number of firms then has no effect on collusion unless δ is close to the threshold. With noise, v^* falls continuously with N and with $\gamma\lambda$ however patient the firms are (Asker and Nocke, 2021, p. 205). Better observability of deviations, a lower λ, lowers the threshold and also raises v^*, because the cartel can punish less often on the path. Take $N = 3$ and $\gamma = 0.2$, our own illustration. With $\lambda = 0.5$ the threshold is $\frac{2}{3(0.9)} \approx 0.741$ and v^* is $\frac{0.7}{0.9} \approx 0.78$ of the perfect-monitoring value. With $\lambda = 0.25$ these become $\frac{2}{3(0.95)} \approx 0.702$ and $\frac{0.85}{0.95} \approx 0.89$. This is the formal content of the view that transparent prices facilitate collusion. Sugaya and Wolitzky (2018) point out a limit. Some information lets a firm tailor its deviation to current conditions. A cartel member that learns in advance that its cost of serving a rival's territory is low can deviate exactly then, which makes collusion harder (Asker and Nocke, 2021, p. 205, note 69).

12.5.3 The original model: Green and Porter (1984)

Question and context. Green and Porter (1984) ask how a cartel can enforce collusion when firms cannot observe each other's outputs and demand is uncertain. Two rigorous formulations of noncooperative collusion existed. In the reaction-function equilibrium of Osborne (1976), firms respond to output changes so as to keep their shares. In the supergame of Friedman (1971), firms revert to Cournot behavior forever after a price drop. In both, incentives are so perfect that deterrence is never observed. Time-series data then cannot tell a collusive equilibrium from a competitive one (Bresnahan, 1982). Green and Porter show that this perfection is an

artifact of certainty. With imperfect information, optimal incentive schemes involve recurrent episodes of the conduct previously called price wars or punishments (pp. 87–88).

Which industries the model describes. The authors list four structural features of a suitable industry (p. 90). First, the industry is stable over time, which makes rational expectations credible and justifies stationary dynamic programming. Second, output is the only decision variable. Firms cannot differentiate products or divide the market, so a suspected cheater cannot be isolated and punished alone. Third, all information except each firm's own output is public. Firms know each other's cost functions, and all observe a common variable that tells them whether the industry is in a collusive or a reversionary state. Fourth, this monitoring variable is imperfectly correlated with conduct. Otherwise reversions would never occur. The fourth feature excludes markets with few, publicly announced transactions, such as contracts awarded by sealed bids. The authors propose the American rail freight industry of the 1880s as an example (p. 94), the cartel analyzed by Porter (1983a) in Section 13.3.

Assumption 12.50 (The Green-Porter environment)**.**

(i) There are N firms producing a homogeneous good. Firm i's net return from producing x_i units and selling at price p is $\pi_i(x_i, p)$. Firms are risk neutral and maximize $\mathbb{E}\big[\sum_{t\geq 0}\delta^t \pi_i(x_{it}, p_t)\big]$.

(ii) The observed price is

$$p_t = \eta_t\, P\Big(\sum_{i=1}^{N} x_{it}\Big), \tag{12.73}$$

where P is a decreasing inverse demand function and the shocks η_t are i.i.d. with cdf F_η, continuous density f_η, and $\mathbb{E}[\eta_t] = 1$. No firm observes η_t.

(iii) Each firm observes the history of prices and its own outputs. It never observes its rivals' outputs.

We change the paper's notation. Its discount factor β is our δ, and its inverse demand $p(\cdot)$ is our $P(\cdot)$. Its demand shock θ_t is our η_t, since θ is the conduct parameter in this book. A *contingent strategy* for firm i is a sequence $s_i = (s_{i0}, s_{i1}, \dots)$, where s_{i0} is an initial output and $s_{i,t+1}(p_0, \dots, p_t)$ gives the output at $t+1$ as a function of past prices. Write $\mathbb{E}_s$ for the expectation under the price process generated by a profile s. A *Nash equilibrium* is a profile $s^* = (s_1^*, \dots, s_N^*)$ such that, for every firm i and every feasible s_i (GP (1), p. 91),

$$\mathbb{E}_{s_1^*,\dots,s_i,\dots,s_N^*}\left[\sum_{t=0}^{\infty}\delta^t \pi_i\big(s_{it}(p_0,\dots,p_{t-1}), p_t\big)\right] \;\leq\; \mathbb{E}_{s^*}\left[\sum_{t=0}^{\infty}\delta^t \pi_i\big(s_{it}^*(p_0,\dots,p_{t-1}), p_t\big)\right]. \tag{12.74}$$

Trigger-price strategies. Let $y = (y_1, \dots, y_N)$ be a profile of *restricted outputs* and $z = (z_1, \dots, z_N)$ the Cournot output profile of the stage game, in which each firm maximizes its expected one-period return. Fix a *trigger price* $\bar{p}$ and an integer $T \geq 2$. Period t is *normal* if (a) $t = 0$, or (b) $t-1$ was normal and $p_{t-1} \geq \bar{p}$, or (c) $t - T$ was normal and $p_{t-T} < \bar{p}$. Every other period is *reversionary*. Firm i produces y_i in normal periods and z_i in reversionary periods (pp. 91–92). If a normal period t ends with $p_t < \bar{p}$, periods $t+1, \dots, t+T-1$ are reversionary and period $t+T$ is normal again. A reversionary episode therefore lasts $T-1$ periods, and prices observed during it are ignored. The length T of the Bertrand version corresponds to $T-1$ here. The strategies are simple enough to coordinate on, and Green and Porter suggest that they would arise from an explicit agreement (p. 89, footnote 5).

Each firm faces a stationary dynamic programming problem with T states: normal, and k periods into a reversion for $k = 1, \dots, T-1$. In a reversionary period the firm's output does not affect future states, so it maximizes its expected current return against rivals' Cournot outputs and produces z_i. A reversion is thus a temporary switch to the static Nash equilibrium. In normal periods the problem is the same every time, so the firm's best policy is a constant output r. The question is when $r = y_i$ is optimal.

Let $w_i = \sum_{j \neq i} y_j$ be the rivals' restricted output. Define firm i's expected return in a normal period when it produces r, and its expected Cournot return, as

$$\bar{\pi}_i(r) = \mathbb{E}_\eta\big[\pi_i\big(r, \eta P(r + w_i)\big)\big], \qquad \pi_i^N = \mathbb{E}_\eta\Big[\pi_i\Big(z_i, \eta P\Big(\sum_j z_j\Big)\Big)\Big] \tag{12.75}$$

(the paper writes $\gamma_i(r)$ and δ_i). Collusion is profitable: $\bar{\pi}_i(y_i) > \pi_i^N$ for every i. A reversion starts after a normal period in which $\eta P(r + w_i) < \bar{p}$, an event with probability

$$F_i(r) \equiv \mathbb{P}\big(\eta P(r + w_i) < \bar{p}\big) = F_\eta\Big(\frac{\bar{p}}{P(r + w_i)}\Big). \tag{12.76}$$

This probability rises with r, since more output lowers $P(r + w_i)$. Overproduction is detected only statistically, through a higher chance of a low price.

Proposition 12.51 (The value of a trigger-price strategy)**.** *Under Assumption 12.50, suppose rivals follow the trigger-price strategies, and firm i produces r in all normal periods and z_i in all reversionary periods. Let $V_i(r)$ be its expected discounted value in a normal period. Then (GP (2), p. 92)*

$$V_i(r) = \bar{\pi}_i(r) + \delta\big[1 - F_i(r)\big]V_i(r) + F_i(r)\left[\sum_{t=1}^{T-1} \delta^t \pi_i^N + \delta^T V_i(r)\right], \tag{12.77}$$

and its solution is (GP (3), p. 92)

$$V_i(r) = \frac{\pi_i^N}{1 - \delta} + \frac{\bar{\pi}_i(r) - \pi_i^N}{1 - \delta + (\delta - \delta^T)F_i(r)}. \tag{12.78}$$

Proof. In a normal period the firm earns $\bar{\pi}_i(r)$ in expectation. With probability $1 - F_i(r)$ the price stays above $\bar{p}$, and the next period is normal with value $\delta V_i(r)$. With probability $F_i(r)$ a reversion follows. The firm earns π_i^N in each of the $T - 1$ reversionary periods and returns to a normal period after T periods. This gives (12.77). To solve it, use the geometric sum

$$\sum_{t=1}^{T-1} \delta^t = \frac{\delta - \delta^T}{1 - \delta}$$

and collect the terms in $V_i(r)$:

$$V_i(r)\big[1 - \delta + \delta F_i(r) - \delta^T F_i(r)\big] = \bar{\pi}_i(r) + F_i(r)\,\frac{\delta - \delta^T}{1 - \delta}\,\pi_i^N.$$

Let $\Delta_i(r) \equiv 1 - \delta + (\delta - \delta^T)F_i(r)$ denote the bracket. Then

$$V_i(r) = \frac{\bar{\pi}_i(r) + F_i(r)\frac{\delta - \delta^T}{1 - \delta}\pi_i^N}{\Delta_i(r)}.$$

Subtract $\frac{\pi_i^N}{1-\delta} = \frac{\Delta_i(r)\,\pi_i^N}{(1-\delta)\Delta_i(r)}$ from both sides. The numerator on the right becomes

$$\bar{\pi}_i(r) + F_i(r)\frac{\delta - \delta^T}{1-\delta}\pi_i^N - \frac{1-\delta+(\delta-\delta^T)F_i(r)}{1-\delta}\pi_i^N = \bar{\pi}_i(r) - \pi_i^N,$$

which gives (12.78). □

Equation (12.78) says that the firm's value equals its value in a permanently Cournot industry plus the one-period gain from colluding, capitalized at the rate $\Delta_i(r)$. That rate exceeds $1-\delta$ because the collusive gain is interrupted by reversions. A larger trigger probability $F_i(r)$ or a longer reversion raises $\Delta_i(r)$ and lowers the value of collusion.

Equilibrium conditions. The trigger-price profile is a Nash equilibrium if and only if no firm gains by changing its normal-period output (GP (4), p. 93):

$$V_i(r) \le V_i(y_i) \quad \text{for all } r \text{ and all } i. \tag{12.79}$$

The first-order condition is $V_i'(y_i) = 0$ (GP (5)). The next result writes it out.

Proposition 12.52 (The first-order condition)**.** *Let $Y = \sum_j y_j$ and $k = \frac{\bar{p}}{P(Y)}$. At an interior equilibrium, for every i (GP (6), p. 93),*

$$\left[1-\delta+(\delta-\delta^T)F_\eta(k)\right]\bar{\pi}_i'(y_i) + (\delta-\delta^T)\,f_\eta(k)\,\frac{\bar{p}\,P'(Y)}{P(Y)^2}\left[\bar{\pi}_i(y_i) - \pi_i^N\right] = 0. \tag{12.80}$$

Equivalently,

$$\underbrace{\bar{\pi}_i'(y_i)}_{\text{marginal gain}} \quad \Delta_i(y_i) = \underbrace{(\delta-\delta^T)\,f_\eta(k)\,k\,\frac{-P'(Y)}{P(Y)}}_{\text{marginal rise in the risk of reversion}} \quad \underbrace{\left[\bar{\pi}_i(y_i) - \pi_i^N\right]}_{\text{loss per period of reversion}}. \tag{12.81}$$

Proof. By (12.78), $V_i(r) = \frac{\pi_i^N}{1-\delta} + \frac{n(r)}{\Delta_i(r)}$ with $n(r) = \bar{\pi}_i(r) - \pi_i^N$. Its derivative is zero if and only if $n'(r)\Delta_i(r) - n(r)\Delta_i'(r) = 0$. Here $n'(r) = \bar{\pi}_i'(r)$ and, by the chain rule,

$$\Delta_i'(r) = (\delta-\delta^T)\,f_\eta\!\left(\frac{\bar{p}}{P(r+w_i)}\right)\cdot\left(-\frac{\bar{p}\,P'(r+w_i)}{P(r+w_i)^2}\right).$$

Substituting and evaluating at $r = y_i$, so that $r + w_i = Y$, gives (12.80). Since $\frac{\bar{p}}{P(Y)^2} = \frac{k}{P(Y)}$, moving the second term to the right gives (12.81). □

Equation (12.81) balances two margins (p. 93). The marginal return from producing more in normal periods is exactly offset by the marginal rise in the risk of a reversion, valued at the loss it causes. Both sides are positive, since $P' < 0$. Hence $\bar{\pi}_i'(y_i) > 0$: each firm produces less than its static best response to its rivals' restricted outputs. The threat of reversion sustains that gap. The N conditions (12.80) restrict the vector y, so a given output profile, such as the one that maximizes joint profits, need not be supportable. A cartel that chooses $(y, \bar{p}, T)$ to maximize its members' values subject to (12.79) faces a trade-off. A lower trigger price or a shorter reversion destroys less surplus on the path but deters less. Green and Porter report that Porter (1983b) solves this problem for symmetric firms. The optimal normal-period output differs from the monopoly output: firms give up some normal-period profit to reduce the frequency and duration of reversions (p. 93, footnote 9). The next example illustrates the trade-off.

Example 12.53 (A linear duopoly with lognormal shocks)**.** Let $N = 2$, $P(Q) = 1 - Q$, zero marginal cost and $\pi_i(x_i, p) = p x_i$. Let $\ln \eta \sim \mathcal{N}(-\frac{\sigma^2}{2}, \sigma^2)$, so that $\mathbb{E}[\eta] = 1$, with $\sigma = 0.1$ and $\delta = 0.95$. Each firm's Cournot output is $\frac{1}{3}$ with $\pi_i^N = \frac{1}{9} = 0.1111$, and splitting the monopoly output gives $y_i = \frac{1}{4}$ with $\bar{\pi}_i = \frac{1}{8} = 0.125$. With symmetric restricted output y, $\bar{\pi}_i(r) = r(1-r-y)$, so $\bar{\pi}_i'(y) = 1 - 3y$ and $\frac{-P'(Y)}{P(Y)} = \frac{1}{1-2y}$. Writing $u = \frac{1}{\sigma}\left(\ln k + \frac{\sigma^2}{2}\right)$ in standard units, $F_\eta(k) = \Phi(u)$ and $f_\eta(k)k = \frac{\phi(u)}{\sigma}$, where Φ and ϕ are the standard normal cdf and density. Condition (12.81) becomes

$$(1 - 3y)\left[1 - \delta + (\delta - \delta^T)\Phi(u)\right] = (\delta - \delta^T)\,\frac{\phi(u)}{\sigma}\,\frac{y(1-2y) - \frac{1}{9}}{1 - 2y}.$$

For each (y, T) we solve for the trigger with the smallest reversion probability, check the global condition (12.79) on a grid of outputs, and compute the normalized value $(1 - \delta)V_i(y)$. Table 12.7 reports the best y for several T. Three features stand out. The monopoly split $y = \frac{1}{4}$ can be supported only with long reversions, $T \geq 14$. For every T the best restricted output exceeds $\frac{1}{4}$, as in Porter (1983b): producing more lowers the gain from overproduction and the trigger probability needed to deter it. Finally, the cartel captures about two thirds of the gain from monopoly over Cournot, since $\frac{0.1206 - 0.1111}{0.125 - 0.1111} = 0.68$.

Table 12.7: Best symmetric trigger-price equilibria in the linear duopoly of Example 12.53

T	Best y	Trigger $\bar{p}$	$\mathbb{P}$(reversion)	Long-run share in reversion	$(1-\delta)V_i$
4	0.2925	0.380	0.205	0.380	0.1177
8	0.2800	0.380	0.079	0.357	0.1194
16	0.2750	0.376	0.040	0.374	0.1201
50	0.2725	0.369	0.021	0.507	0.1205
∞	0.2700	0.373	0.020	1	0.1206
14 ($y = \frac{1}{4}$)	0.2500	0.447	0.144	0.653	0.1171

Notes: $P(Q) = 1 - Q$, zero cost, $\ln \eta \sim \mathcal{N}(-\frac{\sigma^2}{2}, \sigma^2)$ with $\sigma = 0.1$, $\delta = 0.95$. Outputs are searched on a grid of step 0.0025 in $[0.20, 0.33]$. Reversions last $T - 1$ periods. $\mathbb{P}$(reversion) $= F_\eta(\frac{\bar{p}}{P(2y)})$ is the probability that a normal period triggers a reversion. The long-run share of reversionary periods is $\frac{(T-1)G}{1+(T-1)G}$ with $G = \mathbb{P}$(reversion) (Proposition 12.54). With $T = \infty$ the first reversion is permanent. The last row is the shortest reversion that supports the monopoly split. With $T = 2$ no output in the grid is an equilibrium. Benchmarks: Cournot 0.1111, monopoly split 0.125. Source: our computation, `figures/ch12/src/gp_design.py`.

The example also shows that, in a discounted model, the cartel may prefer an infinite reversion although it ends collusion for good in the long run. With $\delta = 0.95$, the expected wait of fifty periods before the first reversion makes its distant cost small. This is a property of the restricted class of trigger strategies with Cournot reversion. Richer punishments do better, as we discuss below.

Properties of the equilibrium. Two observations complete the formal model (pp. 93–94). First, no firm ever defects. Every firm can compute what every other firm will produce, so a low price reveals information about demand only. In equilibrium the frequency of reversions from normal periods is $F_\eta\left(\frac{\bar{p}}{P(\sum_j y_j)}\right)$. Second, firms take part in reversions although they know that low prices reflect demand. A reversion is a temporary switch to a static Nash equilibrium, so no firm gains by deviating from it unilaterally. If firms ignored low prices and kept colluding,

the first-order condition (12.80) would fail in normal periods, and restricted output would no longer be individually optimal. Green and Porter add that the equilibrium is perfect, citing Green (1980) for a formal statement (p. 93, footnote 10).

A reversal of the traditional interpretation. The model reverses the traditional reading of a common price pattern (p. 94). Consider an episode in which price drops sharply, stays low, and then recovers without any cost or demand shock. Such an episode was read as predation against an entrant, or as the breakdown and re-establishment of a cartel. Either way it signaled fragile collusion. Some argued that intervention was redundant in markets with such episodes, since the market was already resisting collusion. In the Green-Porter equilibrium the same episodes are an essential part of a stable collusive scheme. An industry with the four structural features will show price instability as a stationary feature of collusion. The policy conclusion is the opposite of the traditional one.

12.5.4 The price process and its estimation

Because both collusive and reversionary behavior are observed over time, the collusive equilibrium can be identified statistically. The appendix of Green and Porter (1984) characterizes the price process and shows that its parameters can be estimated consistently.

The switching process. A *switching process* has four parts (p. 96). The first is a state process $\{W_t\}$ with values in a set S and normal states $S_0 \subset S$. The others are an observed process $\{X_t\}$ and two latent processes $\{Y_t\}$ and $\{Z_t\}$. The latent variables are independent, the Y_t have a common cdf G, the Z_t have a common cdf H, and $\{W_t\}$ is Markov with stationary transition probabilities. The observed variable is $X_t = Y_t$ when $W_t \in S_0$ and $X_t = Z_t$ otherwise. (In this subsection G and H are local symbols for price distributions.) The usual case has $S = \{0, 1\}$ and a Bernoulli state process independent of prices.

For the collusive price process, Y_t is the price that would prevail in a normal period and Z_t the price in a reversionary one. Under (12.73),

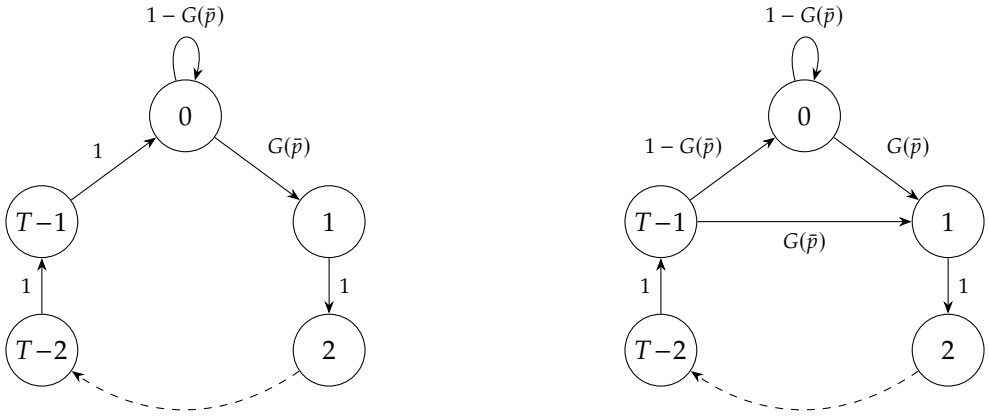
$$G(p) = F_\eta\Big(\frac{p}{P(\sum_j y_j)}\Big), \qquad H(p) = F_\eta\Big(\frac{p}{P(\sum_j z_j)}\Big).$$

The states are $S = \{0, 1, \ldots, T-1\}$ with $S_0 = \{0\}$, where state $k \geq 1$ means k periods into a reversion. The transitions are (GP (A7) to (A10), p. 96)

$$W_{t+1} = \begin{cases} 0 & \text{if } W_t = 0 \text{ and } Y_t \geq \bar{p}, \\ 1 & \text{if } W_t = 0 \text{ and } Y_t < \bar{p}, \\ k+1 & \text{if } W_t = k \text{ with } 1 \leq k < T-1, \\ 0 & \text{if } W_t = T-1. \end{cases} \tag{12.82}$$

Since the Y_t are i.i.d., $\{W_t\}$ is a Markov chain with stationary transition probabilities. Its transition graph is panel (a) of Figure 12.10. Unlike the usual switching model, the state depends on past prices.

Stationarity and ergodicity. Green and Porter show that the initial state can be chosen so that $\{X_t\}$ is a stationary ergodic process (pp. 95–96). Since X_t is a function of (W_t, Y_t, Z_t), it suffices that the joint process is a stationary Markov process with a unique invariant distribution. A stationary process is *ergodic* if every event that is unchanged when the time index is shifted has probability zero or one. The *ergodic theorem* then extends the strong law of large numbers to



(a) Price process **(b)** Approximating process

Figure 12.10: Transition graphs of the state W_t. State 0 is normal, and state $k \geq 1$ is the k-th period of a reversion. In the price process (a), a normal period with a price below $\bar{p}$ starts a reversion. The approximating process (b) deletes these triggering periods, so the state leaves $T-1$ for state 1 directly when the next normal price would trigger a reversion. Redrawn from Green and Porter (1984), Figures 1 and 2.

the process, so sample averages converge to population moments. This is the foundation for the asymptotic theory of estimators, and it implies that consistent estimators of $\bar{p}$ and T exist (p. 95).

Proposition 12.54 (Stationary distribution of the regimes)**.** *Let ψ_k be the stationary probability of state k under* (12.82)*. Then*

$$\psi_0 = \big[1 + (T-1)G(\bar{p})\big]^{-1}, \qquad \psi_k = G(\bar{p})\,\psi_0 \quad (k = 1, \ldots, T-1). \tag{12.83}$$

The long-run share of reversionary periods is $\frac{(T-1)G(\bar{p})}{1+(T-1)G(\bar{p})}$.

Proof. Under the stationary distribution, $\mathbb{P}(W_1 = j) = \mathbb{P}(W_0 = j) = \psi_j$ for every j. For $1 \leq k < T-1$, the only way to reach state $k+1$ is from state k, with probability one. Hence (GP (A21)) $\psi_{k+1} = \psi_k$. The only way to reach state 1 is from state 0 with $Y_0 < \bar{p}$. Since Y_0 is independent of W_0, this gives (GP (A22)) $\psi_1 = \psi_0 G(\bar{p})$. So $\psi_k = G(\bar{p})\psi_0$ for $k = 1, \ldots, T-1$. The probabilities sum to one:

$$\psi_0 + (T-1)G(\bar{p})\psi_0 = 1,$$

which gives (GP (A23)) the first formula. The share of reversionary periods is $1 - \psi_0$. □

The share formula matches (12.69) with γ replaced by $G(\bar{p})$ and T by $T-1$. In equilibrium $G(\bar{p}) = F_\eta(\frac{\bar{p}}{P(\sum_j y_j)})$, the frequency of reversions noted above.

The approximating process and contamination. Maximum likelihood estimation of the price process is awkward, because the regime depends on past prices. Porter (1983a) instead estimates a related process that keeps the dependence of the regime on its own past but makes the regime independent of prices (p. 97). This *approximating process* has three properties. Normal prices are drawn from the distribution of Y conditional on $Y \geq \bar{p}$ (GP (A11)),

$$J(p) = \max\Big[\frac{G(p) - G(\bar{p})}{1 - G(\bar{p})},\, 0\Big].$$

The regime, normal prices and reversionary prices are mutually independent (GP (A12)). The regime is a stationary Markov chain with the transitions in panel (b) of Figure 12.10 (GP (A13)). The advantage is that existing work on the maximum likelihood estimation of switching processes applies. The estimator is cheap to compute, and results on its consistency and asymptotic normality are available (p. 97).

The approximating process is obtained from the price process by deleting the triggering observations, the normal periods in which $Y_t < \bar{p}$ (pp. 97–98). A *stopping time* is a random date whose occurrence is determined by the history up to that date. Formally, define stopping times by $\tau_0 = 1$ if $W_0 = 0$ and $Y_0 < \bar{p}$, $\tau_0 = 0$ otherwise, and

$$\tau_{t+1} = \begin{cases} \tau_t + 2 & \text{if } W_{\tau_t+1} = 0 \text{ and } Y_{\tau_t+1} < \bar{p}, \\ \tau_t + 1 & \text{otherwise.} \end{cases}$$

We set $X'_t = X_{\tau_t}$ and re-index the state and latent variables in the same way (GP (A14) to (A17)). Because the chain restarts afresh at each such date (the *strong Markov property*), the censored state process is a stationary Markov chain, now independent of prices. Conversely, the observed price series is a *contaminated* sample path of the approximating process. The contaminating observations are the triggering prices, which the approximating process does not contain.

Proposition 12.55 (The contamination ratio)**.** *With probability one (GP (A24), p. 99),*

$$\lim_{t\to\infty} \frac{\tau_t - t}{\tau_t} = \frac{G(\bar{p})}{1 + (T-1)G(\bar{p})}. \tag{12.84}$$

Proof. Let $a(W, Y) = 1$ if $W = 0$ and $Y < \bar{p}$, and $a(W, Y) = 0$ otherwise. Each deleted observation is a period with $a = 1$, so $\tau_t = t + \sum_{u=0}^{\tau_t} a(W_u, Y_u)$ and (GP (A18))

$$\frac{\tau_t - t}{\tau_t} = \frac{1}{\tau_t} \sum_{u=0}^{\tau_t} a(W_u, Y_u).$$

By the ergodic theorem the average converges almost surely to $\mathbb{P}(W_0 = 0, Y_0 < \bar{p})$ (GP (A19)). The state W_0 depends only on draws before period 0, and the Y_t are i.i.d.. Hence W_0 and Y_0 are independent, and the limit is $\psi_0 G(\bar{p})$ (GP (A20)). Substituting ψ_0 from Proposition 12.54 gives (12.84). □

Table 12.8 reproduces the authors' numerical illustration (p. 99). With weekly data, $G(\bar{p}) = 0.025$ and $T = 11$, a normal episode lasts forty weeks on average and a reversion ten weeks. A reversion therefore occurs about once a year, and about one price observation a year is a triggering price that the approximating process would not contain. The contamination ratio is one in fifty. The estimator splits the sample into a subsample attributed to G and one attributed to H, and estimates each distribution separately. If the contaminating observations were spread in proportion, each subsample would be 2 percent contaminated. If all of them were assigned to the normal subsample, its contamination would be 2.5 percent, which still seems negligible. If all of them were assigned to the reversionary subsample, which is only one fifth of the data, its contamination would be 10 percent. In this worst case the low draws from G could bias the estimate of H seriously. Green and Porter note that these parameter values are approximately those that Porter (1983a) reports for the rail freight cartel. They conclude that the bias is plausibly slight under optimistic assumptions, while acknowledging an element of judgment (p. 99). Sections 13.2 and 13.3 develop the estimator and Porter's results.

Table 12.8: Green and Porter's illustration of the contamination of the approximating process

Quantity	Formula	Value
Probability that a normal week triggers a reversion	$G(\bar{p})$	0.025
Length of a reversion (weeks)	$T-1$	10
Expected length of a normal episode (weeks)	$\frac{1}{G(\bar{p})}$	40
Long-run share of normal weeks	$\psi_0 = [1+(T-1)G(\bar{p})]^{-1}$	$\frac{1}{1.25} = 0.8$
Contamination ratio	$\psi_0 G(\bar{p})$	$\frac{0.025}{1.25} = 0.02$
Contamination of each subsample used by the estimator		
Triggering prices split proportionally		2 percent
All triggering prices in the normal subsample	$\frac{0.02}{0.8}$	2.5 percent
All triggering prices in the reversionary subsample	$\frac{0.02}{0.2}$	10 percent

Notes: A period is one week, as when a trade association circulates weekly prices. The parameter values $G(\bar{p}) = 0.025$ and $T = 11$ and the contamination levels are those of the example in Green and Porter (1984, p. 99). The intermediate quantities are computed from Propositions 12.54 and 12.55.

12.5.5 Testable implications, extensions and critiques

Testable implications. The model makes several predictions that distinguish it from collusion under perfect monitoring. Conduct switches between discrete regimes, so the supply relation shifts between a collusive and a Cournot (or Bertrand) regime. Reversions start after unexpectedly low prices, which reflect unobserved negative demand shocks rather than observable booms. Reversions have a fixed and finite length in the simplest version. In normal periods output exceeds the joint-profit level when the cartel designs its scheme optimally. Chapter 13 tests these predictions with the data of the Joint Executive Committee and compares them with those of Section 12.4 (Sections 13.2 and 13.3). The regime switches also imply that a single conduct parameter estimated over the whole sample averages two conducts, the problem discussed in Chapter 3.

Extensions. Green and Porter study only the simplest trigger-price strategies. Firms might, for example, condition the length of a reversion on how far the price falls below $\bar{p}$ (p. 92, footnote 8). Porter (1983b) chooses the trigger price, the reversion length and the restricted output optimally. Abreu et al. (1986) characterize optimal symmetric equilibria of a Green-Porter industry without restricting strategies. We follow the account of Tirole (1988, section 6.7.1.2). Two assumptions give sharp results. First, the firms' payoff functions are concave. Second, the distribution of the market price given aggregate output satisfies the *monotone likelihood ratio property* (MLRP). Informally, a low price is more likely to come from a high output than from a low one. Under these assumptions, attention can be restricted to two phases with values V^+ and V^-, the best and the worst payoffs in the set of symmetric perfect equilibria. In the collusive phase each firm produces q^+, and a punishment starts if the price falls below a threshold p^+. This *tail test* is the trigger of Green and Porter (1984). The punishment phase has no fixed length. Each firm produces a high output q^-. Play stays in the punishment phase as long as the price exceeds a second threshold p^-, and it returns to the collusive phase when the price falls below p^-. This *inverse tail test* looks odd at first. A harsh punishment requires an output higher than each firm would choose privately. A high price signals low output, so it is a high price that prolongs the punishment. The two phases follow a Markov process, and punishments can be harsher than Cournot reversion. Abreu et al. (1990) develop the recursive

method behind this result (Section 12.2.7). Fudenberg et al. (1994) give conditions on how the distribution of the public signal responds to each player's actions under which a folk theorem holds with imperfect public monitoring. When signals are private to each firm, as with secret sales, the problem is harder, and Section 12.7.3 studies how cartels solve it with reports and transfers.

Critiques. Several limitations qualify the model. First, the restriction to trigger strategies with Cournot reversion is not innocuous: as noted above, richer punishments do better. Second, wars are costly to the cartel, and firms that know nobody cheated have a reason to renegotiate them away. Third, the source of the inference problem matters. Section 12.6 shows that when firms have private information about costs and prices are public, optimal collusion typically needs no wars at all. Fourth, real cartels communicate, exchange sales data and make transfers, which changes the monitoring problem (Section 12.7). Fifth, Levenstein and Suslow (2006) find that many price wars in documented cartels arise from bargaining over shares rather than from noise (Section 12.9). Sixth, the shocks are i.i.d.. Green and Porter note that a martingale specification would suit durable goods better and accept that the i.i.d. assumption is restrictive (p. 91, footnote 7). Finally, the four structural conditions are demanding, and the authors concede that the direct applicability of the model is severely limited (p. 94).

Contribution. Green and Porter (1984) provided the first equilibrium theory of price wars as part of a working cartel. They turned Stigler's policing problem into a repeated game with imperfect public monitoring, reversed the received reading of price instability, and showed that the resulting price process can be estimated. The paper set the template for the theory of repeated games with imperfect monitoring and, through Porter (1983a), for the empirical study of cartel regimes in Chapter 13.

12.6 Private Information about Costs: Collusion and Price Rigidity

The models so far share one feature: firms are identical in every period. In practice each firm's costs move with input prices, breakdowns and the quality of its own operations, and rivals do not observe them. A cartel that wants the lowest-cost firm to serve the market must then learn who has low costs, and firms have an incentive to lie. This section studies Athey et al. (2004a), abbreviated ABS, who analyze collusion when prices are public and costs are private. We work from the November 1998 working-paper version. Page and result numbers refer to it and may differ from the published article.

12.6.1 Question and motivation

ABS place their model as the third canonical extension of the standard collusion model (pp. 1–2). In Rotemberg and Saloner (1986), demand shocks are public and collusive prices vary with them, without wars on the path (Section 12.4.2). In Green and Porter (1984), actions are hidden and wars follow bad shocks. This is a model of repeated *moral hazard*, or hidden action. ABS study repeated *adverse selection*, or hidden information: each firm privately observes its cost, while prices are observed by all.

The application is the relation between collusion and price rigidity. Empirical studies going back to the 1920s, including Carlton (1986, 1989), find that prices are more rigid in concentrated industries (p. 2). Scherer (1980) summarizes studies in which collusion is implemented by rules of thumb, such as a fixed percentage above a common wholesale price. The price then ignores members' private cost positions. The best-known theory of rigidity is the kinked demand

curve (Sweezy, 1939; Hall and Hitch, 1939), which assumes that rivals match price cuts but not increases. As ABS note, it rests on an ad hoc behavioral postulate, compresses a dynamic story into a static model, and does not determine the price. Economists therefore fell back on an informal view. Carlton (1989, pp. 914–915) states it as follows: "Anytime a price change occurs in an oligopoly, there is a risk that a price war could break out. Hence, firms are reluctant to change price." ABS give this view a rigorous form.

Tirole (1988, section 6.2.1) spells out the static story and its weakness. Each of two firms with cost c conjectures that its rival will match any cut below a *focal price* p^f and will ignore any increase. A firm's perceived demand is then $\frac{D(p)}{2}$ below p^f and zero above it. If $(p-c)D(p)$ is quasi-concave, the best price under this conjecture is p^f when $p^f \leq p^m$. Every focal price between c and p^m is therefore consistent with the conjectures. The story explains too much, and it says nothing about how the focal price responds to a change in cost. Maskin and Tirole (1988) give the kinked demand curve an equilibrium foundation. Firms set prices in alternate periods and keep each price for two periods, so a firm's current price affects its rival's profit. In a *Markov perfect equilibrium*, each firm's price depends only on the rival's current price. One such equilibrium has a focal price at the monopoly level. A firm that raises its price is not followed, and a firm that undercuts provokes a price war, after which the firms eventually return to the focal price (Tirole, 1988, section 6.4.1). Tirole reports two further results (section 6.4.2). Industry profit in every Markov perfect equilibrium is bounded away from zero. For discount factors close to one, the average profit in a symmetric equilibrium is at least half the monopoly profit. Other Markov equilibria never settle and produce cycles of price wars and relenting, the Edgeworth cycles of Section 13.6.3. Retaliation in this model has a tangible motive, unlike the bootstrap strategies of Section 12.2.6. ABS reach rigidity by a different route. In their model a rigid price is the cheapest way to collude when costs are private, whereas in Maskin and Tirole it follows from short-run commitment to prices.

12.6.2 The static game

Assumption 12.56 (The ABS stage game)**.**

(i) $N \geq 2$ firms compete in prices in a homogeneous-good market (ABS write n).

(ii) Firm i's unit cost c_i is its private information. Costs are i.i.d. across firms with cdf F on $[\underline{c}, \bar{c}]$ and a density f that is positive everywhere (ABS write θ for the cost).

(iii) A unit mass of identical consumers has demand $D(p)$. Demand is either *inelastic*, with $D(p) = 1$ for $p \leq \bar{v}$ and zero above, where the reservation value satisfies $\bar{v} \geq \bar{c}$ (ABS write r), or *downward sloping*: positive, twice continuously differentiable and decreasing.

(iv) The profit of a firm that serves the whole market, $\pi(p, c) = (p - c)D(p)$, is strictly quasi-concave in p with a unique maximizer $p^m(c)$.

(v) The lowest price wins, and ties are split equally.

Under inelastic demand $p^m(c) = \bar{v}$ for every c, and the game is a first-price procurement auction. With downward-sloping demand $p^m(c)$ increases with c. A *pricing schedule* $p_i(c)$ maps costs into prices, and is continuously differentiable except at finitely many points, so that jumps are allowed. Let $\mathbf{p} = (p_1, \ldots, p_N)$ be a vector of realized prices. Firm i's market share $m_i(\mathbf{p})$ equals one if p_i is strictly lowest, $\frac{1}{k}$ if p_i ties with $k-1$ rivals for the lowest price, and zero otherwise. Its *interim profit*, the expected profit given its cost c_i and price p_i when rivals use

schedules $p_{-i}(\cdot)$, is

$$\Pi_i(p_i, p_{-i}, c_i) = \pi(p_i, c_i)\,\mathbb{E}\big[m_i(p_i, p_{-i}(c_{-i}))\big], \tag{12.85}$$

where the expectation is over the rivals' costs. The product form shows the trade-off. A lower price reduces the profit if the firm wins but raises the probability of winning.

Firms of different types weigh this trade-off differently. The cross-partial derivatives satisfy

$$\pi_c(p, c) = -D(p) < 0, \qquad \pi_{pc}(p, c) = -D'(p) \geq 0, \tag{12.86}$$

with strict inequality under downward-sloping demand. A lower-cost firm earns more if it wins, so it values the extra chance of winning more. A price cut also reduces its profit-if-win by less, because its extra units cost less. This is a *single-crossing property*: lower types find a price cut more attractive than higher types. As in mechanism design, it implies that equilibrium schedules are non-decreasing in cost.

Proposition 12.57 (The static equilibrium, Spulber, 1995)**.** *Under Assumption 12.56, the static game has a unique Nash equilibrium (ABS Proposition 1, p. 10). It is symmetric, $p_i = p^e$ for all i. The schedule p^e is continuously differentiable and strictly increasing on $(\underline{c}, \bar{c})$ and lies below the monopoly price, $p^e(c) < p^m(c)$ for $c < \bar{c}$. Every type except $\bar{c}$ earns a positive interim profit, and $p^e(\bar{c}) = \bar{c}$.*

Under inelastic demand the equilibrium is the low-bid equilibrium of Proposition 14.91. A firm with cost c wins when all $N-1$ rivals have higher costs, an event with probability $[1-F(c)]^{N-1}$, and

$$p^e(c) = c + \frac{\int_c^{\bar{c}} [1-F(t)]^{N-1}\,dt}{[1-F(c)]^{N-1}}. \tag{12.87}$$

Example 12.58 (Uniform costs)**.** Let costs be uniform on $[0,1]$ and $\bar{v} = 1$. Then $[1-F(t)]^{N-1} = (1-t)^{N-1}$ and $\int_c^1 (1-t)^{N-1}dt = \frac{(1-c)^N}{N}$, so

$$p^e(c) = c + \frac{1-c}{N}.$$

Type c earns the interim profit $(p^e(c)-c)(1-c)^{N-1} = \frac{(1-c)^N}{N}$, and the ex ante profit per firm is

$$\int_0^1 \frac{(1-c)^N}{N}\,dc = \frac{1}{N(N+1)}.$$

With two firms, $p^e(c) = \frac{1+c}{2}$, interim profit is $\frac{(1-c)^2}{2}$, and ex ante profit is $\frac{1}{6}$. If instead both firms always charged $\bar{v} = 1$ and split the market, each would earn $\frac{1-\mathbb{E}c}{2} = \frac{1}{4}$ per period. This rigid price gives up efficiency but raises profit by half.

The static equilibrium has no flat segments and no jumps (p. 10). If the schedule jumped up at $\hat{c}$, a firm of type $\hat{c}$ would raise its price into the gap without losing any sales. If the schedule were flat on an interval, a firm on it would shade its price slightly and turn ties into wins. These arguments rely on the winner-take-all nature of the one-shot game, and they fail in the repeated game.

12.6.3 The repeated game and its recursive formulation

Information and strategies. Firms play the stage game in every period. Costs are drawn independently across firms and periods. At the start of a period a firm knows its own past costs and schedules and the realized prices of all firms, but not its rivals' costs or schedules (pp. 10–11). A *public strategy* conditions only on the history of realized prices. A *sequential equilibrium* specifies strategies and beliefs about rivals' private information. Each player's strategy must be optimal after every history given its beliefs, and beliefs must follow Bayes' rule wherever possible. A perfect public equilibrium (PPE) is a profile of public strategies that is a sequential equilibrium. It is immune to deviations that condition on private histories (Fudenberg et al., 1994). Because costs are i.i.d., the continuation of a PPE after any public history is itself a PPE (ABS Lemma 2, p. 11).

Definition 12.59 (Symmetric perfect public equilibrium)**.** A PPE is a *symmetric perfect public equilibrium* (SPPE) if after every public history all firms use the same pricing schedule.

Symmetry means that firms share punishments and rewards. A firm that keeps charging implausibly low prices risks an industry-wide breakdown, which is the "fear of breakdown" of the informal literature (p. 12). Symmetric schemes are also the only option when firms see the prices offered without knowing who offered them. Procurement auctions with more than two bidders that announce the winning bid, but not the name of the winner, are an example (p. 7).

Two kinds of deviations. A collusive scheme must deter two kinds of deviations (p. 11). An *off-schedule* deviation is a price that no type is supposed to charge. It reveals a deviation for sure, so a punishment can follow, and if the punishment deters it the punishment never occurs. An *on-schedule* deviation is a price assigned to another type, typically a lower price assigned to a lower cost. Rivals cannot tell it from truthful behavior. Deterring it with a punishment after low prices is costly, because the punishment then occurs on the path whenever costs are truly low.

The repeated game also allows schedules that the static game rules out (p. 12). A flat schedule can be supported if undercutting it triggers a war. Lowering one's price now changes three things: the chance of winning, the profit-if-win, and the continuation value. The mix of the two incentive problems is chosen by the firms. A fully flat schedule has an acute off-schedule problem and no on-schedule problem. A schedule that spans all relevant prices has no off-schedule problem but possibly an acute on-schedule problem. By choosing the schedule, firms choose the support of the public signal.

The Factored Program. Let $\Pi(p)$ be a firm's ex ante profit when all firms use schedule p, and $\Pi(p', p)$ its profit when it uses p' and its rivals use p. Let $\mathcal{V}$ be the set of SPPE continuation values, with supremum $\bar{\mathcal{V}}$. A symmetric public profile can be factored into a first-period schedule p and a continuation function $v : \mathbb{R}_+^N \to \mathbb{R}$ that gives the common continuation value after each vector of first-period prices. Each firm's payoff is $\Pi(p) + \delta \mathbb{E} v(\mathbf{p})$, where $\mathbf{p}$ is the random price vector generated by p. ABS consider the following problem (p. 13):

$$\begin{aligned} \max_{p,\, v} \quad & \Pi(p) + \delta \mathbb{E} v(\mathbf{p}) \\ \text{s.t.} \quad & v(\mathbf{p}) \in \mathcal{V} \quad \text{for all } \mathbf{p} \in \mathbb{R}_+^N, \\ & \Pi(p) + \delta \mathbb{E} v(\mathbf{p}) \geq \Pi(p', p) + \delta \mathbb{E} v(p', p) \quad \text{for all } p'. \end{aligned} \tag{12.88}$$

Lemma 12.60 (Factorization)**.** *If a symmetric public profile factors into* (p^*, v^*) *and* (p^*, v^*) *solves* (12.88)*, the profile is an optimal SPPE (ABS Lemma 3, p. 13).*

The lemma follows because (p, v) is the factorization of some SPPE if and only if it satisfies the two constraints. Every SPPE has continuation values in $\mathcal{V}$ by the recursion property, and it must be immune to deviations in the first period. Conversely, appending to p the SPPE continuations that deliver $v(\mathbf{p})$ yields a profile that is an SPPE by the one-shot deviation principle. This is the self-generation logic of Abreu et al. (1990) described in Section 12.2.7.

The Interim Program. Splitting the incentive constraint by type and by kind of deviation gives an equivalent problem (p. 14). Let $\mathbb{E}_{-i}$ denote the expectation over rivals' costs when rivals use p, and write $v(p_i, \mathbf{p}_{-i})$ for the continuation value after firm i charges p_i and rivals charge $\mathbf{p}_{-i}$. The firms choose p and v to maximize $\mathbb{E}_c\left[\Pi(p(c), p, c) + \delta \mathbb{E}_{-i} v(p(c), \mathbf{p}_{-i})\right]$ subject to two sets of constraints. The *off-schedule constraints* must hold for every price $p' \notin p([\underline{c}, \bar{c}])$:

$$v(p', \mathbf{p}_{-i}) \in \mathcal{V} \quad \text{for all } \mathbf{p}_{-i}, \tag{IC-off1}$$

$$\Pi(p(c), p, c) + \delta \mathbb{E}_{-i} v(p(c), \mathbf{p}_{-i}) \geq \Pi(p', p, c) + \delta \mathbb{E}_{-i} v(p', \mathbf{p}_{-i}) \quad \text{for all } c. \tag{IC-off2}$$

The *on-schedule constraints* must hold for every announced type $\hat{c}$:

$$v(p(\hat{c}), \mathbf{p}_{-i}) \in \mathcal{V} \quad \text{for all } \mathbf{p}_{-i}, \tag{IC-on1}$$

$$\Pi(p(c), p, c) + \delta \mathbb{E}_{-i} v(p(c), \mathbf{p}_{-i}) \geq \Pi(p(\hat{c}), p, c) + \delta \mathbb{E}_{-i} v(p(\hat{c}), \mathbf{p}_{-i}) \quad \text{for all } c. \tag{IC-on2}$$

The on-schedule constraint (IC-on2) is written in direct form. A firm of type c must prefer the price of its own type to the price of any other type $\hat{c}$, as in a truth-telling constraint.

The Mechanism Design Program. Define a firm's interim profit when its true cost is c and it charges the price of type $\hat{c}$:

$$U(\hat{c}, c; p) \equiv \Pi\big(p(\hat{c}), p, c\big) = \pi\big(p(\hat{c}), c\big)\, M(\hat{c}; p), \qquad M(\hat{c}; p) \equiv \mathbb{E}_{-i}\left[m_i\big(p(\hat{c}), \mathbf{p}_{-i}\big)\right]. \tag{12.89}$$

Here $M(\hat{c}; p)$ is the expected market share of a firm that charges $p(\hat{c})$, and ABS write H for U. Define the expected *war* that follows the price of type c,

$$\mathcal{T}(c) \equiv \delta\left[\bar{\mathcal{V}} - \mathbb{E}_{-i} v\big(p(c), \mathbf{p}_{-i}\big)\right] \geq 0, \tag{12.90}$$

the discounted shortfall of the continuation value below its supremum (ABS write T). The *Mechanism Design Program* (p. 15) is

$$\max_{p, \mathcal{T}} \ \mathbb{E}\big[U(c, c; p) - \mathcal{T}(c)\big] \quad \text{s.t.} \quad \mathcal{T}(c) \geq 0 \text{ for all } c, \tag{12.91}$$

$$U(c, c; p) - \mathcal{T}(c) \geq U(\hat{c}, c; p) - \mathcal{T}(\hat{c}) \quad \text{for all } c, \hat{c}. \tag{IC-onM}$$

Since $\mathbb{E}[U - \mathcal{T}] = \mathbb{E}[\Pi(p(c), p, c) + \delta \mathbb{E}_{-i} v] - \delta \bar{\mathcal{V}}$, the objective is that of the Interim Program up to a constant. Any (p, v) that satisfies the Interim Program's constraints maps through (12.90) into a pair $(p, \mathcal{T})$ that satisfies (IC-onM), with $\mathcal{T} \geq 0$ because $v \leq \bar{\mathcal{V}}$. The Mechanism Design Program is therefore a relaxation. It drops the off-schedule constraints, which patient firms can satisfy, and the requirement that the wars be implementable by continuation values in $\mathcal{V}$.

Table 12.9 records the analogy with static mechanism design (pp. 3–4, 42). The analogy has a twist. In a standard principal-agent problem a principal extracts rents from the agent, and incentive compatibility puts a lower bound on the agent's profit. Here the agents design their own scheme to maximize their joint profit, and incentive compatibility puts an upper bound on what each type can be given (p. 17).

Table 12.9: Collusion with private costs as a mechanism design problem

Repeated game	Static mechanism design	Difference
On-schedule constraint (no type mimics another)	Incentive compatibility (truth-telling)	None
Off-schedule constraint (no type undercuts the schedule)	Participation constraint	The outside option depends on the type, the schedule and the future value of collusion
Continuation values after each price vector	Transfers	Restricted: a war is borne by all firms, is wasteful, and cannot be negative (no subsidies, $\mathcal{T} \geq 0$)
Pricing schedule $p(c)$	Allocation rule	The allocation $M(c;p)$ is induced by prices and the tie rule

Notes: Based on Athey et al. (2004a), working-paper version, pp. 3–4, 14–15 and 41–43. Asymmetric equilibria (Section 12.6.8) also allow transfers from one firm to another.

Proposition 12.61 (Staticizing)**.** *Suppose the Mechanism Design Program is solved by $(p^*, \mathcal{T}^*)$ with $\mathcal{T}^* \equiv 0$. Then there is $\delta_0 \in (0,1)$ such that, for $\delta \geq \delta_0$ (ABS Proposition 4, p. 16):*

(i) The schedule p^* maximizes $\mathbb{E}U(c,c;p)$ subject to $U(c,c;p) \geq U(\hat{c},c;p)$ for all $c, \hat{c}$.

(ii) In an optimal SPPE, firms use p^* after all equilibrium-path histories.

(iii) The best SPPE value is $\bar{\mathcal{V}} = \frac{\mathbb{E}U(c,c;p^*)}{1-\delta}$, and it belongs to $\mathcal{V}$.

The argument is as follows (pp. 15–16). Replace the requirement $v \in \mathcal{V}$ by $v \in \mathcal{V} \cup \{\bar{\mathcal{V}}\}$ in the Interim Program. Setting $v \equiv \bar{\mathcal{V}}$ after all on-schedule prices solves the relaxed problem, so $\mathbb{E}U(c,c;p^*) + \delta\bar{\mathcal{V}} \geq \bar{\mathcal{V}}$, that is, $\frac{\mathbb{E}U(c,c;p^*)}{1-\delta} \geq \bar{\mathcal{V}}$. Since $\mathcal{T}^* \equiv 0$, the schedule p^* satisfies the on-schedule constraints with any continuation that does not vary across types. Repeating p^* forever, with reversion to the static Nash equilibrium after off-schedule prices, is then an SPPE for patient firms, as long as p^* beats static Nash profits. Its value $\frac{\mathbb{E}U(c,c;p^*)}{1-\delta}$ lies in $\mathcal{V}$ and therefore equals $\bar{\mathcal{V}}$. The problem of finding an optimal SPPE thus reduces to a static mechanism design problem. The rest of the analysis asks when the solution has no wars.

12.6.4 Incentive compatibility and efficiency rents

Write $Q(c;p) \equiv D(p(c))M(c;p)$ for the expected quantity sold by type c. Since $U(\hat{c},c;p) = (p(\hat{c}) - c)D(p(\hat{c}))M(\hat{c};p)$ is affine in the true cost c, its derivative with respect to c is

$$U_c(\hat{c},c;p) = -D\big(p(\hat{c})\big)M(\hat{c};p) = -Q(\hat{c};p). \tag{12.92}$$

Lemma 12.62 (Constraint reduction)**.** *A pair $(p,\mathcal{T})$ satisfies (IC-onM) if and only if (i) the expected quantity $Q(c;p)$ is non-increasing in c, and (ii) for every c,*

$$U(c,c;p) - \mathcal{T}(c) = U(\bar{c},\bar{c};p) - \mathcal{T}(\bar{c}) + \int_c^{\bar{c}} D\big(p(t)\big)M(t;p)\,dt. \tag{12.93}$$

Proof. Let $R(c) \equiv U(c, c; p) - \mathcal{T}(c)$ be the payoff of truthful type c, net of wars.

Necessity of (i). Take $c < c'$. Constraint (IC-onM) for type c against c', and for type c' against c, reads

$$R(c) \geq U(c', c; p) - \mathcal{T}(c'), \qquad R(c') \geq U(c, c'; p) - \mathcal{T}(c).$$

Adding the two and cancelling the wars gives $U(c, c) - U(c, c') \geq U(c', c) - U(c', c')$. Since $U(\hat{c}, \cdot)$ is affine with slope $-Q(\hat{c})$, the left side equals $(c' - c)Q(c)$ and the right side equals $(c' - c)Q(c')$. Hence $Q(c) \geq Q(c')$.

Necessity of (ii). Under (IC-onM), $R(c) = \max_{\hat{c}}[U(\hat{c}, c; p) - \mathcal{T}(\hat{c})]$. This is a maximum of affine functions of c, so R is convex and absolutely continuous. By the envelope theorem (Appendix B), $R'(c) = U_c(c, c; p) = -Q(c; p)$ wherever R is differentiable. Integrating from c to $\bar{c}$ gives $R(c) = R(\bar{c}) + \int_c^{\bar{c}} Q(t; p)\, dt$, which is (12.93).

Sufficiency. Suppose (i) and (ii) hold, and take any c and $\hat{c}$. By (ii), $R(c) - R(\hat{c}) = \int_c^{\hat{c}} Q(t)\, dt$, with the usual sign convention when $\hat{c} < c$. By the affine form of U, $U(\hat{c}, c) - U(\hat{c}, \hat{c}) = (\hat{c} - c)Q(\hat{c})$. Therefore

$$R(c) - \big[U(\hat{c}, c) - \mathcal{T}(\hat{c})\big] = \big[R(c) - R(\hat{c})\big] - \big[U(\hat{c}, c) - U(\hat{c}, \hat{c})\big] = \int_c^{\hat{c}} \big[Q(t) - Q(\hat{c})\big] dt.$$

If $\hat{c} > c$, the integrand is non-negative because Q is non-increasing. If $\hat{c} < c$, the integral runs backward over an interval where $Q(t) \leq Q(\hat{c})$, so it is again non-negative. Hence (IC-onM) holds. □

ABS state condition (i) as "$p(c)$ is weakly increasing" (ABS Lemma 5, p. 16). The two statements agree up to reorderings that do not affect payoffs, because a lower price weakly raises both demand and the chance of winning. The result is standard in mechanism design (Fudenberg and Tirole, 1991). Equation (12.93) is ABS's equation (1) combined with Lemma 5 (pp. 16–18).

The formula has a clear interpretation (p. 17). The payoff of type c, net of wars, is the *profit at the top*, earned by the highest-cost type $\bar{c}$, plus the *efficiency rents* $\int_c^{\bar{c}} Q(t)dt$ accumulated over all higher types. Raising the profit at the top makes type $\bar{c}$ less tempted to mimic lower types. The type just below can then be given more profit without inducing mimicry, and the effect cascades down the cost range. Efficiency rents are larger when demand is larger, that is, when prices are lower. Lower types are more attracted to low prices and high demand, so they are most profitably kept truthful when demand is high.

Wars and the slope of the schedule are two instruments for sorting types. A useful result separates them. Let c_K be the lowest type that charges the price of the highest type. ABS restrict attention to schemes with $U(c_K, c_K; p) - \mathcal{T}(c_K) \geq 0$, which loses no generality (p. 18).

Lemma 12.63 (Wars do not expand sorting)**.** *Let $(p, \mathcal{T})$ be incentive compatible, with allocation $M(c; p)$. Then there is an incentive-compatible scheme $(\tilde{p}, \tilde{\mathcal{T}} \equiv 0)$ with the same allocation, $M(c; \tilde{p}) = M(c; p)$, and the same profit at the top, $U(\bar{c}, \bar{c}; \tilde{p}) = U(\bar{c}, \bar{c}; p) - \mathcal{T}(\bar{c})$ (ABS Lemma 6, p. 18).*

Proof. ABS prove the lemma for step schedules and note that strictly increasing schedules are analogous (p. 49). We give the step case. Let the schedule have K steps. Step k covers the types $[c_k, c_{k+1})$, with $\underline{c} = c_1 < c_2 < \cdots < c_{K+1} = \bar{c}$, and charges the price p_k, with $p_1 < \cdots < p_K$. A war depends on a type only through its price, so all types on step k share the war $\mathcal{T}_k$ and the expected market share M_k. A firm on a lower step beats every rival on a higher step, so $M_1 > M_2 > \cdots > M_K$. We treat the case in which the restriction $U(c_K, c_K; p) - \mathcal{T}(c_K) \geq 0$ holds strictly, which avoids ties in the construction.

The top step. We look for a price $\tilde{p}_K$ that gives type $\bar{c}$ the same payoff without a war:

$$\pi(\tilde{p}_K, \bar{c})M_K = \pi(p_K, \bar{c})M_K - \mathcal{T}_K.$$

At the price p_K the left side is at least the right side. The restriction gives $\pi(p_K, c_K)M_K > \mathcal{T}_K$, so $p_K > c_K$ and

$$\pi(p_K, \bar{c})M_K - \mathcal{T}_K > \pi(p_K, \bar{c})M_K - \pi(p_K, c_K)M_K = -(\bar{c} - c_K)D(p_K)M_K \geq -(\bar{c} - c_K)D(c_K)M_K,$$

where the last step uses $D(p_K) \leq D(c_K)$. The final expression is the left side at the price c_K. By the intermediate value theorem there is a solution $\tilde{p}_K \in (c_K, p_K]$.

Lower steps. Suppose that $\tilde{p}_{k+1} > c_{k+1}$ has been chosen. We look for a price $\tilde{p}_k$ that keeps the break type c_{k+1} indifferent between the two steps without wars:

$$\pi(\tilde{p}_k, c_{k+1})M_k = \pi(\tilde{p}_{k+1}, c_{k+1})M_{k+1}.$$

The right side is positive. At the price c_{k+1} the left side is zero. At the price $\tilde{p}_{k+1}$ it exceeds the right side, because $M_k > M_{k+1}$. So there is a solution $\tilde{p}_k \in (c_{k+1}, \tilde{p}_{k+1})$. Since $\tilde{p}_k > c_{k+1} > c_k$, the construction continues down to step 1.

Incentive compatibility. The new prices increase strictly across the same steps, so the allocation is unchanged, $M(c; \tilde{p}) = M(c; p)$. The expected quantity $\tilde{Q}_k = D(\tilde{p}_k)M_k$ falls from each step to the next, since both factors fall. This is condition (i) of Lemma 12.62. On step k the payoff $\tilde{R}(c) = \pi(\tilde{p}_k, c)M_k$ is affine in c with slope $-\tilde{Q}_k$, and it is continuous at each break point by construction. Integrating the slope from c to $\bar{c}$ gives $\tilde{R}(c) = \tilde{R}(\bar{c}) + \int_c^{\bar{c}} \tilde{Q}(t)\,dt$, which is condition (ii). By Lemma 12.62, the scheme $(\tilde{p}, 0)$ satisfies (IC-onM). By the choice of $\tilde{p}_K$, its profit at the top is $\pi(\tilde{p}_K, \bar{c})M_K = U(\bar{c}, \bar{c}; p) - \mathcal{T}(\bar{c})$. □

The lemma lets firms choose the degree of sorting first and decide afterward whether to implement it with wars. It does not say which types prefer the no-war version. That depends on demand.

12.6.5 Inelastic demand: full sorting, no wars, and rigid prices

With inelastic demand $D \equiv 1$ on the relevant prices, so $Q(c; p) = M(c; p)$ and (12.93) becomes (ABS (2), p. 19)

$$U(c, c; p) - \mathcal{T}(c) = U(\bar{c}, \bar{c}; p) - \mathcal{T}(\bar{c}) + \int_c^{\bar{c}} M(t; p)\,dt. \tag{12.94}$$

Prices and wars enter the payoff of every type in the same way. On a step where all types share the market share M, raising the price by Δ and the war by $M\Delta$ leaves every type's payoff and incentives unchanged. A higher price trades against a higher war at the fixed rate $\frac{1}{M}$ (p. 20). This is the source of the next result, well known from auction theory.

Lemma 12.64 (Revenue equivalence)**.** *Let demand be inelastic. Suppose $(p, \mathcal{T})$ and $(\tilde{p}, \tilde{\mathcal{T}})$ satisfy* (IC-onM)*, induce the same allocation, $M(\cdot; p) = M(\cdot; \tilde{p})$, and give the same profit at the top. Then they give every type the same payoff net of wars (ABS Lemma 7, p. 19).*

Proof. Both payoffs are given by (12.94), whose right side depends only on the profit at the top and on M. □

The revenue equivalence theorem fails when $\pi_{pc} > 0$, as with downward-sloping demand (p. 20). We return to that case in Section 12.6.6.

Full sorting cannot beat Nash. A scheme is *fully sorting* if $p(c)$ is strictly increasing. The lowest-cost firm then always serves the market, which is the efficiency benefit of sorting. Monopoly-like prices with full sorting are possible only if wars follow low prices.

Proposition 12.65 (Full sorting)**.** *Let demand be inelastic. Among fully sorting schemes, for any F and any δ, an optimal SPPE repeats the static Nash equilibrium after all histories (ABS Proposition 8, p. 21).*

Proof. Under full sorting a firm wins exactly when all rivals have higher costs, so $M(c;p) = [1-F(c)]^{N-1}$ for every fully sorting schedule. The highest type never wins, so its profit at the top is $-\mathcal{T}(\bar{c})$. By (12.94) (ABS (3), p. 20),

$$U(c,c;p) - \mathcal{T}(c) = -\mathcal{T}(\bar{c}) + \int_c^{\bar{c}} [1-F(t)]^{N-1}\,dt.$$

The best fully sorting scheme therefore sets $\mathcal{T}(\bar{c}) = 0$, and every type then earns $\int_c^{\bar{c}}[1-F(t)]^{N-1}dt$. The static Nash schedule p^e is strictly increasing, satisfies (IC-onM) with $\mathcal{T} \equiv 0$ because it is an equilibrium of the stage game, and gives the highest type zero profit. By Lemma 12.64 it attains the same payoff for every type. Repeating it is an SPPE for any δ, since it involves no off-schedule temptation beyond the stage game. □

In the uniform example, $\int_c^1 (1-t)\,dt = \frac{(1-c)^2}{2}$, the Nash interim profit of Example 12.58. Any attempt to raise prices above Nash while keeping full sorting must be backed by wars after low prices, and by Lemma 12.64 the wars exactly offset the higher prices. It is better to have low prices and no wars than high prices and wars (p. 5).

No wars on the equilibrium path. The same exchange of wars for lower prices works for any allocation.

Proposition 12.66 (No wars)**.** *Let demand be inelastic, and let F be arbitrary. Suppose an optimal SPPE uses wars, with $\mathcal{T}(c) > 0$ for some c. Then, for δ large enough, there is another optimal SPPE in which firms use a schedule $\tilde{p} \le p$ after all histories. It has $\tilde{\mathcal{T}} \equiv 0$ and $\tilde{\mathcal{V}} = \frac{\mathbb{E}U(c,c;\tilde{p})}{1-\delta}$ (ABS Proposition 9, p. 21).*

By Lemma 12.63 there is a no-war scheme with the same allocation and profit at the top, and by Lemma 12.64 it gives every type the same payoff. It replaces each war by a lower price. The staticizing argument of Proposition 12.61 then applies. Wars have no value with inelastic demand.

Rigid prices are optimal. The central result of the paper identifies the optimal scheme.

Proposition 12.67 (Price rigidity)**.** *Let demand be inelastic and F log-concave, so that $\frac{F}{f}$ is non-decreasing. Suppose δ is large enough that the off-schedule constraints hold. Then the equilibrium path of the optimal SPPE has two properties (ABS Proposition 10, p. 22).*

(i) The price is rigid: $p^*(c) = \bar{v}$ for every c.

(ii) There are no wars: $\mathcal{T}^*(c) = 0$ for every c.

Each firm earns $\frac{\bar{v}-\mathbb{E}c}{N}$ per period.

Proof. Take any scheme that satisfies (IC-onM). By (12.93), the expected payoff net of wars is

$$\mathbb{E}\big[U(c,c;p)-\mathcal{T}(c)\big] = R(\bar{c}) + \int_{\underline{c}}^{\bar{c}} f(c) \int_{c}^{\bar{c}} Q(t)\,dt\,dc,$$

with $R(\bar{c}) = \pi(p(\bar{c}),\bar{c})M(\bar{c};p) - \mathcal{T}(\bar{c})$. Exchange the order of integration (a standard step in optimal auction theory, Myerson, 1981):

$$\int_{\underline{c}}^{\bar{c}} f(c) \int_{c}^{\bar{c}} Q(t)\,dt\,dc = \int_{\underline{c}}^{\bar{c}} Q(t)\Big[\int_{\underline{c}}^{t} f(c)\,dc\Big]dt = \int_{\underline{c}}^{\bar{c}} Q(t)F(t)\,dt = \mathbb{E}\Big[\frac{F(c)}{f(c)}Q(c)\Big].$$

Hence (ABS (4), p. 23)

$$\mathbb{E}\big[U(c,c;p)-\mathcal{T}(c)\big] = \pi\big(p(\bar{c}),\bar{c}\big)M(\bar{c};p) - \mathcal{T}(\bar{c}) + \mathbb{E}\Big[\frac{F(c)}{f(c)}\,D\big(p(c)\big)M(c;p)\Big]. \tag{12.95}$$

With inelastic demand $D = 1$ and $p(\bar{c}) \le \bar{v}$. Every unit of demand is served, so by symmetry each firm's expected share is $\mathbb{E}[M(c;p)] = \frac{1}{N}$. By Lemma 12.62, $M(\cdot;p)$ is non-increasing. We bound the two terms of (12.95).

The first term is at most $(\bar{v}-\bar{c})M(\bar{c};p)$. A non-increasing function with mean $\frac{1}{N}$ has its minimum at most $\frac{1}{N}$, so $M(\bar{c};p) \le \frac{1}{N}$. For the second term, $\frac{F}{f}$ is non-decreasing and M is non-increasing, so their covariance is non-positive:

$$\mathbb{E}\Big[\frac{F}{f}M\Big] \le \mathbb{E}\Big[\frac{F}{f}\Big]\mathbb{E}[M] = \frac{1}{N}\mathbb{E}\Big[\frac{F}{f}\Big] = \frac{1}{N}\int_{\underline{c}}^{\bar{c}} F(c)\,dc = \frac{\bar{c}-\mathbb{E}c}{N},$$

where the last step integrates by parts. Adding the bounds,

$$\mathbb{E}\big[U(c,c;p)-\mathcal{T}(c)\big] \le \frac{\bar{v}-\bar{c}}{N} + \frac{\bar{c}-\mathbb{E}c}{N} = \frac{\bar{v}-\mathbb{E}c}{N}.$$

The rigid scheme $p \equiv \bar{v}$ with no wars gives every firm the share $\frac{1}{N}$ and the payoff $\frac{\bar{v}-\mathbb{E}c}{N}$, so it attains the bound. It satisfies (IC-onM), since every type charges the same price. Any war at the top would lower the first term strictly. By Proposition 12.61, patient firms repeat this scheme forever. □

The intuition runs through the two terms of (12.95) (p. 22). Since incentive compatibility forbids decreasing schedules, the profit at the top is highest when everyone charges the same price, so that the highest type is never undercut. The ratio $\frac{F(c)}{f(c)}$ measures how much an increase in type c's profit contributes to expected profit. Such an increase relaxes the incentive constraints of all lower types, whose mass is $F(c)$, while type c itself has density $f(c)$. Log-concavity makes this measure increasing, so it pays to move market share toward higher types, up to the point where all types share equally. Many common distributions are log-concave, including the uniform, normal, logistic and exponential (p. 23, footnote 22). In procurement theory the same condition makes optimal contracts fully sorting, because a principal minimizes the agent's "virtual cost" $c + \frac{F(c)}{f(c)}$. Here the firms maximize their own information rents, so the condition favors pooling instead (p. 23, footnote 22).

Rigidity has an evident cost. A low-cost firm and a high-cost firm split the market, so the industry does not produce at least cost. The proposition says that the informational benefit

of rigidity outweighs this loss when F is log-concave. Since (12.95) is a pointwise objective, the argument extends to any F. The optimal rule sorts on intervals where $\frac{F}{f}$ decreases and pools elsewhere. Because $f(\underline{c}) > 0$, the ratio $\frac{F}{f}$ rises near $\underline{c}$, so pooling at the bottom is always optimal. Patient firms can therefore earn more than static Nash profits for any distribution (p. 23). In Example 12.58 with two firms, the rigid scheme earns $\frac{1}{4}$ per period against $\frac{1}{6}$ at Nash.

McAfee and McMillan (1992) obtained a closely related result for "weak" bidding rings, which cannot make side payments. Such a ring does best in a first-price auction when all members bid the same price (p. 24). ABS derive the static mechanism from a repeated game, and they show that rigidity remains optimal when sorting can be sustained by wasteful transfers, that is, by wars. The result offers a theory of identical bidding in procurement rings (Sections 13.8 and 13.9). Bid rotation corresponds to the asymmetric take-turns scheme of Section 12.6.8, which needs more patience.

Why there are no wars here. The contrast with Section 12.5.3 is stark (p. 24). One can view a firm's schedule $p(c)$ as its hidden action and the realized price as a public signal. In Green and Porter the support of the public signal does not depend on firms' actions. Every outcome can arise on the path, so punishments must follow some outcomes that are consistent with compliance. In ABS the firms choose the support of the signal. Under a rigid schedule only one price is ever observed, so every deviation is off-schedule and wars stay off the path. ABS call this *endogenous imperfect monitoring*.

12.6.6 Downward-sloping demand

With downward-sloping demand, $\pi_{pc} > 0$ and two new issues arise (p. 24). Revenue equivalence fails, so wars may have value. The monopoly price $p^m(c)$ also rises with cost, which adds a cost to rigidity: a rigid price is too high for low types and too low for high types. The envelope formula keeps the factor $D(p(t))$ (ABS (5), p. 25):

$$U(c, c; p) - \mathcal{T}(c) = U(\bar{c}, \bar{c}; p) - \mathcal{T}(\bar{c}) + \int_c^{\bar{c}} D\big(p(t)\big) M(t; p)\, dt. \tag{12.96}$$

Proposition 12.68 (Collusion with downward-sloping demand)**.** *Let demand be downward sloping, let F be arbitrary, and let $(p, \mathcal{T})$ solve the Mechanism Design Program.*

(i) Among fully sorting schemes, for any δ, the optimal SPPE repeats the static Nash equilibrium, and every other fully sorting scheme is strictly worse (ABS Proposition 11, p. 25).

(ii) There are no wars at the extremes, $\mathcal{T}(\underline{c}) = \mathcal{T}(\bar{c}) = 0$. If p is constant on $[\underline{c}, c']$ and increases strictly at c', then $p(c') < p^m(c')$. If p is constant on $[c'', \bar{c}]$ and increases strictly at c'', then $p^m(c'') \le p(c'')$ (ABS Proposition 12, p. 27).

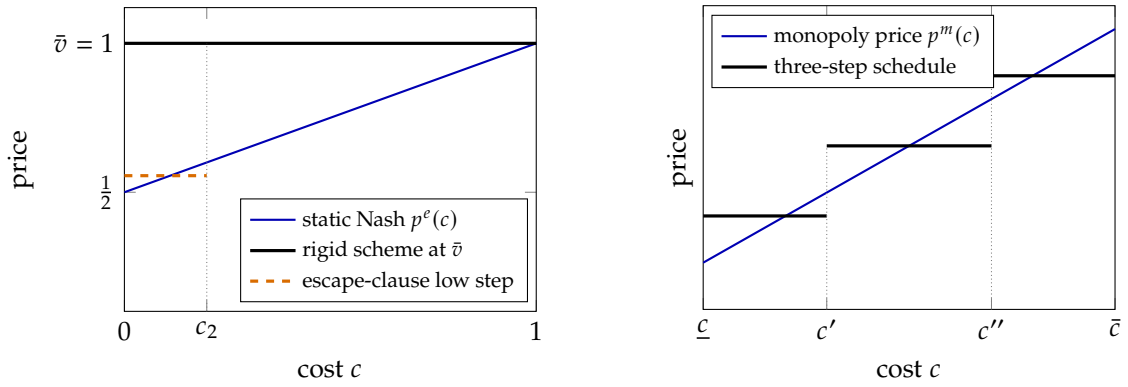
(iii) Wars on a set of positive measure have stringent necessary conditions. The schedule p must have at least two points of strict increase and a flat bottom step, priced at or above the lowest type's monopoly price. There are no wars if every no-war, incentive-compatible scheme with at least three prices and a bottom step prices that step below $p^m(\underline{c})$. This holds when demand is inelastic enough (ABS Proposition 13, p. 28).

(iv) Some rigidity is always optimal: there is an interval $[\underline{c}, c')$ with a rigid price and no wars. For any F, no wars are used on a fully sorting interval where the schedule has non-negligible slope. On any fully sorting interval where F is log-concave and f is non-decreasing, no wars are used. If demand is sufficiently inelastic and F is log-concave, a single rigid price is used for all types and there are no wars (ABS Proposition 14, p. 32).

Part (i) strengthens Proposition 12.65. Any fully sorting scheme with prices above Nash lowers demand and hence the efficiency rents in (12.96), so it is strictly worse (p. 25). The result contains a discontinuity (p. 26). If costs were observed, patient firms would collude on monopoly prices with full efficiency. With private costs, monopoly pricing needs wars and is dominated by Nash pricing. This holds for any F, even one that puts probability $1-\varepsilon$ on $\mathbb{E}c$, so the monopoly scheme is best only when costs are perfectly observed.

Parts (ii) and (iii) limit the scope for wars. Consider a schedule with three steps. With inelastic demand a war on any step can be removed by lowering that step's price until its highest type is indifferent. Every type on the step has the same market share, so all are indifferent, and incentives are preserved. With downward-sloping demand the same change makes lower types on the step strictly better off. On the bottom or top step this is harmless, so wars there are never optimal (pp. 26–27). On an intermediate step, the lowest type on the step now gains, so types on the step below would mimic it unless their own payoff rises. Raising the bottom step's price toward the monopoly price of its highest type can do this, but it may lower average profit on that step. A war on the middle step can then be the cheaper way to keep lower types truthful (pp. 27–28). Incentive constraints can thus bind in both directions, and ABS obtain both "no distortion at the top" and "no distortion at the bottom" for wars (p. 28). The no-subsidy constraint $\mathcal{T} \geq 0$ is the reason. If firms could give a "negative war" to the bottom step, the intermediate war could be removed without changing the bottom price (p. 29).

Part (iv) says that rigidity survives. The optimality conditions show a force toward pooling when $\frac{F}{f}$ rises, and a force toward sorting from the extra demand that low prices bring to low types (pp. 30–32). When the monopoly price varies little over most of the cost range and sharply over a small part, a two-step schedule that tracks it can beat a single rigid price (p. 32). A rigid price at the bottom always pays, so patient firms always beat Nash.



(a) Inelastic demand

(b) Downward-sloping demand (schematic)

Figure 12.11: Collusive pricing schedules with private costs. Panel (a): two firms, costs uniform on $[0,1]$, reservation value $\bar{v} = 1$. The static Nash schedule is $p^e(c) = \frac{1+c}{2}$. The rigid scheme charges $\bar{v}$, which is also the monopoly price, for every cost. A two-step escape-clause scheme charges $\bar{v}$ above the break point c_2 and a low price on $[0, c_2)$ that keeps type c_2 indifferent (here $c_2 = 0.2$ and the low price is 0.556). In this uniform example the escape clause is not an equilibrium for $\delta < \delta^*$ (Proposition 12.72), so the panel only shows its shape. Panel (b): a three-step schedule. The bottom step lies below the monopoly price of its highest type c', and the top step lies above the monopoly price of its lowest type c'', as Proposition 12.68(ii) requires.

12.6.7 Impatient firms

Return to inelastic demand and suppose firms are not patient enough to make the off-schedule constraints slack. After an off-schedule deviation, firms move to a war continuation value $w \in \mathcal{V}$, for example the worst SPPE value or reversion to static Nash forever. Its per-period equivalent $\pi^w = (1-\delta)w$ satisfies (ABS (7), p. 33)

$$0 \le \pi^w < \frac{1}{N}\pi(\bar{v}, \mathbb{E}c). \tag{12.97}$$

The first inequality holds in any SPPE. The second says that the war is a punishment relative to rigid collusion. Here $\pi(\bar{v}, \mathbb{E}c) = \bar{v} - \mathbb{E}c$ is the expected profit from serving the whole market at $\bar{v}$.

Proposition 12.69 (The threshold discount factor)**.** *Let demand be inelastic. A stationary rigid scheme with price $p^r \in [\underline{c}, \bar{v}]$ and war value π^w satisfies the off-schedule constraints if and only if (ABS (8), p. 34)*

$$\frac{N-1}{N}\,\pi(p^r, \underline{c}) \;\le\; \frac{\delta}{1-\delta}\Big[\frac{1}{N}\pi(p^r, \mathbb{E}c) - \pi^w\Big]. \tag{12.98}$$

At $p^r = \bar{v}$ this holds if and only if $\delta \ge \delta^*$, where

$$\delta^* = \frac{(N-1)\pi(\bar{v}, \underline{c})}{(N-1)\pi(\bar{v}, \underline{c}) + \pi(\bar{v}, \mathbb{E}c) - N\pi^w} \;\in\; \Big(\frac{N-1}{N}, 1\Big). \tag{12.99}$$

If $\delta < \delta^*$, no stationary rigid scheme at any price $p^r \le \bar{v}$ satisfies (12.98)*.*

Proof. The constraint. Under a rigid scheme a firm of type c that undercuts p^r slightly wins the whole market instead of the share $\frac{1}{N}$. Its current gain is $\frac{N-1}{N}\pi(p^r, c)$, which is largest for the lowest type, since $\pi(p^r, c) = p^r - c$. The deviation is off-schedule, so the continuation drops from the collusive value, worth $\frac{1}{N}\pi(p^r, \mathbb{E}c)$ per period, to the war, worth π^w per period. The loss from the next period on is $\frac{\delta}{1-\delta}[\frac{1}{N}\pi(p^r, \mathbb{E}c) - \pi^w]$. Price increases are unattractive because they forgo all current sales. The binding constraint is therefore that of type $\underline{c}$, which is (12.98).

The threshold. Let $a = (N-1)\pi(\bar{v}, \underline{c})$ and $b = \pi(\bar{v}, \mathbb{E}c) - N\pi^w$, which is positive by (12.97). Multiply (12.98) at $p^r = \bar{v}$ by $N(1-\delta)$:

$$(1-\delta)a \le \delta b \quad\Longleftrightarrow\quad a \le \delta(a+b) \quad\Longleftrightarrow\quad \delta \ge \frac{a}{a+b} = \delta^*.$$

Since $b > 0$, $\delta^* < 1$. Moreover $\delta^* > \frac{N-1}{N}$ if and only if $(N-1)(a+b) < Na$, that is, $(N-1)b < a$, or $\pi(\bar{v}, \mathbb{E}c) - N\pi^w < \pi(\bar{v}, \underline{c})$. This holds because $\pi(\bar{v}, \underline{c}) > \pi(\bar{v}, \mathbb{E}c)$ and $\pi^w \ge 0$.

Lower rigid prices. Both sides of (12.98) are affine in p^r, with slopes $\frac{N-1}{N}$ on the left and $\frac{\delta}{(1-\delta)N}$ on the right. If $\frac{N-1}{N} < \delta < \delta^*$, the right side rises faster, so the gap between the right and left sides increases in p^r. It is negative at $p^r = \bar{v}$ and hence negative at every lower p^r. If $\delta \le \frac{N-1}{N}$, the gap is non-increasing in p^r, so the best case is $p^r = \underline{c}$. There the left side is zero and the right side is negative, since $\pi(\underline{c}, \mathbb{E}c) = \underline{c} - \mathbb{E}c < 0$. In both cases the constraint fails (p. 52). □

ABS extend the last statement to nonstationary schemes. If $\delta < \delta^*$, no SPPE has a rigid price in every period (ABS Proposition 15, pp. 34 and 52–53). The reason is that the highest rigid price on the path would be easier to sustain if it were kept forever. Combining the result with Proposition 12.67, if F is log-concave and $\delta \ge \delta^*$, the optimal SPPE has a rigid price at $\bar{v}$ (ABS Corollary 16, p. 35).

Example 12.70 (Cost shocks make collusion harder)**.** Let $N = 2$, costs uniform on $[0, 1]$, $\bar{v} = 1$, and Nash reversion after an off-schedule deviation (p. 35). By Example 12.58, $\pi^w = \frac{1}{6}$. Also $\pi(1, 0) = 1$ and $\pi(1, \mathbb{E}c) = \frac{1}{2}$. By (12.99),

$$\delta^* = \frac{1}{1 + \frac{1}{2} - \frac{2}{6}} = \frac{1}{\frac{7}{6}} = \frac{6}{7} \approx 0.857.$$

Without cost shocks, collusion at a price above a common cost needs only $\delta \geq \frac{1}{2}$ (Proposition 12.14). The same computation for N firms uses $\pi^w = \frac{1}{N(N+1)}$ and gives

$$\delta^*(N) = \frac{N - 1}{(N - 1) + \frac{1}{2} - \frac{1}{N+1}} = \frac{2(N + 1)}{2N + 3},$$

so $\delta^*(3) = \frac{8}{9}$ and $\delta^*(4) = \frac{10}{11}$, against $\frac{2}{3}$ and $\frac{3}{4}$ without cost shocks. (This general formula is our own computation. It simplifies because the denominator equals $\frac{(2N+3)(N-1)}{2(N+1)}$.)

The benchmark $\frac{N-1}{N}$ is the value of (12.99) when $\underline{c} = \mathbb{E}c$ and $\pi^w = 0$. Cost fluctuations raise the required patience because the scheme must survive the period in which a firm draws a cost far below the one it expects in the future (p. 35). This holds even if the punishment drives profits to zero, and the threshold rises further when the punishment is milder. The result fits the common view that collusion is harder when costs vary across firms and over time (Scherer, 1980, p. 205).

Proposition 12.71 (No wars for impatient firms)**.** *Let demand be inelastic, and let F and δ be arbitrary. Consider an SPPE with schedule p and continuation function v, and let $z \equiv \sup_{c'} \mathbb{E}_{-i} v(p(c'), \mathbf{p}_{-i})$. Suppose that $\mathbb{E}_{-i} v(p(c), \mathbf{p}_{-i}) < z$ for some c, and that a mild regularity condition holds at the top step. Then there is an SPPE with the same expected payoff in which the continuation value equals z after every on-schedule price (ABS Proposition 17, p. 37).*

The proof compares off-schedule constraints. Let c_k be the lowest type on a flat step. With war continuation w, this type's constraint in the original scheme is (ABS (11), p. 53)

$$\pi\big(p(c_k), c_k\big)\big[(1 - F(c_k))^{N-1} - M(c_k; p)\big] \leq \delta z - \mathcal{T}(c_k) - \delta w.$$

Here $\mathcal{T}(c_k) = \delta[z - \mathbb{E}_{-i} v(p(c_k), \mathbf{p}_{-i})]$, and the bracket on the left is the gain in the probability of winning from a slight undercut. The no-war alternative of Lemma 12.63 has the same allocation and a price $\tilde{p}(c_k) < p(c_k)$ wherever $\mathcal{T}(c_k) > 0$. Its constraint is (ABS (12))

$$\pi\big(\tilde{p}(c_k), c_k\big)\big[(1 - F(c_k))^{N-1} - M(c_k; p)\big] \leq \delta z - \delta w.$$

The left side is smaller and the right side larger. Moving profit from the present (a lower price today) to the future (no war tomorrow) reduces the temptation to cheat and raises the value of cooperation at the same time. Wars are thus doubly harmful for impatient firms with inelastic demand. With downward-sloping demand a war on a step can still help by relaxing the constraints of types on lower steps (pp. 37–38).

An escape clause. Impatient firms cannot keep a rigid price, but they may support a two-step scheme with a high price $\bar{v}$ and a lower price for rare low-cost draws.

Proposition 12.72 (Escape clause)**.** *Let demand be inelastic and $N = 2$. If*

$$f(\underline{c}) < \frac{\frac{1}{2}\pi(\bar{v}, \mathbb{E}c) - \pi^w}{\bar{v}\,\pi^w}, \tag{12.100}$$

there is $\delta^\circ < \delta^*$ such that, for every $\delta \in (\delta^\circ, \delta^*)$, a two-step schedule with prices $p_2 = \bar{v} > p_1$ and a break point $c_2 \in (\underline{c}, \bar{c})$ is an SPPE (ABS Proposition 18, p. 39).

We do not reproduce the existence proof (pp. 53–55), which is a continuity argument. At $\delta = \delta^*$ and $c_2 = \underline{c}$ the two-step scheme is the rigid one, and its off-schedule constraints bind. Under (12.100), raising c_2 slightly makes these constraints slack. The slack lets a two-step scheme survive for δ slightly below δ^*.

The on-schedule constraint pins down the low price (ABS (13), p. 53). Type c_2 must be indifferent between the two steps. With two firms, a firm on the low step wins unless the rival is also on it, in which case they tie, so $M_1 = 1 - \frac{F(c_2)}{2}$. A firm on the high step wins half the time when the rival is also high, so $M_2 = \frac{1-F(c_2)}{2}$. Indifference, $(p_1 - c_2)M_1 = (\bar{v} - c_2)M_2$, gives

$$p_1 = c_2 + (\bar{v} - c_2)\,\frac{1 - F(c_2)}{2 - F(c_2)}. \tag{12.101}$$

As $c_2 \to \underline{c}$, $p_1 \to \frac{\bar{v}+\underline{c}}{2}$. With $\underline{c}$ near zero the low price is about half the high price, the 50 percent cut that ABS report for their construction with c_2 close to $\underline{c}$ (p. 39, footnote 32). In the uniform example with $c_2 = 0.2$, $p_1 = 0.2 + \frac{0.64}{1.8} = 0.556$ (Figure 12.11).

The escape clause works through two effects (pp. 38–39). The lowest-cost firm now expects more than the share $\frac{1}{N}$, at a lower price, so its gain from undercutting is smaller. With c_2 close to $\underline{c}$, one can check from (12.101) that the most tempted type becomes the break-point type c_2. Its best deviation is a price just below $\bar{v}$, and its cost exceeds $\underline{c}$. Against this, a two-step scheme earns less than the rigid scheme when F is log-concave, so a deviator also has less to lose. A small density at the bottom keeps the second effect small, which is what (12.100) requires. The condition is restrictive. For $F(c) = c^\alpha$ on $[0, 1]$ it holds when $\alpha > 1$ and fails for $\alpha \le 1$ (p. 39). In the uniform example the right side of (12.100) is $\frac{\frac{1}{4}-\frac{1}{6}}{\frac{1}{6}} = \frac{1}{2} < 1 = f(0)$. There, two-step schemes fail the off-schedule constraint for exactly the same discount factors as the rigid scheme (pp. 39–40).

The escape clause has an interpretation that matters for reading cartel histories (pp. 39, 47). Collusion among impatient firms may be marked by occasional, large price cuts by single firms after favorable cost draws, which rivals do not punish. They are a permitted exception, firm by firm, much as Rotemberg and Saloner (1986) allow prices to fall when demand is high. In that model, however, all firms adjust together in response to a public shock.

Finally, under log-concavity and a non-decreasing density, an optimal stationary SPPE for impatient firms that beats Nash has no open interval of strictly increasing prices (ABS Proposition 19, p. 41). It is a step function: partial rigidity. The analysis is a static mechanism design problem with two unusual features. The participation constraints depend on the type, and they are endogenous, because the value of the outside option depends on the scheme itself (pp. 40–42).

12.6.8 Asymmetric schemes

Symmetric equilibria allow only wasteful transfers, borne by all firms. Asymmetric perfect public equilibria also let firms transfer value from one firm to another through the continuation,

for example by favoring in future periods a firm that has sold little (p. 43). ABS illustrate with two simple schemes, using two firms, inelastic demand, uniform costs on $[0, 1]$, $\bar{v} = 1$ and Nash reversion.

Taking turns. In a *take-turns* scheme the firms alternate in serving the market at $\bar{v}$. With inelastic demand it offers no efficiency gain over rigid pricing, since the winner's identity is independent of costs. It needs more patience. The most tempted firm is one whose turn it is to sit out and which has drawn cost zero. Undercutting gives it $\pi(1, 0) = 1$ now and the Nash value $\frac{\delta}{1-\delta} \cdot \frac{1}{6}$ afterward. Conforming gives nothing now and the expected profit $\frac{1}{2}$ in every other period from the next one on, worth $\frac{\delta}{1-\delta^2} \cdot \frac{1}{2}$. The constraint is

$$\frac{\delta}{2(1-\delta^2)} \geq 1 + \frac{\delta}{6(1-\delta)}.$$

Multiply by $6(1-\delta^2)$ to get $3\delta \geq 6(1-\delta^2) + \delta(1+\delta)$, that is, $5\delta^2 + 2\delta - 6 \geq 0$. The positive root is $\frac{\sqrt{31}-1}{5} = 0.9135$, above $\delta^* = 0.857$ (p. 44, footnote 38).

A two-price scheme. In the *two-price scheme* $(p^l, \bar{v})$, each firm may charge the low price p^l exactly once in every two-period cycle and $\bar{v}$ in the other period (p. 44). In the first period of a cycle a firm chooses between the sequences $(p^l, \bar{v})$ and $(\bar{v}, p^l)$. Using the low price now forfeits it tomorrow, when the firm's cost may be lower, so only firms with low current costs take it. Types below a cutoff $c^\dagger$ choose $(p^l, \bar{v})$. (ABS write θ^* for the cutoff.) Indifference of type $c^\dagger$ when the rival uses the same cutoff gives (ABS (10), p. 45)

$$F(c^\dagger)\,\frac{\pi(p^l, c^\dagger) + \delta\pi(\bar{v}, \mathbb{E}c)}{2} + [1 - F(c^\dagger)]\,\pi(p^l, c^\dagger) \\ = F(c^\dagger)\,\delta\pi(p^l, \mathbb{E}c) + [1 - F(c^\dagger)]\,\frac{\pi(\bar{v}, c^\dagger) + \delta\pi(p^l, \mathbb{E}c)}{2}.$$

The left side is the expected two-period profit from using the low price first, and the right side from using it second.[2] With p^l close to $\bar{v} = 1$ and uniform costs, let $x = c^\dagger = F(c^\dagger)$. The difference between the two sides reduces to $\frac{1-x}{2} - \frac{\delta}{4}$, so $c^\dagger \approx \frac{2-\delta}{2}$, which lies in $(\frac{1}{2}, 1]$ (p. 45). A firm with cost below $c^\dagger$ uses its low price in the first period, so some sorting occurs at almost no price distortion, and the scheme beats rigid pricing. Sorting rises with δ, and as $\delta \to 1$ the cutoff tends to the median cost. The scheme still needs patience, $\delta \geq \delta^{**} \approx 0.88$, above δ^* though below the take-turns threshold (p. 46, footnote 41). Its novel prediction is that a firm's market share is negatively correlated over time. ABS suggest that such schemes suit small groups of firms that track each other's sales and communicate explicitly. Athey and Bagwell (2001) study optimal asymmetric collusion with communication about costs.

12.6.9 Testable implications, limitations and contribution

Table 12.10 collects the main results. They yield several predictions (pp. 46–48). Collusive prices are rigid with respect to firm-specific, privately observed cost shocks. They respond to public cost shocks, such as a change in a common wholesale price, because the whole scheme can be re-tailored to a public change. Prices are more rigid in concentrated, collusive industries.

[2] The equation printed as (10) in the working paper (p. 45) has no factor δ on the term $\pi(\bar{v}, \mathbb{E}c)$ in its top line. We restore it, because the second-period profit must be discounted like every other second-period term. With the factor restored, the approximation $c^\dagger \approx \frac{2-\delta}{2}$ that ABS state follows, and without it the approximation does not hold.

Optimal collusion among patient firms involves no price wars, unlike Section 12.5.3. Impatient cartels may show occasional large price cuts by single firms that rivals ignore. ABS offer this as an alternative reading of apparent unpunished cheating, an issue raised for the Sugar Institute by Genesove and Mullin (2001), whose working-paper version ABS cite (p. 47, footnote 43). ABS also combine private costs with the persistent demand phases of Bagwell and Staiger (1997). They conjecture that off-schedule constraints are easier to meet in booms when growth rates are positively correlated, so prices may be more rigid in booms (p. 48).

Table 12.10: Optimal symmetric collusion with private costs

	Inelastic demand	Downward-sloping demand
Fully sorting schemes	Best is repeated static Nash (Proposition 12.65)	Best is repeated static Nash, and all others are strictly worse (Proposition 12.68(i))
Patient firms: wars	Never needed (Proposition 12.66)	Never at the top or bottom step, possible only on intermediate steps (Proposition 12.68(ii) and (iii))
Patient firms: prices	Rigid at $\bar{v}$ if F is log-concave (Proposition 12.67)	Rigid at the bottom, single rigid price if demand is inelastic enough and F log-concave (Proposition 12.68(iv))
Impatient firms	Rigid price at $\bar{v}$ if and only if $\delta \geq \delta^*$ (Proposition 12.69), no wars (Proposition 12.71), escape clause for small $f(\underline{c})$ (Proposition 12.72), step functions	Wars on a step may relax lower types' constraints

Notes: SPPE, costs i.i.d. across firms and periods. Source: Athey et al. (2004a), working-paper version, Propositions 8 to 19.

Limitations. The analysis restricts attention to symmetric equilibria, which ABS defend on three grounds (pp. 6–7). Under many conditions the optimal SPPE is stationary and simple. Symmetric schemes capture the fear of industry-wide breakdowns, and they are the only option when the identity of the seller is not observed. Asymmetric schemes do better when firms are patient and sophisticated. Costs are i.i.d. over time. With persistent costs a firm's current price reveals information about its future costs, which changes the incentive problem. Athey and Bagwell (2008) study that case. The clean results rely on inelastic demand, and with downward-sloping demand the characterization is partial. There is no communication in the symmetric analysis. Harrington and Skrzypacz (2011, p. 2431) contrast their setting with the asymmetric extension of this analysis with communication (Athey and Bagwell, 2001, 2008). There, prices are public and firms report private costs so that the low-cost firm can be given more market share. In the model of Harrington and Skrzypacz, prices and sales are private, and firms report sales so that the cartel can monitor compliance (Section 12.7.3).

Contribution. ABS identify a basic trade-off for colluding firms with private information. Sorting by cost buys productive efficiency at an informational cost, paid in distorted prices or in wars. Rigidity removes the informational cost at the price of efficiency. They show that

rigidity usually wins and that optimal collusion rarely needs wars, which gives an equilibrium foundation to the old association between collusion and rigid prices. Methodologically, they connect repeated games with hidden information to static mechanism design, with restricted transfers and endogenous, type-dependent participation constraints. Section 12.7 turns to the way real cartels use communication to relax these constraints.

12.7 How Cartels Organize: Communication, Facilitating Practices, and Transfers

The models of Sections 12.3 to 12.6 treat collusion as an equilibrium of a non-cooperative repeated game. Firms in those models never meet, never talk and never sign anything. The cartels that antitrust authorities prosecute look different. Their members meet regularly, agree on target prices, divide sales, exchange sales figures, hire auditors and pay one another compensation. This section asks what these practices accomplish, and why firms take the legal risk of using them when tacit collusion is available in theory.

The answer turns on information. Suppose that monitoring is perfect and that demand and costs are common knowledge. An agreement can then do little more than select one of the many equilibria of the repeated game. Once prices, sales or costs are private, communication and transfers change what the cartel can enforce. Section 12.7.1 describes the common design of explicit cartels and maps each design element to the problem it solves. Section 12.7.2 studies business practices and market features that relax the incentive constraints of Section 12.3 without an explicit agreement, including multimarket contact and the threat of entry. Section 12.7.3 develops in depth the model of Harrington and Skrzypacz (2011). It shows that quotas, self-reported sales and transfers form an equilibrium when prices and sales are private. Section 12.7.4 previews a model in which cartels tolerate deliberate cheating, which Section 13.7 develops in full.

12.7.1 The anatomy of explicit cartels

A cartel, as defined in Section 12.1.1, colludes explicitly: its members coordinate through direct communication about prices, quantities, customers or bids. The repeated-game models of this chapter apply to explicit and tacit collusion alike. They describe which outcomes the threat of future competition can enforce, whatever the means by which firms coordinate. The records of prosecuted cartels raise a second question, which concerns the organization of the agreement itself.

Marshall and Marx (2012, pp. 105–108) build their account of cartel organization on Stigler (1964). For them the central problem of a cartel is to avert secret deviations by its members. A cartel solves it with three complementary *collusive structures*. *Pricing structures* implement price increases and output reductions. *Allocation structures* divide the collusive gain, through market shares, territories or customers, and set up mechanisms to redistribute gains among members. *Enforcement structures* monitor compliance and establish the threat of punishment. Marshall and Marx stress that each structure is insufficient alone. An agreement on price without an agreement on allocation and enforcement will almost surely collapse through secret deviations. A cartel that has suppressed rivalry among its members can then turn to the forces outside it, such as entrants, producers of substitutes, buyers and suppliers (Marshall and Marx, 2012, pp. 143–144). We first state the two constraints that every cartel must satisfy. We then take four internal elements in turn, treating monitoring separately from punishment, and attach each to

the theory of this chapter. Table 12.11 summarizes the mapping, and the subsection ends with the plus factors that these elements leave behind.

Two constraints. Asker and Nocke (2021, pp. 187–188) organize the economics of cartels around two constraints. Let C be a set of potential members. Firm $i \in C$ joins only if it satisfies the *participation constraint*, also called the internal stability condition,

$$V_i^{\text{comp}} \;\le\; V_i^{\text{coll}} - \eta_i. \tag{12.102}$$

Here V_i^{coll} is the firm's value inside the cartel. V_i^{comp} is its value if it stays out while the other firms in C join. The one-time cost η_i of joining captures the frictions of organizing. No court enforces a cartel agreement, so each member must also satisfy the *no-cheating constraint*

$$V_i^{\text{coll}} \;\ge\; \pi_i^{\text{dev}} + \delta\, V_i^{\text{ret}}. \tag{12.103}$$

Here π_i^{dev} is the profit in the period of cheating and V_i^{ret} the continuation value after retaliation. Constraint (12.103) is the incentive constraint of every model so far. Constraint (12.102) is new. It asks whether each firm wants to be inside at all.

The participation constraint can fail even when collusion is very profitable. Asker and Nocke (2021, pp. 192–193) give an example. Six firms with marginal cost c compete in quantities against inverse demand $P(Q) = a - bQ$. Let $A = \frac{(a-c)^2}{b}$. In the Cournot equilibrium with M symmetric players each earns $\frac{A}{(M+1)^2}$, so each of the six firms earns $\frac{A}{49}$. A cartel of all six earns the monopoly profit $\frac{A}{4}$, or $\frac{A}{24}$ per member. Suppose one firm refuses to join. The other five then act as one player in a Cournot duopoly with the outsider, and each of the two players earns $\frac{A}{9}$. Each insider gets $\frac{A}{45} > \frac{A}{49}$, so the five still gain by colluding. The outsider gets $\frac{A}{9}$, far more than $\frac{A}{24}$. Every firm would like to be the one that stays out. Negotiations over who is in and who gets what are therefore hard, and a threat to stay out unless paid extra is credible. The example mirrors the merger paradox of quantity competition. Bos and Harrington (2010) endogenize cartel formation among firms with different capacities. Smaller firms are more likely to stay out. The cartel sets a price that serves as an umbrella, and the noncartel firms price below it and produce at capacity.

Agreeing on price. Repeated-game theory predicts a whole set of sustainable prices. In the Bertrand supergame every price between marginal cost and the monopoly price is sustainable once $\delta \ge 1 - \frac{1}{N}$ (Corollary 12.15). Firms that collude tacitly must somehow land on the same element of this set. An explicit agreement solves this selection problem directly. The members of the lysine cartel, for example, met in July 1992. They agreed to raise the price to \$1.05 per pound by September 30, 1992, and to \$1.20 per pound by December 30, 1992 (Harrington and Skrzypacz, 2011, p. 2426). A notorious invitation to collude shows how a single proposal can do the same. In 1982 Robert Crandall, chief executive of American Airlines, telephoned Howard Putnam of Braniff, a rival on routes out of Dallas-Fort Worth. Crandall proposed that Braniff raise its fares by twenty percent and promised to raise his own the next morning. Putnam recorded the call and turned it over to the Department of Justice (Asker and Nocke, 2021, pp. 188–189). The proposal named the price point, a simple rule of thumb across many fares, and left the threat of continued fare wars implicit. Green and Porter (1984) made a similar point about their own trigger strategies. In view of their complexity and the close coordination they need, it seemed natural to assume that the equilibrium arises from an explicit agreement (p. 89, footnote 5).

Tacit coordination is possible, but it can be slow. Byrne and de Roos (2019) study retail gasoline in Perth, Australia, from 2001 to 2015 (Asker and Nocke, 2021, pp. 189–191). Stations

had to commit to prices a day ahead and post them on Fuelwatch, a government website meant to help consumers search. Between 2009 and 2013 the BP chain led the market to higher margins and synchronized price jumps. BP first raised prices on Wednesdays, and by mid-2010 Caltex, the next-largest chain, followed with jumps on Thursdays. BP then moved its own jumps to Thursday and occasionally stopped leading, to test whether the market would coordinate without it. The market settled on Thursday jumps of 2 cents per liter. Market interaction alone thus supplied enough communication to coordinate, through price leadership and experimentation, over several years.

Laboratory evidence points the same way. Cooper and Kühn (2014) study a two-stage game that is a reduced form of a repeated Bertrand game. The first stage is a pricing game with a low, a medium and a high price. The second is a coordination game with three equilibria, which are Pareto ranked. Without communication, matched subjects reach the high price in the first stage in fewer than 10 percent of cases. With limited communication the share is at most 50 percent, and it falls below 20 percent as subjects gain experience. In the least restrictive treatment, which allows unrestricted chat, the share exceeds 80 percent (Asker and Nocke, 2021, p. 191). Kaplow cites a coordination experiment with a less regular pattern (Section 12.8.4).

Pricing algorithms raise the question in a new form (Asker and Nocke, 2021, p. 192). In simulations by Calvano et al. (2020), agents that learn to play a repeated Bertrand game through a reinforcement-learning algorithm reach supracompetitive prices. Assad et al. (2020) find that the inferred adoption of algorithmic pricing by German gasoline retailers coincided with increases in margins of up to 28 percent. Whether such outcomes count as agreements is the question of Section 12.8.4.

Agreement is harder when members differ. A low-cost firm prefers a lower collusive price than a high-cost firm, and asymmetries change who gains most from a deviation (Section 12.3). The resulting bargaining problems are frequent in the historical record. In the case studies surveyed by Levenstein and Suslow (2006), bargaining problems end more cartels than secret cheating does (Section 12.9).

Allocating sales. Most documented cartels agree on an allocation as well as a price. Lysine and citric acid used quotas in quantities or in market shares (Table 12.12). The nucleotide cartel of Section 13.7.1 assigned customers. Other cartels drew exclusive territories, and bidding rings used bid rotation or knockout auctions (Section 13.8). An allocation does three things. First, it turns the problem of policing secret price cuts into a problem of policing quantities. A firm that steals customers ends up with sales above its quota, and sales are easier to count than the discounts behind them. This is the logic of Stigler (1964), who saw the detection of secret price cuts through shifts of customers as the central problem of oligopoly (Section 12.5). Second, an allocation fixes the division of the collusive profit, which removes one source of bargaining. Third, an allocation can raise joint profit by directing production to the lowest-cost members. Section 12.6 shows the limits of this third role. Without communication, firms with private costs often do best with a rigid price that ignores costs (Proposition 12.67). When firms can report their costs, the cartel can give more of the market to the member with the lowest cost (Athey and Bagwell, 2001).

Monitoring. A cartel monitors compliance by gathering information about the prices or sales of its members. In lysine one member compiled self-reported sales into monthly "scorecards". In citric acid outside Swiss auditors checked the reports. The Sugar Institute of Section 13.4.1 collected reports through a trade association, and many cartels relied on published price lists. Marshall and Marx (2012, p. 106) distinguish two kinds of deviation that monitoring must handle. *Unintentional deviations* arise, for example, when a sales staff that does not know of

the cartel bids too aggressively or wins a customer it should not have won. If management acknowledges such mistakes quickly, the cartel can correct them by reallocating future contracts, by subcontracting, or by end-of-period transfers. *Secret deviations* are special deals that the perpetrator does not acknowledge, and uncovering them requires costly intelligence. Many cartels delegate part of the monitoring to outsiders. Marshall and Marx review the twenty-two decisions on industrial-product cartels that the European Commission issued from 2000 through 2005 (pp. 125–127). In eleven of them, the decision mentions a third-party facilitator, such as a trade association or a consulting or accounting firm (their Table 6.1, our count). The Swiss consultancy AC-Treuhand, which served several European chemical cartels, was itself prosecuted for its services to the heat-stabilizers cartel (Asker and Nocke, 2021, p. 197). The information structure decides which theory applies. In Green and Porter (1984), firms see a public price that depends on hidden outputs and on demand (Section 12.5). In Athey et al. (2004a), prices are public and costs are private (Section 12.6). In the industrial cartels studied by Harrington and Skrzypacz (2011), both prices and sales were private, so monitoring had to rely on what firms told one another (Section 12.7.3).

Enforcement and transfers. The basic enforcement device of repeated-game theory is a price war that hurts every member. A war destroys profit, and it punishes the innocent along with the guilty. Many cartels also used targeted compensation. Under the lysine cartel's "guaranteed buy-ins" and the citric acid cartel's "buy-back system", a firm that sold more than its quota bought output from members below quota. The International Steel Agreement of 1926 ran a common fund into which over-quota producers paid (Section 12.7.3 gives the details). An interfirm sale at a price above cost transfers surplus from the buyer to the seller. Such sales also aroused little suspicion, because they were common in these industries (Harrington and Skrzypacz, 2011, p. 2433). Transfers of this kind are *asymmetric punishments*. They penalize the member that sold too much and leave industry profit intact. Harrington and Skrzypacz (2007) first argued that asymmetric punishments are essential to effective collusion when firms observe one another's sales (Harrington and Skrzypacz, 2011, p. 2442). Section 12.7.3 extends the argument to sales that are private.

Plus factors and the cost of communication. Communication helps a cartel, but it also creates evidence. Price-fixing law in the United States and the European Union condemns agreements, and proof of an agreement usually rests on proof of communication (Section 12.8). Economists who assist courts therefore look for *plus factors*, the body of economic circumstantial evidence of collusion beyond the parallel movement of prices. A plus factor that delivers a strong inference of collusion is a *super-plus factor* (Marshall and Marx, 2012, p. 213). Marshall and Marx organize plus factors by the collusive structure that generates them, in nine baskets of cartel conduct (pp. 213–214). Pricing structures produce four of them: (1) prices elevated above their level without the conspiracy and (2) industry output restricted below that level. They also produce (3) steps to reduce buyers' resistance to price increases and (4) changes in incentives within member firms that inhibit rivalry between them. Allocation structures produce (5) an allocation of the collusive gain among members and (6) redistributions of gains and losses that maintain compliance, such as end-of-period purchases from one another (p. 106). Enforcement structures produce (7) communication and monitoring, especially of production, sales and market shares, and (8) a readiness to abandon collusion if members keep cheating. A cartel that has suppressed rivalry among its members may finally seek further profits through (9) dominant-firm conduct. Courts often ask in addition for actions that would be against a firm's interest if taken independently (Kaplow, 2013, p. 110).

Marshall and Marx measure the evidential value of a plus factor with Bayes' rule (pp. 234–

Table 12.11: The design elements of explicit cartels

Element	Problem it solves	Documented examples	Theory in this book
Price	Select one price from the set of sustainable prices. Settle the level among members with different interests.	Lysine targets of \$1.05 and \$1.20 per pound (1992)	Corollary 12.15, Section 12.9
Allocation	Turn secret price cuts into visible excess sales. Divide the gains. Direct output to efficient members.	Lysine and citric acid quotas (Table 12.12). Customer allocation (nucleotides). Bid rotation and knockouts (stamp ring).	Sections 12.5, 12.6 and 12.7.3
Monitoring	Verify compliance when prices or sales are private.	Monthly sales scorecards (lysine). Swiss auditors (citric acid). Trade association rules and reports (Sugar Institute).	Sections 12.5, 12.7.3 and 13.5
Enforcement	Deter deviations at the least cost to the cartel.	Guaranteed buy-ins (lysine). Buy-backs (citric acid). A fund of \$4 and \$2 per ton (steel, 1926). Price wars (railroads, 1880s).	Sections 12.3, 12.7.3 and 13.3

Notes: Our synthesis. The examples come from Harrington and Skrzypacz (2011), Genesove and Mullin (2001), Bernheim and Madsen (2017) and Asker (2010), which Chapter 13 discusses.

235). Let C be the event that the firms collude and F the event that a plus factor is observed. Their equation (11.1) is

$$\mathbb{P}[C \mid F] = \frac{\mathbb{P}[F \mid C]\,\mathbb{P}[C]}{\mathbb{P}[F \mid C]\,\mathbb{P}[C] + \mathbb{P}[F \mid \text{not } C]\,\mathbb{P}[\text{not } C]}. \tag{12.104}$$

An observed conduct is a plus factor if $\mathbb{P}[C \mid F] > \mathbb{P}[C]$. Define the *strength* of the plus factor and the baseline odds against a cartel as

$$S = \frac{\mathbb{P}[F \mid C]}{\mathbb{P}[F \mid \text{not } C]}, \qquad O = \frac{\mathbb{P}[\text{not } C]}{\mathbb{P}[C]}.$$

Divide the numerator and the denominator of (12.104) by $\mathbb{P}[F \mid C]\mathbb{P}[C]$. The second term of the denominator becomes $\frac{O}{S}$, so

$$\mathbb{P}[C \mid F] = \frac{1}{1 + \frac{O}{S}} \tag{12.105}$$

(p. 235, note 42). The posterior rises with S, and the conduct is a plus factor if and only if $S > 1$. A super-plus factor is one that is unlikely without a cartel. When $\mathbb{P}[F \mid \text{not } C]$ is close to zero, S is large and $\mathbb{P}[C \mid F]$ is close to one. Marshall and Marx give an example (p. 236, note 44). Suppose actual prices leave the 95 percent confidence band of an econometric model fitted to noncollusive benchmark data, so that $\mathbb{P}[F \mid \text{not } C] = 0.05$. With $\mathbb{P}[F \mid C] = 0.99$ and baseline odds $O = 2$, that is $\mathbb{P}[C] = \frac{1}{3}$, the strength is $S = 19.8$ and $\mathbb{P}[C \mid F] = \frac{1}{1+\frac{2}{19.8}} \approx 0.908$. Plus factors that are weak alone can be strong together, and S extends to groups of plus factors (p. 235).

Marshall and Marx list six super-plus factors (pp. 235–236).

(1) Transaction prices above predicted levels. A reliable econometric model accounts for all material noncollusive effects and is estimated on benchmark data where conduct was presumably noncollusive. Its predicted prices are inconsistent with the actual path at a specified confidence level.

(2) Communication and information sharing. A firm knows the details of another firm's transactions, production, sales or inventories, which the latter would be disadvantaged to convey unilaterally.

(3) Interfirm transfers that are largely void of productive noncollusive motives.

(4) Within-firm incentives. In an industry with a largely homogeneous product, several firms change the incentives of their sales forces at the same time. The incentives shift from the pursuit of market share to the maintenance of high prices.

(5) Dominant-firm conduct by nondominant firms. A subset of firms with a large enough joint share engages jointly in dominant-firm conduct, although no single member has the market power to act as a dominant firm.

(6) Economic evidence in combination. While prices and profits are high and rising, a subset of firms restricts production, or keeps stable market shares, customer incumbency or geographic dominance despite excess capacity.

Cartels respond (pp. 236–237). If courts treat a conduct as a super-plus factor, colluding firms try to avoid it, but avoidance is costly. A cartel that stops making interfirm transfers must police market shares more tightly, with no deviations left at year end. A cartel that manufactures volatility in market shares to hide their stability can destabilize itself, especially if it rests on a market-share agreement. The econometric screens of Chapter 13 are attempts to produce the first super-plus factor.

Kaplow (2013) questions why the law should focus on communication at all (Section 12.8.4). The theory of this section shows when communication matters most. It matters when firms hold private information that the agreement needs.

12.7.2 Facilitating practices and market structure

A *facilitating practice* is a business practice that makes collusion easier to sustain without itself being an agreement on price. Such practices work on the two sides of the incentive constraint of Section 12.3. Some lower the one-period gain from a deviation. Others make a deviation more likely to be detected or the punishment more severe. Market structure acts through the same channels, by way of the number of firms, the frequency of interaction and the pattern of contact across markets.

Information exchange and price transparency. Exchanges of information about prices, sales or capacities raise the probability that a secret price cut is detected. Proposition 13.19 formalizes the effect. In the N-firm Bertrand supergame with Nash reversion, let a deviation be detected with probability μ_d (written μ in Chapter 13). Collusion at the monopoly price is then sustainable if and only if

$$\delta \geq \frac{N-1}{N-1+\mu_d}. \tag{12.106}$$

The threshold falls from 1 as $\mu_d \to 0$ to $1 - \frac{1}{N}$ at $\mu_d = 1$. With noisy signals, transparency also raises the value of collusion far above the threshold, because the cartel needs fewer

punishments on the path (Proposition 12.49). Transparency can also cut the other way, because buyers who see prices respond more strongly to a deviator's price cut (Remark 13.22). Danish concrete prices rose after a competition authority began to publish firm-level transaction prices (Section 13.5.2). The airline tariff case concerned fares that carriers announced in advance through a common publishing system (Section 13.5.3). Advance notice of price changes lets rivals answer an announced increase before it takes effect, which lowers the risk of leading a price increase (Holt and Scheffman, 1987, pp. 187 and 193). Under the Sugar Institute's moves system, rivals matched an announced price cut before buyers purchased. Public cuts were therefore unprofitable, and only secret concessions could raise a refiner's share (Remark 13.16). Public price information is often viewed as benign, or even desirable, because secrecy breeds suspicion. Kaplow (2013, pp. 202–203, note 56) argues that this impression is often mistaken. Secrecy makes cheating more attractive, while publicity eases coordination. In the *Container* case, firms verified with competitors the claims of buyers that they had been offered lower prices. Government auctions that publish bids afterward alert bidders at once to any cheating. Public prices help buyers mainly when each buyer is small, buys rarely and finds search costly. Information sharing among firms thus raises concerns close to those of collusion, but its effect on the market is ambiguous (Asker and Nocke, 2021, p. 189, note 26).

Meeting-competition and most-favored-customer clauses. A *meeting-competition clause* is a promise by a seller to match any lower price that a customer documents from a rival, or to release the customer from the contract. A *most-favored-customer clause* is a promise to extend to a customer any lower price that the seller grants to other customers. Both clauses look like discounts to buyers. Both also change the payoff of a secret price cut. The meeting-competition clause turns the customers of each firm into informants and keeps them from switching, as the next result shows.

Proposition 12.73 (Meeting-competition clauses)**.** *Consider the Bertrand supergame of Proposition 12.14, with N firms, marginal cost c, monopoly profit π^m, and collusion at p^m supported by Nash reversion after a deviation. Customers are identical in size, and on the collusive path each firm serves a fraction $\frac{1}{N}$ of them. A fraction $\chi \in [0,1]$ of each firm's customers hold a meeting-competition clause with their current supplier. A firm can make offers to individual customers. A covered customer who receives a lower offer shows it to its supplier, which matches it and keeps the customer. Every deviation is observed at the end of the period. Then collusion at p^m is a subgame perfect equilibrium if and only if*

$$\delta \;\geq\; \underline{\delta}(\chi) \equiv \frac{(1-\chi)(N-1)}{1+(1-\chi)(N-1)}. \tag{12.107}$$

The threshold falls from $1-\frac{1}{N}$ at $\chi = 0$ to 0 at $\chi = 1$.

Proof. After a deviation every firm prices at c forever, which is a Nash equilibrium of every continuation game. The clauses create no gain there, because no price below c is ever offered. On the path a firm earns $\frac{\pi^m}{N}$ per period, worth $\frac{\pi^m}{N(1-\delta)}$. In a one-period deviation the best a firm can do is to keep its own customers at p^m and offer slightly less than p^m to the rivals' customers. The covered rival customers stay with their suppliers, which match. The uncovered ones, a mass $(1-\chi)\frac{N-1}{N}$, switch. As the price cut shrinks to zero, the deviation profit approaches

$$\pi^m\left[\frac{1}{N}+(1-\chi)\frac{N-1}{N}\right] = \frac{\pi^m}{N}\big[1+(1-\chi)(N-1)\big].$$

The deviator earns zero afterwards. No deviation is profitable if and only if

$$\frac{\pi^m}{N(1-\delta)} \;\geq\; \frac{\pi^m}{N}\big[1+(1-\chi)(N-1)\big].$$

Multiply both sides by $\frac{N}{\pi^m} > 0$:

$$\frac{1}{1-\delta} \;\geq\; 1 + (1-\chi)(N-1).$$

Invert both sides and subtract from 1:

$$\delta \;\geq\; 1 - \frac{1}{1+(1-\chi)(N-1)} = \frac{(1-\chi)(N-1)}{1+(1-\chi)(N-1)}.$$

The right side is increasing in $(1-\chi)(N-1)$, so it falls in χ. Substituting $\chi = 0$ and $\chi = 1$ gives the limits. □

With $N = 4$ the threshold is $\frac{3}{4}$ without clauses, $\frac{3}{5}$ when half the customers are covered, and $\frac{3}{8}$ when 80 percent are covered. The proposition isolates the effect on the temptation to cheat. The clause also helps detection. A covered customer who brings a rival's offer to its supplier reveals the deviation, so the clause raises the detection probability μ_d in (12.106). In the limit $\chi = 1$ no customer can be stolen. The threshold (12.107) is then zero, so in this model the monopoly price is an equilibrium even of the static game. Salop (1986) analyzes meeting-competition and most-favored-customer clauses as practices that credibly facilitate coordination (Kaplow, 2013, p. 284, notes 69 and 71). Kaplow (2013, p. 284) adds two qualifications. Even without a clause, a customer can convey a rival's cut to its regular supplier, which would respond if the cut is cheating. The clause matters most when customers have switching costs, so that they prefer to stay and use the rival's offer to extract a lower price. A clause also requires the rival's offer to be credibly conveyed, the problem at issue in the *Container* case.

The most-favored-customer clause works through commitment. Under a retroactive clause, a firm that later cuts its price must rebate the difference to customers who bought earlier. A price cut then costs the firm a rebate on all past sales, so the firm commits itself to soft pricing, and rivals answer with higher prices of their own (Cooper, 1986). A contemporaneous clause, which extends any discount to all current customers, makes selective discounts unprofitable. A firm that cuts its price to win one customer must cut it to all of them. Kaplow (2013, p. 284) adds two conditions and a caveat. Other customers must have a sufficient chance of eventually detecting the secret cut. The firms must coordinate on adopting the clauses, because a firm that abstains gains a stronger incentive to cut, knowing that its bound rivals find punishment costly. Even industry-wide adoption has a cost for the cartel, since a clause makes punishment more costly as well as cheating (note 70).

Holt and Scheffman (1987, pp. 188–194) study meeting-competition and most-favored-customer clauses together, which they call *best-price policies*, in a homogeneous-good market with advance public notice of list prices. With both clauses in place, a rival can match a discount and keep its sales, while the discounter must extend the discount to all its customers. A discount offered to all buyers then works like a Cournot expansion of output, so any list price above the Cournot price invites such discounts (their Proposition 1). With identical costs and equal shares, every list price above the competitive level and no higher than the Cournot price is a subgame-perfect equilibrium without discounts (their Proposition 2). Competition is likely to intensify when a firm can offer discounts selectively to some of a rival's customers (their Proposition 3). The result holds when an unmatched discount wins a larger share of new buyers than the rival would win by matching it.

Another facilitating practice is *basing-point pricing*. Every seller quotes a delivered price equal to a common base price plus freight from an agreed basing point, whatever its own location. Delivered prices are then identical across sellers, which removes freight absorption as

a hidden discount. The practice also standardizes the price structure. The firms then need to agree on, and adjust, only one or a few base prices instead of a price at every location (Kaplow, 2013, p. 282).

Multimarket contact. Firms that meet in several markets can link their behavior across them. A deviation in one market can then be punished in all of them. Bernheim and Whinston (1990) show that this linkage pools the incentive constraints of the separate markets. We state the logic in a simple stationary form. Two firms meet in markets $k = 1, 2$. In market k a one-period deviation from the collusive scheme raises the deviator's profit by $g_k > 0$ in the deviation period. The punishment that follows lowers its profit by $\ell_k > 0$ in every later period.

Proposition 12.74 (Pooling incentive constraints across markets)**.** *If each market punishes only deviations in that market, collusion in market k is sustainable if and only if $\delta \geq \delta_k \equiv \frac{g_k}{g_k+\ell_k}$. If a deviation in either market is punished in both, collusion in both markets is sustainable if and only if*

$$\delta \;\geq\; \delta_{12} \equiv \frac{g_1 + g_2}{g_1 + g_2 + \ell_1 + \ell_2} = w\,\delta_1 + (1 - w)\,\delta_2, \qquad w = \frac{g_1 + \ell_1}{g_1 + \ell_1 + g_2 + \ell_2}. \tag{12.108}$$

Hence δ_{12} lies between δ_1 and δ_2, and it equals both when $\delta_1 = \delta_2$.

Proof. With separate punishments, a deviation in market k gains g_k now and loses ℓ_k in each later period. It is unprofitable if and only if

$$g_k \;\leq\; \sum_{t \geq 1} \delta^t \ell_k = \frac{\delta}{1 - \delta}\,\ell_k.$$

Multiply by $1-\delta$ and collect terms in δ: $g_k \leq \delta(g_k + \ell_k)$, which is $\delta \geq \delta_k$. With joint punishments, any deviation triggers both punishments. A firm that deviates in one market therefore loses nothing more by deviating in the other market as well, so the best deviation is a deviation in both. It gains $g_1 + g_2$ and costs $\ell_1 + \ell_2$ per later period. The same algebra gives $\delta \geq \delta_{12}$. For the weighted average, the definition of δ_k gives $g_k = \delta_k(g_k + \ell_k)$. Summing over k,

$$g_1 + g_2 = \delta_1(g_1 + \ell_1) + \delta_2(g_2 + \ell_2).$$

Dividing by $g_1 + g_2 + \ell_1 + \ell_2$ gives (12.108). □

Suppose market 1 has $g_1 = 1$ and $\ell_1 = 3$, while market 2 has $g_2 = 3$ and $\ell_2 = 1$. Market 2 might be one where orders are large and rare, so that one secret sale is worth a lot. Then $\delta_1 = \frac{1}{4}$, $\delta_2 = \frac{3}{4}$ and $\delta_{12} = \frac{1}{2}$. For $\delta \in [\frac{1}{2}, \frac{3}{4})$, linking the markets sustains collusion in market 2 that the firms could not sustain there alone. The slack in the easy market is transferred to the hard one. When the two markets are identical, linking them changes nothing.

Tirole (1988, section 6.3.2.5) gives a version in which the markets differ in how often they meet. Two firms collude at the monopoly price in two identical markets, each worth $\frac{\pi^m}{2}$ per firm and meeting. Market 1 meets every period and market 2 only in even periods, so market 2 alone has the discount factor δ^2. If $\delta^2 < \frac{1}{2} \leq \delta$, collusion is sustainable in market 1 alone and not in market 2 alone. With multimarket contact, the strongest temptation arises in even periods, when both markets are open, and a deviator undercuts in both. It gains $\frac{\pi^m}{2}$ in each market and loses all future collusive profits. Full collusion is sustainable if

$$2 \cdot \frac{\pi^m}{2} \;\leq\; \frac{\pi^m}{2}\big(\delta + \delta^2 + \delta^3 + \cdots\big) + \frac{\pi^m}{2}\big(\delta^2 + \delta^4 + \cdots\big) = \frac{\pi^m}{2}\Big(\frac{\delta}{1 - \delta} + \frac{\delta^2}{1 - \delta^2}\Big).$$

Multiply by $\frac{2(1-\delta^2)}{\pi^m}$ to get $2(1-\delta^2) \le \delta(1+\delta)+\delta^2$, that is, $4\delta^2+\delta-2 \ge 0$, or $\delta \ge \frac{\sqrt{33}-1}{8} \approx 0.593$ (Tirole's equation 6.9). At $\delta = 0.6$, contact sustains full collusion in both markets, although market 2 alone supports none. Tirole's Exercise 6.6 replaces the lower frequency by a longer information lag. Market 2 then needs $\delta^2 \ge \frac{1}{2}$ alone, and contact lowers the requirement to $\delta \ge 0.64$ approximately.

Bernheim and Whinston (1990) establish the irrelevance result for symmetric and independent Bertrand markets with constant returns and perfect monitoring. The short-run gain from deviating and the long-run loss from forgone collusion are both multiplied by the number of markets. Neither the threshold nor the value per market changes (Asker and Nocke, 2021, pp. 205–206). Contact matters when markets are asymmetric or firms are heterogeneous. Asker and Nocke give an example with as many markets as firms (p. 206). The same N firms compete in prices in each of N markets. Each firm has a home market in which its marginal cost is c_L, and its cost is $c_H > c_L$ in the other markets. The cost gap is small, so that $p^m(c_L) > c_H$. Under *efficient collusion* each firm serves only its home market, at the price $p^m(c_L)$, and earns $\pi_L^m = \big(p^m(c_L)-c_L\big)D\big(p^m(c_L)\big)$ per period.

If each market punishes only deviations in that market, efficient collusion fails for every discount factor. A firm earns nothing in a foreign market on the path. By undercutting there it earns $g = \big(p^m(c_L)-c_H\big)D\big(p^m(c_L)\big) > 0$, and Bertrand reversion in that market leaves it zero, the same as before. With multimarket contact, a deviation anywhere triggers reversion everywhere. The best deviation then undercuts in all $N-1$ foreign markets at once. Reversion leaves the firm the limit-price profit $\pi_B = (c_H - c_L)D(c_H)$ in its home market. The incentive constraint is

$$\frac{\pi_L^m}{1-\delta} \;\ge\; \pi_L^m + (N-1)\,g + \frac{\delta\,\pi_B}{1-\delta}.$$

Multiply by $1-\delta$ and collect the terms in δ:

$$\delta \;\ge\; \frac{(N-1)\,g}{(N-1)\,g + \pi_L^m - \pi_B}.$$

As the cost gap shrinks, $g \to \pi_L^m$ and $\pi_B \to 0$, so the threshold tends to $\frac{N-1}{N}$, the value that Asker and Nocke report. Contact lets the firms divide the markets into spheres of influence. The pooled constraints need not raise prices everywhere. Tirole (1988, ch. 6, note 22) notes that, as Bernheim and Whinston show, contact may raise the price in one market and lower it in another.

Under imperfect monitoring, contact helps even when markets are symmetric (Matsushima, 2001). Return to the noisy-signal model of Assumption 12.48, replicated in $\bar{k}$ independent markets with independent signals. Suppose the cartel reverts to competition everywhere, with some probability, only when the signal equals one in every market. For δ close to one this is optimal, and the binding temptation is to deviate in a single market. Asker and Nocke report the resulting value per firm and market (p. 206),

$$v_{\bar{k}}^{*} = \frac{\bar{k}-(\bar{k}-1+N)\gamma\lambda}{(1-\gamma\lambda)\,\bar{k}} \cdot \frac{\bar{\pi}}{N} = \frac{1}{1-\gamma\lambda}\Big[1-\gamma\lambda-\frac{(N-1)\gamma\lambda}{\bar{k}}\Big]\frac{\bar{\pi}}{N}.$$

With $\bar{k}=1$ this is (12.72). The value rises with the number of markets and tends to the perfect-monitoring value $\frac{\bar{\pi}}{N}$. Pooling the signals lets the cartel punish only after bad news in every market, which a single deviation rarely produces. Nocke and Strausz (2020) call this the *informativeness effect* (Asker and Nocke, 2021, p. 207). Evans and Kessides (1994) find higher

airline fares on routes served by carriers that meet on many other routes, and Miller (2010) revisits their regression (Section 13.5.3).

Cross-ownership. A firm that owns part of a rival internalizes part of the rival's profit. Consider the Bertrand duopoly with Nash reversion, and let each firm own a share $a \in [0, 1)$ of the other's profit. On the collusive path each firm's objective is worth $(1 + a)\frac{\pi^m}{2}$ per period. A deviator captures π^m for one period while its stake in the rival yields nothing, and both earn zero afterwards. Collusion is sustainable if and only if

$$\frac{(1 + a)\,\pi^m}{2(1 - \delta)} \;\geq\; \pi^m \quad\Longleftrightarrow\quad \delta \;\geq\; 1 - \frac{1 + a}{2} = \frac{1 - a}{2}.$$

Cross-ownership lowers the threshold because the deviator steals business from a firm it partly owns. Under Cournot competition partial ownership also makes the static equilibrium less competitive, which weakens Nash reversion as a punishment. Malueg (1992, pp. 29–34) studies a Cournot duopoly with a one-parameter family of demand curves and finds that the net effect depends on the curvature of demand. When demand is linear or concave, more cross-ownership lowers the threshold. When demand is convex, it raises the threshold over a range of ownership shares. For some convex demands, collusion is then easier with no cross-ownership than with a high but incomplete share. The same partial internalization of rivals' profits drives unilateral effects of partial ownership (O'Brien and Salop, 2000) and the pricing model of Section 11.8.5.

Entry. High collusive prices attract entrants, one of the four problems that McAfee and McMillan (1992) say every cartel must solve (Asker and Nocke, 2021, pp. 202 and 207–209). Predation and collusion can be complements, because a cartel can deter entry by starting or threatening a price war against entrants. They can also be substitutes, because a strong firm can earn high profits either by colluding or by driving weaker rivals out. Wiseman (2017) studies a stochastic game in which each firm's financial strength evolves with its profits and a firm in a bad enough state must exit. Without entry, and under further conditions, an anti-folk theorem holds. For discount factors close to one, every Nash equilibrium has a price war until only one firm remains. When entry is possible, firms may collude instead. Scott Morton (1997) studies 47 entry events on the routes of British shipping cartels around 1900. The cartel was more likely to start a price war when the entrant was weaker, that is, smaller and less experienced. The pattern fits the long-purse theory of predation. Asker and Hemphill (2020) document how refiners and wholesalers in the Canadian sugar market of the late 1880s used exclusionary vertical arrangements to keep out competition and support collusive prices. If cartels often deter entry, the harm from collusion lasts longer than the cartel's own conduct suggests.

Market structure. The remaining structural determinants act through the comparative statics of Section 12.3. Fewer firms, more frequent interaction, faster detection and growing demand all lower the threshold discount factor (Proposition 12.16). Symmetric firms find it easier to agree, and a maverick with low cost or spare capacity makes agreement harder (Section 12.3). Section 12.9 confronts these predictions with the evidence on which cartels succeed.

12.7.3 Harrington and Skrzypacz (2011): private monitoring, sales reports and transfers

The question and the facts

The question. How can a cartel sustain high prices when neither prices nor sales are publicly observed? And why did so many prosecuted cartels adopt the same design of quotas, self-reported sales and interfirm transfers? Harrington and Skrzypacz (2011) answer both questions with one equilibrium. The second question matters for enforcement. If the design is an equilibrium response to private information, its elements are markers that authorities can look for. The theory of repeated games with private monitoring and communication (Compte, 1998; Kandori and Matsushima, 1998) had derived folk theorems, which describe the set of equilibrium payoffs as $\delta \to 1$. Harrington and Skrzypacz have a different aim. They construct one equilibrium, in a specific oligopoly game, that matches the documented practices (Harrington and Skrzypacz, 2011, p. 2428).

The evidence. The evidence is narrative. Unless noted otherwise it comes from decisions of the European Commission, compiled by Harrington (2006). There is no econometric estimation. The model is judged by whether its equilibrium reproduces the design of the agreements.

Lysine is an amino acid added to livestock feed. In the early 1990s the five major producers formed a global cartel that lasted until mid-1995. Ajinomoto and Sewon proposed exclusive geographic markets. Archer Daniels Midland (ADM) pushed for a sales-quota scheme instead, and the members accepted it. Panel A of Table 12.12 reports the 1992 allocation. The members also coordinated on price, as described in Section 12.7.1. Kanji Mimoto of Ajinomoto prepared monthly "scorecards". Each company telephoned or mailed its sales volume to him, and he distributed a spreadsheet at the quarterly meetings. Under "guaranteed buy-ins", a company that sold more than its quota had to buy output from producers below quota. There were isolated reports of underreporting. Cheil told the Commission that it had supplied "misleading" sales information, and Ajinomoto hid 3,500 tons from the cartel's auditors. An internal memo read "Hide 1,000 tons in Thailand internal business." The agreement was nevertheless largely successful (Harrington and Skrzypacz, 2011, pp. 2425–2426).

From early 1991 to mid-1995 the five largest producers of citric acid operated a cartel. They made up about 60 percent of world production and 67 percent of production in the European Union. The quotas were market shares, set at the average of each firm's sales over the previous three years (Panel B). Each month every company reported its sales to an executive of Hoffmann-La Roche, who assembled the data and reported them back to the members by telephone. Independent Swiss auditors checked the reported sales. Enforcement used a "buy-back system". A company that exceeded its quota in one year had to buy product in the following year from the companies below quota. At a meeting in November 1991 the members determined that Haarmann and Reimer had to buy 7,000 tons from ADM, and the purchase seems to have been made. Actual production adhered very closely to the plan (Harrington and Skrzypacz, 2011, p. 2426).

The design was widespread. Cartels in carbonless paper, choline chloride, copper plumbing tubes, graphite electrodes, plasterboard, vitamins and zinc phosphate set sales quotas and monitored them through reported sales. For carbonless paper the Commission confirmed ex post that the sales figures exchanged at meetings were accurate. Transfer schemes based on reported sales are documented for choline chloride, organic peroxides, sodium gluconate, sorbates, vitamins and zinc phosphate. In choline chloride, for example, Akzo Nobel, UCB and BASF could claim 35, 28 and 15 percent of the market. The members accepted that

Table 12.12: Sales allocations in three quota cartels

Panel A. Lysine market allocation, 1992 (tons)

Company	Global	Europe	Global share (%)
Ajinomoto	73,500	34,000	39.7
Archer Daniels Midland	48,000	5,000	25.9
Kyowa	37,000	8,000	20.0
Sewon	20,500	13,500	11.1
Cheil	6,000	5,000	3.2
Total	185,000	65,500	100.0

Panel B. Citric acid, 1991

Company	Share (%)
Haarmann and Reimer	32.0
Archer Daniels Midland	26.3
Jungbunzlauer	23.0
Hoffmann-La Roche	13.7
Cerestar Bioproducts	5.0

Panel C. International Steel Agreement, 1926

Country	Share (%)
Germany	40.45
France	31.89
Belgium	12.57
Luxemburg	8.55
Saar Territory	6.54

Notes: Panels A, B and C reproduce Tables 1, 2 and 3 of Harrington and Skrzypacz (2011). Their sources are European Commission decisions (Case COMP/36.545/F3 for lysine and Case COMP/E-1/36.604 for citric acid) and Plummer (1938) for steel. The column of global lysine shares and the totals are our computations. Citric acid quotas are the average of each firm's sales in the previous three years. Steel shares are allocated market shares by country. Rounded shares need not add to exactly 100.

compensation was due if these shares were exceeded. The practice is old. The International Steel Agreement of 1926 fixed the quotas of Panel C and measured each country's crude steel production monthly. A country whose quarterly production exceeded its quota paid \$4 per excess ton into a common fund. A country below its quota received \$2 per ton short from the fund (Harrington and Skrzypacz, 2011, pp. 2427–2428).

Five common properties. Harrington and Skrzypacz (2011, p. 2427) distill five properties of these agreements. First, buyers were industrial firms that negotiated prices bilaterally, so prices and firm sales were private information. Second, the agreement allocated sales, beyond coordinating on a common price. Third, the cartel monitored the agreement by comparing sales with quotas. Fourth, monitoring used self-reported sales, which on the whole were not verifiable. Fifth, the agreement was at least partly enforced by transfers. Firms that reported sales above quota made payments, through interfirm purchases, to firms that reported sales below quota. The puzzle is then sharp. What stops a firm from undercutting the collusive price and then underreporting its sales to avoid the transfer?

The model

We change the paper's notation in four places. We write N for its n, $\mu(m)$ for its probability function $\rho(m)$, $\mathbb{E}[m]$ for its mean μ, and ω_0 for its exponent ω.

Assumption 12.75 (Environment)**.**

(i) There are $N \geq 2$ risk-neutral firms with common discount factor $\delta \in (0,1)$ and common constant marginal cost c. In each period of an infinite horizon, the firms simultaneously choose prices from a compact set, and each firm supplies whatever demand it receives.

(ii) Market demand m_t is integer valued and independently and identically distributed over time on $\{\underline{m}, \underline{m}+1, \dots, \bar{m}\}$, with $0 \le \underline{m} < \bar{m} < \infty$. Its probability function is $\mu(m)$ and its mean is $\mathbb{E}[m] = \sum_{m=\underline{m}}^{\bar{m}} \mu(m)\, m$. Market demand does not depend on prices.

(iii) Given m and the price vector $\mathbf{p} = (p_1, \dots, p_N)$, the vector of firm sales $\mathbf{q} = (q_1, \dots, q_N)$, with $\sum_i q_i = m$, is drawn from a probability function $\Psi(\mathbf{q}; m, \mathbf{p})$. Each firm's sales lie in $\{0, 1, \dots, \bar{q}\}$ with $\bar{q} \le \bar{m}$.

(iv) Each firm observes only its own price and its own sales. Reports and payments, introduced below, are public.

Market demand is perfectly inelastic, while each firm's demand responds to prices. Harrington and Skrzypacz (2011, footnote 8) read this as demand that is inelastic up to a choke price, set for example by the price of an alternative input, and zero above it. The results then hold for prices below the choke price. Let $\psi_i(q; m, \mathbf{p})$ be the marginal probability that firm i sells q units. Firm i's belief about total demand after selling q units follows from Bayes' rule:

$$\sigma_i(m \mid q, \mathbf{p}) = \frac{\mu(m)\, \psi_i(q; m, \mathbf{p})}{\sum_{m'=\underline{m}}^{\bar{m}} \mu(m')\, \psi_i(q; m', \mathbf{p})}. \tag{12.109}$$

The paper imposes three conditions (Harrington and Skrzypacz, 2011, pp. 2429–2430).

A1. *Symmetry.* Ψ is invariant to permutations of firm identities applied jointly to $\mathbf{q}$ and $\mathbf{p}$.

A2. *Top demand is always possible.* $\sigma_i(\bar{m} \mid q, \mathbf{p}) > 0$ for all q and $\mathbf{p}$.

A3. *Sales are good news about demand.* If $q' > q''$, then $\sigma_i(\cdot \mid q', \mathbf{p})$ first-order stochastically dominates $\sigma_i(\cdot \mid q'', \mathbf{p})$.

A2 and A3 hold, for example, when each of the m customers independently picks a firm, so that ψ_i is binomial (Harrington and Skrzypacz, 2011, footnote 9).

Timing. Each period has four stages. In the price stage each firm chooses a nonnegative price. In the sales stage each firm learns its own sales. In the report stage firms simultaneously send public, costless messages $r_i \in \{\varnothing, 0, 1, \dots, \bar{q}\}$, where $\varnothing$ means no message. A message is read as a sales report. In the transfer stage each firm makes a public, nonnegative payment, which is divided equally among the other $N-1$ firms.

The contrast with Green and Porter (1984) is instructive. There firms choose quantities, the market price is a public signal, and only quantities are hidden. Here prices and quantities are both private, and the only public information is what firms choose to say and pay. The model also differs from the earlier work of Harrington and Skrzypacz (2007), where sales are public, demand is fixed, and firms may charge customer-specific prices (Harrington and Skrzypacz, 2011, pp. 2430–2431).

The static benchmark. Firm i's expected stage profit is

$$\pi_i(p_1, \dots, p_N) = \sum_{m=\underline{m}}^{\bar{m}} \mu(m)\, (p_i - c) \sum_{q=0}^{m} q\, \psi_i(q; m, \mathbf{p}). \tag{12.110}$$

Let $p^N(c)$ denote a symmetric Nash equilibrium price of the stage game when marginal cost is c.

A4. For every $c \ge 0$, the stage game has a symmetric Nash equilibrium price $p^N(c)$ that is increasing, continuous and unbounded in c.

We read "increasing" as strictly increasing, so the inverse function $(p^N)^{-1}$ exists, as the paper's formulas presuppose. A sufficient condition for A4 is that ψ_i depends only on pairwise price differences, as it does when consumers have quasi-linear preferences, together with an interior equilibrium characterized by its first-order condition. Under these conditions $p^N(c) = c + \kappa_0$ for a constant markup κ_0 (Harrington and Skrzypacz, 2011, p. 2431).

Example 12.76 (Logit allocation of customers)**.** Let each of the m customers buy from firm i with probability $s_i(\mathbf{p}) = \frac{\exp(-\alpha p_i)}{\sum_{k=1}^{N} \exp(-\alpha p_k)}$, with $\alpha > 0$. Then firm i's expected sales are $\mathbb{E}[m]\, s_i(\mathbf{p})$, and its expected profit is $(p_i - c)\,\mathbb{E}[m]\, s_i(\mathbf{p})$. Using $\frac{\partial s_i}{\partial p_i} = -\alpha s_i(1 - s_i)$, the first-order condition is

$$\mathbb{E}[m]\left[s_i - \alpha(p_i - c)\, s_i(1 - s_i)\right] = 0 \quad \Longleftrightarrow \quad p_i - c = \frac{1}{\alpha(1 - s_i)}.$$

In a symmetric equilibrium $s_i = \frac{1}{N}$, so

$$p^N(c) = c + \kappa_0, \qquad \kappa_0 = \frac{N}{\alpha(N-1)}.$$

The markup does not depend on c, and A4 holds. The allocation is binomial for each firm, so A2 and A3 hold too.

Remark 12.77 (Observable demand makes the problem easy). Suppose total demand m_t were common knowledge, either because it is fixed or because it is observed. If the others report truthfully, a firm that misreports makes the total of reports differ from m_t. The other firms cannot tell who lied. They all learn, however, that someone did. A common punishment after any total different from m_t then induces truthful reports when firms are patient. Once reports are truthful, sales are effectively public, and the scheme of Harrington and Skrzypacz (2007) sustains collusion (Harrington and Skrzypacz, 2011, p. 2432). The interesting case is therefore stochastic and unobserved market demand.

The lysine strategy profile

Definition 12.78 (Lysine strategy profile)**.** The profile has a collusive phase and a noncollusive phase, and play starts in the collusive phase. Let $\hat{p}$ be a collusive price, $z > 0$ a payment per unit of reported sales, and $\phi : \{0, 1, 2, \dots\} \to [0, 1]$ a *breakdown function*. In the collusive phase:

(a) Each firm sets price $\hat{p}$.

(b) Each firm reports its sales truthfully, $r_i = q_i$.

(c) If all firms reported, each firm pays $z r_i$, divided equally among the other $N - 1$ firms. If some firm did not report, each firm pays nothing.

(d) If all firms reported and each paid $z r_j$, a public randomization keeps the industry in the collusive phase with probability $1 - \phi(\sum_{j=1}^{N} r_j)$. With probability $\phi(\sum_{j=1}^{N} r_j)$ it moves the industry to the noncollusive phase. After a missing report or payment, the industry moves to the noncollusive phase for sure.

In the noncollusive phase, which is absorbing, each firm sets $p^N(c)$, makes no report and pays nothing.

The profile fits the documented practices well. Firms report their sales, and transfers move from firms that report high sales to firms that report low sales. In practice the transfers took the form of interfirm sales. As long as the price of an interfirm sale exceeds cost, such a sale acts like a monetary transfer, although the records do not reveal those prices. One element of the profile is missing from the case records, namely the rule under which the cartel collapses. Even the 1926 steel agreement did not say what would happen if a country refused to pay $4 per excess ton. The working assumption is that egregious behavior, such as a missing payment or an incredible report, risks the collapse of the cartel (Harrington and Skrzypacz, 2011, p. 2433).

Definition 12.79 (Semipublic perfect equilibrium)**.** A *semipublic perfect equilibrium* (Compte, 1998) is a sequential equilibrium with two properties. Each firm's prices and payments depend only on the public history of reports and payments. Each firm's report depends only on the public history and on its own price and sales in the current period.

The solution concept keeps beliefs simple. A firm never needs to infer the private history of its rivals, because nothing they do depends on it beyond the current period.

Pricing: the transfer as a tax on business stealing

Let V and V^N be a firm's expected discounted values at the start of a period in the collusive and the noncollusive phase. Under truthful reporting, each firm's expected net transfer is zero, and each firm sells $\frac{\mathbb{E}[m]}{N}$ on average by symmetry. The expected stage profit on the collusive path is therefore

$$\hat{\pi}(z) = \big[\hat{p} - c\big]\frac{\mathbb{E}[m]}{N}, \tag{12.111}$$

with $\hat{p}$ tied to z as shown next. The static Nash profit is $\hat{\pi}(0) = [p^N(c) - c]\frac{\mathbb{E}[m]}{N}$.

Proposition 12.80 (Effective marginal cost)**.** *Suppose that in the collusive phase every firm reports truthfully and pays $z r_i$ after any price it sets. Then the price-stage incentive constraint holds if and only if*

$$\hat{p} = p^N\!\left(c + \frac{N}{N-1}\,z\right), \tag{12.112}$$

so each firm prices as a static oligopolist with marginal cost $c + \frac{N}{N-1}z$. Under A4, for every $\hat{p} > p^N(c)$ there is a unique transfer $z > 0$ that sustains $\hat{p}$, namely

$$z = \frac{N-1}{N}\Big[(p^N)^{-1}(\hat{p}) - c\Big]. \tag{12.113}$$

Proof. Fix rivals at $\hat{p}$ and let firm 1 set p_1, with price vector $\mathbf{p}$. If firm 1 sells q units in a period with market demand m, it pays zq and receives $\frac{z}{N-1}$ times the others' reported sales $m - q$. With truthful reports the total of reports is m, whatever the split. The continuation value therefore depends on m only. Firm 1's expected payoff is (Harrington and Skrzypacz, 2011, equation (9))

$$\sum_{m=\underline{m}}^{\bar{m}} \mu(m) \sum_{q=0}^{m} \psi_1(q; m, \mathbf{p}) \left[(p_1 - c)q + z\,\frac{m-q}{N-1} - zq\right] + \delta \sum_{m=\underline{m}}^{\bar{m}} \mu(m)\big[\phi(m)V^N + (1-\phi(m))V\big].$$

Collect the terms in q inside the bracket:

$$(p_1 - c)q - zq - \frac{z}{N-1}\,q = \left(p_1 - c - \frac{N}{N-1}\,z\right)q.$$

The remaining term $z\frac{m}{N-1}$ does not depend on q. Its expectation is $\frac{z\mathbb{E}[m]}{N-1}$. The payoff becomes

$$\sum_{m}\mu(m)\sum_{q}\psi_1(q;m,\mathbf{p})\left(p_1-c-\frac{N}{N-1}z\right)q+\frac{z\,\mathbb{E}[m]}{N-1}+\delta\sum_{m}\mu(m)\big[\phi(m)V^N+(1-\phi(m))V\big].$$

Only the first term depends on p_1, and it is the static profit (12.110) at marginal cost $c+\frac{N}{N-1}z$. Hence $\hat{p}$ is optimal against $\hat{p}$ if and only if it is a symmetric static Nash price at that cost, which is (12.112). By A4 the map $z\mapsto p^N(c+\frac{N}{N-1}z)$ is continuous and strictly increasing, equals $p^N(c)$ at $z=0$, and is unbounded. Every $\hat{p}>p^N(c)$ is therefore reached by exactly one $z>0$. Inverting (12.112) gives $c+\frac{N}{N-1}z=(p^N)^{-1}(\hat{p})$, which is (12.113). □

The intuition is simple (Harrington and Skrzypacz, 2011, p. 2435). When a firm sells a unit that a rival would otherwise have sold, it pays z instead of receiving $\frac{z}{N-1}$. The net cost of stealing one unit is

$$z+\frac{z}{N-1}=\frac{N}{N-1}\,z.$$

The transfer works like a sales tax that is rebated to the industry. It removes part of the incentive to steal business, and the collusive price is the static equilibrium price at the taxed cost. The cartel does not need punishments to deter price cuts at all, since a price cut is never a profitable deviation at $\hat{p}$. The burden of enforcement shifts entirely to the reporting stage.

With a constant markup, $p^N(c)=c+\kappa_0$, the price rises one for one with the effective cost:

$$\hat{p}-p^N(c)=\frac{N}{N-1}\,z. \tag{12.114}$$

In Example 12.76 the collusive price is $\hat{p}=c+\frac{N}{N-1}z+\frac{N}{\alpha(N-1)}$. A cartel of five firms that wants a price 10 cents above the static Nash price needs a transfer of 8 cents per unit of reported sales.

Reporting: why firms tell the truth

Underreporting saves the payment z on each unreported unit. The cartel must offset this temptation. Its only tool is the breakdown function ϕ, which makes the end of collusion more likely when total reported sales are low. Let firm 1 have price p_1 and true sales q_1, and let the others report truthfully and pay. If firm 1 reports r_1, the total of reports is $m-q_1+r_1$. Its expected payoff is

$$\begin{aligned}W(r_1;q_1,p_1)=\sum_{m=\underline{m}}^{\bar{m}}\sigma_1(m\mid q_1,\mathbf{p})\Big\{&(p_1-c)q_1+\frac{z}{N-1}(m-q_1)-zr_1\\&+\delta\big[\phi(m-q_1+r_1)V^N+\big(1-\phi(m-q_1+r_1)\big)V\big]\Big\}.\end{aligned} \tag{12.115}$$

Truthful reporting requires $W(q_1;q_1,p_1)\geq W(r_1;q_1,p_1)$ for every r_1, q_1 and p_1. Write the continuation term as $\delta V-\delta\phi\,(V-V^N)$ and subtract. The terms that do not depend on the report cancel, and the condition becomes

$$z\,(r_1-q_1)+\delta(V-V^N)\sum_{m=\underline{m}}^{\bar{m}}\sigma_1(m\mid q_1,\mathbf{p})\big[\phi(m-q_1+r_1)-\phi(m)\big]\;\geq\;0. \tag{12.116}$$

The first term is the change in the payment. The second is the change in the expected loss from a breakdown. Taking $r_1 = q_1 - 1$ gives the constraint against underreporting by one unit (Harrington and Skrzypacz, 2011, equation (5)):

$$\delta(V - V^N) \sum_{m=\underline{m}}^{\bar{m}} \sigma_1(m \mid q_1, \mathbf{p}) \big[\phi(m-1) - \phi(m)\big] \;\geq\; z. \tag{12.117}$$

The right side is the payment saved. The left side is the expected increase in the probability of a breakdown, times the value $V - V^N$ that a breakdown destroys.

Lemma 12.81 (Reduction of the reporting constraints)**.** *Suppose $\phi(m-1) - \phi(m)$ is nonincreasing in m for $m \leq \bar{m}$, and A3 holds. Then truthful reporting is preferred to every underreport, for every q_1 and p_1, if and only if* (12.117) *holds at $q_1 = \bar{q}$ for every p_1.*

Proof sketch. The argument follows the appendix of Harrington and Skrzypacz (2011). Fix q_1 and compare a report r with $r - 1$ for $r \leq q_1$. Lowering the report by one more unit raises the breakdown probability by $\phi(x-1) - \phi(x)$ at the total $x = m - q_1 + r \leq m$. Because these increments are nonincreasing, each additional unit of underreporting raises the breakdown probability at least as much as the first unit, while it saves the same z. So if underreporting by one unit does not pay, no larger underreport pays. Next compare sales levels. A firm with lower sales puts more weight on low demand by A3, where the increments $\phi(m-1) - \phi(m)$ are larger. The left side of (12.117) is therefore largest for low q_1 and smallest at $q_1 = \bar{q}$. The constraint at $\bar{q}$ implies all the others. □

The breakdown function. Harrington and Skrzypacz use the following breakdown function in the proof of their theorem (Harrington and Skrzypacz, 2011, equation (3)):

$$\phi(x) = \begin{cases} \beta(\bar{m} - x)(1 - \delta) & \text{if } x \leq \bar{m}, \\ (1 - \delta)^{\omega_0} & \text{if } x > \bar{m}. \end{cases} \tag{12.118}$$

Here x is the total of reports and $\omega_0 \in (0, 1)$. The slope parameter $\beta > 0$ is unrelated to the taste coefficients of the demand chapters. Figure 12.12 draws the function. The function falls linearly in total reports up to the largest possible demand $\bar{m}$, where it reaches zero. Low totals are taken as evidence of underreporting. Totals above $\bar{m}$ cannot occur under truthful reporting, so they reveal an overreport, and the breakdown probability jumps up. As $\delta \to 1$ the jump level $(1 - \delta)^{\omega_0}$ becomes large relative to every on-path value, because $\omega_0 < 1$. The linear part satisfies the condition of Lemma 12.81, since $\phi(m-1) - \phi(m) = \beta(1 - \delta)$ is constant for $m \leq \bar{m}$.

The value of collusion.

Lemma 12.82 (Value of the collusive phase)**.** *Under the lysine strategy profile with truthful reports (Harrington and Skrzypacz, 2011, equation (7)),*

$$V - V^N = \frac{\big[\hat{p} - p^N(c)\big] \frac{\mathbb{E}[m]}{N}}{1 - \delta + \delta \sum_{m=\underline{m}}^{\bar{m}} \mu(m)\phi(m)}. \tag{12.119}$$

With the breakdown function (12.118)*, the expected breakdown probability on the path is (Harrington and Skrzypacz, 2011, equation (8))*

$$\sum_{m=\underline{m}}^{\bar{m}} \mu(m)\phi(m) = \sum_{m=\underline{m}}^{\bar{m}} \mu(m)\, \beta(\bar{m} - m)(1 - \delta) = \beta\big(\bar{m} - \mathbb{E}[m]\big)(1 - \delta). \tag{12.120}$$

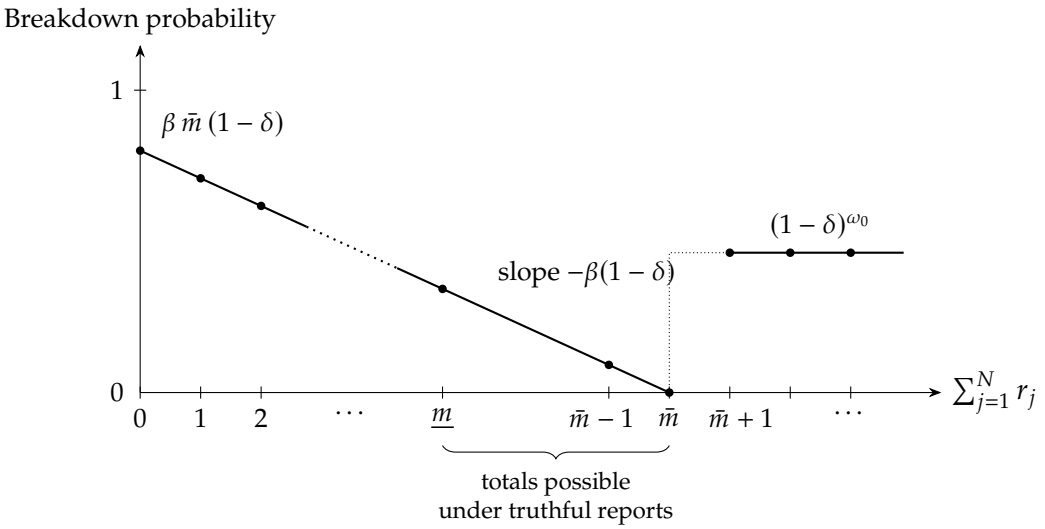


Figure 12.12: The breakdown function (12.118): the probability that collusion ends as a function of total reported sales. On the equilibrium path the total equals market demand, which lies in $\{\underline{m}, \dots, \bar{m}\}$. The probability falls by $\beta(1-\delta)$ per unit of reported sales up to $\bar{m}$, and jumps to $(1-\delta)^{\omega_0}$ for totals that exceed the largest possible demand. Redrawn and annotated from Harrington and Skrzypacz (2011), Figure 1.

Proof. The noncollusive phase repeats the static equilibrium, so $V^N = \hat{\pi}(0) + \delta V^N$. In the collusive phase the firm earns $\hat{\pi}(z)$ and then continues in the collusive phase unless a breakdown occurs:

$$V = \hat{\pi}(z) + \delta \sum_m \mu(m)\big[\phi(m)V^N + (1-\phi(m))V\big].$$

Subtract the equation for V^N:

$$V - V^N = \hat{\pi}(z) - \hat{\pi}(0) + \delta\Big(1 - \sum_m \mu(m)\phi(m)\Big)(V - V^N).$$

Collect the terms in $V - V^N$:

$$(V - V^N)\Big[1 - \delta + \delta \sum_m \mu(m)\phi(m)\Big] = \hat{\pi}(z) - \hat{\pi}(0).$$

By (12.111), $\hat{\pi}(z) - \hat{\pi}(0) = [\hat{p} - p^N(c)]\frac{\mathbb{E}[m]}{N}$, which gives (12.119). For (12.120), every on-path total satisfies $m \le \bar{m}$, so the linear branch of (12.118) applies, and $\sum_m \mu(m)(\bar{m} - m) = \bar{m} - \mathbb{E}[m]$. □

The value of collusion rises with the collusive price and falls with the breakdown rate. Here lies the tension (Harrington and Skrzypacz, 2011, p. 2437). A higher z supports a higher $\hat{p}$, which raises $V - V^N$. But z is also the saving from underreporting a unit, so a higher z strengthens the temptation that (12.117) must contain. The constraint can hold only if the collusive gain is large relative to z, and only if breakdowns are rare enough to keep $V - V^N$ large.

The main result

Theorem 12.83 (Harrington and Skrzypacz, Theorem 1)**.** *Let Assumption 12.75 and A1 to A4 hold. For any $\hat{p} > p^N(c)$ and any $\varepsilon_0 > 0$ there is $\underline{\delta} < 1$ such that the following is true. If $\delta > \underline{\delta}$ and*

$$\frac{\mathbb{E}[m]}{\bar{m} - \mathbb{E}[m]} \;>\; \frac{(N-1)\big[(p^N)^{-1}(\hat{p}) - c\big]}{\hat{p} - p^N(c)}, \tag{12.121}$$

then the lysine strategy profile is a semipublic perfect equilibrium, and $\max\{\phi(m) : \underline{m} \le m \le \bar{m}\} < \varepsilon_0$.

Condition (12.121) is the paper's condition (1). The right side is positive, because $\hat{p} > p^N(c)$ implies $(p^N)^{-1}(\hat{p}) > c$. The left side grows without bound as $\mathbb{E}[m]$ approaches $\bar{m}$. The condition therefore says that demand must not be too volatile, in the restricted sense that average demand is close to maximal demand. The proof combines the steps below.

Step 1: the binding constraint. With (12.118), the increment $\phi(m-1) - \phi(m)$ equals $\beta(1-\delta)$ for every $m \in \{\underline{m}, \dots, \bar{m}\}$. Beliefs sum to one, so the left side of (12.117) equals $\delta(V - V^N)\beta(1-\delta)$ whatever the firm's sales and price. By Lemma 12.81, all underreporting constraints reduce to

$$\delta\,\beta\,(1-\delta)\,(V - V^N) \;\ge\; z. \tag{12.122}$$

Step 2: substitute the value of collusion. Write $\Delta \equiv \hat{p} - p^N(c)$ for the price gap in this subsection only. By Lemma 12.82, the denominator of (12.119) is $1 - \delta + \delta\beta(\bar{m} - \mathbb{E}[m])(1-\delta)$, so

$$V - V^N = \frac{\Delta\,\frac{\mathbb{E}[m]}{N}}{(1-\delta)\big[1 + \delta\beta(\bar{m} - \mathbb{E}[m])\big]}.$$

Substitute into (12.122) and cancel $1-\delta$:

$$\frac{\delta\beta\,\Delta\,\frac{\mathbb{E}[m]}{N}}{1 + \delta\beta(\bar{m} - \mathbb{E}[m])} \;\ge\; z.$$

Multiply by the positive denominator and by N:

$$\delta\beta\,\Delta\,\mathbb{E}[m] \;\ge\; Nz + \delta\beta\,Nz\,(\bar{m} - \mathbb{E}[m]).$$

Collect the terms in $\delta\beta$ (Harrington and Skrzypacz, 2011, equation (26)):

$$\delta\beta\Big[\Delta\,\mathbb{E}[m] - Nz\,(\bar{m} - \mathbb{E}[m])\Big] \;\ge\; Nz. \tag{12.123}$$

Step 3: when a slope exists. The right side of (12.123) is positive. If the bracket is zero or negative, no $\beta > 0$ satisfies the constraint. If the bracket is positive, every slope at or above

$$\beta_{\min} \equiv \frac{Nz}{\delta\big[\Delta\,\mathbb{E}[m] - Nz\,(\bar{m} - \mathbb{E}[m])\big]} \tag{12.124}$$

satisfies it. This is the paper's bound (4), since $Nz = (N-1)[(p^N)^{-1}(\hat{p}) - c]$ by (12.113). Within this family of breakdown functions, the underreporting constraints can therefore be met if and only if

$$\frac{\Delta\,\frac{\mathbb{E}[m]}{N}}{z} \;>\; \bar{m} - \mathbb{E}[m], \tag{12.125}$$

which is the paper's condition (6). The left side is the per-firm gain from collusion per unit of transfer. The right side is the gap between maximal and average demand.

Step 4: back to the price. Multiply both sides of (12.125) by Nz and substitute $Nz = (N-1)[(p^N)^{-1}(\hat{p}) - c]$ on the right:

$$\Delta\,\mathbb{E}[m] \;>\; (N-1)\Big[(p^N)^{-1}(\hat{p}) - c\Big](\bar{m} - \mathbb{E}[m]).$$

Divide both sides by $\Delta(\bar{m} - \mathbb{E}[m]) > 0$ to obtain (12.121).

Step 5: probabilities, overreports and payments. Three loose ends remain. First, $\beta_{\min}$ stays bounded as $\delta \to 1$, so every value of ϕ on the linear branch is at most $\beta\bar{m}(1-\delta)$, which goes to zero. This delivers both $\phi \leq 1$ and the bound ε_0 on the path. Second, an overreport raises the payment, and with positive probability it pushes the total above $\bar{m}$ (by A2, $\sigma_1(\bar{m} \mid q_1, \mathbf{p}) > 0$). There the breakdown probability jumps to $(1-\delta)^{\omega_0}$. As $\delta \to 1$ this jump outweighs the small reduction in ϕ on the linear branch, so overreports do not pay. Third, a firm that reports and then fails to pay triggers a breakdown for sure. Reporting zero and paying nothing is better than that, and truthful reporting is at least as good as reporting zero. So the prescribed payment is optimal (Harrington and Skrzypacz, 2011, pp. 2447–2449).

Remark 12.84 (Overreports at the smallest slope). At the smallest admissible slope, the payment alone deters overreports, with or without the jump. This is our observation, which the paper does not make. At $\beta = \beta_{\min}$, (12.122) binds, so $\delta\beta(1-\delta)(V - V^N) = z$. In state m, an overreport by k units lowers the breakdown probability by at most $\beta(1-\delta)\min\{k, \bar{m} - m\}$. It would lower it by exactly that much if ϕ were zero above $\bar{m}$. The expected benefit is therefore at most $z\,\mathbb{E}_\sigma[\min\{k, \bar{m} - m\}]$, where $\mathbb{E}_\sigma$ takes expectations under the firm's beliefs, and the cost is zk. A2 puts positive weight on $m = \bar{m}$, where the benefit is zero, so the benefit falls short of zk. The jump to $(1-\delta)^{\omega_0}$ is what makes overreports unprofitable for every steeper slope once δ is close to one. Footnote 17 of the paper adds a practical reason. Invoices or customer lists can prove that a sale was made, but nothing can prove that a sale was not made, so underreporting is the harder problem.

The cost of truthful reporting. Normalize the value of collusion by $1-\delta$. Step 2 gives

$$(1-\delta)(V - V^N) = \frac{\Delta\,\frac{\mathbb{E}[m]}{N}}{1 + \delta\beta(\bar{m} - \mathbb{E}[m])}.$$

At the most profitable admissible slope $\beta_{\min}$,

$$1 + \delta\beta_{\min}(\bar{m} - \mathbb{E}[m]) = 1 + \frac{Nz(\bar{m} - \mathbb{E}[m])}{\Delta\,\mathbb{E}[m] - Nz(\bar{m} - \mathbb{E}[m])} = \frac{\Delta\,\mathbb{E}[m]}{\Delta\,\mathbb{E}[m] - Nz(\bar{m} - \mathbb{E}[m])}.$$

Substituting (Harrington and Skrzypacz, 2011, p. 2438),

$$(1-\delta)(V - V^N) = \frac{1}{N}\Big[\Delta\,\mathbb{E}[m] - Nz\,(\bar{m} - \mathbb{E}[m])\Big]. \tag{12.126}$$

The first term, $\frac{\Delta\mathbb{E}[m]}{N}$, is the per-period gain from collusion if breakdowns never occurred. The second term, $z(\bar{m} - \mathbb{E}[m])$ per firm, is the expected cost of the breakdowns that keep reports truthful. The cost does not depend on δ. As firms become patient the breakdown probability goes to zero, but the breakdowns become correspondingly more costly, and the loss stays bounded away from zero. Each member in effect pays z per period for each unit by which expected demand falls short of maximal demand. Condition (12.125) is exactly the condition that (12.126) be positive.

Corollary 12.85 (Constant markup (Harrington and Skrzypacz, Corollary 2))**.** *Suppose* $p^N(c) = c + \kappa_0$*. Then condition* (12.121) *becomes*

$$\frac{\mathbb{E}[m]}{\bar{m} - \mathbb{E}[m]} > N - 1 \quad \Longleftrightarrow \quad \frac{\mathbb{E}[m]}{\bar{m}} > \frac{N-1}{N}. \tag{12.127}$$

If it holds, then for any $\hat{p} > p^N(c)$ *and* $\varepsilon_0 > 0$ *the conclusion of Theorem 12.83 holds for* δ *close to one. The scheme retains the fraction*

$$1 - (N-1)\,\frac{\bar{m} - \mathbb{E}[m]}{\mathbb{E}[m]} \tag{12.128}$$

of the first-best collusive gain, whatever $\hat{p}$ *and* δ*. If market demand is uniform on* $\{\underline{m}, \dots, \bar{m}\}$*,* (12.127) *holds for* $N = 2$ *if and only if* $\underline{m} > 0$*, and for* $N \geq 3$ *if and only if*

$$\frac{\bar{m}}{\underline{m}} < \frac{N}{N-2}. \tag{12.129}$$

Proof. With $p^N(c) = c + \kappa_0$, the inverse is $(p^N)^{-1}(\hat{p}) = \hat{p} - \kappa_0$. Hence $(p^N)^{-1}(\hat{p}) - c = \hat{p} - c - \kappa_0 = \hat{p} - p^N(c)$, and the right side of (12.121) equals $N-1$. For the second form, $\mathbb{E}[m] > (N-1)(\bar{m} - \mathbb{E}[m])$ rearranges to $N\mathbb{E}[m] > (N-1)\bar{m}$. For the retained fraction, divide (12.126) by $\frac{\Delta \mathbb{E}[m]}{N}$ and use $Nz = (N-1)\Delta$ from (12.114):

$$1 - \frac{Nz(\bar{m} - \mathbb{E}[m])}{\Delta\,\mathbb{E}[m]} = 1 - (N-1)\frac{\bar{m} - \mathbb{E}[m]}{\mathbb{E}[m]}.$$

For the uniform case, $\mathbb{E}[m] = \frac{\underline{m} + \bar{m}}{2}$ and $\bar{m} - \mathbb{E}[m] = \frac{\bar{m} - \underline{m}}{2}$. Condition (12.127) becomes

$$\frac{\underline{m} + \bar{m}}{\bar{m} - \underline{m}} > N - 1 \quad \Longleftrightarrow \quad \underline{m} + \bar{m} > (N-1)\bar{m} - (N-1)\underline{m} \quad \Longleftrightarrow \quad N\underline{m} > (N-2)\bar{m}.$$

For $N = 2$ the last inequality reads $\underline{m} > 0$. For $N \geq 3$ divide by $(N-2)\underline{m}$, which is positive because the inequality forces $\underline{m} > 0$. □

With a constant markup the transfer cancels from the condition (Harrington and Skrzypacz, 2011, footnote 19). The smallest slope also simplifies. Substituting $Nz = (N-1)\Delta$ into (12.124) gives

$$\beta_{\min} = \frac{N-1}{\delta\big[\mathbb{E}[m] - (N-1)(\bar{m} - \mathbb{E}[m])\big]}, \tag{12.130}$$

which does not depend on the target price either. The required fraction $\frac{N-1}{N}$ in (12.127) is the same number as the Bertrand threshold discount factor of Proposition 12.14. Table 12.13 shows how fast the condition tightens with the number of firms. A duopoly tolerates any uniform demand with a positive lower bound. With three firms the top of the support must be less than three times the bottom, and with four firms less than twice the bottom. Harrington and Skrzypacz argue that these bounds are reasonable for the commodities that cartels usually sell. The variation that matters is unanticipated, and the cartel can control for anticipated cycles and trends when it sets quotas (Harrington and Skrzypacz, 2011, pp. 2437–2438).

Example 12.86 (A five-firm cartel)**.** Let $N = 5$, as in lysine, with a constant markup and market demand uniform on $\{80, \dots, 100\}$. Then $\mathbb{E}[m] = 90$ and $\bar{m} - \mathbb{E}[m] = 10$. Condition (12.127) holds, since $\frac{90}{10} = 9 > 4$. Equivalently, $\frac{\bar{m}}{\underline{m}} = \frac{5}{4} < \frac{5}{3}$. By (12.128) the scheme retains the fraction

$$1 - 4 \cdot \frac{10}{90} = \frac{5}{9} \approx 0.56$$

Table 12.13: Demand volatility compatible with the lysine strategy profile under a constant markup

Number of firms N	2	3	4	5	6	7
Smallest admissible $\frac{\mathbb{E}[m]}{\bar{m}}$, equal to $\frac{N-1}{N}$	$\frac{1}{2}$	$\frac{2}{3}$	$\frac{3}{4}$	$\frac{4}{5}$	$\frac{5}{6}$	$\frac{6}{7}$
Largest admissible $\frac{\bar{m}}{\underline{m}}$ (uniform demand), equal to $\frac{N}{N-2}$	any	3	2	$\frac{5}{3}$	$\frac{3}{2}$	$\frac{7}{5}$

Notes: Our computation from Corollary 12.85. Both bounds are strict. For $N = 2$ any uniform demand with $\underline{m} > 0$ qualifies. The script `hs_example.py` in `figures/ch12/src` prints these values.

of the first-best collusive gain. By (12.130) the smallest slope is $\beta_{\min} = \frac{4}{50\delta} = \frac{0.08}{\delta}$. The expected breakdown probability per period follows from (12.120):

$$\beta_{\min}\,(\bar{m} - \mathbb{E}[m])\,(1-\delta) = \frac{0.8\,(1-\delta)}{\delta}.$$

With $\delta = 0.95$ this is 0.042, so the collusive phase lasts 23.75 periods on average, and the largest on-path breakdown probability (at $m = 80$) is 0.084. With $\delta = 0.99$ the expected breakdown probability is 0.0081, and the collusive phase lasts 123.75 periods on average. In both cases the normalized gain is $\frac{5}{9}$ of its first-best value. We checked all reporting constraints numerically, with a binomial allocation of customers and $\omega_0 = \frac{1}{2}$. At $\beta_{\min}$ every constraint holds, and the underreporting constraint binds. With a slope of $1.5\beta_{\min}$ and $\delta = 0.95$, a firm that sold nothing would gain by reporting four units, so the overreporting constraint fails. With the same slope and $\delta = 0.99$ every constraint holds again. The script `figures/ch12/src/hs_example.py` prints these numbers.

Interpretation, robustness and limitations

Price wars on the equilibrium path. Breakdowns occur with positive probability on the path, after low reported sales. Nobody cheats, and everybody knows it. The breakdowns are nevertheless needed, since without them every firm would underreport. In this respect the equilibrium resembles Green and Porter (1984), where wars follow low prices that nobody caused (Proposition 12.45). With infinite reversion a breakdown ends the cartel. With finite reversion the same mechanism produces periodic price wars (Harrington and Skrzypacz, 2011, footnote 15). The answer to the puzzle of credible reports is now clear. An unverifiable report is credible because a low total raises the chance that the valuable collusive phase ends. An inflated report that pushes the total beyond $\bar{m}$ reveals itself and raises the breakdown risk. Below $\bar{m}$, an inflated report costs payments that exceed the breakdown risk it saves, at least at the slope the cartel prefers (Remark 12.84).

Less frequent reports and transfers. In practice reports were often less frequent than sales, and transfers less frequent than reports. Delayed transfers change little, because a firm's current incentives depend only on the change in accumulated transfers that its current actions cause. Suppose instead that firms report and make transfers every τ periods. The theorem still holds with condition (12.121) replaced by (Harrington and Skrzypacz, 2011, p. 2441)

$$\frac{\mathbb{E}[m]}{\bar{m} - \mathbb{E}[m]} > \frac{(N-1)\left[(p^N)^{-1}(\hat{p}) - c\right]}{\hat{p} - p^N(c)} \cdot \frac{\delta^\tau - \delta^{\tau+1}}{\delta - \delta^{\tau+1}}. \tag{12.131}$$

The last factor equals 1 when $\tau = 1$. Our own algebra, writing $1 - \delta^\tau = (1 - \delta)(1 + \delta + \cdots + \delta^{\tau-1})$, shows that it equals

$$\frac{\delta^{\tau-1}}{1 + \delta + \cdots + \delta^{\tau-1}},$$

which is below 1 for $\tau \geq 2$ and tends to $\frac{1}{\tau}$ as $\delta \to 1$. Less frequent reporting therefore relaxes the volatility condition in this sense, because collusion is assured between reports. Why firms delayed reports remains open. Larger transfers may attract the attention of antitrust authorities, and delay in information can improve the efficiency of equilibria in related repeated games (Harrington and Skrzypacz, 2011, p. 2441).

Limitations stated by the authors. Harrington and Skrzypacz (2011, pp. 2438–2441) discuss four limitations. First, market demand is perfectly inelastic, so total sales carry no information about prices. With elastic demand, total sales would be a signal of prices, and better equilibria may exist. The authors conjecture that the lysine profile would remain an equilibrium, with prices given by a modified static game. Inelastic demand is plausible for inputs such as lysine and citric acid, which are a small part of the buyer's cost. It is plausible at least over the range of prices that would not alert buyers to a cartel. The assumption fails when the cartel is not all-inclusive. Outside supply, such as the Chinese producers of vitamin C, makes total cartel sales sensitive to cartel prices. Second, condition (12.121) may fail. The online appendix gives two examples. In one, a duopoly with a positive lower bound on demand uses quantity quotas of $\frac{m}{2}$, compensates shortfalls and punishes only off the path. In the other, with $m \in \{0, 1, 2\}$, condition (12.121) is tight for semipublic equilibria without delay. Third, some cartels hired auditors, which the model omits. Auditors provide only a noisy signal, because members can hide sales, as Ajinomoto did. Fourth, the timing of reports differs from practice, as discussed above. In citric acid, for example, Hoffmann-La Roche added its own report after seeing the others (footnote 10).

Further critiques. Three further points deserve mention. The equilibrium has no misreporting, while the lysine record shows hidden sales and misleading reports. A version with noisy external signals of sales, or with imperfectly controlled employees, would be needed to fit those episodes. The analysis is confined to symmetric firms and a symmetric profile, while the documented quotas are far from equal (Table 12.12). Finally, the lysine profile is one equilibrium. It need not be the best one, and Awaya and Krishna (2016) and others have since studied more generally when cheap talk about private sales helps firms collude.

Contrast with the other models of this chapter. Athey et al. (2004a) also study price competition with private information, but the private information is about costs, and prices are public (Section 12.6). In their symmetric equilibria without communication, rigid pricing removes the incentive to misrepresent costs at the price of productive efficiency. When firms can report costs, the motive for communication is to allocate production to the lowest-cost firm (Athey and Bagwell, 2001). In Harrington and Skrzypacz (2011), by contrast, the motive for reporting sales is monitoring (Harrington and Skrzypacz, 2011, p. 2431). In Green and Porter (1984) the public price is the monitoring signal and nobody communicates. Here the signal is the total of cheap-talk reports, and transfers do most of the work that punishments do elsewhere.

Implications for enforcement. For markets with industrial buyers and private prices, the theory points to three markers of collusion (Harrington and Skrzypacz, 2011, p. 2442). The first is the exchange of sales reports, in secret or through a trade association. The second is interfirm sales or other compensation, because asymmetric punishments are what make the agreement work. The third is periodic price wars, because the threat of a war is what keeps reports truthful.

Each marker alone is weak evidence. Together they form a pattern that independent conduct would rarely produce.

Contribution. The paper gives the first equilibrium account of the quota, report and transfer design that recurs in modern international cartels. It connects the abstract theory of private monitoring and communication to documented practice. It explains why cartels with private prices agree on sales allocations in addition to prices. It also shows how a cartel can turn unverifiable statements into reliable monitoring at a bounded cost. Section 13.7.1 returns to the same cases as evidence, and Section 13.8 studies a cartel whose internal transfers are recorded in detail.

12.7.4 Tolerated cheating: a preview

Remark 12.87 (Tolerated cheating). In every model so far, equilibrium involves no deliberate cheating, and any detected deviation would be punished. The records of prosecuted cartels show both deliberate price cuts and business stealing that went unpunished, in lysine, nucleotides and citric acid among others (Section 13.7.1). Bernheim and Madsen (2017) explain this pattern. Each of two firms has a home market where its cost is lower, and quoting a price in any market has a fixed cost. When firms are too impatient for perfect market division at the home monopoly price, the optimal stationary agreement sets a price floor p^{fl}. Each home firm mixes over prices between the floor and its monopoly price, with atoms at both. The away firm occasionally raids at prices above the floor and sometimes wins, and these raids go unpunished. A quote at or below the floor triggers a short, harsh price war. The threat of tolerated raids keeps each home firm from raising its own price. Punishments cannot do that job, because all available punishment power is already used to deter raids at or below the floor. As the discount factor rises to the threshold for perfect collusion, the floor rises to the home monopoly price. The model answers the puzzle of tolerated cheating. Its environment, theorems and numerical examples are developed in Section 13.7.2, and we do not repeat them here.

12.8 Antitrust Enforcement and Leniency

The models of the previous sections treat collusion as a problem that firms solve among themselves. Competition law adds a third party that can detect a cartel and punish it. This section asks how enforcement enters the incentive constraints of a cartel. Section 12.8.1 describes the legal instruments. Section 12.8.2 adds fines to a collude-or-compete supergame. Section 12.8.3 studies leniency programs in the model of Chen and Rey (2013), and Section 12.8.4 discusses the critique by Kaplow (2013) of the legal requirement of an agreement.

In this section F denotes a fine. It is neither a fixed cost nor a distribution function. Page, equation and proposition numbers for Chen and Rey (2013) refer to their working-paper version of January 2012. We change the paper's notation in two places. The detection probability ρ becomes ϱ, because ρ is pass-through elsewhere in the book. The amnesty rate q becomes ℓ, because q is a quantity.

12.8.1 The legal framework

Section 12.1.4 introduced the prohibitions of Section 1 of the Sherman Act and of Article 101, and noted that individuals are jailed for cartel conduct every year. Here we describe the sanctions and the leniency programs that enforce them. In the United States the Antitrust Division of

the Department of Justice prosecutes price fixing as a crime, against firms and against the executives involved. Fines per case have risen steeply since the early 1980s (Section 12.1.5). The vitamin cartels of the 1990s show the scale. Roche paid a criminal fine of 500 million dollars in the United States and BASF one of 225 million dollars. Purchasers recovered billions of dollars in damages through civil litigation, and several executives of the major producers served time in prison (Marshall and Marx, 2012, pp. 1–2). Private suits under the Sherman Act carry treble damages. Section 5 of the Federal Trade Commission Act, by contrast, allows no private suits, treble damages or criminal penalties (Kaplow, 2013, p. 60, note 21). Kaplow regards the threat of imprisonment and fines on individuals as a useful supplement to corporate fines, given agency problems within firms (p. 12). Chen and Rey (2013, footnote 8) give 100 million dollars as the statutory maximum for a corporate fine in the United States. The vitamin fines show that this maximum is not a hard ceiling. U.S. law also allows an alternative fine based on the gain from the offense or on the loss it caused. A convicted organization may be fined up to the greater of twice the gross gain and twice the gross loss to others (United States Code, 2024, § 3571(c)(2) and (d)). The alternative does not apply when imposing it would unduly complicate or prolong the sentencing process. In the European Union the Commission imposes administrative fines of up to 10 percent of a firm's turnover (Chen and Rey, 2013, footnote 8). Under the Commission's 2006 guidelines, the fine starts from an amount based on the value of the sales affected by the cartel and on the number of years of infringement. The Commission then adjusts it for the circumstances of the case (Chen and Rey, 2013, footnote 8). Table 12.2 lists the largest fines imposed so far.

Cartels hide their agreements, so the hardest part of enforcement is proving that firms colluded. Leniency programs, also called whistleblower programs, address this problem by rewarding a member that reports the cartel. The United States adopted a corporate leniency program in 1978. Its 1993 revision introduced two rules (Chen and Rey, 2013, p. 1). The *first-informant rule* guarantees amnesty to the first firm that reports, and only to that firm. The *post-investigation amnesty rule* keeps the first informant eligible after an investigation has started. Levenstein and Suslow (2006, p. 50, footnote 21) attribute the surge in U.S. prosecutions of international cartels in the 1990s primarily to this revision. Miller (2009) finds that the revision raised cartel discoveries by 60 percent, as Section 12.1.5 describes. The European Commission adopted a program in 1996 and revised it in 2002 (Chen and Rey, 2013, footnote 1). The EU program reduces fines by 75 to 100 percent for a report made before an investigation. Once an investigation is under way, the reduction falls to 50 to 75 percent (Chen and Rey, 2013, footnote 6 and p. 29). Programs differ elsewhere. South Korea can pay monetary rewards to individual informants, and Greece never grants amnesty to repeat offenders (Chen and Rey, 2013, footnote 1 and p. 14).

Many recent prosecutions began with a report from inside or near the cartel. The U.S. investigation of the graphite electrodes cartel started with a complaint by a steel firm, a customer of the cartel (Levenstein and Suslow, 2006, p. 62). The stamp-auction ring studied by Asker (2010) came to light after a dealer outside the ring alerted the authorities. Asker also suggests that strong members kept weak ones inside the ring because an expelled member could report it and seek leniency (Section 13.8). Leniency therefore shapes how a cartel is organized as well as whether it survives. Section 13.10.1 describes how the cartels studied in Chapter 13 came to light and what this implies for the selection of observed cartels.

Enforcement raises three economic questions. How do fines and leniency change the incentive constraints of a cartel? Which leniency rate deters collusion in the largest set of industries? Should leniency continue after an investigation opens, extend to more than one informant, or extend to repeat offenders? The rest of this section answers them with

repeated-game models.

12.8.2 Fines in the repeated game

We embed enforcement in the simplest collusion game, following Chen and Rey (2013, Section 2). We state the model for N firms because it costs nothing, and we specialize to the duopoly that Chen and Rey study.

The stage game. In each period, N identical firms choose whether to collude or to compete. If all collude, each earns a gross profit $B > 0$, the *stake* of collusion. If one firm deviates while the others collude, the deviator earns NB and the others earn zero. If firms compete, each earns zero. The Bertrand supergame of Proposition 12.14 has this form. With homogeneous goods and constant marginal cost, collusion at the monopoly price gives each firm $B = \frac{\pi^m}{N}$. A deviator slightly undercuts and captures nearly the whole monopoly profit $\pi^m = NB$. Competition gives zero profit, which is both the static Nash payoff and the minmax payoff. Without enforcement, grim trigger sustains collusion if and only if

$$\frac{B}{1-\delta} \geq NB \iff \delta \geq 1 - \frac{1}{N}.$$

The industries of the economy share the discount factor δ and differ in the stake B. A larger B makes collusion more profitable and also raises the one-period gain from a deviation.

Assumption 12.88 (Enforcement without leniency)**.**

(i) In each period, collusion generates evidence if and only if all firms agree to collude at the start of the period. The evidence lasts one period, so a cartel cannot be prosecuted for past periods.

(ii) In each period with evidence, the authority finds it with probability $\varrho \in (0, 1)$, independently across periods. Each firm then pays the fine $F > 0$.

(iii) The discount factor satisfies $\delta > \frac{N-1}{N}$, so that collusion is a concern absent enforcement.

(iv) A deviation from the collusive agreement is followed by competition forever.

The timing within a period has three stages. At stage 0 each firm decides whether to enter a collusive agreement. If any firm refuses, the firms compete and the period ends. At stage 1 each firm colludes or deviates in the product market, and rivals observe the choice only at the end of the period. At stage 2 firms may report the evidence to the authority. Without a leniency program a report only exposes the reporter, so nobody reports.

Definition 12.89. The *deterrence threshold* of an enforcement policy is the smallest stake B at which collusion is a subgame perfect equilibrium outcome. The policy deters collusion in every industry whose stake lies below the threshold.

Because industries differ only in B, a policy with a higher threshold deters collusion in a superset of industries. Maximizing the deterrence threshold is therefore optimal whatever the distribution of stakes across industries. This is the objective of the authority in Chen and Rey (2013).

Proposition 12.90 (Collusion with fines)**.** *Under Assumption 12.88,* normal collusion *(collude in every period, never report, compete forever after a deviation) is a subgame perfect equilibrium if and only if*

$$B \geq \underline{B} \equiv \frac{\delta \varrho F}{N\delta - (N-1)}. \tag{12.132}$$

For $N = 2$ the threshold is $\underline{B} = \frac{\delta \varrho F}{2\delta - 1}$, equation (1) of Chen and Rey (2013). The threshold $\underline{B}$ rises with ϱ, with F and with N, and falls with δ.

Proof. On the collusive path each firm earns B and pays the fine F with probability ϱ in every period. The value of normal collusion is

$$V_N = \sum_{t=0}^{\infty} \delta^t (B - \varrho F) = \frac{B - \varrho F}{1 - \delta}. \tag{12.133}$$

The punishment phase repeats the static Nash equilibrium, so it is subgame perfect (Proposition 12.6). By the one-shot deviation principle (Proposition 12.5), it remains to check one-period deviations on the collusive path. Consider first a deviation at stage 1. The deviator earns NB. All firms agreed at stage 0, so evidence exists and the deviator still pays F with probability ϱ. From the next period on it earns zero. The deviation is unprofitable if and only if

$$\begin{aligned} \frac{B - \varrho F}{1 - \delta} &\geq NB - \varrho F \\ B - \varrho F &\geq (1 - \delta) NB - (1 - \delta) \varrho F \\ B\left[1 - N(1 - \delta)\right] &\geq \delta \varrho F. \end{aligned}$$

Part (iii) of Assumption 12.88 gives $1 - N(1 - \delta) = N\delta - (N - 1) > 0$. Dividing by it yields (12.132).

Consider next a refusal at stage 0. It yields zero in the current period and zero afterwards, so it is unprofitable if and only if $V_N \geq 0$, that is, $B \geq \varrho F$. The threshold satisfies $\underline{B} \geq \varrho F$, because

$$\frac{\delta}{N\delta - (N-1)} \geq 1 \iff (N-1)(1-\delta) \geq 0.$$

Hence every $B \geq \underline{B}$ also deters a refusal, and the stage-1 deviation is the binding one.

For the comparative statics, the numerator of $\underline{B}$ rises with ϱ and F. The denominator falls with N, because its derivative with respect to N is $\delta - 1 < 0$. Finally,

$$\frac{\partial \underline{B}}{\partial \delta} = \varrho F \, \frac{[N\delta - (N-1)] - N\delta}{[N\delta - (N-1)]^2} = -\frac{(N-1)\varrho F}{[N\delta - (N-1)]^2} < 0. \qquad \square$$

The incentive constraint has a transparent form. Rearranging the third line of the proof gives

$$\frac{\delta}{1 - \delta} (B - \varrho F) \geq (N - 1) B. \tag{12.134}$$

The left side is the discounted value of future collusion net of expected fines. The right side is the one-period gain from a deviation. The expected fine of the current period does not appear, because the deviator pays it as well. Fines deter collusion only by lowering the value of future collusion. Enforcement thus works like a fall in the discount factor. It deters collusion in industries with small stakes and leaves large-stake industries untouched.

Remark 12.91 (Maximal fines and fines proportional to the stake). Deterrence depends on the expected fine ϱF. Raising F is cheap, while raising ϱ requires investigations. The economics of optimal enforcement (Becker, 1968; Polinsky and Shavell, 2000) therefore recommends setting the fine at its maximum, and Chen and Rey (2013) interpret F as the maximal fine. In practice fines are capped by law, as described in Section 12.8.1. The model takes F to be independent of B. Suppose instead that the fine is proportional to the stake, $F = \phi B$, as the EU guidelines suggest by basing fines on affected sales. Then (12.132) becomes

$$N\delta - (N-1) \geq \delta\varrho\phi,$$

which does not depend on B. Enforcement then deters collusion either in every industry or in none. Heterogeneity in stakes matters for policy design only because fines do not scale with the gains from collusion. Private damages raise the expected sanction further. Levenstein and Suslow (2006, p. 62, footnote 60) note an argument that customers may anticipate damages in their demand, so that only unanticipated damages deter.

12.8.3 Chen and Rey (2013): the design of leniency programs

Question. Leniency programs have two opposite effects. They destabilize collusion, because a member can cheat and report, escaping part of the fine. They can also lower the expected fine of a cartel that has no intention of breaking up. Motta and Polo (2003, p. 349), as quoted by Chen and Rey (2013, p. 1), warn that reduced fines may have an ex ante pro-collusive effect. Wils (2008, p. 137), also quoted there, imagines cartel members that take turns applying for leniency whenever a cartel is about to be detected. Earlier work mostly took the leniency rate as given. Chen and Rey (2013) ask which amnesty rate deters collusion in the largest set of industries. They also ask whether leniency should continue after an investigation starts, whether it should be restricted to the first informant, and whether repeat offenders should be excluded.

Setting and model. Chen and Rey study the duopoly version of Assumption 12.88, so $N = 2$ and a deviator earns $2B$. Absent enforcement, collusion requires $\delta \geq \frac{1}{2}$, and they assume $\delta > \frac{1}{2}$. A leniency program changes stage 2. If at least one firm reports, the cartel is detected for sure. The first informant pays the reduced fine $(1-\ell)F$ and the other firm pays F. The parameter ℓ is the *amnesty rate*. A value $\ell \in [0,1]$ is a fine reduction, and $\ell > 1$ is a reward of $(\ell - 1)F$. If nobody reports, the authority detects the cartel with probability ϱ, and both firms pay F. In this first version investigations are secret, so firms do not know whether one is under way. The policy is stationary and treats all industries alike. The paper contains no data. Its empirical content comes from laboratory evidence and from the policy facts of Section 12.8.1.

Leniency enlarges the set of collusive strategies. Chen and Rey show that two of them matter (Chen and Rey, 2013, p. 10 and footnote 12).

- *Normal collusion* (N). Firms collude in every period and never report. After a deviation they compete forever.
- *Collude and report* (R). Firms collude in every period, and both report the evidence at stage 2 of every period. Each is the first informant with probability $\frac{1}{2}$. After a product-market deviation they compete forever.

They also argue that no other form of collusion is sustainable when these two are not. Symmetric strategies and collusion in every period maximize the value of collusion, and randomizing between reporting and not reporting is not sustainable when neither pure strategy is.

Normal collusion under leniency. Leniency adds a new deviation to normal collusion, "cheat and report."

Lemma 12.92. *Under normal collusion, a firm that deviates in the product market prefers to report at stage 2 if and only if*

$$\ell > \underline{\ell} \equiv 1 - \varrho. \tag{12.135}$$

A firm that colludes and then reports is worse off than a firm that deviates and reports.

Proof. After a deviation the firms compete forever whether or not the deviator reports, so only the current fine matters. The rival does not plan to report, so a reporting deviator is the first informant and pays $(1-\ell)F$. A silent deviator pays F with probability ϱ. Reporting is better if and only if $(1-\ell)F < \varrho F$, which is (12.135). A firm that colludes and reports earns B instead of $2B$ in the current period, pays the same fine, and faces the same competitive future, since its report breaks the agreement. □

When $\ell > \underline{\ell}$, the relevant deviation yields $2B - (1-\ell)F$, and normal collusion survives it if and only if

$$\begin{aligned} \frac{B - \varrho F}{1-\delta} &\geq 2B - (1-\ell)F \\ B - \varrho F &\geq 2(1-\delta)B - (1-\delta)(1-\ell)F \\ (2\delta - 1)B &\geq [\varrho - (1-\delta)(1-\ell)]F. \end{aligned}$$

Hence normal collusion requires

$$B \geq B_N^r(\ell) \equiv \frac{\varrho - (1-\delta)(1-\ell)}{2\delta - 1} F, \tag{12.136}$$

which is equation (2) of Chen and Rey (2013). The threshold rises linearly in ℓ. Comparing it with $\underline{B} = \frac{\delta \varrho F}{2\delta - 1}$ gives

$$B_N^r(\ell) - \underline{B} = \frac{(1-\delta)(\ell - \underline{\ell})}{2\delta - 1} F. \tag{12.137}$$

Leniency makes normal collusion harder exactly when it induces deviators to report. Normal collusion is sustainable if and only if

$$B \geq B_N(\ell) \equiv \max\{\underline{B},\, B_N^r(\ell)\}. \tag{12.138}$$

Collude and report. Under collude and report, each firm pays the reduced fine with probability $\frac{1}{2}$ and the full fine otherwise. Its expected fine per period is $\frac{1}{2}(1-\ell)F + \frac{1}{2}F = (1 - \frac{\ell}{2})F$. The value of this form of collusion is

$$V_R(\ell) = \frac{B - \left(1 - \frac{\ell}{2}\right) F}{1-\delta}. \tag{12.139}$$

Reporting is self-enforcing. If the rival reports, a silent firm pays F, while a reporting firm pays $(1 - \frac{\ell}{2})F < F$ in expectation, for any $\ell > 0$. A product-market deviator therefore still reports. Chen and Rey assume that the two reports are not ranked by a race, so the deviator is the

first informant with probability $\frac{1}{2}$ (Chen and Rey, 2013, footnote 11). The deviation yields $2B - (1 - \frac{\ell}{2})F$ and then zero. Collude and report is sustainable if and only if

$$\begin{aligned}\frac{B - \left(1 - \frac{\ell}{2}\right) F}{1 - \delta} &\geq 2B - \left(1 - \frac{\ell}{2}\right) F \\ B - \left(1 - \frac{\ell}{2}\right) F &\geq 2(1 - \delta)B - (1 - \delta)\left(1 - \frac{\ell}{2}\right) F \\ (2\delta - 1)B &\geq \delta\left(1 - \frac{\ell}{2}\right) F.\end{aligned}$$

Hence collude and report requires

$$B \geq B_R(\ell) \equiv \frac{\delta\left(1 - \frac{\ell}{2}\right)}{2\delta - 1} F, \tag{12.140}$$

which is equation (3) of Chen and Rey (2013). This threshold falls in ℓ. More generous leniency lowers the expected fine of a reporting cartel and makes it more robust. It is more robust than normal collusion without leniency when $B_R(\ell) < \underline{B}$, that is, when $1 - \frac{\ell}{2} < \varrho$, or

$$\ell > \bar{\ell} \equiv 2(1 - \varrho). \tag{12.141}$$

We call such rates *excessive leniency*. The threshold is twice the rate at which deviators start to report, $\bar{\ell} = 2\underline{\ell}$.

The optimal amnesty rate. Some form of collusion is sustainable in an industry if and only if $B \geq \min\{B_N(\ell), B_R(\ell)\}$. The authority therefore chooses ℓ to maximize the deterrence threshold

$$B(\ell) \equiv \min\{B_N(\ell),\ B_R(\ell)\}. \tag{12.142}$$

Proposition 12.93 (Optimal leniency, Chen and Rey, 2013, Proposition 1)**.** *Let $\frac{1}{2} < \delta < 1$ and $0 < \varrho < 1$.*

(a) The deterrence threshold $B(\ell)$ has a unique maximizer,

$$\hat{\ell}(\varrho) = \frac{1 - \varrho}{1 - \frac{\delta}{2}}, \tag{12.143}$$

which satisfies $\underline{\ell} < \hat{\ell} < \bar{\ell}$. It solves $B_N^r(\hat{\ell}) = B_R(\hat{\ell})$.

(b) The maximal deterrence threshold is

$$\hat{B}(\varrho) = \frac{\delta(1 - \delta + \varrho)}{(2\delta - 1)(2 - \delta)} F > \underline{B}. \tag{12.144}$$

(c) The optimal rate $\hat{\ell}$ falls as ϱ rises, and it exceeds 1, so that the first informant receives a reward, if and only if $\varrho < \frac{\delta}{2}$. The threshold $\hat{B}$ rises with ϱ.

(d) In industries with $B \geq \hat{B}$, both forms of collusion are sustainable at $\ell = \hat{\ell}$, and normal collusion is more valuable:

$$V_N - V_R(\hat{\ell}) = \frac{1 - \varrho}{2 - \delta} F > 0. \tag{12.145}$$

Equations (12.143) and (12.144) are equations (4) and (5) of Chen and Rey (2013).

Proof. We first describe the two functions. By (12.137), $B_N(\ell) = \underline{B}$ for $\ell \le \underline{\ell}$, and $B_N(\ell) = B_N^r(\ell)$ is strictly increasing for $\ell \ge \underline{\ell}$. The function $B_R(\ell)$ is strictly decreasing.

Step 1 (no leniency below $\underline{\ell}$ helps). At $\ell = \underline{\ell} = 1 - \varrho$ we have $1 - \frac{\ell}{2} = \frac{1+\varrho}{2}$, so

$$B_R(\underline{\ell}) = \frac{\delta(1+\varrho)}{2(2\delta - 1)} F > \frac{\delta\varrho}{2\delta - 1} F = \underline{B},$$

because $\frac{1+\varrho}{2} > \varrho$ when $\varrho < 1$. Since B_R is decreasing, $B_R(\ell) > \underline{B}$ for all $\ell \le \underline{\ell}$. Hence $B(\ell) = \underline{B}$ on $[0, \underline{\ell}]$.

Step 2 (excessive leniency hurts). At $\ell = \bar{\ell}$ we have $1 - \frac{\bar{\ell}}{2} = \varrho$, so $B_R(\bar{\ell}) = \underline{B}$. For $\ell \ge \bar{\ell}$, $B(\ell) \le B_R(\ell) \le \underline{B}$.

Step 3 (the crossing). On $(\underline{\ell}, \bar{\ell})$, $B_N = B_N^r$ is increasing and B_R is decreasing. At $\underline{\ell}$, $B_N^r = \underline{B} < B_R$. At $\bar{\ell}$, $B_N^r > \underline{B} = B_R$. The two lines cross at a unique $\hat{\ell} \in (\underline{\ell}, \bar{\ell})$. To the left of $\hat{\ell}$ the minimum is B_N^r, which rises. To the right it is B_R, which falls. So $\hat{\ell}$ maximizes $B(\ell)$, and $\hat{B} = B_N^r(\hat{\ell}) > B_N^r(\underline{\ell}) = \underline{B}$.

Step 4 (closed forms). Setting $B_N^r(\ell) = B_R(\ell)$ and cancelling $\frac{F}{2\delta - 1}$ gives

$$\begin{aligned} \varrho - (1-\delta)(1-\ell) &= \delta\left(1 - \frac{\ell}{2}\right) \\ \ell\left[(1-\delta) + \frac{\delta}{2}\right] &= \delta + (1-\delta) - \varrho \\ \ell\left(1 - \frac{\delta}{2}\right) &= 1 - \varrho, \end{aligned}$$

which is (12.143). Substituting into B_R,

$$1 - \frac{\hat{\ell}}{2} = 1 - \frac{1-\varrho}{2-\delta} = \frac{1-\delta+\varrho}{2-\delta}, \qquad \text{so} \qquad \hat{B} = \frac{\delta}{2\delta - 1} \cdot \frac{1-\delta+\varrho}{2-\delta} F,$$

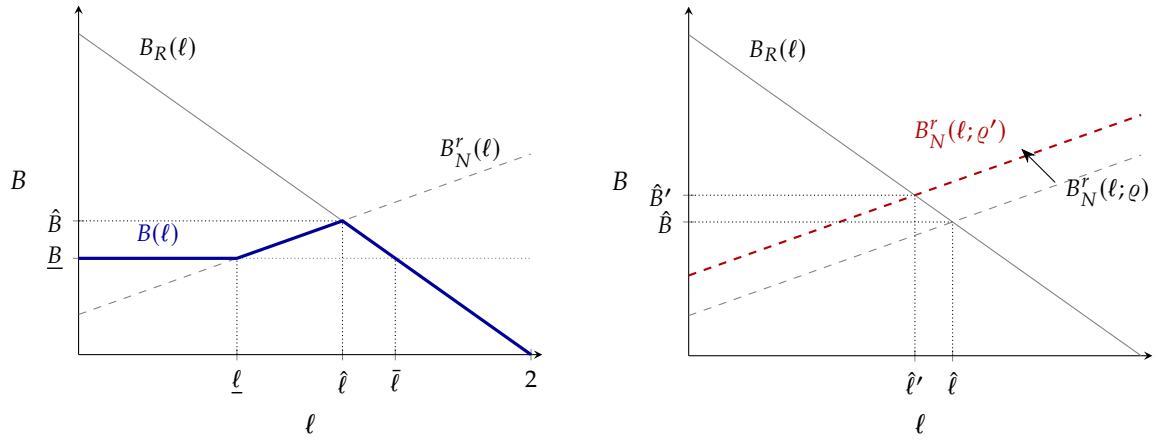
which is (12.144). Since $1 - \frac{\delta}{2} \in (\frac{1}{2}, 1)$, we get $\hat{\ell} > 1 - \varrho = \underline{\ell}$ and $\hat{\ell} < 2(1-\varrho) = \bar{\ell}$.

Step 5 (comparative statics and values). From (12.143), $\frac{\partial \hat{\ell}}{\partial \varrho} = -\frac{1}{1 - \frac{\delta}{2}} < 0$. Also $\hat{\ell} > 1$ if and only if $1 - \varrho > 1 - \frac{\delta}{2}$, that is, $\varrho < \frac{\delta}{2}$. From (12.144), $\frac{\partial \hat{B}}{\partial \varrho} = \frac{\delta F}{(2\delta - 1)(2 - \delta)} > 0$. Finally, by (12.133) and (12.139),

$$V_N - V_R(\hat{\ell}) = \frac{\left(1 - \frac{\hat{\ell}}{2}\right) - \varrho}{1 - \delta} F = \frac{1}{1-\delta} \cdot \frac{1 - \delta + \varrho - 2\varrho + \delta\varrho}{2 - \delta} F = \frac{(1-\delta)(1-\varrho)}{(1-\delta)(2-\delta)} F,$$

which simplifies to (12.145). □

Interpretation. Figure 12.13 shows the trade-off. Rates below $\underline{\ell}$ do nothing, because a deviator would not report. Rates between $\underline{\ell}$ and $\hat{\ell}$ deter normal collusion in more industries, because they make "cheat and report" attractive. Rates above $\hat{\ell}$ hand the cartel a cheaper way to collude, by reporting itself every period. At $\hat{\ell}$ the *marginal industry*, with $B = \hat{B}$, is on the edge of both forms of collusion. A lower rate would let it collude normally without fear of a reporting deviator. A higher rate would let it collude and report without fear of a product-market deviator. Chen and Rey describe the instruments as a stick, the probability ϱ of random detection, and a carrot, the amnesty rate ℓ. The weaker the stick, the larger the optimal carrot. With no stick at all ($\varrho = 0$), $\underline{\ell} = 1$, so a pure fine reduction ($\ell \le 1$) is useless and only rewards can work (Chen and Rey, 2013, footnote 13).



(a) The optimal amnesty rate

(b) A higher detection probability

Figure 12.13: Optimal leniency in the model of Chen and Rey (2013), drawn for $\delta = 0.8$ and $F = 1$. Panel (a): with $\varrho = 0.3$, normal collusion survives above $\max\{\underline{B}, B_N^r(\ell)\}$ and collude and report survives above $B_R(\ell)$. The deterrence threshold $B(\ell)$ (thick line) is the lower envelope. It equals $\underline{B} = 0.4$ up to $\underline{\ell} = 0.7$ and peaks at $\hat{\ell} = \frac{7}{6}$, where $\hat{B} = \frac{5}{9}$. Excessive leniency starts at $\bar{\ell} = 1.4$. Panel (b): raising ϱ from 0.3 to $\varrho' = 0.4$ shifts B_N^r up and leaves B_R unchanged, so the optimal rate falls to $\hat{\ell}' = 1$ and the threshold rises to $\hat{B}' = \frac{2}{3}$. Redrawn with computed values from Chen and Rey (2013), Figures 1 and 2.

Part (d) of Proposition 12.93 explains why "collude and report" is rarely observed even though it is the constraint that pins down the optimal rate. At the optimal rate, every industry that can collude prefers normal collusion. The threat of self-reporting cartels shapes the policy without appearing in the data.

Example 12.94 (Leniency with numbers)**.** Let $\delta = 0.8$, $\varrho = 0.3$ and $F = 1$, as in Figure 12.13a. Without leniency, $\underline{B} = \frac{0.8\times0.3}{0.6} = 0.4$. Deviators report once $\ell > 0.7$, and leniency becomes excessive at $\bar{\ell} = 1.4$. The optimal rate is $\hat{\ell} = \frac{0.7}{0.6} = \frac{7}{6}$. The first informant thus pays no fine and receives a reward of $\frac{1}{6}$ of the fine. The deterrence threshold rises to $\hat{B} = \frac{0.8\times0.5}{0.6\times1.2} = \frac{5}{9} \approx 0.556$. Leniency extends deterrence from industries with stakes below $0.4F$ to industries with stakes below $0.556F$, a rise of about 39 percent. In industries that still collude, normal collusion beats collude and report by $\frac{0.7}{1.2}F \approx 0.583F$ per firm. These values are computed in `figures/ch12/src/chenrey_check.py`.

Laboratory evidence. Hinloopen and Soetevent (2008), as described by Chen and Rey (2013, p. 13), ran laboratory experiments with $\varrho = 0.4$ and $\delta = 0.8$. The model then prescribes full amnesty, since $\hat{\ell} = \frac{1-0.4}{1-0.4} = 1$. One treatment set the rate at this level. The other granted full amnesty to a sole reporter and a 90 percent reduction to each firm when both reported (Chen and Rey, 2013, footnote 14). Under collude and report each firm then pays $0.1F = (1 - \frac{\ell}{2})F$, which corresponds to $\ell = 1.8$. Subjects never colluded and reported in the first treatment. More than 70 percent of subjects did so in every period of the second treatment, as the model predicts. Our own computation shows how generous the second treatment is. With $\varrho = 0.4$, excessive leniency starts at $\bar{\ell} = 1.2$. At $\ell = 1.8$, $B_R = \frac{0.8\times0.1}{0.6}F \approx 0.133F$, far below $\underline{B} = \frac{0.8\times0.4}{0.6}F \approx 0.533F$. The program would make collusion sustainable in industries that enforcement without leniency deters.

Spagnolo (2004) proposes to reward the first informant with the fines paid by the other cartel members, which corresponds to $\ell = 2$ in this model. Chen and Rey (2013, p. 13) counsel

caution, because $\hat{\ell} < \bar{\ell} < 2$. Actual programs grant reductions of up to 100 percent and rarely pay rewards. By Proposition 12.93, such rates may lie below the optimum when random detection is weak ($\varrho < \frac{\delta}{2}$).

Remark 12.95 (The first-informant rule). Suppose both informants receive the reduced fine. Normal collusion is unaffected, because a deviator reports alone. Under collude and report, however, each firm now pays $(1-\ell)F$ for sure. Repeating the derivation of (12.140) with $(1-\ell)$ in place of $(1-\frac{\ell}{2})$ gives

$$B_R'(\ell) = \frac{\delta(1-\ell)}{2\delta - 1} F < B_R(\ell). \tag{12.146}$$

At $\ell = \underline{\ell} = 1 - \varrho$, $B_R'(\underline{\ell}) = \frac{\delta\varrho F}{2\delta - 1} = \underline{B}$. For $\ell > \underline{\ell}$, $B_R'(\ell) < \underline{B} \leq B_N(\ell)$, so the threshold falls below $\underline{B}$. For $\ell \leq \underline{\ell}$, the threshold equals $\underline{B}$. Without the first-informant rule, leniency cannot raise deterrence at all (Chen and Rey, 2013, pp. 13–14). The authors suggest that this may explain why the U.S. program achieved little before its 1993 revision. The point agrees with Spagnolo (2004) and Harrington (2008a).

Repeat offenders. Some jurisdictions deny leniency to repeat offenders, which seems to block cartels that report every period. Chen and Rey show that the restriction backfires.

Proposition 12.96 (Once-only leniency, Chen and Rey, 2013, Proposition 2)**.** *Suppose each industry can obtain leniency only once. Then, for any amnesty rate $\ell \geq 0$, the strategy "report once and never again" is sustainable whenever $B \geq \underline{B}$. Once-only leniency therefore cannot deter collusion in any industry that collusion without leniency fails to deter.*

Proof. Under "report once," the firms collude in every period, both report in the first period, and nobody reports afterwards. Each firm's value is

$$V_O = B - \left(1 - \frac{\ell}{2}\right) F + \delta V_N = B - \left(1 - \frac{\ell}{2}\right) F + \delta \frac{B - \varrho F}{1 - \delta}.$$

After the first report, leniency is no longer available. Reporting then only exposes the reporter, so play continues as normal collusion without leniency. By Proposition 12.90, it is sustainable if and only if $B \geq \underline{B}$. In the first period, reporting is self-enforcing, as under collude and report. A product-market deviator still reports and pays $(1-\frac{\ell}{2})F$ in expectation. It earns $2B$ and nothing afterwards. The first-period constraint is

$$\begin{aligned} B - \left(1 - \frac{\ell}{2}\right) F + \delta V_N &\geq 2B - \left(1 - \frac{\ell}{2}\right) F \\ \delta \frac{B - \varrho F}{1 - \delta} &\geq B \\ (2\delta - 1)B &\geq \delta\varrho F, \end{aligned}$$

which is again $B \geq \underline{B}$. Both constraints hold whenever $B \geq \underline{B}$. □

The logic is that one report uses up the industry's access to leniency. Afterwards no member can gain from reporting, which removes the threat that made normal collusion fragile. Chen and Rey quote Wils (2008) on the same paradox, that excluding recidivists from leniency may encourage recidivism. When exposed cartels face closer scrutiny afterwards, excluding repeat offenders still weakens the program but no longer makes it useless (Chen and Rey, 2013, p. 17).

Closer scrutiny after exposure. So far an exposed cartel could collude again in the next period. Suppose instead that an exposed industry is kept under tight supervision for T periods, during which it cannot collude. Define

$$\beta_T \equiv \delta^{T+1}, \qquad \gamma_T \equiv (1-\varrho)\delta + \varrho\beta_T, \tag{12.147}$$

so that $\beta_T < \gamma_T < \delta$ for $T \geq 1$. (Chen and Rey write $\beta(T)$ and $\gamma(T)$.) A cartel that reports every period is exposed every period, so its future is discounted at β_T:

$$V_R(\ell;T) = B - \left(1 - \frac{\ell}{2}\right)F + \beta_T V_R(\ell;T) \quad \Longrightarrow \quad V_R(\ell;T) = \frac{B - \left(1-\frac{\ell}{2}\right)F}{1-\beta_T}.$$

A normal cartel is exposed only with probability ϱ:

$$V_N(T) = B - \varrho F + (1-\varrho)\delta V_N(T) + \varrho\beta_T V_N(T) \quad \Longrightarrow \quad V_N(T) = \frac{B - \varrho F}{1-\gamma_T}.$$

Repeating the derivations of (12.132), (12.136) and (12.140) with these values gives

$$\underline{B}(T) = \frac{\gamma_T \varrho F}{2\gamma_T - 1}, \qquad B_N^r(\ell;T) = \frac{\varrho - (1-\gamma_T)(1-\ell)}{2\gamma_T - 1}F, \qquad B_R(\ell;T) = \frac{\beta_T\left(1-\frac{\ell}{2}\right)}{2\beta_T - 1}F. \tag{12.148}$$

The last expression requires $\beta_T > \frac{1}{2}$.[3] If $\beta_T \leq \frac{1}{2}$ and $\ell < 2$, collude and report cannot be sustained at any stake. The authority can then raise the amnesty rate up to that bound without inviting self-reporting cartels. Equating $B_N^r(\ell;T)$ and $B_R(\ell;T)$ gives the optimal rate

$$\hat{\ell}(T) = \frac{2(1-\varrho)(\beta_T + \delta - 1)}{(2\beta_T - 1) + (2\gamma_T - 1)(1-\beta_T)}, \tag{12.149}$$

which reduces to (12.143) at $T = 0$, where $\beta_0 = \gamma_0 = \delta$.

Proposition 12.97 (Scrutiny, Chen and Rey, 2013, Proposition 3)**.** *Assume $\beta_T > \frac{1}{2}$. A longer period T of close scrutiny for exposed cartels raises the maximal deterrence threshold $\hat{B}(T)$ and also raises the optimal amnesty rate $\hat{\ell}(T)$.*

Scrutiny lowers the value of both forms of collusion, but it hurts collude and report more, because that cartel is exposed in every period. The authority can then offer more amnesty without inviting self-reporting cartels. With $\delta = 0.9$ and $\varrho = 0.2$, for instance, our computations give $\hat{\ell} = 1.455$ and $\hat{B} = 0.307F$ at $T = 0$, $\hat{\ell} = 1.534$ and $\hat{B} = 0.371F$ at $T = 2$, and $\hat{\ell} = 1.873$ and $\hat{B} = 0.539F$ at $T = 5$. At $T = 6$, $\beta_T = 0.9^7 < \frac{1}{2}$, and collude and report is no longer sustainable.

Remark 12.98 (More than two firms). The model extends directly to N firms, an extension we derive here. A deviator earns NB, and under collude and report each firm is the first informant with probability $\frac{1}{N}$, so its expected fine is $(1 - \frac{\ell}{N})F$. The derivations above give

$$B_N^r(\ell) = \frac{\varrho - (1-\delta)(1-\ell)}{N\delta - (N-1)}F, \qquad B_R(\ell) = \frac{\delta\left(1-\frac{\ell}{N}\right)}{N\delta - (N-1)}F,$$

[3] Footnote 20 of the working paper (p. 16) prints this assumption as $\beta(T) < \frac{1}{2}$. That inequality contradicts the paper's own formula for $B_R(q;T)$, whose denominator $2\beta(T) - 1$ must be positive. It also contradicts the footnote's own parenthetical remark, which treats $\gamma(T) > \frac{1}{2} > \beta(T)$ as the case in which collude and report cannot be sustained. We state the condition that the formula needs.

and the optimal rate solves $\varrho - (1-\delta) + (1-\delta)\ell = \delta - \frac{\delta\ell}{N}$, so

$$\hat{\ell}_N = \frac{1-\varrho}{1-\frac{N-1}{N}\delta}, \qquad \hat{B}_N = \frac{\delta[(N-1)(1-\delta)+\varrho]}{[N\delta-(N-1)][N(1-\delta)+\delta]}F.$$

Excessive leniency starts at $\bar{\ell}_N = N(1-\varrho)$. Both $\hat{\ell}_N$ and $\bar{\ell}_N$ rise with N. A reporting cartel with many members spreads the amnesty thinly, so the authority can afford a larger reward. With $\delta = 0.9$ and $\varrho = 0.3$, $\hat{\ell}_N$ equals 1.27, 1.75 and 2.15 for $N = 2$, 3 and 4. This extension keeps the restriction to the two strategies N and R.

Leniency before and after an investigation. The final part of Chen and Rey (2013, Section 4) separates the launch of an investigation from its outcome. Absent any report, the authority opens an investigation with probability $\iota \in (0,1)$. An open investigation uncovers the cartel, absent any report, with probability $\varsigma \in (0,1)$. (Chen and Rey write α and p.) Both probabilities are likely to be small in practice. If investigations are secret, firms face the overall detection probability $\varrho = \iota\varsigma$, and Proposition 12.93 applies with this ϱ. If the rates before and after an investigation differ, the relevant secret rate is the expected one, $\iota\ell_a + (1-\iota)\ell_b$ (Chen and Rey, 2013, footnote 22).

If investigations are public, the authority can set two rates. A first informant pays $(1-\ell_b)F$ if it reports before an investigation and $(1-\ell_a)F$ if it reports after one has opened. Stages 0 to 2 are as before. At stage 3, if nobody has reported, the authority opens an investigation with probability ι. At stage 4 the firms may report again, and an unreported cartel under investigation is uncovered with probability ς. Public investigations create a third collusive strategy, *collude and report if investigated* (I).

The authority can always do as well with public investigations as with secret ones, by setting $\ell_a = 0$. A report after an investigation then raises the probability of conviction from ς to 1 without reducing the fine, so nobody reports at stage 4. The choice between N and R is then the same as with secret investigations. The question is whether $\ell_a > 0$ can do strictly better.

Each strategy faces several deviations, and we derive each threshold from a comparison of values. Normal collusion now has value $V_N = \frac{B-\iota\varsigma F}{1-\delta}$. It must deter four deviations. Deviating without reporting gives $\underline{B} = \frac{\delta\iota\varsigma F}{2\delta-1}$. Deviating and reporting at stage 2 gives $B_N^r(\ell_b) = \frac{\iota\varsigma-(1-\delta)(1-\ell_b)}{2\delta-1}F$. Deviating and reporting only if investigated yields $2B - \iota(1-\ell_a)F$, and $V_N \geq 2B - \iota(1-\ell_a)F$ gives

$$B \geq B_N^i(\ell_a) \equiv \frac{\iota\varsigma - \iota(1-\delta)(1-\ell_a)}{2\delta-1}F.$$

Colluding but reporting once an investigation opens compares $-\varsigma F + \delta V_N$ (stay silent and keep the cartel) with $-(1-\ell_a)F$ (report and lose it). Staying silent is better if and only if

$$B \geq B_N^c(\ell_a) \equiv \frac{\varsigma(1-\delta+\iota\delta) - (1-\delta)(1-\ell_a)}{\delta}F.$$

Normal collusion is therefore sustainable if and only if

$$B \geq B_N(\ell_b, \ell_a) \equiv \max\{B_N^i(\ell_a),\, B_N^r(\ell_b),\, B_N^c(\ell_a),\, \underline{B}\}, \tag{12.150}$$

equation (6) of Chen and Rey (2013). Collude and report is sustainable if and only if $B \geq B_R(\ell_b) = \frac{\delta(1-\frac{\ell_b}{2})F}{2\delta-1}$, as before. Under collude and report if investigated, each firm pays

$(1-\frac{\ell_a}{2})F$ when an investigation opens, so $V_I = \frac{B-\iota(1-\frac{\ell_a}{2})F}{1-\delta}$. Reporting when investigated is self-enforcing, since it cuts the expected fine from F to $(1-\frac{\ell_a}{2})F$ when the rival reports. Strategy I must deter a deviation with a report at stage 2, which yields $2B-(1-\ell_b)F$, and a deviation with a report only if investigated, which yields $2B-\iota(1-\frac{\ell_a}{2})F$. These give

$$B \geq B_I(\ell_b,\ell_a) \equiv \max\left\{ \frac{\delta\iota\left(1-\frac{\ell_a}{2}\right)}{2\delta-1}F,\ \frac{\iota\left(1-\frac{\ell_a}{2}\right)-(1-\delta)(1-\ell_b)}{2\delta-1}F \right\}, \tag{12.151}$$

where the two terms are $B_I^i(\ell_a)$ and $B_I^r(\ell_b,\ell_a)$, equation (7) of Chen and Rey (2013). The authority maximizes $\min\{B_N(\ell_b,\ell_a),\ B_I(\ell_b,\ell_a),\ B_R(\ell_b)\}$. Without post-investigation leniency, the optimum is $\ell_b = \hat{\ell}(\iota\varsigma)$ with threshold $\hat{B}(\iota\varsigma)$, from (12.143) and (12.144).

Post-investigation leniency can destabilize normal collusion in two ways. The first route makes "deviate and report if investigated" the binding deviation. This requires $B_N^i(\ell_a) > B_N^r(\hat{\ell}_b)$, that is, $\iota(1-\ell_a) < 1-\hat{\ell}(\iota\varsigma)$. It must not make strategy I more robust, which requires $B_I^r(\hat{\ell}_b,\ell_a) > B_N^r(\hat{\ell}_b)$, that is, $\varsigma < 1-\frac{\ell_a}{2}$. Both conditions hold for some ℓ_a if and only if

$$\varsigma < \tilde{\varsigma}_1(\iota) \equiv \frac{\iota(2-\delta)-\delta}{2\iota(1-\delta)}, \tag{12.152}$$

equation (9) of Chen and Rey (2013). To verify it, substitute $1-\hat{\ell}(\iota\varsigma) = \frac{2\iota\varsigma-\delta}{2-\delta}$ into the first condition and combine it with $\ell_a < 2(1-\varsigma)$. Then reduce ℓ_b slightly below $\hat{\ell}$ to raise B_R as well. The best policy of this kind equalizes the three binding thresholds, $B_N^i(\tilde{\ell}_a^1) = B_I^r(\tilde{\ell}_b^1,\tilde{\ell}_a^1) = B_R(\tilde{\ell}_b^1)$, which gives

$$\tilde{\ell}_b^1 = \frac{2[(1-\iota)(2-\delta)+\iota(1-\varsigma)]}{2(1-\delta)^2+2-\delta}, \qquad \tilde{\ell}_a^1 = \frac{2}{\iota}\cdot\frac{\delta(1-\delta)(1-\iota)+\iota(1-\varsigma)(2-\delta)}{2(1-\delta)^2+2-\delta}, \tag{12.153}$$

and the deterrence threshold

$$\tilde{B}_1 = \frac{2(1-\delta)^2+\iota(1-\delta+\varsigma)}{2(1-\delta)^2+2-\delta}\cdot\frac{\delta F}{2\delta-1}, \tag{12.154}$$

equations (10) and (11) of Chen and Rey (2013). It exceeds $\hat{B}(\iota\varsigma)$ if and only if $\varsigma \leq \tilde{\varsigma}_1(\iota)$. The second route makes "collude but report if investigated" the binding deviation. It is available if and only if

$$\varsigma \leq \tilde{\varsigma}_2(\iota) \equiv \frac{(1-\delta)(3\delta-2)}{(2\delta-1)(2-\delta)+2\iota\delta(1-\delta)}, \tag{12.155}$$

which is positive only when $\delta > \frac{2}{3}$. Its best version $(\tilde{\ell}_b^2,\tilde{\ell}_a^2)$ equalizes B_N^c, B_I^r and B_R, with threshold

$$\tilde{B}_2 = \frac{2(1-\delta)^2+\iota(1-\delta)+(1-\delta+\iota\delta)\iota\varsigma}{2(2\delta-1)(1-\delta)(2-\delta)+\iota\delta^2}\,\delta F, \tag{12.156}$$

equations (12) to (14) of Chen and Rey (2013). The first route beats the second if and only if $\varsigma \geq \tilde{\varsigma}(\iota)$, where

$$\tilde{\varsigma}(\iota) \equiv \frac{2(1-\delta)(2\delta-1)+\iota(2\delta^2-1)-\iota^2\delta}{\iota(2\delta-1)(3-2\delta)+4\iota^2(1-\delta)^2}, \tag{12.157}$$

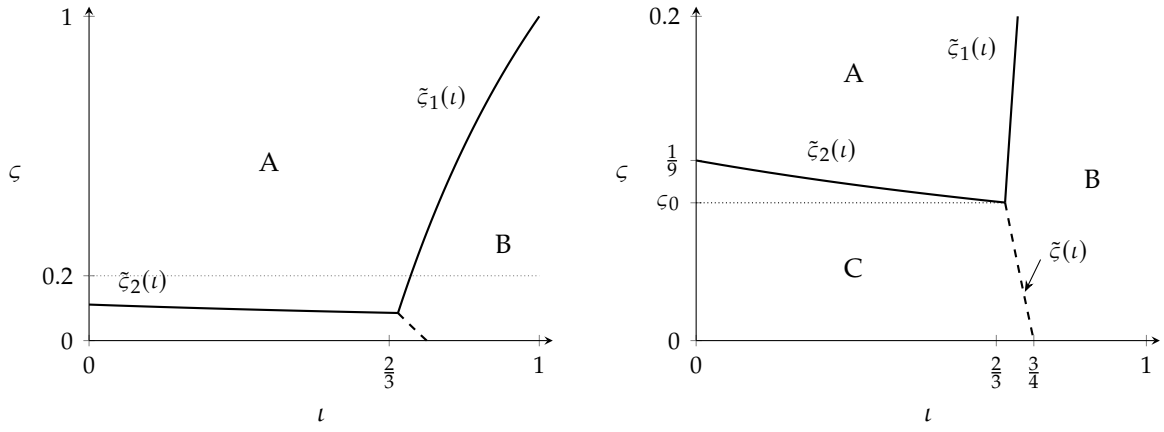
which is nonpositive for $\iota \geq \iota_1 \equiv \frac{2\delta-1}{\delta}$. We checked every formula in this paragraph symbolically in `chenrey_check.py`.

Proposition 12.99 (Pre- and post-investigation leniency, Chen and Rey, 2013, Proposition 4)**.** *It is always optimal to offer leniency before an investigation.*

(a) If firms are patient ($\delta > \frac{2}{3}$), it is optimal to keep offering some leniency once an investigation is under way if and only if $\varsigma \leq \max\{\tilde{\varsigma}_1(\iota), \tilde{\varsigma}_2(\iota)\}$. The optimal policy is then $(\tilde{\ell}_b^1, \tilde{\ell}_a^1)$ if $\varsigma \geq \tilde{\varsigma}(\iota)$ and $(\tilde{\ell}_b^2, \tilde{\ell}_a^2)$ if $\varsigma \leq \tilde{\varsigma}(\iota)$.

(b) If firms are less patient ($\frac{1}{2} < \delta \leq \frac{2}{3}$), it is optimal to keep offering some leniency once an investigation is under way if and only if $\iota \geq \underline{\iota} \equiv \frac{\delta}{2-\delta}$ and $\varsigma \leq \tilde{\varsigma}_1(\iota)$. The optimal policy is then $(\tilde{\ell}_b^1, \tilde{\ell}_a^1)$.

In all other cases the optimal policy is $(\hat{\ell}(\iota\varsigma), 0)$.



(a) The unit square

(b) Detail for $\varsigma \leq 0.2$

Figure 12.14: Optimal leniency policies with public investigations for $\delta = 0.8$, computed from (12.152), (12.155) and (12.157). The horizontal axis is the probability ι that an investigation opens, and the vertical axis the probability ς that it succeeds without a report. Here $\tilde{\varsigma}_1(\iota) = 3 - \frac{2}{\iota}$ and $\tilde{\varsigma}_2(\iota) = \frac{1}{9+4\iota}$, and the three curves meet at $\iota_0 \approx 0.686$, $\varsigma_0 \approx 0.085$. In region A no leniency is offered after an investigation opens. In region B the optimal policy is $(\tilde{\ell}_b^1, \tilde{\ell}_a^1)$, and in region C it is $(\tilde{\ell}_b^2, \tilde{\ell}_a^2)$. Panel (b) enlarges the strip $\varsigma \leq 0.2$ of panel (a). Redrawn with computed boundaries from Chen and Rey (2013), Figure 4.

Figure 12.14 draws the regions for $\delta = 0.8$. Post-investigation leniency pays when an investigation, once opened, is unlikely to succeed without a report. It also needs investigations to be frequent enough for the threat of one to matter at the margin. If deviations in the product market are detected quickly, a deviator cannot wait for an investigation before reporting. Then only the second route remains, and post-investigation leniency is optimal if and only if $\varsigma \leq \tilde{\varsigma}_2(\iota)$ (Chen and Rey, 2013, footnote 26).

Proposition 12.100 (Comparative statics, Chen and Rey, 2013, Propositions 5 and 6)**.**

(a) A higher ς or a higher ι makes the leniency program more effective.

(b) A higher ς calls for less leniency both before and after an investigation.

(c) A higher ι calls for less leniency before an investigation. The post-investigation rate $\tilde{\ell}_a^1$ falls with ι, while $\tilde{\ell}_a^2$ rises with ι.

(d) Offering post-investigation leniency lowers the pre-investigation rate: $\tilde{\ell}_b^1 < \hat{\ell}$ and $\tilde{\ell}_b^2 < \hat{\ell}$.

(e) *More leniency is offered after than before an investigation when investigations are unlikely to succeed:* $\tilde{\ell}_b^1 < \tilde{\ell}_a^1$ *if and only if* $\varsigma < \hat{\varsigma}_1(\iota)$*, and* $\tilde{\ell}_b^2 < \tilde{\ell}_a^2$ *if and only if* $\varsigma < \hat{\varsigma}_2(\iota)$*, where*

$$\hat{\varsigma}_1(\iota) = (1-\delta)\,\frac{\iota^2 + \delta(1-\iota)}{\iota(2-\delta-\iota)}, \qquad \hat{\varsigma}_2(\iota) = \frac{1-\delta}{2\delta-1} \cdot \frac{\delta(1-\delta)+\iota(2\delta-1)}{(1-\delta+\iota\delta)(2-\delta-\iota)}.$$

Part (d) has a simple logic. Without post-investigation leniency, the marginal industry is on the edge of both normal collusion and collude and report. Post-investigation leniency destabilizes normal collusion further, and the pre-investigation rate must then fall to keep collude and report in check. Part (e) speaks to actual programs. The U.S. program grants complete amnesty to the first informant whether or not an investigation is under way. The EU program grants 75 to 100 percent before an investigation and only 50 to 75 percent after. Neither offers more leniency after an investigation opens. Chen and Rey (2013, p. 29) conclude that such policies may not be optimal when investigations rarely succeed without a report.

Interpretation. The model gives sharp answers to the policy questions of Section 12.8.1. Some leniency always helps, and the optimal amount falls as random detection improves. Leniency should go to the first informant only. Excluding repeat offenders can disable the program. Leniency after an investigation opens is valuable when investigations alone rarely uncover cartels, which is the realistic case. In repeated-game terms, leniency adds the deviation "cheat and report" to the incentive constraint, and its generosity is limited by a second constraint for cartels that report themselves.

Critiques and limitations. The model is deliberately stark, and several of its simplifications matter.

(1) Conduct is binary. With a continuum of collusive prices, leniency would also change the price that a cartel sets, as Chen and Rey (2013, footnote 7) acknowledge.

(2) Evidence lasts one period, so a cartel cannot be prosecuted for past conduct. Real fines grow with the duration of the infringement, and past evidence accumulates. Detection risk then changes over time, which creates a "race to the courthouse" when an investigation looms. Harrington (2008a) models this race. With a detection probability that changes stochastically over time, leniency has two opposing effects (Asker and Nocke, 2021, p. 209). The *deviator amnesty effect* lets a member that has just undercut its rivals also report the cartel and escape the fine, which tightens the no-cheating constraint. The *cartel amnesty effect* lowers the expected fines that members pay, which raises the value of colluding. A more lenient program can also trigger a switch from no firm applying to all firms racing to apply, which raises expected fines.

(3) The probabilities ϱ, ι and ς are exogenous. Reports free investigative resources, and Motta and Polo (2003) study how an authority allocates a budget between investigation and prosecution. Detection may also depend on conduct, since price wars and abrupt price rises draw attention.

(4) Firms are symmetric. A member that plans to exit, or one with little to lose, has a stronger motive to report. Asker's weak ring members (Section 13.8) illustrate how asymmetries shape the threat of reporting.

(5) Only firms are sanctioned and rewarded. Aubert et al. (2006) argue that rewards to individual employees can deter more effectively. Prison terms for executives make schemes of taking turns at reporting unattractive, as Wils notes in the passage quoted by Chen and Rey (2013, p. 2).

(6) The evidence is mostly experimental. Field evaluation is hard, because the number of detected cartels rises both when leniency destabilizes cartels and when more cartels form or report themselves. Harrington and Chang (2009) build a model of cartel birth and death to evaluate policy from detected cartels, and Proposition 13.73 shows how detection shapes the cartels we observe.

Contribution. Chen and Rey (2013) turn an informal worry into a tractable design problem. The optimal amnesty rate balances two incentive constraints, one for cartels that fear a reporting deviator and one for cartels that report themselves. The framework rationalizes the first-informant rule and post-investigation amnesty, the two innovations of the 1993 U.S. revision. It also warns against generous rewards and against excluding repeat offenders.

12.8.4 The agreement requirement: Kaplow (2013)

Kaplow (2013) questions the legal foundation on which this enforcement rests. Under Section 1 of the Sherman Act and Article 101, liability for price fixing requires an agreement among competitors. The conventional view distinguishes *pure interdependence*, in which firms refrain from price cutting because each expects retaliation, from classic cartels, whose members meet in hotel rooms to discuss prices. It treats the first as insufficient for liability and the second as more than sufficient (p. 4). Since the *Theatre Enterprises* decision, courts have held conscious parallelism by itself to be insufficient. A plaintiff must also show "plus factors", such as actions contrary to the defendants' interests if taken independently and a motive to agree (pp. 109–110). On the conventional view an agreement turns on the use of certain interfirm communications (p. 21). Kaplow argues that this focus is misplaced. The harm from coordinated price elevation depends on the extent and duration of supracompetitive pricing, not on the means used to reach or maintain the understanding (pp. 9–10). That harm is the same whether firms coordinate in a hotel room or by reading one another's prices.

The repeated-game theory of this chapter supports the premise. In the perfect-monitoring supergames of Section 12.3, tacit and explicit collusion are the same equilibrium. The incentive constraint of Proposition 12.14 does not mention communication, and talk is cheap. If communication changes anything, it selects among the many sustainable prices of Corollary 12.15.

A test based on communications is hard to state (ch. 3). In its ordinary meaning, communication is any exchange of information through a common system of symbols, signs or behavior (p. 51). Price moves are behavior conveyed by signs, so a rule triggered by any communication would cover all interdependent pricing (p. 52). A narrower rule must count only some communications. It could limit them by mode, counting meetings and emails and excluding hand signals. It could limit them by content, counting talk about future prices and excluding talk about current ones. Or it could limit them by setting, counting hotel rooms and excluding public announcements. Modes of communication are close substitutes, however. A fixed list of forbidden modes invites circumvention, and a rule that includes all functional equivalents covers every successful interdependence (p. 53). Kaplow draws a striking conclusion. If liability requires certain communications, then "truly naked price fixing is per se legal," and illegality flows from the communications that clothe it (p. 61).

Noncooperative game theory has no word for agreement, but its central concept is close to the legal one (pp. 196–199). Courts and dictionaries often define an agreement as a meeting of the minds. An equilibrium of a repeated game is a mutual understanding about current prices and about the consequences of defection. In any equilibrium each firm acts in its own interest, given what it expects its rivals to do. A nonbinding agreement that is not in

every member's interest is not honored, so it is not an equilibrium. In Kaplow's words, "All nonbinding agreements that work are equilibria, and all equilibria are nonbinding agreements that work" (p. 197). Not every equilibrium is objectionable. In repeated static play, no firm refrains from cutting its price because it expects others to respond, so that equilibrium needs no meeting of the minds (pp. 197–198). Kaplow therefore reads agreement as successful oligopolistic interdependence, the firms' mutual understanding that sustains supracompetitive prices (pp. 198–199). On this reading the legal notion maps onto the most collusive equilibria of Section 12.2.5.

Communications do not appear in the theory of oligopoly, yet they can matter in two ways (pp. 199–204). The first is equilibrium selection. Without words, firms may settle on the monopoly price as a focal point, or they may not. Negotiation helps when the firms disagree about the monopoly price because their costs or their views of demand differ, and when they sell several products. It can also fail where simple price signaling would quickly converge on a round number (pp. 200–201). The experimental evidence that Kaplow cites is mixed. In one coordination game, players reached the good equilibrium 48 percent of the time without communication, 55 percent with two-way communication and 95 percent with one-way communication (p. 201, note 54). The second role is enforcement when prices are unobservable. Firms that infer cheating from their own sales risk accidental price wars, and credible information can avoid them. Cheap talk about compliance is not credible, so verification, such as audits of invoices, matters more than talk (pp. 202–203). Communication can also hurt a cartel. If firms expect to negotiate an end to any price war, punishments become brief and cheating more attractive (p. 203). Kaplow concludes that communications help explain coordinated pricing but do not illuminate the notion of agreement (p. 206). He reaches the same conclusion about promises and assurances (pp. 206–214).

Kaplow points to what he calls the *paradox of proof* (pp. 6–7 and ch. 6). It arises from two features of the conventional rule. Agreement requires more than successful interdependence, for example the use of certain communications. And because firms hide their communications, the factfinder must infer them from circumstantial evidence, notably from how conducive market conditions are to coordination. Conditions such as few sellers, homogeneous products and transparent prices make successful price elevation more likely. Beyond some point, they also make it more likely that firms coordinated without the prohibited means of communication. Evidence of a greater danger of coordinated pricing can thus reduce the likelihood that an agreement, in the legal sense, exists (p. 7). A rule that turns on communication tends to exonerate the industries where collusion is most likely.

A stylized calculation of our own, not taken from Kaplow, makes the point concrete. Consider a duopoly with stake $B \geq \underline{B}$, so that collusion is sustainable with or without fines. Without communication its firms reach the collusive equilibrium with probability $\zeta \in [0, 1]$ and otherwise compete forever. The parameter ζ measures how easy tacit coordination is. With communication they always coordinate, but they face the expected fine ϱF per period of Section 12.8.2. Firms communicate if and only if

$$\frac{B - \varrho F}{1 - \delta} > \frac{\zeta B}{1 - \delta} \iff \zeta < 1 - \frac{\varrho F}{B}. \tag{12.158}$$

Industries where tacit coordination is easy collude silently and face no sanction. Industries where it is hard communicate and are exposed to fines. Tougher enforcement of the agreement requirement lowers the cutoff in (12.158). The industries it moves switch from explicit to tacit collusion. They still collude with probability ζ, so enforcement deters collusion in them only with probability $1 - \zeta$. The sanction falls where collusion would otherwise be least likely.

Kaplow proposes a *direct approach*, in which liability turns on evidence that firms engaged in successful coordinated price elevation, whatever the means (pp. 9–15). Such evidence includes price increases not matched by changes in cost, price wars, markups estimated from prices and marginal costs or from demand elasticities, and the conduciveness of market conditions (p. 11). Internal evidence, including interfirm communications, remains relevant as one source of proof (p. 12). Liability and sanctions should be set by weighing deterrence benefits against the chilling of desirable behavior and the costs of administration (p. 10). Kaplow argues that, if the burden of proof under the direct approach is set to find liability in as many cases as the conventional rule, the direct approach dominates. It targets cases with greater social danger and a lower risk of chilling (p. 14). The debate is old. Turner (1962) accepted that interdependence could count as agreement as a matter of statutory language, but rejected it as a basis for liability as a matter of policy. Posner (1969) first argued that this policy analysis was unsound (Kaplow, 2013, p. 447).

The theory of this chapter gives precise content to Kaplow's second role and so gives reasons to treat communication as more than a proxy. When information is private, communication changes what can be sustained. In the model of Harrington and Skrzypacz (2011) (Theorem 12.83), sales reports and transfers make collusion possible when unobserved prices would otherwise undermine it. Without communication, the optimal scheme of Athey et al. (2004a) uses rigid prices and gives up productive efficiency (Section 12.6). With communication about costs, Athey and Bagwell (2001) show that cartels can do better. Explicit agreements may thus raise prices in markets where tacit coordination would fail. An outcome-based rule faces a measurement problem as well. It must show that prices exceed a noncooperative benchmark, the identification problem of Chapter 3. Conduct that varies with demand, as in the Corts critique (Corts, 1999), makes that benchmark hard to estimate. The detection methods of Chapter 13 show both what such evidence can achieve and how often it is ambiguous.

12.9 What Determines Cartel Success?

Theory tells us which collusive outcomes can be sustained. It does not tell us how often cartels form, how long they last, or why they end. Levenstein and Suslow (2006) survey the empirical studies of explicit cartels to answer four questions (p. 43). Can cartels succeed? If so, for how long? What impact do they have? What causes them to break up? Their survey combines cross-section studies of many cartels with nineteen case studies of individual industries. It is the main bridge between the theory of this chapter and the evidence of Chapter 13. Page references are to the journal article.

12.9.1 Theory and measurement

Levenstein and Suslow (2006, p. 45) organize the theory around three problems. A cartel must *coordinate* its members on a collusive outcome and a division of profits, often among multiple equilibria. It must deter *cheating*. It must prevent *entry* by outsiders attracted by high prices. The theoretical literature concentrates on cheating, and they summarize it with the N-firm Bertrand constraint of Proposition 12.14, whose threshold rises with the number of firms (p. 46). They distinguish two kinds of price war. A punishment war, as in Green and Porter (1984), sustains collusion. A breakdown, as in Stigler (1964), ends it. Following Levenstein's work on bromine, they add *bargaining price wars*, which erupt when members disagree over the terms of the agreement after conditions change (p. 56). Entry, finally, is largely ignored by the models

even though it is one of the largest challenges cartels face (p. 49).

The survey covers explicit, "hard core" agreements to fix prices or divide markets, both legal and illegal (p. 49, footnote 18). It excludes state-run cartels such as OPEC and tacit collusion. The cross-section studies fall into four groups (pp. 49–50): cartels convicted by antitrust authorities, legal international cartels, legal national cartels, and legal export cartels. The nineteen case studies were chosen for the quality of the analysis, not at random (footnote 19).

Duration is the most common measure of success because it is the easiest to observe (p. 50). It is a poor measure of economic impact. Some cartels survive on paper with little effect on prices. Dating is also hard. Suslow, who dates the end of a cartel by a specific event that ends or restructures it, finds the shortest average duration, 3.7 years. This suggests that dates of formal dissolution overstate the economic life of cartels (p. 50). Many cartels form, break down and re-form. Table 3 of Levenstein and Suslow (2006) lists such on-and-off episodes for aluminum, coffee, copper, steel, sugar, sulfur and tin. In copper each episode lasted longer than the one before, a pattern suggestive of learning (p. 55). The empiricist must decide whether she observes one long cartel or several short ones, and the answer depends on whether the intervening price wars are punishments or breakdowns. Prosecutions add their own artifacts. In plea bargains the government announces a continuous cartel period, so the on-and-off pattern disappears from the record (p. 55, footnote 37).

Every sample is selected. Cross-sections of convicted cartels are, in the authors' words, "literally selected by prosecutors" (p. 44). Legal cartels reflect the legal regime of their time and place. Case studies reflect which records survived and which histories interested researchers. Proposition 13.73 shows how detection can bias the duration of observed cartels in either direction.

12.9.2 How long cartels last

Table 12.14 reproduces the cross-section evidence. Average duration ranges from 3.7 to 10 years (p. 50). The standard deviation within studies ranges from 2.4 to 6.3 years. About half of the cartels lasted less than five years, but between 12 and 37 percent lasted ten years or more (p. 54). Durations range from less than one year to 29 years. The longest average, 10 years, comes from Japanese export cartels that the state actively supported.

The duration story is similar for contemporary international cartels (p. 52). The authors' own sample covers 42 cartels prosecuted in the 1990s by the United States or the European Commission. In Table 1 it has a mean duration of 5 years and a standard deviation of 4.5. The text reports approximately 5.4 years with a standard deviation of 4.7 for the 1990s sample of their 2004 study. Short-lived cartels coexist with long-lived ones. The aluminum phosphide cartel lasted from January to November 1990, because a major producer refused to cooperate. Cartonboard (1986–1991), graphite electrodes (1992–1997), maltol (1989–1995) and sorbates (1979–1997) lasted much longer. Figure 12.15 shows the distribution. It is bimodal, with many cartels lasting one year, about twice as many lasting four to six years, and a long right tail.

Case studies give longer durations (Table 12.15). The nineteen industries contain fifty episodes of cooperation, with a mean duration of 14 years, a median of 6 years and a standard deviation of 19.6 years (p. 52). The median is close to the cross-section evidence, while the mean and the dispersion are much larger. The authors attribute the difference partly to researchers' tendency to study industries with long or eventful cartel histories. The DeBeers diamond cartel lasted 100 years before its first breakdown, while several cartels in the sample barely got off the ground (p. 54). The Joint Executive Committee, the most studied cartel in modern economics (Section 13.3), is the least stable in the sample. Its pools generally lasted two to five

Table 12.14: Cartel duration in cross-section studies

Study	Cartels	Sample	Mean	S.d.	Range	Under 5 yrs (%)	10 yrs or more (%)
Eckbo, sample 1[a,c]	23	International cartels, 1819–1964	3.8	2.4	1–18	60	12
Eckbo, sample 2[a,c]	29	International cartels, 1819–1964	4.6	4.7	0–18[d]	57	18
Griffin, Marquez[b]	54	International cartels, 1888–1984	7.3	6.3	1–29	43	32
Suslow[e]	71	International cartels, 1920–1939	3.7	3.0	1–13	40	37
Posner[f]	989	U.S. Department of Justice cases, 1890–1969	7.5				
Dick[g]	125	Webb-Pomerene export associations, 1918–1965	5.3			39	24
Gallo et al.	1348	U.S. Department of Justice cases, 1955–1997	5.4				
Jacquemin et al.	40	Japanese export cartels, 1967–1972	10	4.5	1–19	12.5	37.5
Levenstein and Suslow	42	International cartels, 1990s	5	4.5	0–20		

Notes: Durations in years. Blank cells are not reported. The table transposes Table 1 of Levenstein and Suslow (2006), p. 51, where the studies are columns. (a) Excludes an iodine cartel lasting sixty-one years. (b) Marquez uses Griffin's sample without two episodes (54 versus 52). (c) Eckbo calls a cartel efficient if it raised price 200 percent above the unit cost of production and distribution. Efficient cartels lasted 5 years on average in sample 1 and 8 years in sample 2, inefficient ones 3.1 and 2.7 years. (d) Episodes shorter than a year are coded 0. (e) The mean over all 71 episodes is 8.3 years (s.d. 6.2). The reported mean is for the 28 episodes not censored by World War II. (f) Posner reports durations only for cases from 1950–1969. (g) Median, from survival probabilities. Dick reports a median of about 4.5 years for cartels operating common sales agencies and 7.4 years for cartels whose members shipped individually. Source: Levenstein and Suslow (2006), Table 1.

years and broke down through entry or secret cheating (p. 56). Cooperation among southern U.S. railroads lasted three times as long on average (footnote 40).

Is a typical life of five to six years long or short? The authors offer two benchmarks (pp. 56–57). The graphite electrodes cartel, which lasted from mid-1992 to mid-1997, drew fines of more than 600 million U.S. dollars from U.S. and European authorities. A cartel of average duration can thus inflict large damage. Firms themselves are not long-lived either. Geroski reports that 61.5 percent of U.S. entrants exit within five years and 79.6 percent within ten, as quoted by the authors. Cartels are less than perfectly stable. Yet they are about as durable as many other economic organizations. The lesson is that cartels cannot be described simply as unstable. Some fail quickly, and others solve the problems of coordination, cheating and entry for decades.

12.9.3 Determinants of cartel duration

Levenstein and Suslow (2006, p. 57) give two answers to the question of how cartels survive. Surviving cartels operate in industries whose exogenous features make collusion easier. They also organize themselves to overcome coordination, cheating and entry. Both are necessary and neither is sufficient.

Number of firms and concentration. The Bertrand constraint predicts that collusion is harder with more firms. The evidence is mixed. Most case-study cartels and most contemporary

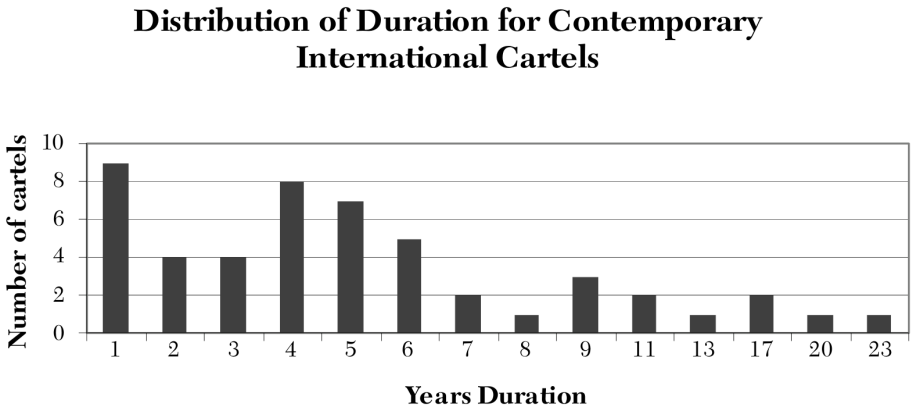


Figure 12.15: Distribution of the duration of contemporary international cartels. The horizontal axis lists only the durations that occur, so it is not to scale. The underlying tabulation is from the authors' 2004 study (their source note cites "Levenstein and Suslow (2004b), table 1"). Source: Levenstein and Suslow (2006), Figure 1.

Table 12.15: Cartel duration in selected case studies

Industry	First year	Mean duration	Episodes	Maximum	Minimum
Beer (U.S.)	1933	9	1	9	9
Beer (Sweden)	1894	29	2	50	8
Bromine	1885	6.25	4	10	3
Cement	1922	40	1	40	40
Coal	1893	20	1	20	20
Diamonds	1870s	60	2	100	20
Electrical equipment	1950	8	1	8	8
Ocean shipping	1870s	51	3	54	50
Oil	1871	2	3	3	1
Parcel post	1851	28.5	2	40	17
Potash	1877	9.4	8	20	1
Railroad (U.S. Midwest)	1879	1.7	3	2	1
Railroad (U.S. South)	1873	5	2	8	1
Railroad and oil	1871	7	5	30	< 1
Rayon	1932	8	1	8	8
Steel (Europe)	1926	7.3	4	13	4
Steel (U.S.)	1933	6	1	6	6
Sugar	1887	6.75	4	10	2
Tea	1929	3.5	2	6	1

Notes: Durations in years. "First year" is the first year of the first episode covered by the case studies. "Episodes" counts the distinct cartels that the studies date clearly. The episode-weighted mean of the column of mean durations is 14 years, the figure reported in the text of the survey. Source: Levenstein and Suslow (2006), Table 2.

international cartels operated in concentrated industries (p. 58). Yet the number of participants in contemporary international cartels ranged from two to several hundred. Whenever there were more than about half a dozen firms, an industry association or a government helped organize the agreement. In U.S. price-fixing cases the mean number of conspirators is 7.25 in the sample of Hay and Kelley, which excludes four cases with 50 or more conspirators. It is 16.7 in the sample of Fraas and Greer and 29.1 in that of Posner. Gallo et al. report a mean of 2.45 over all 2,689 Commerce Clearing House cases, not only horizontal conspiracies (Table 5). The medians are 7, 8, and between 6 and 10. The shares of cartels with fewer than ten members are 79, 60 and 64 percent, and the average four-firm concentration ratio in Hay and Kelley's sample is 77 percent (Table 5).

Effects on duration also conflict (Table 6, p. 61). Dick finds a statistically significant positive effect of the number of firms on duration. Suslow finds a negative effect, which is not significant, and Hay and Kelley find no significant pattern. Posner finds that 52 percent of the 79 cases with ten or fewer firms persisted six years or more, against 64 percent of the 28 cases with more than ten firms. Hay and Kelley do find a positive association between industry concentration and duration. Most of the conspiracies in their sample that lasted ten years or more were in highly concentrated markets (Table 6, note d, and p. 60). More consistently, duration rises with the share of the market controlled by cartel members. The effect is positive and significant for Dick and Marquez, and positive but not significant for Suslow. Marquez also finds a significant positive effect of cartel concentration, measured by a Herfindahl index of the members' shares of cartel output. The authors offer three explanations for the weak link with concentration (p. 58). Prosecutors may catch large cartels and association-run cartels more easily. Very concentrated industries may collude tacitly and never appear in samples of explicit cartels. And concentration is endogenous, since collusion lets more firms survive. Symeonidis finds a concave relation between the prevalence of collusion and concentration across 151 British industries (p. 60).

Trade associations are the organizational answer to large numbers. Posner reports that 44 percent of the cartels in his sample used an industry association. Hay and Kelley, and Fraas and Greer, find associations in about a third of U.S. conspiracies (p. 61). In the language of Section 12.7, an association supplies the communication and monitoring that large groups cannot achieve tacitly.

Large customers. Stigler (1964) predicted that large buyers would tempt cartel members to cut prices secretly. The only explicit econometric test, by Dick, finds that Webb-Pomerene export cartels selling to relatively larger buyers dissolved more quickly (p. 61). Other evidence is less supportive. The citric acid cartel sold to firms such as Mars, Coca-Cola and Procter & Gamble, and the vitamins cartel to Kellogg, Quaker Oats and Tyson Foods (p. 62). These buyers do not seem to have used their resources to break the cartels. The graphite electrodes investigation, started by a steel producer's complaint, is the one exception the authors know. In five of the nineteen case studies, customers tried to break the cartel (p. 62 and Table 7). In bromine and potash they tried to integrate backward, and in rayon they spread rumors of cheating. In other cases customers helped stabilize a cartel and shared its rents. Customer size may destabilize a cartel, while customer concentration may have the opposite effect.

Demand. Eckbo finds that cartels raised prices substantially only when demand was sufficiently inelastic with few short-run substitutes (p. 64). The brewing industry, with a demand elasticity of -10.3, had an unsuccessful cartel, with price wars in every year of the study (p. 64 and Table 8).

Demand instability matters more than the business cycle as such (Table 9). Dick finds that

instability shortens Webb-Pomerene cartels and that anticipated downturns end them, while unanticipated cycles have no significant effect. Suslow finds significant negative effects of demand growth, of the business cycle and of unanticipated cycles. Marquez finds a negative but insignificant effect of demand growth. Across case studies, macroeconomic fluctuations seem to have had little relevance (p. 67 and Table 10). The international steel cartel is the only one reported to have collapsed because of an observable demand shock. The authors read this as consistent with the Green-Porter and Abreu literature, in which price wars follow unobserved rather than observed fluctuations. Their conclusion is that unanticipated shocks and very rapid growth undermine cartels, while predictable cyclical fluctuations do not (p. 86).

This evidence must be mapped to the theory with care. The theories of Sections 12.4 and 12.5 predict changes in collusive prices or temporary price wars, not the end of a cartel. A Green-Porter reversion would appear as a breakdown only if the researcher dates episodes by price wars. The finding that anticipated downturns end Webb-Pomerene cartels fits the logic of Haltiwanger and Harrington (1991) and Bagwell and Staiger (1997), in which collusion is hardest when future demand looks weak. It does not test whether the cartels died or merely punished.

Organization and learning. Successful cartels build organizations that monitor members, adjust the agreement to changing conditions, and settle disputes (pp. 67–74). A joint sales agency is the strongest form, since it removes each firm's discretion over price. Seven of the nineteen case-study industries used one: bromine, cement, diamonds, ocean shipping, oil, potash and European steel. Most of these were among the more successful cartels (p. 69). Dick finds that a single sales agent lowers the likelihood of cartel failure. Table 11 of the survey covers four U.S. cross-sections: Hay and Kelley, Fraas and Greer, Posner, and Gallo et al. Trade associations were involved in 29, 36, 44 and 23 percent of their cases, and market allocation in 35, 26, 26 and 27 percent. Suslow finds that self-imposed penalties significantly lengthen cartel life (p. 71).

Hierarchies separate policy from day-to-day management. In the electrical equipment conspiracy of the 1950s, a working group of sales managers devised the "phases of the moon" formula. It rotated the winning bidder for switchgear orders every two weeks (pp. 72–73). In the citric acid cartel of 1991 to 1995, senior executives, nicknamed "the masters," set the broad agreement. Lower-level "sherpas" ran it. They shared monthly sales figures, and a firm that sold more than its quota had to buy citric acid from a member below quota the next year (p. 73). This is the quota-and-transfer scheme that Harrington and Skrzypacz (2011) rationalize (Theorem 12.83).

Cartels learn. Dick and Suslow both find that prior cartel experience lengthens duration (Table 12). Within a single episode, Dick finds that the hazard of dissolution rises with age. A cartel in its tenth year was 28 to 48 percent more likely to dissolve than one in its fifth year. Several case-study cartels got off to a rocky start and later lasted for long periods. Swedish brewers formed a cartel in 1894 with better control machinery than earlier attempts, and a cartel formed in 1906 lasted fifty years (p. 74).

Entry and exclusion. Entry is a central threat. Dick finds that export associations formed where entry was slow, and Symeonidis that collusion is more likely in capital-intensive industries (p. 74). Successful cartels create barriers to entry. Scott Morton documents 47 cases of attempted entry against British shipping cartels. A typical price war against an entrant lasted three months and cut prices by 50 percent on the routes the entrant served (p. 75). Nineteenth-century U.S. salt producers, by contrast, saw each collusive arrangement collapse within a year or two because entry barriers were too low (pp. 74–75).

12.9.4 Why cartels break down

Table 12.16 reproduces the causes of breakdown in international cross-sections. In Eckbo's first sample, internal conflict or defection ended ten of twenty-three cartels, roughly 44 percent, and in his second sample 59 percent (p. 75). In Suslow's sample about a quarter ended because of internal conflict and cheating. Only World War II ended a larger share. Griffin finds that half of his cartels ended for political or external reasons (p. 76). Entry or substitutes contributed to a third of his failures, and "behavioral problems" to another third. World War II ended twelve of his cartels, and technological change ended four (rubber, zinc, sulfur and nitrate). The category "cheating and disagreement" mixes monitoring failures with bargaining failures, which the theory treats very differently.

Table 12.16: Causes of cartel breakdown in international cross-section studies (percent of episodes)

Cause of breakdown	Eckbo, sample 1	Eckbo, sample 2	Griffin[a]	Suslow
Cheating and disagreement	43.5	58.6	33.3	23.9
External shock	30.4		50.0[c]	42.3
Entry and substitution[b]	26.1	41.4	33.3	15.5
Entry	13.0[b]		25.9	15.5
Substitution	8.7[b]		9.3	
Technological change			9.3	
Antitrust indictment				18.3
Total number of episodes	23	29	54	71

Notes: Blank cells are not reported. (a) Based on Griffin's discussion and on his Table 4. Griffin lists more than one cause for several cartels, so his column sums to more than 100. The survey's text names four cartels ended by technological change (4 of 54, or 7.4 percent), while the table reports 9.3 percent. Its footnote 90 notes that Griffin's own text and table differ. We reproduce both figures as printed. (b) Entry and substitution do not always add to the total, because Eckbo leaves one episode unclassified and Griffin counts two cartels under both. Of Eckbo's six episodes in this category, three ended through entry, two through substitution and one is unclassified. (c) Griffin groups wars, antitrust and other government actions, and cartel reorganizations. Some reorganizations may be bargaining problems, so the entry overstates external shocks as classified here. Source: Levenstein and Suslow (2006), Table 13.

Case studies separate these causes better (Table 14 of the survey, p. 77). Entry was the primary cause of disruption in just over a third of the episodes. World Wars I and II ended about 15 percent and legal action a little over 10 percent. Only three episodes, fewer than 10 percent, ended because of cheating (p. 78). Bargaining problems affected virtually every cartel and ended about a quarter of the episodes. Many case-study authors report that cheating was simply not a problem.

Successful cartels avoided costly punishments. The Sugar Institute "served as a court in which an accused firm might prove its innocence" (Genesove and Mullin, 2001, p. 389), as quoted by Levenstein and Suslow (2006, p. 78). Outside the South, deviations "were either ignored or matched" rather than met by reversion to competition (Genesove and Mullin, 2001, pp. 390–391) (see Section 13.4.1). In steel in the 1930s, unexpected declines in demand led to "shallow episodes of increased competition," in Baker's words, rather than severe price wars. In bromine, violations were answered with negotiated side payments rather than price wars (Levenstein, 1997, Section 13.4.3). The authors conclude that Cournot reversion is an inefficient way to sustain collusion, as the cartel members themselves repeatedly discovered (p. 78).

Levenstein and Suslow (2006, p. 79) draw three lessons. First, the outbreak of a price war, as opposed to its threat, is rarely a sign of cartel success. Second, the most successful cartels develop alternative punishments and threats that sustain collusion at lower cost. Third, cartels

break down sometimes because of cheating, but more often because of entry, exogenous shocks and dynamic changes within the industry.

12.9.5 Effects on prices

Rigorous counterfactual estimates of cartel overcharges are rare (p. 45). The available evidence nonetheless shows that many cartels raised prices substantially (pp. 80–81). Eckbo finds that nineteen of fifty-one cartels raised price 200 percent above the unit cost of production and distribution. Griffin finds an average markup of 45 percent over marginal cost. His most successful cartel, rubber from 1923 to 1928, had a markup of 400 percent, while his least successful, wheat from 1933 to 1934, priced below cost. For contemporary international cartels, reported price increases, mostly from the trade press, range from 10 to 100 percent. Graphite electrode prices rose more than 50 percent in the United States from 1992 to 1997. In Canada, where two firms held more than 90 percent of the market, they rose more than 90 percent. Some evidence points the other way. Fölster and Peltzman find that legal Swedish cartels did not raise prices, although a re-examination of the same data by Ciarreta finds that they did. In 25 price-fixing cases from 1973 to 1984, Sproul finds that prices four years after indictment were slightly higher, by 7 percent.

Case studies seldom measure success against a counterfactual (p. 81 and Table 15). Hausman finds that the regulations of the "Limitation of the Vend," a coal cartel in northeast England from 1770 to 1845, raised the equilibrium price by about 6 to 8 percent. Bromine prices came close to the joint-profit-maximizing level in some periods and barely exceeded the Cournot level in others. Ocean shipping was close to the joint-profit level. The German steel cartel priced below the joint-profit level but one-third above the world price. The cement cartel priced 10 percent above the world price. Diamond prices nearly doubled after the cartel formed, and tea prices rose 80 percent in 1933 after the cartel was reestablished. The U.S. beer cartel of the 1930s may even have priced above the monopoly level, under political pressure to keep alcohol expensive. Yet it had price wars in each of the three years it tried to collude. Success must be judged over the whole life of a cartel, not only during its collusive periods (p. 81). The methods for estimating overcharges and damages are developed in Section 13.10.2.

12.9.6 What the evidence says about the theory

The survey speaks to each part of the theory in this chapter.

(1) *Structure.* The perfect-monitoring theory of Section 12.3 predicts that collusion is easier with fewer firms. Concentration helps, but organization can substitute for it, and concentration is itself shaped by collusion.

(2) *Demand.* Unanticipated shocks and rapid growth undermine cartels, while predictable cycles do not. This pattern matches the role of unobserved shocks in Green and Porter (1984). The evidence on anticipated downturns fits the persistent-demand models of Section 12.4. Cross-section data on cartel deaths cannot test the within-cartel price dynamics these models predict. That requires the time-series studies of Section 13.3.

(3) *Price wars.* Many observed price wars are bargaining wars or breakdowns. Successful cartels prefer monitoring, courts and side payments to Green-Porter reversions. This supports the shift of the theory toward communication and transfers (Section 12.7) and toward tolerated cheating (Remark 12.87, Section 13.7).

(4) *Organization.* Joint sales agencies, reporting systems, penalties and hierarchies lengthen cartel life. Theory treats them as devices that make information public or transfers possible, as in Harrington and Skrzypacz (2011).

(5) *Entry.* Entry is the most common cause of breakdown in the case studies, yet most repeated-game models hold the set of firms fixed. This is the largest gap between the theory and the evidence.

(6) *Enforcement.* Antitrust action ended 18.3 percent of Suslow's interwar international cartels and a little over 10 percent of case-study episodes. Enforcement also selects which cartels we observe, as Section 12.8 and Section 13.10.1 discuss.

The survey has limits. It aggregates studies with different definitions of a cartel, of an episode and of a cause of breakdown. Most of its quantitative statements are counts and percentages, not estimates with standard errors. Selection is unavoidable and of unknown sign. The cross-section regressions it summarizes use duration as the dependent variable, which is a noisy measure of success, and they rarely control for the endogeneity of structure and organization. Its contribution is to replace the presumption that cartels are inherently unstable with a set of facts. Cartels often last for years. They end more often through entry, shocks and bargaining than through secret cheating. The successful ones invest in organization.

12.10 Synthesis: What the Theory Predicts and How to Test It

Table 12.17 collects the models of this chapter. Each row states what firms observe, why collusion is hard, what the most collusive equilibrium looks like, whether price wars occur on the equilibrium path, and what the model predicts for prices. The last column points to the section of Chapter 13 where the prediction meets data.

The table carries five lessons for empirical work.

The first lesson is that theory delivers a set of sustainable outcomes and leaves the choice among them open. The folk theorem and Corollary 12.15 imply that a wide range of prices can be sustained in the same environment. Empirical work that tests "collusion" must therefore commit to a specific model of how the cartel operates. The common selection, the most collusive equilibrium, is a convention.

The second lesson is that conduct varies over time. In Rotemberg and Saloner, Haltiwanger and Harrington, and Bagwell and Staiger, collusive margins move with current and expected demand. In Green and Porter, conduct switches between regimes. A constant conduct parameter then averages over states, which is the critique of Corts (1999) discussed in Chapter 3. Estimation must allow for regimes or for state-dependent conduct, as the methods of Section 13.2 do.

The third lesson is that a price war is an ambiguous signal. In Green and Porter (1984) it is part of a working cartel. In Stigler (1964) and in the bargaining wars documented by Levenstein and Suslow (2006), it marks a failing one. The timing of wars relative to demand helps discriminate. Wars after unexpected drops in demand point to Green and Porter. Low prices in booms point to Rotemberg and Saloner. Wars around entry or renegotiation point to bargaining. Ellison (1994) uses exactly this logic to test Green and Porter against Rotemberg and Saloner in the railroad cartel of Porter (1983a) (Section 13.3.5).

The fourth lesson is that communication and transfers are observable in prosecuted cartels, and they matter most when information is private. The anatomy of the lysine and citric acid cartels, with quotas, sales reports and buy-backs, is predicted by Harrington and Skrzypacz

(2011). The identical bidding of many rings is predicted by Athey et al. (2004a), and their take-turns scheme is a model of bid rotation. Evidence on the internal organization of cartels can thus discriminate among models in a way that price data alone cannot.

The fifth lesson is that detection needs a competitive benchmark and a theory of the specific cartel. Overcharges are measured against a but-for price. Tests of bid rigging compare suspected firms with a model of noncooperative bidding. Enforcement determines which cartels enter the data, so every finding is conditional on how the cartels were found.

Table 12.17: Models of collusion and their testable implications

Model	What firms observe	Source of the incentive problem	Most collusive equilibrium and price pattern	Price wars on the path?	Testable implication	Tested in
Perfect monitoring, Bertrand and Cournot (Section 12.3)	All past prices or outputs	One-period gain from undercutting against the loss of future collusion	Stationary price, monopoly if $\delta \geq \underline{\delta}(N)$. Any price in $[c, p^m]$ can be sustained	No	Collusion is easier with fewer, more symmetric firms, frequent interaction and transparency	Section 13.5, Chapter 11
Rotemberg and Saloner (Section 12.4)	Current demand (i.i.d.) and past prices	Gain from cheating rises with current demand, future loss is constant	Monopoly price in low states, capped profit in high states. Countercyclical margins	No, unless prices are restricted to collude or compete	Margins fall when current demand is high relative to expected demand	Section 13.3, Section 13.6
Haltiwanger and Harrington (Section 12.4)	A known demand cycle	Future loss is small when demand is about to fall	Prices lowest when demand is about to fall, and at the peak only for impatient firms	No	Margins rise with expected future demand	Section 13.6
Bagwell and Staiger (Section 12.4)	Current growth phase (Markov)	Gain and loss both move with the phase	Procyclical prices if growth rates are positively correlated, countercyclical if negatively	No	Cyclicality depends on the persistence and expected durations of phases	Section 13.2.1
Green and Porter (Section 12.5)	Market price only	A low price may reflect cheating or low demand	Trigger price, reversion of finite length. Regime switching	Yes, after unexpectedly low prices	Wars follow negative demand shocks and have finite length	Section 13.3
Athey, Bagwell and Sanchirico (Section 12.6)	Public prices, private i.i.d. costs	Low-cost firms want more market share	Patient firms: one rigid price, equal shares. Impatient firms: an escape clause	No (inelastic demand)	Rigid, identical prices that ignore firm-specific costs	Section 13.9, Section 13.4
Harrington and Skrzypacz (Section 12.7)	Own sales and public reports	Secret price cuts, unverifiable sales reports	Quotas, sales reports and per-unit transfers. Breakdown after low total reports	Yes, rare breakdowns	Quota schemes with buy-backs, breakdowns after low sales	Section 13.7
Bernheim and Madsen (Remark 12.87)	All quotes, with costly quoting and home cost advantages	Raiding the rival's home market	Price floor below the home monopoly price. Dispersed prices	No. Raids above the floor are tolerated	Business stolen at higher prices is less likely to be punished	Section 13.7
Chen and Rey (Section 12.8.3)	Own conduct, random detection, leniency	Cheat and report, or collude and report	Normal collusion if the stake exceeds the deterrence threshold	No (binary conduct)	Excessive leniency induces systematic self-reporting	Section 13.10, Section 13.8

Notes: Our synthesis of the models in this chapter. Bernheim and Madsen (2017) is developed in Section 13.7. Price wars on the path refer to the most collusive equilibrium of each model.

Chapter 13 takes these lessons to data. It begins with the econometrics of regime switching (Section 13.2) and the Joint Executive Committee (Section 13.3), where the Green-Porter and Rotemberg-Saloner predictions are tested. It continues with the rules and communication of legal cartels, information exchange, retail gasoline, tolerated cheating, the internal organization of a bidding ring, and the statistical detection of bid rigging. It ends with enforcement and the measurement of damages (Section 13.10).

12.11 Bibliographic notes

The modern theory of collusion begins with Stigler (1964), who saw a cartel's central problem as the detection of secret price cuts. Friedman (1971) showed that the threat of reverting to static Nash play sustains collusion as a noncooperative equilibrium of a supergame. Fudenberg and Maskin (1986) proved the folk theorem with minmax punishments, and Abreu (1986, 1988) characterized optimal punishments and simple penal codes. Farrell and Maskin (1989) asked which punishments survive renegotiation. Benoit and Krishna (1985) and Kreps et al. (1982) showed how multiple stage equilibria and incomplete information restore cooperation in finitely repeated games. Brock and Scheinkman (1985) and Compte et al. (2002) added capacity constraints. Fudenberg and Tirole (1991) and Mailath and Samuelson (2006) are the standard references for the theory of repeated games. Chapter 6 of Tirole (1988) remains the classic textbook treatment of its applications to oligopoly, including the kinked demand curve and the alternating-move model of Maskin and Tirole (1988). Asker and Nocke (2021) survey the modern literature on collusion in the Handbook of Industrial Organization. They cover the prevalence of cartels, how agreements start and are structured, imperfect monitoring, multimarket contact, entry and detection.

Green and Porter (1984) brought imperfect public monitoring into the theory of collusion and showed that price wars can be part of a working cartel. Porter (1983b) studied optimal trigger strategies. Abreu et al. (1986, 1990) developed the recursive methods that now dominate the field, and Fudenberg et al. (1994) proved a folk theorem for games with imperfect public monitoring. Collusion under fluctuating demand starts with Rotemberg and Saloner (1986), whose working paper (Rotemberg and Saloner, 1984) contains the evidence. Haltiwanger and Harrington (1991), Kandori (1991), Staiger and Wolak (1992) and Bagwell and Staiger (1997) studied persistent demand, correlated shocks and capacity.

Private information about costs entered with Athey and Bagwell (2001) and Athey et al. (2004a), and Athey and Bagwell (2008) allowed costs to be persistent. McAfee and McMillan (1992) analyzed bidding rings with and without side payments. The theory of private monitoring and communication includes Compte (1998) and Kandori and Matsushima (1998). Harrington and Skrzypacz (2007, 2011) connected it to the practices of prosecuted cartels, and Awaya and Krishna (2016) studied when cheap talk about sales helps. Bernheim and Madsen (2017) explained why cartels tolerate some cheating. Bernheim and Whinston (1990) is the classic analysis of multimarket contact, and Matsushima (2001) extended it to imperfect monitoring. Sugaya and Wolitzky (2018) showed that more information can hinder collusion. Bos and Harrington (2010) studied which firms join a cartel. Byrne and de Roos (2019) documented how firms learn to coordinate tacitly, and Calvano et al. (2020) opened the study of collusion by pricing algorithms.

On enforcement, Motta and Polo (2003) and Spagnolo (2004) began the economic analysis of leniency programs. Aubert et al. (2006) studied rewards to individual informants, Harrington (2008a) the race to report, and Chen and Rey (2013) the optimal design of a program. Miller

(2009) measured the effect of the 1993 U.S. revision on detection and deterrence. Kaplow (2013) questions the agreement requirement on which enforcement rests. His chapters 2, 3 and 7 examine the meaning of agreement, the role of communication and the link between equilibrium and agreement. Marshall and Marx (2012) give a book-length account of how cartels and bidding rings are organized, of when explicit collusion is needed, and of the plus factors that reveal it. Kawai and Nakabayashi (2020) and Conley and Decarolis (2016) estimate how widespread collusion is in public procurement. Levenstein and Suslow (2006) survey the evidence on cartel duration, organization and breakdown, which Chapter 13 develops further.

12.12 Exercises

1. *Detection lags.* A deviation is detected only k periods after it starts.
   (a) Extend Proposition 12.16 to the linear Cournot supergame of Proposition 12.18: show that with a k-period detection lag, grim trigger sustains q^m if and only if $\delta^k \geq \delta^*(N)$.
   (b) In the Bertrand supergame with demand growth, use (12.11) to compute the threshold for $N = 4$, $k = 2$ and $g = 0.05$, and compare it with the value for $g = 0$. You should find about 0.825 and about 0.866.
   (c) Let $N = 4$, $\delta = 0.8$ and $g = 0$. Find the longest detection lag that a Cournot cartel can tolerate, and the longest that a Bertrand cartel can tolerate. You should find $k = 2$ and $k = 1$. Explain what the difference implies for the value to each cartel of exchanging sales reports.

2. *Capacity constraints.* Three firms with zero marginal cost face demand $D(p) = 1 - p$. Each can produce at most K units per period, with $\frac{1}{6} < K < \frac{1}{2}$. Rationing is efficient. Assume that a deviator can be held to its minmax payoff in every period after a deviation.
   (a) Show that the best deviation from collusion at $p^m = \frac{1}{2}$ earns almost $\frac{K}{2}$.
   (b) Show that the minmax payoff is $K(1 - 3K)$ for $K \leq \frac{1}{4}$ and $\frac{(1-2K)^2}{4}$ for $K \geq \frac{1}{4}$.
   (c) Use the bound of Example 12.17 to show that the threshold discount factor is $\frac{1}{6K}$ for $K \leq \frac{1}{4}$ and $\frac{6K-1}{18K-12K^2-3}$ for $K \geq \frac{1}{4}$.
   (d) Show that the threshold falls with K up to $K = \frac{1}{3}$, where it equals $\frac{3}{5}$, and rises afterward toward $\frac{2}{3}$, the value without capacity constraints. Explain the two forces at work.

3. *Stick and carrot with three firms.* Three Cournot firms face $P(Q) = a - bQ$ at every output and have marginal cost $c < a$.
   (a) Set $a - c = b = 1$. Show that the carrot and stick constraints of Proposition 12.21 become $\frac{1}{36} \leq \delta\frac{(6x-1)^2}{12}$ and $\frac{(4x-1)^2}{4} \leq \delta\frac{(6x-1)^2}{12}$.
   (b) Show that the best stick output is $x = \frac{a-c}{3b}$ per firm, that the stick drives the price down to marginal cost, and that monopoly sharing is sustainable for $\delta \geq \frac{1}{3}$. Compare this with the threshold $\frac{4}{7}$ under Nash reversion.
   (c) Explain why the stick constraint must bind at the optimum. Would the answer change if the price could not fall below zero and c were close to zero (Remark 12.23)?

4. *Booms of different frequency.* Modify the two-state model of Assumption 12.26 so that the high state occurs with probability $\mu \in (0, 1)$.

(a) Show that the incentive constraints become $\pi_s(p_s) \le \kappa[\mu\pi_H(p_H) + (1-\mu)\pi_L(p_L)]$ for $s = H, L$, with κ as in (12.30).

(b) Use Lemma 12.28 to show that some collusion is possible if and only if $\kappa \ge 1$, whatever μ. Show that monopoly pricing in both states requires $\kappa \ge \bar{\kappa}(\mu) \equiv \frac{\pi_H^M}{\mu\pi_H^M + (1-\mu)\pi_L^M}$.

(c) In the intermediate regime, show that $p_L = p_L^M$ and $\pi_H(p_H) = \frac{\kappa(1-\mu)\pi_L^M}{1-\kappa\mu}$.

(d) With $D_s(p) = A_s(1-p)$, $c = 0$, $A_H = 1.5$, $A_L = 1$, $\mu = \frac{1}{3}$ and $N = 2$, compute $\bar{\kappa}$ and $\bar{\delta}$, and the boom price at $\kappa = 1.1$. You should find $\bar{\kappa} = \frac{9}{7}$, $\bar{\delta} = \frac{9}{16}$ and $p_H \approx 0.261$. Explain why rarer booms widen the range of discount factors with countercyclical prices.

5. *Noise and the length of price wars.* Use the Bertrand version of Green and Porter (Assumption 12.43) with $\delta = 0.95$ and $\gamma = 0.2$.

(a) Find the shortest war T^* that satisfies (12.66), and the long-run share of periods spent in wars. You should find $T^* = 2$ and $\frac{2}{7}$.

(b) Compute the value of collusion V at T^* and with an infinite war. Explain why the cartel prefers the shorter war although it punishes less.

(c) An econometrician observes many wars in this industry. Explain why the observation, by itself, is not evidence that the cartel is breaking down. What additional data would distinguish this model from Rotemberg and Saloner (1986)?

(d) Now let N firms play the noisy-signal model of Proposition 12.49, with the same δ and γ and with $\lambda = 1$. For $N = 2$, 3 and 4, compute the threshold (12.71), the punishment probability ϕ^* and the ratio of v^* to $\frac{\bar{\pi}}{N}$. You should find ratios of 0.75, 0.5 and 0.25. Explain why the number of firms matters although δ exceeds every threshold. For $N = 2$, compare v^* with $(1-\delta)V$ at T^* from part (b), and explain why a random punishment can do better than the best war of integer length.

6. *Cost dispersion and rigid prices.* Two firms have private costs drawn independently from the uniform distribution on $[0, \bar{c}]$, with $0 < \bar{c} \le 1$. Demand is inelastic with reservation value $\bar{v} = 1$.

(a) Show that the static equilibrium is $p^e(c) = c + \frac{\bar{c}-c}{2}$ and that the ex ante profit per firm is $\frac{\bar{c}}{6}$.

(b) With Nash reversion after an off-schedule price, use Proposition 12.69 to show that the rigid price $\bar{v}$ is sustainable if and only if $\delta \ge \delta^* = \frac{1}{2-\frac{5\bar{c}}{6}}$. Check that $\delta^* = \frac{6}{7}$ for $\bar{c} = 1$ and that $\delta^* \to \frac{1}{2}$ as $\bar{c} \to 0$.

(c) Compute δ^* when the war gives zero profit instead of Nash profit, for $\bar{c} = 1$. Explain why dispersion in costs makes collusion harder even with the harshest punishment.

(d) Explain why patient firms with these costs prefer a rigid price to any fully sorting scheme, and why impatient firms may use an escape clause.

7. *Transfers in quota cartels.*

(a) In the model of Section 12.7.3, suppose that each firm pays z per unit of reported sales into a common fund that is shared equally among all N firms, the payer included. Show that the effective marginal cost is $c + z$, and compare it with $c + \frac{N}{N-1}z$ in Proposition 12.80. Which design deters business stealing more for a given payment?

(b) Let $N = 4$, let the static markup be constant, and let market demand be uniform on $\{60, \dots, 100\}$. Check condition (12.127). Show that the scheme retains a quarter of the first-best collusive gain and that $\beta_{\min} = \frac{0.15}{\delta}$.

(c) Compute the expected breakdown probability per period and the mean length of the collusive phase for $\delta = 0.95$ and $\delta = 0.99$. Compare the answers with Example 12.86 and explain why more volatile demand raises the cost of truthful reporting.

8. *Leniency with more firms.*

(a) Fill in the derivations behind Remark 12.98: derive the thresholds $B_N^r(\ell)$ and $B_R(\ell)$ for N firms, and the optimal amnesty rate $\hat{\ell}_N$.

(b) For $\delta = 0.8$ and $\varrho = 0.4$, show that $\hat{\ell}_2 = 1$ and $\hat{B}_2 = \frac{2}{3}F$, and compute $\hat{\ell}_3$. Explain why larger cartels call for more generous leniency.

(c) In the laboratory treatment of Hinloopen and Soetevent (2008) with $\ell = 1.8$, explain why many subjects colluded and reported in every period.

(d) Explain why leniency is useless without the first-informant rule (Remark 12.95).

Chapter 13

Collusion: Evidence and Detection

Chapter 12 showed that firms that meet repeatedly can sustain prices above the static equilibrium without any enforceable contract. This chapter asks what the data say. Did real cartels behave as the theory predicts? How did they organize themselves, and what did collusion cost their customers? Can an outsider who sees only prices, quantities or bids tell collusion from competition? The answers matter for antitrust policy, which must decide which conduct to prosecute, how to prove it and how to measure the harm. They also matter for the rest of empirical industrial organization, because every model of demand and supply in Chapters 3 and 8 rests on an assumption about how firms compete.

The chapter combines econometric theory with case studies. It derives the testable implications of the repeated-game models and develops, with proofs, the econometrics needed to test them. It then studies the cases that shaped the field in depth. They include a nineteenth-century railroad cartel, the internal records of legal and prosecuted cartels, retail gasoline, a ring of stamp dealers and bid rigging in public procurement. Each case reproduces the estimating equations and the key tables, and each ends with an assessment of what it shows and what it cannot show.

The chapter draws on much of the book. The supply relation and the conduct parameter come from Chapters 2 and 3, and Chapter 3 also treats the pre-1914 sugar price wars that reappear here. The bidding ring and the detection tests rest on the auction theory of Chapter 14 and on the inversion methods of Chapter 15. The methods for measuring damages share their logic with the merger retrospectives of Chapter 11. Appendix A collects the econometric tools used here, including two-stage least squares, maximum likelihood, the bootstrap, selection models and difference in differences.

13.1 Collusion in Practice and the Nature of the Evidence

Collusion matters for understanding how imperfectly competitive markets work, and it is a central concern of antitrust policy. Four questions organize the empirical literature. How often do firms collude? Can we develop methods to detect collusion? How does collusion occur, that is, how do cartels reach agreement, monitor compliance and respond to cheating? Which practices and institutions facilitate it?

Definitions. *Collusion* is coordination among firms that raises their joint profit above the level of noncooperative competition, by raising prices, restricting output or dividing customers. It helps to distinguish two forms. In *explicit collusion* firms communicate directly. They meet to discuss prices, agree on quotas or on the allocation of customers, and sometimes make payments to

one another. In *tacit collusion* firms reach supracompetitive prices without communicating. The high prices are a noncooperative equilibrium of a repeated game, in which the threat of future punishment deters price cuts (Chapter 12). A *cartel* is a group of firms that colludes explicitly. *Bid rigging* is collusion among bidders in auctions or procurement, and a cartel of bidders is called a *bidding ring*. Collusion can also run on the buying side, as in the buyer cartels and no-poach agreements defined in Section 12.1.1.

The scale of cartel enforcement. Cartels are not a historical curiosity. Table 12.2 in Section 12.1.5 lists the ten largest fines that the European Commission has imposed in cartel cases since 1969. The largest, in the trucks case of 2016 and 2017, exceeds 3.8 billion euros. The vitamins case in that table shows how far a single conspiracy can reach. The main vitamin producers pleaded guilty to a worldwide price-fixing conspiracy covering much of the 1990s (Marshall and Marx, 2012, p. 1). It extended to vitamins A, B_1, B_2, B_5, B_6, C, D and E, beta-carotene, biotin, carotenoids, choline chloride and other products. In the United States, Roche paid a criminal fine of $500 million and BASF one of $225 million. U.S. sales of a single product, vitamin A acetate 650 feed grade, were $311,982,095 during the period covered by the plea agreements (p. 2, Figure 1.1). Buyers recovered billions of dollars in civil suits, and several executives went to prison (p. 2).

Fines outside the top ten reach a wide range of markets. Consider the twenty-two Commission decisions on industrial-product cartels from 2000 through 2005. They concern products as varied as amino acids, carbonless paper, citric acid, copper plumbing tubes, graphite electrodes, industrial bags, needles, plasterboard and zinc phosphate (Marshall and Marx, 2012, pp. 125–127, Table 6.1). Section 12.1.5 also reports the Commission's 2025 fines on a buyer cartel and on a no-poach agreement, and how much annual totals vary.

Why the evidence is hard to obtain. Empirical work on collusion is difficult for three reasons. First, collusion is illegal in most markets today, so firms hide it. The records available to researchers come from cartels that were legal, from prosecutions, or from documents that surfaced by accident. Second, the theory admits many outcomes. With N symmetric Bertrand competitors, every price between marginal cost c and the monopoly price p^m can be sustained when $\delta \geq 1 - \frac{1}{N}$ (Chapter 12). A finding that prices exceed cost therefore says little about which equilibrium firms play. Third, most price patterns that look collusive have competitive explanations. Price wars can reflect cost shocks (Proposition 13.9), sawtooth price cycles arise in competitive equilibria (Section 13.6.3), and a rotation of winners can come from capacity constraints (Section 13.9.2).

The empirical approach. The approach of the chapter follows from these difficulties. We start from a baseline of noncooperative behavior, a static Nash equilibrium in prices or, in an auction, in bids. We then take seriously that firms interact repeatedly, so that the threat of future competition can sustain high margins today. Most models in this tradition abstract from entry, exit and other changes in the market over time, and several of the cases show how much these omissions matter. The question in each case is what collusion adds to the baseline that the data can detect.

The evidence comes in three kinds, and the chapter is organized around them. The first is historical studies of cartels that operated openly and left records. Examples are the Joint Executive Committee railroad cartel, the Sugar Institute and the bromine pools. The second is prosecuted cases of price fixing, bid rigging and facilitating practices, whose court records reveal how cartels worked. A *facilitating practice* is conduct that makes coordination easier without itself being an agreement on price. Examples are gasoline retailers in Quebec, the airlines' fare-publishing system, the lysine and citric acid cartels and a ring of stamp dealers.

The third is statistical detection. The researcher writes down a model of noncooperative behavior that implies testable restrictions on prices, quantities or bids, and reads a rejection as possible collusion. Other explanations for a rejection usually remain, and the chapter returns often to the question of what else could produce the same pattern. Section 13.9.1 places these tests within the wider body of market-based evidence and the *plus factors*, circumstantial economic evidence of collusion beyond parallel price movements, that courts look for.

The first of the four questions, how often firms collude, is the hardest to answer. Prosecutions reveal only the cartels that were caught, and the cartels that researchers study in depth are selected again. Enforcement statistics are hard to read. Fewer prosecutions need not mean less collusion. Where collusion can be measured directly, it appears common. Section 13.10.1 reviews this evidence and the evidence on how long detected cartels last (Levenstein and Suslow, 2006). It also shows that the direction of the resulting bias depends on how detection works.

Notation and sources. Section 13.2 fixes the chapter's notation for conduct regimes. Throughout the chapter δ is the discount factor, as in Chapter 12. Later sections introduce local symbols, for example for a paper's variables, and say so at first use. Several papers are available to us only in working-paper versions, whose page, table and theorem numbers can differ from those of the published articles. When we cite such a number we say so, and "WP p." denotes a page of the working paper. Computations that are ours, and not the authors', are labeled as such.

Plan of the chapter. Section 13.2 turns the theories of Chapter 12 into statements about data and develops the econometrics of regime switching. Section 13.3 applies these tools to the Joint Executive Committee (Porter, 1983a; Ellison, 1994). Section 13.4 studies the internal records of the Sugar Institute and of the bromine cartel. Section 13.5 asks how information about prices affects collusion, in theory and in three policy episodes. Section 13.6 examines four studies of retail gasoline that reach different conclusions about similar price patterns, and a fifth on how tacit coordination emerged in Perth. Section 13.7 documents cheating and its toleration in prosecuted cartels and develops the model of Bernheim and Madsen (2017). Section 13.8 studies the internal organization of a bidding ring (Asker, 2010). Section 13.9 reviews market-based evidence and plus factors (Kaplow, 2013; Marshall and Marx, 2012). It then develops statistical tests for bid rigging and applies them to highway paving and school milk (Porter and Zona, 1993, 1999). Section 13.10 discusses enforcement, the selection of observed cartels and the measurement of damages and welfare losses (Asker and Nocke, 2021), and it collects the lessons of the chapter.

13.2 From Theory to Testable Implications: The Econometrics of Regime Switching

The repeated-game models of Chapter 12 make collusion possible without any contract. They also make it hard to see. A supergame equilibrium that sustains high prices looks, in a single period, like a static market with high costs or inelastic demand. Some models predict more than a high price level, however. They predict *price wars*, periods of low prices that occur on the equilibrium path and follow a pattern. A price war is a regime of conduct, and a regime that switches on and off leaves a footprint in prices and quantities. This section turns the theories into statements about data. It then develops the econometrics needed to read those statements: switching regressions, the expectation-maximization (EM) algorithm, Markov switching filters, and tests for regime switching. Section 13.3 applies the tools to the Joint Executive Committee,

the railroad cartel that motivated most of them.

Global notation holds unless we say otherwise. In this chapter δ is always the discount factor. The regime indicator is $I_t \in \{0, 1\}$, with $I_t = 1$ in a collusive period and $I_t = 0$ in a period of reversion, which we call a price war. When regimes are independent over time, $\lambda = \mathbb{P}(I_t = 1)$. The posterior probability that period t is collusive, given the data, is w_t. Markov transition probabilities are $q_{ij,t} = \mathbb{P}(I_{t+1} = j \mid I_t = i, W_t)$, where W_t is a vector of predetermined variables. Demand is log-linear in this section, and its price coefficient $\alpha_1 < 0$ is the log-log price coefficient. The price elasticity is therefore $\varepsilon = -\alpha_1$. This α_1 has nothing to do with the logit price coefficient α of Chapter 7 and Chapter 8.

13.2.1 What the theories predict

Each model of collusion in Chapter 12 answers four questions differently. What is conduct on the equilibrium path? What, if anything, triggers low prices? How long do low prices last? What should an econometrician see? Table 13.1 collects the answers. The last column points to the sections of this chapter where the prediction meets data.

Three features of the table organize the rest of the chapter. First, only the imperfect-monitoring models of Green and Porter (1984) and Abreu et al. (1986) predict discrete switches of conduct on the equilibrium path. These switches are what the regime-switching methods of this section detect. Second, models disagree about what starts a war, so the timing of switches can discriminate between them. Third, several models predict no wars at all. For them the evidence must come from the level and the cyclical pattern of margins, as in the gasoline studies of Section 13.6.

Remark 13.1 (Wars after bad news or wars in booms?). In Green and Porter (1984) a price war follows an unexpectedly low price. In Rotemberg and Saloner (1986) prices are lowest when demand is highest. The two predictions look opposite, but they answer different questions. Three features of demand decide which one applies. The first is observability. Green and Porter's firms cannot tell a demand shock from a rival's secret output expansion, so low realized demand is bad news about cheating. Rotemberg and Saloner's firms observe demand before they set prices, so a high current state is a temptation and nothing else. The second is persistence. Rotemberg and Saloner assume i.i.d. demand, so high demand today says nothing about the future, and the gain from cheating is largest when current demand is high. With persistent demand, the value of future collusion moves with current demand, and margins can be procyclical (Haltiwanger and Harrington, 1991; Bagwell and Staiger, 1997). The third is anticipation. A demand innovation that firms could not predict is the Green-Porter trigger. Predictable variation, from seasonality or from serially correlated shocks, is the source of a Rotemberg-Saloner "boom." Ellison (1994) uses exactly this split in Section 13.3.5. He separates the innovation V_{1t} from the predictable part of demand and asks which one starts the wars of the Joint Executive Committee.

13.2.2 A supply relation with switching conduct

We now derive the estimating equations of Porter (1983a). The model is a homogeneous-good oligopoly in which conduct switches between two values. The derivation shows exactly which assumptions turn firm-level first-order conditions into a single industry supply relation with a regime dummy.

Assumption 13.2 (Switching-conduct oligopoly)**.**

Table 13.1: Testable implications of models of collusion

Model	Conduct on the equilibrium path	Low prices are triggered by	Length of low-price phases	Observable implication	Tested in
Static Nash: Bertrand ($\theta = 0$) or Cournot ($\theta = HHI$)	Constant conduct	Nothing	No price wars	Prices move only with current demand and cost. One supply regime.	Sections 13.2.3 and 13.3
Supergame with perfect monitoring	Stable collusive price, any $p \in [c, p^m]$ when $\delta \geq 1 - \frac{1}{N}$	Observed deviations, never on the path	No wars on the path	Stable high prices. Theory does not pin down the level.	Section 13.4
Green and Porter (1984)	Collusive phases alternate with reversion phases	An unexpectedly low price or a low own share	Fixed length $T - 1$	Regimes are Markov of order $T - 1$. Wars follow negative demand innovations. Collusive price below static monopoly (Porter, 1983b).	Sections 13.2.6 and 13.3
Abreu et al. (1986)	Two states, collusion and punishment	A low public signal	Random length	Regimes follow a first-order Markov process.	Sections 13.2.6 and 13.4.3
Rotemberg and Saloner (1986)	Margins adjust to current demand	Current demand high relative to future demand	No discrete wars	Countercyclical margins when demand is i.i.d.	Section 13.3.5
Haltiwanger and Harrington (1991), Bagwell and Staiger (1997)	Margins follow expected future demand	An expected fall in demand	No discrete wars	Margins are higher when demand is expected to rise.	Section 13.6
Athey et al. (2004a)	Rigid collusive price	Nothing (private cost shocks are not passed through)	No wars	Prices insensitive to cost shocks.	Sections 13.4 and 13.6
Harrington and Skrzypacz (2011)	Sales reports, quotas and transfers	Low reported total sales	Breakdown	Inter-firm sales act as transfers.	Sections 12.7.3 and 13.7.1
Bernheim and Madsen (2017)	A price floor with tolerated business stealing above it	A price below the floor	Punishment phase	Unpunished cheating at high prices.	Section 13.7.2
Stigler (1964)	Collusion limited by detection	Secret price cuts	Not specified	Prices rise when transactions become observable.	Section 13.5

Notes: Compiled by us from the models of Chapter 12. θ is the conduct parameter of Chapter 2, N the number of firms, c marginal cost and p^m the monopoly price.

(a) A homogeneous good is sold by N firms at a common price p_t. Market demand is

$$\log Q_t = \alpha_0 + \alpha_1 \log p_t + \alpha_2 L_t + U_{1t}, \qquad \alpha_1 < 0, \tag{13.1}$$

where L_t is an observed demand shifter and U_{1t} is a demand shock.

(b) Firm i has cost $C_i(q) = a_i q^{\psi} + F_i$ with $a_i > 0$ and $\psi > 1$, so marginal cost is $MC_i(q) = \psi a_i q^{\psi-1}$, increasing in output.

(c) Each firm's output satisfies the *firm-level supply relation*

$$p_t \left(1 + \frac{\theta_{it}}{\alpha_1}\right) = MC_i(q_{it}), \tag{13.2}$$

where $\theta_{it} \in [0, 1]$ is the conduct of firm i in period t.

Porter writes δ for the cost elasticity ψ and D for the constant A defined below. We rename both because δ is the discount factor and D denotes demand in this book.

Condition (13.2) nests the standard conduct assumptions of Section 2.7.1. Let $P(Q)$ be inverse demand. Since $\frac{d \log P}{d \log Q} = \frac{1}{\alpha_1}$ for demand (13.1),

$$QP'(Q) = \frac{P(Q)}{\alpha_1}.$$

A firm whose perceived marginal revenue is $p + \theta_{it} QP'(Q)$ therefore sets $p(1 + \frac{\theta_{it}}{\alpha_1}) = MC_i$. Price taking, which Porter calls Bertrand behavior, gives $p = MC_i$ and $\theta_{it} = 0$. A Cournot firm sets $p + q_{it} P'(Q) = MC_i$. Writing $q_{it} = s_{it} Q$ with market share s_{it},

$$p + q_{it} P'(Q) = p + s_{it} QP'(Q) = p \left(1 + \frac{s_{it}}{\alpha_1}\right),$$

so $\theta_{it} = s_{it}$. A cartel that maximizes joint profit equates every firm's marginal cost to industry marginal revenue $p + QP'(Q) = p(1 + \frac{1}{\alpha_1})$, so $\theta_{it} = 1$.

Proposition 13.3 (The switching supply relation)**.** *Let Assumption 13.2 hold.*

(i) For any conduct profile, the share-weighted average of (13.2) *is the* industry supply relation

$$p_t \left(1 + \frac{\theta_t}{\alpha_1}\right) = \sum_{i=1}^{N} s_{it}\, MC_i(q_{it}), \qquad \theta_t = \sum_{i=1}^{N} s_{it} \theta_{it}. \tag{13.3}$$

(ii) If all firms have the same conduct, $\theta_{it} = \theta_t$ with $0 \le \theta_t < -\alpha_1$, then

$$q_{it} = \left(\frac{m_t}{\psi a_i}\right)^{\frac{1}{\psi - 1}}, \qquad s_i = \frac{a_i^{\frac{1}{1-\psi}}}{\sum_{j=1}^{N} a_j^{\frac{1}{1-\psi}}}, \tag{13.4}$$

where $m_t = p_t(1 + \frac{\theta_t}{\alpha_1}) > 0$. Market shares do not depend on t or on conduct.

(iii) Under the conditions of (ii),

$$p_t \left(1 + \frac{\theta_t}{\alpha_1}\right) = A\, Q_t^{\psi - 1}, \qquad A = \psi \left(\sum_{j=1}^{N} a_j^{\frac{1}{1-\psi}}\right)^{1-\psi}. \tag{13.5}$$

(iv) If conduct takes the value $\theta > 0$ in collusive periods and 0 in price wars, so that $\theta_t = \theta I_t$, then

$$\log p_t = \beta_0 + \beta_1 \log Q_t + \beta_3 I_t, \qquad \beta_0 = \log A, \quad \beta_1 = \psi - 1, \quad \beta_3 = -\log\left(1 + \frac{\theta}{\alpha_1}\right) > 0. \tag{13.6}$$

Proof. (i) Multiply (13.2) by s_{it} and sum over i. Since $\sum_i s_{it} = 1$,

$$\sum_i s_{it}\, p_t \left(1 + \frac{\theta_{it}}{\alpha_1}\right) = p_t \left(1 + \frac{1}{\alpha_1} \sum_i s_{it} \theta_{it}\right) = p_t \left(1 + \frac{\theta_t}{\alpha_1}\right),$$

and the right side becomes $\sum_i s_{it} MC_i(q_{it})$.

(ii) With common conduct the left side of (13.2) is the same number m_t for every firm. It is positive because $\theta_t < -\alpha_1$ implies $\frac{\theta_t}{\alpha_1} > -1$. Each firm solves $\psi a_i q_{it}^{\psi-1} = m_t$, so

$$q_{it} = \left(\frac{m_t}{\psi a_i}\right)^{\frac{1}{\psi-1}} = \left(\frac{m_t}{\psi}\right)^{\frac{1}{\psi-1}} a_i^{\frac{1}{1-\psi}}.$$

The factor $(\frac{m_t}{\psi})^{\frac{1}{\psi-1}}$ is common to all firms and cancels from $s_{it} = \frac{q_{it}}{\sum_j q_{jt}}$, which gives (13.4).

(iii) Write $\Sigma_a = \sum_j a_j^{\frac{1}{1-\psi}}$, so $s_i = \frac{a_i^{\frac{1}{1-\psi}}}{\Sigma_a}$. Marginal cost at $q_{it} = s_i Q_t$ is $MC_i = \psi a_i s_i^{\psi-1} Q_t^{\psi-1}$. Then

$$\sum_i s_i MC_i = \psi Q_t^{\psi-1} \sum_i a_i s_i^{\psi}.$$

For each i,

$$a_i s_i^{\psi} = s_i \cdot a_i s_i^{\psi-1} = s_i \cdot a_i \left(\frac{a_i^{\frac{1}{1-\psi}}}{\Sigma_a}\right)^{\psi-1} = s_i \cdot a_i\, a_i^{-1}\, \Sigma_a^{1-\psi} = s_i\, \Sigma_a^{1-\psi},$$

because $\frac{\psi-1}{1-\psi} = -1$. Summing over i gives $\sum_i a_i s_i^{\psi} = \Sigma_a^{1-\psi}$, so $\sum_i s_i MC_i = \psi \Sigma_a^{1-\psi} Q_t^{\psi-1} = A Q_t^{\psi-1}$. Part (i) completes the argument.

(iv) Take logarithms of (13.5):

$$\log p_t = \log A + (\psi - 1) \log Q_t - \log\left(1 + \frac{\theta_t}{\alpha_1}\right).$$

With $\theta_t = \theta I_t$, the last term is 0 when $I_t = 0$ and $-\log(1 + \frac{\theta}{\alpha_1})$ when $I_t = 1$. Since $\alpha_1 < 0$ and $\theta > 0$, $1 + \frac{\theta}{\alpha_1} < 1$ and $\beta_3 > 0$. □

The estimating equation adds the structural dummies S_t and an error,

$$\log p_t = \beta_0 + \beta_1 \log Q_t + \beta_2^{\top} S_t + \beta_3 I_t + U_{2t}. \tag{13.7}$$

The error U_{2t} is a multiplicative shock to the cost constant A. Entry changes A, and the proposition predicts the sign of the change. A new firm adds a positive term to Σ_a, and $1 - \psi < 0$, so $A = \psi \Sigma_a^{1-\psi}$ falls. Entry lowers the intercept of the supply relation because output is spread over more plants with rising marginal cost.

Remark 13.4 (Cournot reversion). Porter states that shares are constant in the Bertrand, Cournot and collusive cases. Part (ii) covers only common conduct. Under Cournot, $\theta_{it} = s_{it}$ differs across firms. Each firm's condition becomes $p_t(1 + \frac{s_{it}}{\alpha_1}) = \psi a_i (s_{it} Q_t)^{\psi-1}$, the shares solve a fixed point, and a firm with a low a_i has both a large share and a high markup. Industry conduct is then $\theta_t = \sum_i s_{it}^2 = HHI$ by (13.3), and the aggregation in (iii) holds only approximately. The approximation is good when shares are similar or when demand is elastic relative to the shares.

Corollary 13.5 (Static joint profit maximization)**.** *Under Assumption 13.2, perfect collusion ($\theta = 1$) requires elastic demand, $\alpha_1 < -1$. It then implies*

$$\beta_3 = -\log\left(1 + \frac{1}{\alpha_1}\right) = \log\frac{\alpha_1}{1 + \alpha_1}. \tag{13.8}$$

If $-1 \leq \alpha_1 < 0$, no price satisfies the monopoly condition.

Proof. Marginal cost is positive, so (13.2) with $\theta_{it} = 1$ needs $1 + \frac{1}{\alpha_1} > 0$. For $\alpha_1 < 0$ this holds if and only if $\alpha_1 < -1$. Then $-\log(1 + \frac{1}{\alpha_1}) = -\log\frac{\alpha_1+1}{\alpha_1} = \log\frac{\alpha_1}{1+\alpha_1}$. When $-1 \leq \alpha_1 < 0$, industry marginal revenue $p(1 + \frac{1}{\alpha_1})$ is zero or negative at every price. Joint profit then increases in price at every price. It grows without bound when $\alpha_1 > -1$ and approaches a bound that no finite price attains when $\alpha_1 = -1$, so no profit-maximizing price exists. □

The corollary gives a test of static joint profit maximization: if estimated demand is inelastic, the cartel did not price at the static monopoly level. Porter (1983b) shows that this is what an optimal trigger-price cartel does when demand is noisy. Higher collusive prices raise the gain from secret cheating, so the cartel keeps the collusive price below the static monopoly price to make the incentive constraint hold at lower cost.

Inverting β_3 recovers a conduct index. From $e^{-\beta_3} = 1 + \frac{\theta}{\alpha_1}$,

$$\theta = \alpha_1 \left(e^{-\beta_3} - 1\right). \tag{13.9}$$

Since $\alpha_1 < 0$ and $e^{-\beta_3} < 1$ when $\beta_3 > 0$, the index is positive. Collusion at the static monopoly level means $\theta = 1$, and (13.9) returns that value when (13.8) holds.

Remark 13.6 (Margins and conduct). Given β_3, the collusive margin does not depend on the demand elasticity. In a collusive week, (13.2) gives $\frac{MC}{p} = 1 + \frac{\theta}{\alpha_1} = e^{-\beta_3}$, so the Lerner index is

$$L^c = \frac{p - MC}{p} = 1 - e^{-\beta_3}. \tag{13.10}$$

The conduct index is $\theta = \varepsilon L^c$, the Lerner index scaled by the elasticity (Section 2.7.1). Two studies that agree on β_3 but disagree on α_1 therefore agree on margins and disagree on conduct. This is the source of the gap between Porter's and Ellison's conduct estimates in Section 13.3. Both readings assume that reversion is price taking. If reversion has conduct $\theta_0 > 0$, the same algebra gives $1 + \frac{\theta}{\alpha_1} = e^{-\beta_3}\left(1 + \frac{\theta_0}{\alpha_1}\right)$, and collusive conduct is higher than (13.9) reports.

Remark 13.7 (The conduct index is an as-if summary). The θ of (13.9) measures the average markup of collusive periods relative to reversion periods. It is not a conjecture that firms hold. Corts (1999) shows that a conduct parameter estimated from the slope of the supply relation can be far from the true markup when conduct varies with demand (Section 3.6.2). Here θ is identified from a discrete shift in the intercept, which avoids part of that problem. The critique still applies within a regime. If collusive margins move with demand, as in Rotemberg and Saloner (1986), the single collusive intercept averages over that variation, and the slope β_1 absorbs part of it.

13.2.3 Identification and an observational-equivalence result

Stack demand (13.1) and supply (13.7) with $y_t = (\log Q_t, \log p_t)^\top$. Let X_t collect the constant, L_t, S_t and seasonal dummies, and let $e_2 = (0,1)^\top$. Then

$$B y_t = \Gamma X_t + e_2 \beta_3 I_t + U_t, \qquad B = \begin{pmatrix} 1 & -\alpha_1 \\ -\beta_1 & 1 \end{pmatrix}, \qquad U_t = \begin{pmatrix} U_{1t} \\ U_{2t} \end{pmatrix} \sim N(0, \Sigma), \tag{13.11}$$

which is Porter's eq. (4). The matrix Γ has a zero for S_t in the demand row and a zero for L_t in the supply row. The determinant is $\det B = 1 - \alpha_1\beta_1$, positive when $\alpha_1 < 0 < \beta_1$. The reduced form is

$$y_t = \Pi X_t + d\, I_t + V_t, \qquad \Pi = B^{-1}\Gamma, \qquad d = B^{-1} e_2 \beta_3 = \frac{\beta_3}{1 - \alpha_1\beta_1} \begin{pmatrix} \alpha_1 \\ 1 \end{pmatrix}, \tag{13.12}$$

with $V_t = B^{-1}U_t \sim N(0, \Omega)$ and $\Omega = B^{-1}\Sigma B^{-\top}$. The coefficients on L_t are $\frac{\alpha_2}{1-\alpha_1\beta_1}(1, \beta_1)^\top$.

Known regimes. If I_t is observed, (13.11) is a standard simultaneous system (Appendix A). Each equation has one endogenous regressor. Demand excludes S_t and I_t, so it is identified when $\beta_3 \neq 0$ or $\beta_2 \neq 0$. Supply excludes L_t, so it is identified when $\alpha_2 \neq 0$. The reduced form makes the logic visible. A switch of regime moves $(\log Q, \log p)$ along the vector d, and the ratio of its components is $\frac{d_1}{d_2} = \alpha_1$. A shift of the supply relation traces out the demand curve. In the same way the lakes dummy moves the outcome along $(1, \beta_1)^\top$ and traces out the supply relation. Two-stage least squares with instruments (I_t, S_t) for demand and L_t for supply is consistent.

Unknown regimes. If I_t is not observed and is independent of (X_t, U_t) with $\mathbb{P}(I_t = 1) = \lambda$, the distribution of y_t given X_t is a two-component normal mixture,

$$y_t \mid X_t \;\sim\; \lambda\, N(\Pi X_t + d, \Omega) + (1 - \lambda)\, N(\Pi X_t, \Omega). \tag{13.13}$$

The components share a covariance matrix and differ only in their means.

Proposition 13.8 (Identification of the switching model)**.** *Suppose I_t is i.i.d. and independent of (X_t, U_t), $U_t \sim N(0, \Sigma)$, $\mathbb{E}[X_t X_t^\top]$ is nonsingular, $\alpha_1\beta_1 \neq 1$ and $\alpha_2 \neq 0$. If $\beta_3 \neq 0$ and $\lambda \in (0,1)$, then $(\Pi, \Omega, d, \lambda)$ are identified up to the relabeling $(\lambda, d, \Pi X_t) \mapsto (1 - \lambda, -d, \Pi X_t + d)$. The normalization $\beta_3 > 0$ selects one labeling, and the structural parameters $(B, \Gamma, \beta_3, \Sigma)$ are then identified. If $\beta_3 = 0$, then λ is not identified. If $\lambda \in \{0, 1\}$, then β_3 is not identified.*

Proof. Fix $X_t = x$ and a direction $c \in \mathbb{R}^2$. By (13.13), $c^\top y_t$ is a mixture of $N(\mu, v)$ with weight $1 - \lambda$ and $N(\mu + \Delta_c, v)$ with weight λ, where $\mu = c^\top \Pi x$, $\Delta_c = c^\top d$ and $v = c^\top \Omega c$. Its moment generating function satisfies

$$\log M(s) = s\mu + \tfrac{1}{2}s^2 v + \log\left(1 - \lambda + \lambda e^{s\Delta_c}\right).$$

The last term grows at most linearly in $|s|$, so $v = \lim_{s\to\infty} \frac{2 \log M(s)}{s^2}$ is identified, and so is $g(s) = \log M(s) - \frac{1}{2}s^2 v$. Suppose $\Delta_c > 0$. As $s \to \infty$, $g(s) = s(\mu + \Delta_c) + \log\lambda + o(1)$. As $s \to -\infty$, $g(s) = s\mu + \log(1 - \lambda) + o(1)$. The slopes and intercepts of the two asymptotes give $(\mu + \Delta_c, \lambda)$ and $(\mu, 1 - \lambda)$. If $\Delta_c < 0$ the roles of the two asymptotes swap. In both cases the pair of components, each a mean with its weight, is identified as an unordered pair. Only the name of each component is lost, which is the relabeling in the statement. If $\Delta_c = 0$, g is linear and λ cannot be recovered from this direction.

Since $\beta_3 \neq 0$, $d \neq 0$, and $\Delta_c \neq 0$ for all c outside a line. Knowing $v = c^\top \Omega c$ for all c identifies Ω. Knowing $c^\top \Pi x$ and $c^\top d$ for all such c identifies Πx and d by linearity, and nonsingular $\mathbb{E}[X_t X_t^\top]$ identifies Π. Then $\alpha_1 = \frac{d_1}{d_2}$, and β_1 is the ratio of the price and quantity coefficients on L_t (which needs $\alpha_2 \neq 0$). The relabeling flips the sign of d and shifts only the intercept, so neither ratio depends on the labeling. Hence $1 - \alpha_1\beta_1$ is identified. Since $\beta_3 = d_2(1 - \alpha_1\beta_1)$ and the relabeling flips the sign of d_2, the normalization $\beta_3 > 0$ selects one labeling. Finally $\Gamma = B\Pi$ and $\Sigma = B\Omega B^\top$. If $\beta_3 = 0$, the two components coincide and λ drops out of the likelihood. If $\lambda \in \{0, 1\}$, only one component is ever observed and d drops out. □

The proposition has a practical meaning. With known regimes the demand curve is traced by an observed instrument. With unknown regimes it is traced by a latent one, and the latent instrument is recovered from the shape of the distribution. Ellison (1994, p. 49) puts it this way: collusion is identified by functional form, because the supply errors are assumed normal while collusive price increases have a two-point support. A non-normal supply error with two modes would be read as two regimes.

The same functional form cannot tell a switch in conduct from a switch in cost. The next result makes this precise.

Proposition 13.9 (Observational equivalence of conduct and cost regimes)**.** *Consider a competitive industry ($\theta_t = 0$ always) with demand* (13.1) *and marginal cost*

$$\log MC_t = \log A + (\psi - 1)\log Q_t + \beta_2^\top S_t + \bar{\kappa} K_t + U_{2t},$$

where $K_t \in \{0, 1\}$ is i.i.d. with $\mathbb{P}(K_t = 1) = \lambda$, independent of (X_t, U_t), and $\bar{\kappa} > 0$. Then the joint distribution of $(\log Q_t, \log p_t)$ given X_t is identical to that of the switching-conduct model (13.11) *with $\beta_3 = \bar{\kappa}$ and the same λ.*

Proof. With $\theta_t = 0$, price equals marginal cost, so $\log p_t = \log A + (\psi - 1)\log Q_t + \beta_2^\top S_t + \bar{\kappa} K_t + U_{2t}$. Together with demand this is $By_t = \Gamma X_t + e_2 \bar{\kappa} K_t + U_t$. This is (13.11) with K_t in place of I_t and $\bar{\kappa}$ in place of β_3. Both K_t and I_t are unobserved Bernoulli(λ) variables independent of (X_t, U_t). The two models therefore imply the same mixture (13.13), and their likelihoods coincide at every parameter value. □

The argument extends to Markov regimes, since a Markov cost process mimics Markov conduct in the same way. Porter (1983a, p. 302) states the caveat himself: switches of this kind could also arise from external supply shocks that the econometrician does not observe. Four kinds of information break the equivalence.

- *Direct cost data.* Genesove and Mullin (1998) measure the marginal cost of sugar refining from the technology. When the cost intercept may shift in price wars, the price and quantity data attribute the wars to cost drops. Only the cost data reveal that costs were stable (Sections 3.7.7 and 13.4.2).
- *Timing.* Theory predicts what starts a conduct switch, such as a negative demand innovation or a large deviation of one firm's share. Cost regimes need not follow such signals. Tests of the triggers, as in Section 13.3.5, use this.
- *Outside information on regimes.* Contemporary reports of price wars are information about conduct. Porter compares his estimated regimes with a trade-press series in Section 13.3.4.
- *Market shares.* Common conduct keeps shares constant across regimes by (13.4). Cost shocks that hit firms unequally move shares.

13.2.4 Estimation with unobserved regimes: the EM algorithm

Let $\vartheta = (B, \Gamma, \beta_3, \Sigma)$ collect the structural parameters and $\varphi = (\vartheta, \lambda)$ all parameters. Given I_t, the density of y_t follows from (13.11) by a change of variables from U_t to y_t:

$$h(y_t \mid I_t; \vartheta) = (2\pi)^{-1} |\Sigma|^{-\frac{1}{2}} |\det B| \exp\left\{-\tfrac{1}{2}\left(By_t - \Gamma X_t - e_2\beta_3 I_t\right)^\top \Sigma^{-1}\left(By_t - \Gamma X_t - e_2\beta_3 I_t\right)\right\}. \tag{13.14}$$

The Jacobian $|\det B| = |1 - \alpha_1\beta_1|$ is what makes this a simultaneous-equations likelihood. Dropping it would treat $\log p_t$ and $\log Q_t$ as exogenous regressors and reproduce the simultaneity bias of least squares. With i.i.d. regimes the density of y_t is the mixture

$$f(y_t; \varphi) = \lambda\, h(y_t \mid 1; \vartheta) + (1 - \lambda)\, h(y_t \mid 0; \vartheta), \tag{13.15}$$

and the log likelihood is $\ell(\varphi) = \sum_{t=1}^{T} \log f(y_t; \varphi)$, Porter's eq. (5). Because Σ is common to the two regimes, the likelihood does not have the degenerate maxima of mixtures with component-specific variances, where one component can collapse onto a single observation.

The algorithm. One could maximize ℓ with a Newton-type method. Kiefer (1980) instead adapted the EM algorithm of Dempster et al. (1977) to switching regressions, and Porter (1983a) extended it to the simultaneous system. EM treats I_t as missing data. If I_t were observed, the *complete-data log likelihood* would be

$$\ell_c(\varphi) = \sum_{t=1}^{T} \Big[I_t \left(\log\lambda + \log h(y_t \mid 1; \vartheta)\right) + (1 - I_t)\left(\log(1-\lambda) + \log h(y_t \mid 0; \vartheta)\right) \Big].$$

Start from a guess $\varphi^{(k)}$ and iterate two steps.

1. *E-step.* Compute the posterior probability of collusion by Bayes' rule,

$$w_t^{(k)} = \mathbb{P}\left(I_t = 1 \mid y_t; \varphi^{(k)}\right) = \frac{\lambda^{(k)} h(y_t \mid 1; \vartheta^{(k)})}{\lambda^{(k)} h(y_t \mid 1; \vartheta^{(k)}) + (1 - \lambda^{(k)}) h(y_t \mid 0; \vartheta^{(k)})}, \tag{13.16}$$

   and form the expected complete-data log likelihood

$$Q(\varphi \mid \varphi^{(k)}) = \sum_{t=1}^{T} \Big[w_t^{(k)} \left(\log\lambda + \log h(y_t \mid 1; \vartheta)\right) + \left(1 - w_t^{(k)}\right)\left(\log(1-\lambda) + \log h(y_t \mid 0; \vartheta)\right) \Big]. \tag{13.17}$$

2. *M-step.* Maximize Q over φ. The terms in λ give $\frac{\sum_t w_t^{(k)}}{\lambda} = \frac{\sum_t (1 - w_t^{(k)})}{1-\lambda}$, so

$$\lambda^{(k+1)} = \frac{1}{T}\sum_{t=1}^{T} w_t^{(k)}. \tag{13.18}$$

   The structural parameters $\vartheta^{(k+1)}$ maximize $\sum_t [w_t^{(k)} \log h(y_t \mid 1; \vartheta) + (1 - w_t^{(k)}) \log h(y_t \mid 0; \vartheta)]$.

Porter stops when the correlation between successive w sequences exceeds 0.999 (p. 306).

The structural M-step has a useful form. Write $e_t = By_t - \Gamma X_t$ and $b = e_2\beta_3$. For any $w \in [0, 1]$ and any positive definite Σ,

$$w\,(e_t - b)^\top \Sigma^{-1}(e_t - b) + (1 - w)\, e_t^\top \Sigma^{-1} e_t = (e_t - wb)^\top \Sigma^{-1}(e_t - wb) + w(1 - w)\, b^\top \Sigma^{-1} b. \tag{13.19}$$

To verify it, expand both sides. The left side is $e_t^\top \Sigma^{-1} e_t - 2w\, b^\top \Sigma^{-1} e_t + w\, b^\top \Sigma^{-1} b$. The right side is $e_t^\top \Sigma^{-1} e_t - 2w\, b^\top \Sigma^{-1} e_t + w^2 b^\top \Sigma^{-1} b + (w - w^2) b^\top \Sigma^{-1} b$, which is the same. Using (13.14) and $b^\top \Sigma^{-1} b = \beta_3^2 (\Sigma^{-1})_{22}$, the structural part of Q is, up to a constant,

$$T \log |\det B| - \frac{T}{2} \log |\Sigma| - \frac{1}{2} \sum_{t=1}^{T} (e_t - e_2 \beta_3 w_t)^\top \Sigma^{-1} (e_t - e_2 \beta_3 w_t) - \frac{\beta_3^2 (\Sigma^{-1})_{22}}{2} \sum_{t=1}^{T} w_t (1 - w_t). \quad (13.20)$$

The first three terms are the full-information likelihood of the system with I_t replaced by w_t. The last term penalizes a large regime effect in proportion to the uncertainty about the regimes. Plugging w_t into the known-regime likelihood and dropping the penalty is a different update, and in general its fixed point is not the maximum likelihood estimator. In the reduced form (13.12) the M-step is a least-squares problem in which the cross moment of the regime with itself is $\sum_t w_t$, because $\mathbb{E}[I_t^2 \mid y_t] = w_t$. This is the version our simulation code uses.

Theorem 13.10 (EM never lowers the likelihood)**.** *Let $\varphi^{(k+1)}$ satisfy $Q(\varphi^{(k+1)} \mid \varphi^{(k)}) \geq Q(\varphi^{(k)} \mid \varphi^{(k)})$. Then $\ell(\varphi^{(k+1)}) \geq \ell(\varphi^{(k)})$.*

Proof. This is Proposition A.45, with φ in place of the appendix's ϑ. Its proof uses only the inequality assumed here, so it also covers M-steps that raise Q without maximizing it. □

The likelihood values along the EM path therefore never fall, and since the likelihood is bounded above they converge. The limit is a stationary point of ℓ, usually a local maximum, and it need not be the global one. In practice we run the algorithm from several starting points and keep the highest likelihood. Porter reports that his algorithm converged to the same estimates from several disparate starting points (p. 309). EM does not deliver standard errors as a by-product. They come from the curvature of ℓ at the maximum, for example from numerical second derivatives.

Proposition 13.11 (Classifying periods)**.** *Among all rules that assign each period to a regime using the data, the rule $\hat{I}_t = \mathbf{1}\{w_t > \frac{1}{2}\}$ minimizes the expected number of misclassified periods given the data.*

Proof. For any classification $(\hat{I}_1, \dots, \hat{I}_T)$ that depends only on the data,

$$\mathbb{E}\left[\sum_{t=1}^{T} \mathbf{1}\{\hat{I}_t \neq I_t\} \,\middle|\, \text{data} \right] = \sum_{t=1}^{T} \left[\hat{I}_t (1 - w_t) + (1 - \hat{I}_t) w_t \right].$$

Each term is minimized separately by $\hat{I}_t = 1$ if $1 - w_t < w_t$, that is if $w_t > \frac{1}{2}$. □

Lee and Porter (1984) prove this result and use it for the classification that Porter reports. In practice w_t is evaluated at the estimated parameters.

Imperfect sample separation. Contemporary reports of price wars carry information about regimes, but they may be wrong. Lee and Porter (1984) treat a reported indicator PO_t as a noisy signal with $\eta_i = \mathbb{P}(PO_t = 1 \mid I_t = i)$. The joint density of (y_t, PO_t) is then

$$\lambda\, h(y_t \mid 1; \vartheta)\, \eta_1^{PO_t} (1 - \eta_1)^{1 - PO_t} + (1 - \lambda)\, h(y_t \mid 0; \vartheta)\, \eta_0^{PO_t} (1 - \eta_0)^{1 - PO_t}. \quad (13.21)$$

Two special cases bracket the model. With $\eta_1 = 1$ and $\eta_0 = 0$ the reports are exact and the regimes are known. With $\eta_1 = \eta_0$ the reports are uninformative, and (13.21) is the mixture (13.15) times a factor that involves neither ϑ nor λ. Estimating (η_0, η_1) jointly with ϑ measures how accurate the reports are, and the EM algorithm extends directly, with w_t now conditioning on PO_t as well as on y_t.

13.2.5 Markov switching and time-varying transition probabilities

The i.i.d. assumption behind (13.15) is at odds with the theory. A Green-Porter war lasts $T-1$ periods, so a war this week makes a war next week likely. Cosslett and Lee (1985) noted that the estimated price wars of the JEC form continuous episodes. The natural model lets I_t follow a Markov chain whose transition probabilities may depend on observed variables,

$$q_{i1,t} = \mathbb{P}(I_{t+1} = 1 \mid I_t = i, W_t) = \Lambda(\gamma^\top W_t), \qquad \Lambda(x) = \frac{e^x}{1+e^x}, \qquad q_{i0,t} = 1 - q_{i1,t}, \tag{13.22}$$

where W_t contains I_t and other predetermined variables. This is the specification of Ellison (1994, eq. (4)). When W_t contains only a constant, the regimes are independent as in Porter. When $W_t = (I_t, 1-I_t)^\top$, the chain has constant transition probabilities.

The filter. The likelihood of a Markov switching model is computed recursively, by the filter of Hamilton (1989). Let $\mathcal{Y}_t$ denote the data through period t, and let $h_i(y_t) = h(y_t \mid I_t = i, \mathcal{Y}_{t-1}; \vartheta)$ be the regime-i density of y_t given the past. Define the predicted and filtered probabilities

$$\xi_{t|t-1} = \mathbb{P}(I_t = 1 \mid \mathcal{Y}_{t-1}), \qquad \xi_{t|t} = \mathbb{P}(I_t = 1 \mid \mathcal{Y}_t).$$

Suppose $\xi_{t|t-1}$ is known. The joint density of y_t and the event $I_t = 1$ given the past is $\xi_{t|t-1} h_1(y_t)$. By the law of total probability the density of y_t given the past is

$$f(y_t \mid \mathcal{Y}_{t-1}) = \xi_{t|t-1}\, h_1(y_t) + \big(1 - \xi_{t|t-1}\big)\, h_0(y_t). \tag{13.23}$$

Bayes' rule updates the regime probability once y_t is seen:

$$\xi_{t|t} = \frac{\xi_{t|t-1}\, h_1(y_t)}{\xi_{t|t-1}\, h_1(y_t) + \big(1 - \xi_{t|t-1}\big)\, h_0(y_t)}. \tag{13.24}$$

The Markov property and the law of total probability give the forecast for the next period. Since W_t is part of $\mathcal{Y}_t$,

$$\xi_{t+1|t} = \sum_{i \in \{0,1\}} \mathbb{P}(I_{t+1} = 1 \mid I_t = i, W_t)\mathbb{P}(I_t = i \mid \mathcal{Y}_t) = \xi_{t|t}\, q_{11,t} + \big(1 - \xi_{t|t}\big)\, q_{01,t}. \tag{13.25}$$

We start from $\xi_{1|0}$, for example the stationary probability of the chain. The recursion (13.23) to (13.25) then delivers every term of the prediction-error decomposition of the likelihood,

$$\ell(\varphi) = \sum_{t=1}^{T} \log f(y_t \mid \mathcal{Y}_{t-1}) = \sum_{t=1}^{T} \log\left[\xi_{t|t-1} h_1(y_t) + \big(1 - \xi_{t|t-1}\big)\, h_0(y_t)\right], \tag{13.26}$$

and we maximize it over (ϑ, γ). A backward pass through the same quantities gives the smoothed probabilities $\mathbb{P}(I_t = 1 \mid \mathcal{Y}_T)$, which use the whole sample to classify each period. With constant transition probabilities, EM extends to this model. Its E-step uses the smoothed probabilities of single periods and of consecutive pairs, and its M-step updates q_{ij} by the expected share of transitions from i to j.

Remark 13.12 (Serial correlation). Ellison (1994) lets the demand error follow an AR(1) process, $U_{1t} = \rho U_{1,t-1} + V_{1t}$ with $|\rho| < 1$. Here ρ is an autocorrelation, not a pass-through rate. Quasi-differencing gives the density of y_t given the past and I_t. The regime does not enter demand, so the lagged residual $U_{1,t-1}$ is a function of past data and parameters, and the filter still runs on I_t alone. If a regime variable enters the equation with the autocorrelated error, the density depends on the current and the lagged regime. The filter then runs on the pair (I_t, I_{t-1}), a Markov chain with four states. Ellison's hidden demand regimes in Section 13.3.5 are of this kind.

Lemma 13.13 (Spell durations)**.** *Let I_t be a Markov chain with constant transition probabilities $q_{11}, q_{00} \in (0,1)$. A collusive spell lasts exactly $k \geq 1$ periods with probability $q_{11}^{k-1}(1-q_{11})$, and its expected length is $\frac{1}{1-q_{11}}$. A price war has expected length $\frac{1}{1-q_{00}} = \frac{1}{q_{01}}$. The long-run share of collusive periods is $\frac{q_{01}}{(1-q_{11})+q_{01}}$.*

Proof. Once a collusive spell has begun, the Markov property implies that it continues each period with probability q_{11}, independently of its age. It lasts exactly k periods if it continues $k-1$ times and then ends, which has probability $q_{11}^{k-1}(1-q_{11})$. The mean of this geometric distribution is

$$\sum_{k=1}^{\infty} k\, q_{11}^{k-1}(1-q_{11}) = (1-q_{11})\frac{1}{(1-q_{11})^2} = \frac{1}{1-q_{11}},$$

using $\sum_{k\geq 1} k x^{k-1} = \frac{1}{(1-x)^2}$ for $|x|<1$. The same argument applies to wars with $q_{00} = 1-q_{01}$. The stationary probability π_1 solves $\pi_1 = \pi_1 q_{11} + (1-\pi_1)q_{01}$, so $\pi_1(1-q_{11}) = (1-\pi_1)q_{01}$ and $\pi_1 = \frac{q_{01}}{(1-q_{11})+q_{01}}$. □

The lemma separates the two imperfect-monitoring models. With constant transition probabilities the length of a war is geometric, as in Abreu et al. (1986), where a war continues until a signal ends it. In Green and Porter (1984) a war lasts exactly $T-1$ periods after the period that triggers it. The chance that it ends then depends on how long it has lasted, so the regime process is Markov of order $T-1$, the length of a war (Porter, 1983a, p. 306).

Covariates in W_t turn the transition probabilities into a test of what starts a war. A Green-Porter cartel enters a war after a signal that cheating may have occurred, such as an unexpectedly low price or a suspiciously high share for one firm. Such signals should enter the probability of leaving the collusive state, with a negative coefficient in (13.22). This is the heart of Ellison's design. It differs from the approach of Hajivassiliou (1989), who relates covariates to the probability of being in a state. The theory is about the onset of wars, and a variable that starts wars and one that merely prolongs them have different implications (Ellison, 1994, p. 40).

13.2.6 Testing for regime switching and for the order of the regime process

Testing for the presence of switching. The natural null hypothesis is that only one regime is ever observed. Under the null, either $\beta_3 = 0$, and then λ does not enter the likelihood, or $\lambda \in \{0,1\}$, and then β_3 does not enter it. The standard theory of the likelihood-ratio test fails on both counts. A parameter that is not identified under the null is a nuisance parameter present only under the alternative (Davies, 1987). A parameter on the boundary of its space also breaks the usual expansion. As a result, $2(\ell_1 - \ell_0)$ does not have a χ^2_1 distribution under the null. Its distribution depends on the model and must be simulated or bounded (Hansen, 1992).

Porter compares the maximized log likelihood of his switching model, L_1, with that of the model in which the regime shift is zero, $\beta_3 = 0$, which he calls L_0. Both are normalized per observation, and he computes

$$L_1 - L_0 = \left(\log|\det \hat{B}_1| - \tfrac{1}{2}\log|\hat{\Sigma}_1|\right) - \left(\log|\det \hat{B}_0| - \tfrac{1}{2}\log|\hat{\Sigma}_0|\right), \tag{13.27}$$

where $(\hat{B}_1, \hat{\Sigma}_1)$ are the switching estimates and $(\hat{B}_0, \hat{\Sigma}_0)$ those without switching. He reports $2T(L_1 - L_0) = 554.1$ and compares it with the χ^2_1 distribution (p. 312). Two cautions apply. First, (13.27) is the concentrated likelihood of a single-regime normal system evaluated at the

switching estimates. It omits the mixing terms $\sum_t [w_t \log \lambda + (1 - w_t) \log(1 - \lambda)]$ and the entropy of the posterior probabilities w_t. It is therefore not the mixture statistic $2(\ell_1 - \ell_0)$. When the regimes are well separated, it exceeds that statistic by about $2T[-\lambda \log \lambda - (1 - \lambda) \log(1 - \lambda)]$. Second, neither statistic has a χ^2_1 null distribution, for the reasons above. In our simulation of Porter's design without switching, the 95th percentile of $2(\ell_1 - \ell_0)$ is near 10. Porter's statistic has a median near 160 and a 95th percentile near 240 (`figures/ch13/src/porter_lr_check.py`). The observed 554.1 lies far beyond both, so the conclusion survives.

The general remedy is a *parametric bootstrap* of the likelihood-ratio statistic (Appendix A).

1. Estimate the model without switching and record $\hat{\vartheta}_0$ and ℓ_0.
2. Simulate n_b samples of length T from the no-switching model at $\hat{\vartheta}_0$, holding X_t fixed.
3. In each simulated sample, estimate both models, using several EM starting values for the switching model, and record the statistic $LR^{(r)} = 2(\ell_1^{(r)} - \ell_0^{(r)})$.
4. Reject at level a if the observed statistic exceeds the $(1 - a)$ quantile of $LR^{(1)}, \ldots, LR^{(n_b)}$.

Testing the order of the regime process. Berry and Briggs (1988) proposed a test that discriminates between the two imperfect-monitoring models through the order of the regime process. Green-Porter wars of fixed length $T - 1$ make I_t Markov of order $T - 1$. Wars of random length, as in Abreu et al. (1986), make it first order. For each history h of the last k regimes, let N_h be the number of periods that follow h and $\hat{p}_h$ the fraction of them with $I_t = 1$. Under a first-order process, p_h depends only on the most recent element of h. Let R be a matrix whose rows set $p_h - p_{h'} = 0$ for pairs of histories that share their most recent regime. The statistic is

$$W = (R\hat{p})^\top \left(RVR^\top\right)^{-1} (R\hat{p}) \xrightarrow{d} \chi^2_{\operatorname{rank} R}, \qquad V = \operatorname{diag}\left(\frac{\hat{p}_h(1 - \hat{p}_h)}{N_h}\right), \tag{13.28}$$

under the null of a first-order process (Levenstein, 1997, WP fn. 36). The test treats the regime series as known. Berry and Briggs applied it to an estimated JEC series. As reported by Levenstein (1997, WP p. 16), they concluded that the JEC was more likely to have implemented an Abreu-Pearce-Stacchetti agreement than a Green-Porter one. The statistic cannot be computed when every history in a restriction has $\hat{p}_h \in \{0, 1\}$, because $RVR^\top$ is then singular. In practice, restrictions that involve a cell with zero estimated variance are often dropped, which costs degrees of freedom. This happens often with few wars. Section 13.4.3 applies the test to the bromine cartel and shows how Levenstein (1997) handles such cells.

What the methods can and cannot do: a simulation. To see the methods at work, we simulate data from the model of Section 13.2.2 with $T = 328$ weeks, the length of the JEC sample. The demand and supply parameters are Porter's estimates (Table 13.4). The intercepts reproduce his predicted price and quantity in a war week with the lakes closed (Table 13.5). The lakes are open in weeks 16 to 45 of each year. The regimes follow a Markov chain with $q_{00} = 0.9$, so a war lasts 10 weeks on average. We set $q_{11} = 0.939$, which makes the long-run collusive share 0.62, close to the mean of Porter's reported series. We use the same regime path and the same normal draws for two calibrations. The first uses the maximum likelihood column of Porter's Table 3, with separation ratio $\frac{\beta_3}{\sigma_2} = 5.0$. The second uses the two-stage least squares column, with $\frac{\beta_3}{\sigma_2} = 1.6$. For any Σ, $d^\top \Omega^{-1} d = \beta_3^2 (\Sigma^{-1})_{22}$. When the demand and supply errors are uncorrelated this equals $(\frac{\beta_3}{\sigma_2})^2$, so the ratio is the Mahalanobis distance between the two components of (13.13).

Table 13.2: Estimating a switching model on simulated data

	α_1	β_1	β_3	Transitions or $\hat{\lambda}$	Misclassified weeks	Log likelihood
Calibration 1: maximum likelihood column, $\frac{\beta_3}{\sigma_2} = 5.0$						
True values	−0.800	0.090	0.545	$q_{11} = 0.939$, $q_{00} = 0.900$		
Known regimes	−0.593	0.054	0.534			
EM, i.i.d. regimes	−0.594	0.050	0.531	$\hat{\lambda} = 0.622$	2	−106.86
EM, Markov regimes	−0.592	0.053	0.533	$\hat{q}_{11} = 0.946$, $\hat{q}_{00} = 0.918$	0	28.63
Calibration 2: two-stage least squares column, $\frac{\beta_3}{\sigma_2} = 1.6$						
True values	−0.742	0.251	0.382	$q_{11} = 0.939$, $q_{00} = 0.900$		
Known regimes	−0.429	0.174	0.357			
EM, i.i.d. regimes	−4.339	0.109	0.186	$\hat{\lambda} = 0.680$	116	−187.44
EM, Markov regimes	−0.472	0.125	0.361	$\hat{q}_{11} = 0.935$, $\hat{q}_{00} = 0.889$	25	−162.99

Notes: One simulated sample of 328 weeks with 11 price wars and a collusive share of 0.625. Both calibrations use the same regime path and the same normal draws. "Known regimes" is maximum likelihood with the true I_t, which equals two-stage least squares here because each equation is exactly identified. The i.i.d. EM estimates are the best of eight starting values. The i.i.d. model is the special case of the Markov model with $q_{11} = 1 - q_{00}$ and the first regime drawn with the same probability. Within a calibration the two log likelihoods are therefore comparable. Twice their difference, 271 and 49, is a likelihood-ratio statistic against i.i.d. regimes (our computation). Source: our simulation, `figures/ch13/src/regime_sim.py`.

Table 13.2 and Figure 13.1 show three lessons. First, with Porter's maximum likelihood estimates the regimes are almost perfectly separated. EM with i.i.d. regimes misclassifies 2 of 328 weeks, and its estimates are close to the known-regime estimates. Both differ from the true α_1 by about two standard errors of Porter's estimate. That gap is sampling error that knowing the regimes would not remove. Second, separation decides everything. With the 2SLS calibration the supply errors are more than twice as large and the two price clouds overlap. The i.i.d. mixture likelihood then peaks at a point with $\hat{\alpha}_1 = -4.3$, misclassifying 116 weeks. Started at the true regimes, EM converges to a sensible but lower local maximum. Third, persistence helps. The Markov model pools information across neighboring weeks, misclassifies 25 weeks, and estimates the demand slope about as well as knowing the regimes. These are results for one sample. Figure 13.2(b) repeats the exercise.

The Monte Carlo experiments in Figure 13.2 make the lessons general. Panel (a) shows the null distribution of the likelihood-ratio statistic for no switching in samples of 328 weeks. Its 90, 95 and 99 percent quantiles are 8.34, 10.17 and 13.17, against 2.71, 3.84 and 6.63 for χ^2_1. A test that used the χ^2_1 cutoff of 3.84 would reject a true null of no switching in 49 percent of samples. Panel (b) shows that classification deteriorates quickly as separation falls. With i.i.d. regimes the share of misclassified weeks is 0.6 percent at a ratio of 5, 6.7 percent at 3, 18 percent at 2 and 37 percent at 1. At a ratio of 1 this is barely better than calling every week collusive, which errs 38 percent of the time. The Markov model misclassifies 0.1, 1.7, 5.8 and 21 percent. At a ratio of 1 it even beats the i.i.d. Bayes rule with known parameters, whose error is 29 percent, because neighboring weeks carry information about the regime. The estimated demand slope degrades as well. Across samples, the standard deviation of $\hat{\alpha}_1$ from the i.i.d. model is 0.09 at a ratio of 5, the same as with known regimes. It is 0.40 at a ratio of 2 and above 1 at lower ratios, while known regimes keep it near 0.09. Porter's maximum likelihood (ML) estimates imply a ratio of 5.0, so his classification is reliable if his model is right. His 2SLS estimates imply a ratio of 1.6, a reminder that the separation is itself estimated.

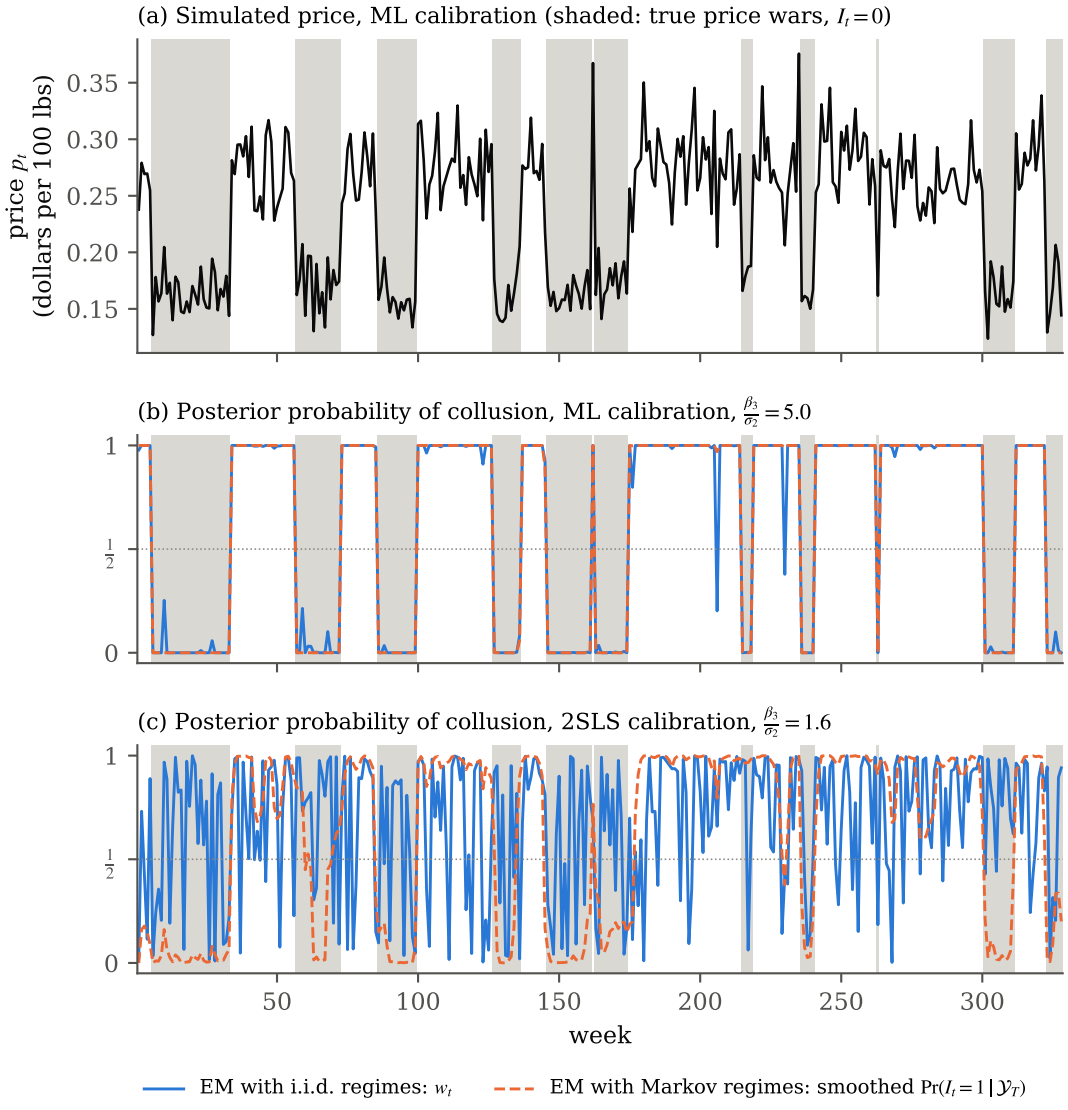

Figure 13.1: A simulated regime-switching price path and the estimated regimes. Panel (a) shows the simulated grain rate for the calibration to the maximum likelihood column of Porter (1983a, Table 3), with true price-war weeks shaded. Panels (b) and (c) show the posterior probability of collusion from EM with i.i.d. regimes (solid) and the smoothed probability from EM with Markov regimes (dashed). Panel (c) uses the two-stage least squares calibration, in which the regimes are less well separated. Source: our simulation calibrated to Porter (1983, Tables 3 and 4).

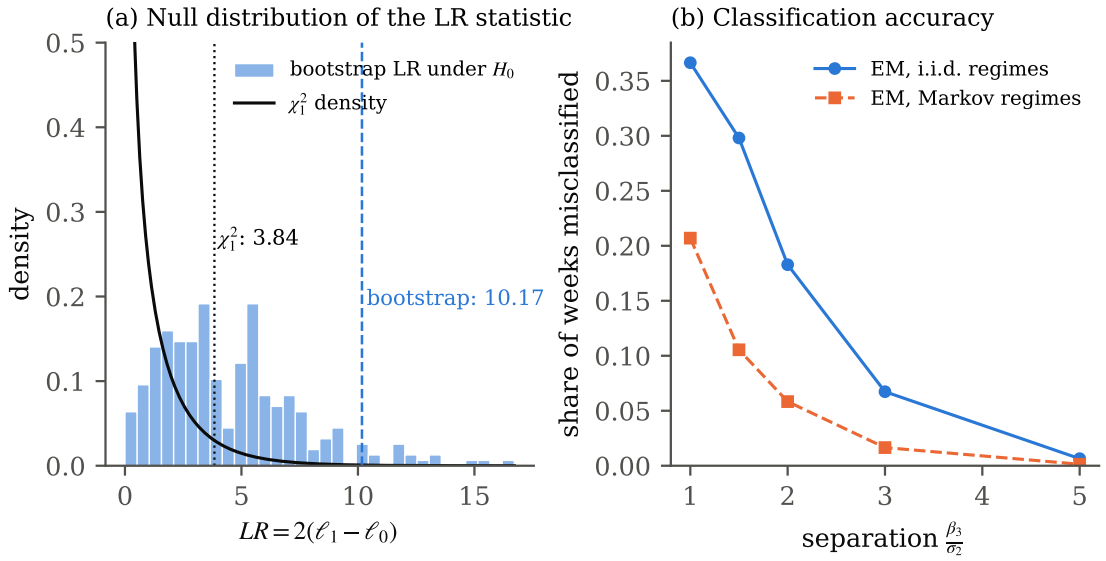

Figure 13.2: Panel (a): null distribution of the likelihood-ratio statistic for no switching, from 300 parametric bootstrap samples of 328 weeks generated without switching, against the χ^2_1 density. The bootstrap 95th percentile is 10.17, against 3.84 for χ^2_1. Panel (b): average share of misclassified weeks over 60 simulated samples for each separation ratio $\frac{\beta_3}{\sigma_2}$, holding the other parameters at the maximum likelihood calibration. Source: our simulation.

The Berry-Briggs test behaves as the theory predicts on simulated regime series of the same length. On a first-order Markov chain with the transition probabilities above, the test of $\mathbb{P}(I_t = 1 \mid 0, 0) = \mathbb{P}(I_t = 1 \mid 1, 0)$, where histories are written (I_{t-2}, I_{t-1}), gives $W = 0.34$. On a Green-Porter chain in which every war lasts exactly 10 weeks, it gives $W = 10.11$. The difference comes from the first week of a war. Under Green and Porter, a war that has just begun never ends the next week, so $\hat{p}_{(1,0)} = 0$, while $\hat{p}_{(0,0)} = 0.110$ because some wars end after ten weeks. With six to eleven wars in real data, power is low, and cells with zero variance are common.

13.3 The Joint Executive Committee Railroad Cartel

The Joint Executive Committee (JEC) is the most studied cartel in empirical industrial organization. It was legal, it kept weekly records, and its history includes price wars that contemporaries reported. Porter (1983a) used its records to estimate the switching model of Section 13.2, and Ellison (1994) re-estimated it with Markov regimes to ask what started the wars. This section treats both papers in depth.

13.3.1 Question and setting

The question. Distinguishing collusion from noncooperative behavior without a smoking gun is hard (p. 301). Porter asks whether the prices of the JEC switched between collusive and noncooperative regimes, as the trigger-price equilibrium of Green and Porter (1984) predicts. The alternative is that shifts in demand and cost explain all movements in price and quantity. The test matters beyond railroads. If wars are part of a collusive equilibrium, an industry with

recurrent price wars is not one in which collusion keeps failing. Green and Porter stress that this undercuts a common argument against antitrust intervention.

The Green-Porter model. In Green and Porter (1984), N firms produce a homogeneous good. The market price is $p_t = \zeta_t \, p\left(\sum_i x_{it}\right)$, where x_{it} is firm i's output and ζ_t is an i.i.d. demand shock with mean one that firms do not observe. Firms see the price but not their rivals' outputs. They produce collusive quantities while the price stays above a trigger price $\bar{p}$. When the price falls below $\bar{p}$, they produce Cournot quantities for $T - 1$ periods and then resume collusion. In equilibrium no firm cheats, yet wars occur whenever a low demand shock pushes the price below the trigger. If F is the distribution of ζ_t and y_i are the collusive outputs, a war starts in each collusive period with probability $F(\frac{\bar{p}}{p(\sum_i y_i)})$. Porter uses three predictions: switches between regimes occur, they follow a pattern, and collusive output exceeds the static joint-profit level (Porter, 1983b).

The cartel. The JEC controlled eastbound freight shipments from Chicago to the Atlantic seaboard. The railroads involved formed it by agreement in April 1879 and acknowledged it publicly. It preceded the Interstate Commerce Act (1887) and the Sherman Act (1890), so it was legal (p. 302). According to Ulen (1979), its enforcement resembled a trigger strategy. In several instances the cartel thought that cheating had occurred, cut prices for a time, and then returned to the collusive price.

The product. Grain accounted for 73 percent of the dead-freight tonnage of the JEC, and the rates for flour and provisions were tied to the grain rate (p. 303). Grain is not perishable, so speed of delivery was not a margin of differentiation. Most of the wheat was exported, and the rates of different railroads adjusted to compensate for differences in ocean shipping rates from their port cities. Porter therefore treats the service as a homogeneous good.

Price setting and monitoring. Railroads set prices, not quantities. Under price setting the natural reversion is Bertrand, which is why the supply relation of Proposition 13.3 has $\theta = 0$ in wars. The agreement allotted market shares, and each firm set its rates individually. The JEC office kept weekly accounts, so each railroad saw total shipments. Actual shares depended on all firms' prices and on unpredictable forces. A firm with a low share could not tell a rival's secret rate cut from bad luck. This is the inference problem of Stigler (1964), and it is close to the Green-Porter problem. Brock and Scheinkman (1985) show that equilibria with similar features exist in price-setting supergames with capacity constraints.

Entry and competition. Entry occurred twice. The Grand Trunk Railway entered in 1880 and the Chicago and Atlantic in 1883. The cartel accepted the entrants and gave them share allotments. A railroad that entered faced a "no-exit" constraint: bankrupt railroads were relieved by the courts of most of their fixed costs and told to cut prices to raise business (p. 303). Predation was therefore pointless. Entry shifted the cost constant A, and collusion continued. The main competition came from lake steamers and sailships, which never joined the agreement. The opening and closing of the Great Lakes to navigation shifted demand predictably, and rates adjusted to the season without disrupting conduct.

13.3.2 Data

The data are weekly from week 1 of 1880 to week 16 of 1886, a total of 328 weeks, compiled by Ulen (1979). Table 13.3 lists the variables and their summary statistics. The price GR is the grain rate in dollars per 100 pounds and the quantity TQG is total grain shipped by JEC members in tons. LAKES equals one when the Great Lakes were open to navigation. PO

equals one unless the trade magazine *Railway Review* reported a price war, and it agrees with the reports of the *Chicago Tribune*. PN is the regime classification that Porter estimates. Four dummies mark changes in the membership of the cartel. Each year is divided into thirteen four-week periods, and twelve "monthly" dummies enter both equations.

Table 13.3: The JEC data, 1880–1886

Variable	Definition	Mean	Std. dev.	Min.	Max.
GR	Grain rate, dollars per 100 lbs	0.2465	0.06653	0.125	0.40
TQG	Total grain shipped, tons per week	25,384	11,632	4,810	76,407
LAKES	= 1 if the Great Lakes were open	0.5732	0.4954	0	1
PO	= 1 unless a price war was reported	0.6189	0.4864	0	1
DM1	Grand Trunk entry (week 28, 1880 to week 10, 1883)	0.4238	0.4949	0	1
DM2	Addition to New York Central (weeks 11–25, 1883)	0.0457	0.2092	0	1
DM3	Chicago and Atlantic entry (week 26, 1883 to week 11, 1886)	0.4329	0.4962	0	1
DM4	Chicago and Atlantic leaves (weeks 12–16, 1886)	0.0152	0.1227	0	1

Notes: 328 weekly observations. Definitions from Porter (1983a, Table 1). Statistics for GR, TQG, LAKES and PO from Porter (1983a, Table 2), and for DM1–DM4 from Ellison (1994, Table 1), which reports the same values for GR, TQG and LAKES (to fewer digits) but not PO.

The dummies cover the sample in five periods. DM1 and DM3 mark the two long periods, 139 and 142 weeks, and together they cover 281 of the 328 weeks (our computation of the 139 and 142). All price wars occurred inside them (p. 308).

Three caveats. First, the price series is suspect. The JEC polled its members and published an index of their rates. Secret price cuts would not show up in such an index, because members had no incentive to report them (p. 307). Wars started by secret cuts may therefore appear in GR with a lag. Porter notes the other side of this coin: an imperfect information structure is exactly what a trigger-price equilibrium requires. Second, the prices charged by lake steamers, the main competitors, are not available, so LAKES stands in for them. Third, the model assumes constant market shares across regimes. Within the DM1 and DM3 periods the average sum of squared deviations from allotted shares was roughly the same in cooperative and war weeks, which supports the assumption (p. 308). The reported regime series PO also conflicts sharply with an index of cartel adherence built by MacAvoy (1965). This conflict is one reason to estimate the regimes from prices and quantities.

13.3.3 Model and estimating equations

The estimating equations are demand (13.1) and the supply relation (13.7), with twelve seasonal dummies added to both:

$$\log TQG_t = \alpha_0 + \alpha_1 \log GR_t + \alpha_2 LAKES_t + \text{seasonal dummies} + U_{1t}, \tag{13.29}$$

$$\log GR_t = \beta_0 + \beta_1 \log TQG_t + \beta_2^{\top}(DM1_t, \ldots, DM4_t)^{\top} + \beta_3 I_t + \text{seasonal dummies} + U_{2t}. \tag{13.30}$$

The errors are i.i.d. bivariate normal with covariance Σ. By Proposition 13.3, if wars are Bertrand reversions, $\beta_0 = \log A$, $\beta_1 = \psi - 1 > 0$ and $\beta_3 > 0$. If cooperative periods maximized static joint profit, β_3 would equal $\log \frac{\alpha_1}{1+\alpha_1}$ (Corollary 13.5). Porter leaves β_3 unrestricted. An optimal trigger-price cartel should set β_3 positive but below that level.

Identification follows Section 13.2.3. LAKES shifts demand and identifies the supply slope β_1. The regime and the entry dummies shift supply and identify the demand slope α_1. Porter estimates the model in two ways. The first treats PO as the true regime series and applies two-stage least squares. The second treats I_t as unknown and i.i.d. Bernoulli(λ), as in (13.15), and maximizes the likelihood by the EM algorithm of Section 13.2.4. Weeks with $w_t > \frac{1}{2}$ are classified as collusive (Proposition 13.11), which yields PN. Porter acknowledges that a Green-Porter regime series would be Markov of order $T-1$. He gives three reasons for not imposing it. Estimating under that constraint is hard. The length of wars should vary as entry changes the cartel's problem. Green and Porter (1984) show that the bias from treating the regime process as exogenous is slight when wars are few relative to the sample (pp. 306–307). He also estimated a linear version of the model and found results that were not significantly different.

13.3.4 Results

Table 13.4 reproduces Porter's estimates. In the 2SLS columns all coefficients have the expected sign, but the fit is modest, with a supply R^2 of 0.320. In the ML columns the demand equation is practically unchanged. The supply equation changes. The regime coefficient rises from 0.382 to 0.545 and its standard error halves, while the supply R^2 rises to 0.863 and the standard error of the regression falls from 0.243 to 0.109.

Table 13.4: Porter's estimates of the JEC demand and supply relations

	2SLS, regimes from PO		ML (EM), regimes estimated	
Variable	Demand	Supply	Demand	Supply
Constant	9.169	−3.944	9.090	−2.416
	(0.184)	(1.760)	(0.149)	(0.710)
LAKES (α_2)	−0.437		−0.430	
	(0.120)		(0.120)	
$\log GR$ (α_1)	−0.742		−0.800	
	(0.121)		(0.091)	
DM1		−0.201		−0.165
		(0.055)		(0.024)
DM2		−0.172		−0.209
		(0.080)		(0.036)
DM3		−0.322		−0.284
		(0.064)		(0.027)
DM4		−0.208		−0.298
		(0.170)		(0.073)
PO or PN (β_3)		0.382		0.545
		(0.059)		(0.032)
$\log TQG$ (β_1)		0.251		0.090
		(0.171)		(0.068)
R^2	0.312	0.320	0.307	0.863
Std. error of regression	0.398	0.243	0.399	0.109

Notes: From Porter (1983a, Table 3). Standard errors in parentheses. $T = 328$ weeks. Twelve seasonal dummies are included in both equations and not reported in the paper. In the ML columns the regime variable is the estimated classification PN.

Demand. Demand is inelastic, with $\hat{\alpha}_1 = -0.742$ or -0.800. Industry marginal revenue $p(1+\frac{1}{\alpha_1})$

is then negative. By Corollary 13.5, the JEC did not maximize static joint profit: marginal revenue would have to equal a share-weighted average of marginal costs, which is positive (p. 308). As expected, open lakes shift rail demand down by 0.43 to 0.44 log points, about 35 percent at a given price.

Supply. Price is significantly higher in cooperative periods. The supply relation slopes up, which suggests weak diseconomies of scale, but $\hat{\beta}_1$ is small and significant only at the 15 percent level in the 2SLS columns. The entry dummies are negative, and DM3 is below DM2, so each entry lowered the supply intercept. This is the sign that Proposition 13.3 predicts for an increase in Σ_a.

Example 13.14 (Conduct and margins in cooperative weeks)**.** Apply (13.9) to the ML estimates:

$$\theta = -0.800\left(e^{-0.545} - 1\right) = -0.800\,(0.580 - 1) = 0.336.$$

Porter reports this value and calls it roughly consistent with Cournot behavior in cooperative periods (pp. 309–310). The 2SLS estimates give $\theta = -0.742(e^{-0.382} - 1) = -0.742\,(0.682 - 1) = 0.236$ (our computation). By (13.10) the Lerner index in cooperative weeks is $1 - e^{-0.545} = 0.42$ in the ML estimates and $1 - e^{-0.382} = 0.32$ in the 2SLS estimates (our computation). Porter stresses that the Cournot label has no special meaning. What matters is that cooperative prices exceed competitive prices but stay below the static joint-profit level, as an optimal trigger-price cartel would set them.

Example 13.15 (Reduced-form effects of collusion and of the lakes)**.** Solve the ML system for the effect of the regime, holding the other variables fixed. Substitute demand into supply:

$$\log p = \beta_0' + \beta_1\left(\alpha_0' + \alpha_1 \log p + \alpha_2 L\right) + \beta_3 I,$$

where primes denote intercepts that absorb the other variables. Collect the $\log p$ terms:

$$(1 - \alpha_1\beta_1)\log p = \beta_0' + \beta_1\alpha_0' + \beta_1\alpha_2 L + \beta_3 I.$$

Hence

$$\frac{\partial \log p}{\partial I} = \frac{\beta_3}{1 - \alpha_1\beta_1} = \frac{0.545}{1 + 0.800 \times 0.090} = \frac{0.545}{1.072} = 0.508,$$
$$\frac{\partial \log Q}{\partial I} = \alpha_1 \frac{\partial \log p}{\partial I} = -0.800 \times 0.508 = -0.407.$$

Collusion multiplies price by $e^{0.508} = 1.66$ and quantity by $e^{-0.407} = 0.67$. Revenue rises by the factor $e^{0.508 - 0.407} = e^{0.101} = 1.11$. For the lakes,

$$\frac{\partial \log Q}{\partial L} = \frac{\alpha_2}{1 - \alpha_1\beta_1} = \frac{-0.430}{1.072} = -0.401,$$
$$\frac{\partial \log p}{\partial L} = \frac{\beta_1\alpha_2}{1 - \alpha_1\beta_1} = 0.090 \times (-0.401) = -0.036.$$

Open lakes multiply quantity by $e^{-0.401} = 0.67$ and price by $e^{-0.036} = 0.965$ (our computation throughout). Because the model is log-linear, these ratios do not depend on where the other variables are held.

Table 13.5 reports Porter's predicted values at the sample means of the other variables. The ratios match the example. Price is 66 percent higher in cooperative weeks ($\frac{0.2780}{0.1673} = 1.66$), quantity 33 percent lower, and revenue 11 percent higher, a difference of about 11,000 dollars a week in 1880 dollars. These are Porter's figures (p. 310). The entries of Table 13.5 give 13,886 dollars with the lakes closed and 8,970 with them open. Porter's text says that price was 4.5 percent lower when the lakes were open. The table implies $\frac{0.1612}{0.1673} = 0.964$, a fall of 3.6 percent, which agrees with the reduced form of Example 13.15. Revenue is about 35 percent lower when the lakes are open. Revenue on grain was 70 to 80 percent of the JEC's revenue from eastbound freight.

Table 13.5: Predicted price, quantity and revenue by regime and season

	Lakes closed (LAKES = 0)		Lakes open (LAKES = 1)	
	War (PN = 0)	Cooperation (PN = 1)	War (PN = 0)	Cooperation (PN = 1)
Price (GR, dollars per 100 lbs)	0.1673	0.2780	0.1612	0.2679
Quantity (TQG, tons per week)	38,680	25,775	25,904	17,261
Revenue (dollars per week)	129,423	143,309	83,514	92,484

Notes: From Porter (1983a, Table 4). Computed from the reduced form of the ML estimates in Table 13.4, with the other explanatory variables at their sample means. Revenue is $20 \times \text{GR} \times \text{TQG}$: a ton is 20 hundredweight, so this converts dollars per 100 pounds times tons into dollars.

Timing of the wars. Figure 13.3 plots the grain rate with the weeks in which PO and PN indicate a war. The two series agree broadly. Wars averaged about 10 weeks and occurred mainly in 1881, 1884 and 1885. In several episodes PO records a war before PN does, and the two return to cooperation together (p. 310). This pattern fits a price index that misses secret cuts at the start of a war. PN was not constrained to resemble PO in any way. Table 13.6 shows that it agrees with the trade-press reports and disagrees with MacAvoy's index of share instability. MacAvoy's index is highest in 1880, a year without any war in either PO or PN.

Table 13.6: Indices of cartel nonadherence by year

		Share of weeks at war	
Year	MacAvoy's index	Reported (PO)	Estimated (PN)
1880	26	0.00	0.00
1881	14	0.67	0.44
1882	18	0.06	0.21
1883	6	0.10	0.00
1884	16	0.58	0.40
1885	10	0.77	0.67
1886 (16 weeks)	15	0.50	0.06

Notes: From Porter (1983a, Table 5), whose first two columns come from Ulen (1979). MacAvoy's index counts months, summed over members, in which a member's share of tonnage deviated from its trend share. A deviation counts when it exceeds the standard error of the member's trend regression. The reported and estimated columns are $\frac{1}{52}\sum_t(1 - PO_t)$ and $\frac{1}{52}\sum_t(1 - \hat{I}_t)$ over the weeks of each year, with denominator 16 in 1886.

Testing for switching. The coefficients on PO and PN are significantly positive, so cooperative periods had significantly higher prices. Porter's likelihood-ratio statistic (13.27) is $2T(L_1 -$

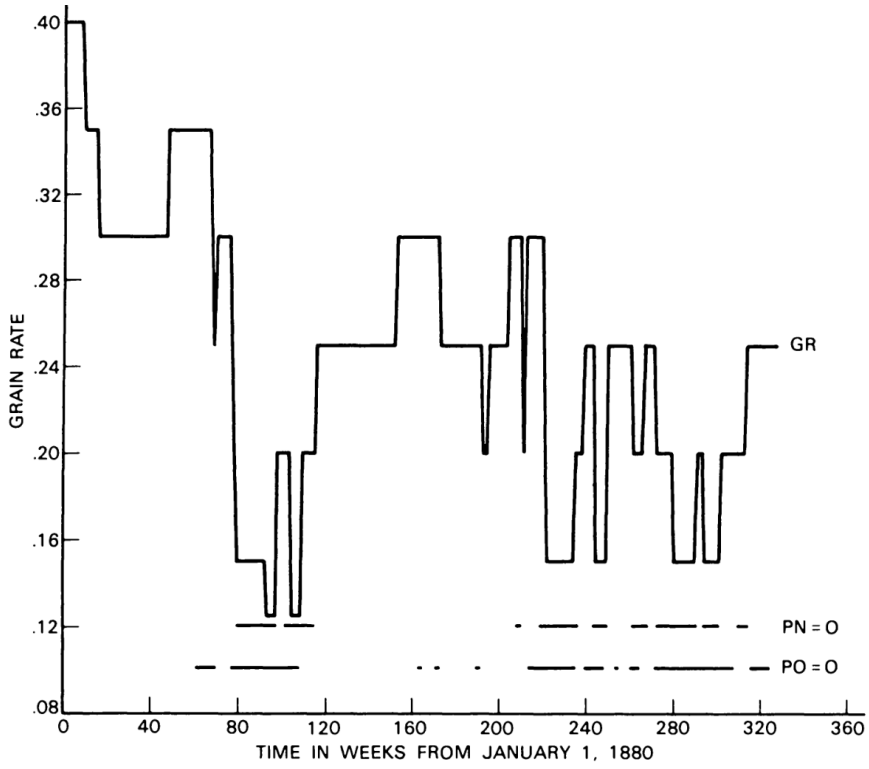

Figure 13.3: The JEC grain rate in dollars per 100 pounds, from January 1880. Upper segments mark the weeks that the estimated series classifies as price wars (PN = 0), and lower segments those of the trade-press series (PO = 0). Source: Porter (1983), Figure 1.

$L_0) = 554.1$. He refers it to the χ^2_1 distribution and rejects the hypothesis of no switching overwhelmingly. As Section 13.2.6 explains, the χ^2_1 reference is invalid, and the statistic omits the mixing terms of the likelihood. Its simulated null distribution, with a 95th percentile near 240 in our calibration, still lies far below 554. Price and quantity changes cannot be attributed to demand and structural shifts alone, given the specification. The agreement between PN and PO also shows that the estimated switches are not an artifact of missing data.

Entry and the frequency of wars. The 1881 and 1884 wars each began about 40 weeks after an entry, of the Grand Trunk and of the Chicago and Atlantic respectively (p. 311). Entry did not cause an immediate reversion. It plausibly raised the chance of later ones. Wars were more frequent, and shorter on average, when the cartel had more members. This fits the general point that enforcement gets harder as the number of firms grows (Chapter 12).

Triggers. Green-Porter wars follow unexpected demand drops. Porter regresses the length of each war on the demand residual in the week before it began and finds little predictive power. Price wars were not preceded by large negative demand residuals. He offers two reasons for caution. The demand residual omits the lake steamers' prices, so it measures unexpected demand poorly. The firms set prices, so wars may have followed unpredictable swings in market shares, as Stigler (1964) predicts.

Table 13.7 gives annual wheat shipments from Chicago by lake and by rail. 1880 was a boom year, which accounts for its high rates. Among the other years, total shipments are not correlated with nonadherence. The war years 1881, 1884 and 1885 stand out by the JEC's high share of intermodal shipments: 50.0, 34.0 and 48.5 percent, against 13.8 to 26.8 percent in 1882, 1883 and 1886. JEC wars did not coincide with lake steamer price wars, and they did not always occur when total demand was low. They were not systematically related to the opening or closing of the lakes either (p. 313).

Table 13.7: Annual eastbound shipments of wheat from Chicago by lake and rail

	Lake		Rail		Total
Year	Millions of bushels	Percent	Millions of bushels	Percent	millions of bushels
1880	16.69	77.9	4.728	22.1	21.42
1881	7.688	50.0	7.680	50.0	15.37
1882	14.94	86.2	2.389	13.8	17.33
1883	7.067	73.2	2.590	26.8	9.66
1884	11.52	66.0	5.928	34.0	17.45
1885	5.436	51.5	5.116	48.5	10.55
1886	10.51	82.6	2.209	17.4	12.72

Notes: From Porter (1983a, Table 6).

13.3.5 Ellison's re-examination

The question. Porter's evidence shows that wars occurred. Ellison (1994, p. 38) argues that the core content of the Green-Porter theory is more specific: wars occur because firms follow strategies in which random demand shocks trigger them. He asks three questions. Did the wars of the JEC start after the signals that trigger strategies would use? Were prices less collusive, or wars more likely, in booms, as Rotemberg and Saloner's logic suggests? Did members cut prices in secret, which no theory of optimal collusion allows?

Adapting the theories. The JEC differs from the textbook Green-Porter model in two ways (pp. 38–39). The railroads set prices, and reputations for service and different route structures differentiated their demands. Secret cuts made prices unobservable. The quantity data, in contrast, were presumably reliable. The cartel even considered using the shipment data to compute side payments by firms that exceeded their allotments. Many trigger strategies could support a nearly optimal outcome in this setting. Ellison lists three plausible triggers. One firm obtaining a suspiciously high market share is the best signal of cheating. High aggregate demand is another, because a price cut expands demand as well as moving shares. An unusually low share for one firm is a third, which a coalition-proof equilibrium might use.

Model and data. Ellison's model follows Porter's closely. Demand is

$$\log Q_t = \alpha_0 + \alpha_1 \log P_t + \alpha_2 LAKES_t + \sum_{k=1}^{12} \alpha_{2+k}\, SEAS_{kt} + U_{1t}, \qquad U_{1t} = \rho U_{1,t-1} + V_{1t}, \tag{13.31}$$

with $|\rho| < 1$. The supply relation is

$$\log P_t = \beta_0 + \beta_1 \log Q_t + \beta_3 I_t + \sum_{k=1}^{4} \beta_{3+k}\, DM_{kt} + U_{2t}, \tag{13.32}$$

where we keep our β_3 for the coefficient that Ellison writes β_2. The errors (V_{1t}, U_{2t}) are bivariate normal. Regimes follow the logit Markov chain (13.22), with

$$\mathbb{P}(I_{t+1} = 1 \mid I_t, Z_t) = \Lambda\left(\gamma_1 I_t + \gamma_0 (1 - I_t) + \gamma_Z^{\top} Z_t I_t\right), \tag{13.33}$$

where Z_t holds candidate triggers. A negative element of γ_Z means that the variable raises the probability that a collusive week is followed by a war. The structural equations and the transitions are estimated jointly by maximum likelihood with the filter of Section 13.2.5, following Cosslett and Lee (1985). Standard errors are robust and computed from numerical derivatives. Joint estimation should date the onset of wars more accurately than Porter's two-step approach and give more power to detect triggers. The data are Ulen's weekly series, the same 328 weeks that Porter used.

Figure 13.4 summarizes the regime structures that Ellison estimates, including the hidden demand regimes introduced below.

The standard model. Table 13.8 reports Ellison's "standard" model, which adds AR(1) demand errors and Markov regimes to Porter's specification, next to a version without serial correlation. The lagged demand error has coefficient $\hat{\rho} = 0.832$ (0.085), and allowing for it changes the demand estimates. The price elasticity rises from 0.84 to 1.80, so the JEC faced elastic demand. The regime effect hardly moves, from 0.660 to 0.637. By (13.9), the conduct index rises with the elasticity,

$$\theta = 0.843\left(1 - e^{-0.660}\right) = 0.41, \qquad \theta = 1.802\left(1 - e^{-0.637}\right) = 0.85$$

(our computation, against Ellison's reported 0.40 and 0.85). Remark 13.6 explains the pattern. The collusive Lerner index $1 - e^{-\beta_3}$ is 0.48 or 0.47 in the two columns, and the elasticity converts the same margin into very different conduct. With elastic demand a static monopoly benchmark exists. Corollary 13.5 gives $\log \frac{1.802}{0.802} = 0.81$, above the estimated 0.637, so the JEC still priced below static monopoly (our computation). Ellison concludes that the JEC was much more aggressive in its pricing than earlier work reported.

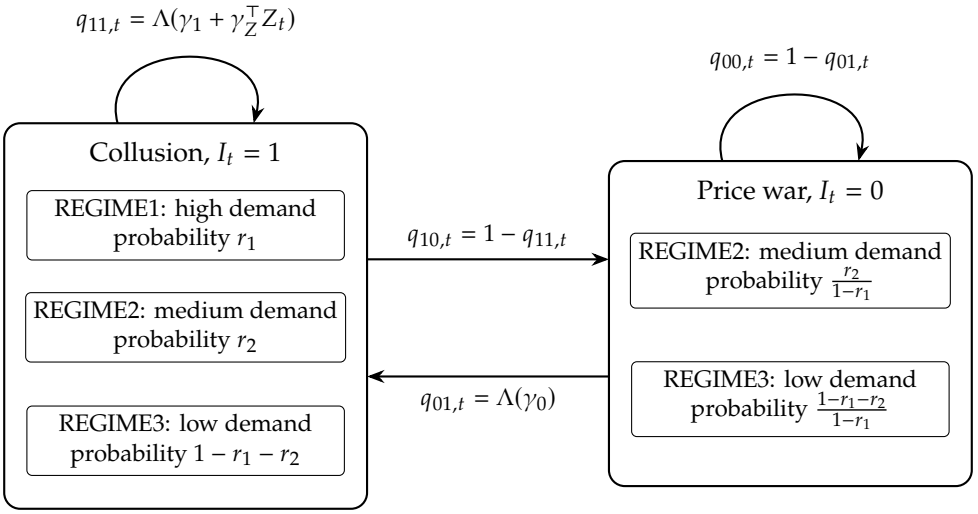

Figure 13.4: The regime structure in Ellison (1994). Conduct follows a two-state Markov chain whose transition probabilities are logits. Candidate triggers Z_t enter only the probability $q_{11,t}$ of staying in collusion. In the hidden-regime models, demand regimes are drawn each week given conduct. REGIME1 occurs only under collusion, and the other regimes keep the same relative probabilities in both conduct states. The standard model has no demand regimes, and model 2 has only REGIME1 and REGIME2. Drawn by us after Ellison's Figures 1 and 3.

Table 13.8: Ellison's standard model of the JEC

Variable	Standard model	No serial correlation
Demand		
Constant	7.677 (1.882)	9.019 (0.361)
$\log P$ (α_1)	−1.802 (1.287)	−0.843 (0.193)
LAKES	−0.009 (0.112)	−0.460 (0.348)
Supply		
Constant	−4.764 (1.863)	−5.649 (9.461)
$\log Q$ (β_1)	0.306 (0.178)	0.398 (0.928)
DM1	−0.154 (0.075)	−0.211 (0.124)
DM2	−0.246 (0.064)	−0.283 (0.160)
DM3	−0.317 (0.076)	−0.373 (0.242)
DM4	−0.198 (0.119)	−0.419 (0.422)
I_t (β_3)	0.637 (0.104)	0.660 (0.406)
Regimes (logit index)		
Constant if $I_t = 1$ (γ_1)	3.675 (0.474)	3.661 (0.513)
Constant if $I_t = 0$ (γ_0)	−2.641 (0.404)	−2.620 (0.476)
Other		
σ_1	0.290 (0.061)	0.396 (0.029)
σ_{12}	−0.007 (0.004)	−0.045 (0.142)
σ_2	0.160 (0.045)	0.191 (0.313)
$U_{1,t-1}$ (ρ)	0.832 (0.085)	
Log likelihood	181.0	37.2

Notes: From Ellison (1994, Table 2). Standard errors in parentheses. Twelve seasonal dummies in demand are included and not shown. The regime constants are the logit indices of $\mathbb{P}(I_{t+1} = 1 \mid I_t)$.

The regime constants imply strong persistence. The probability that collusion continues is $\Lambda(3.675) = \frac{e^{3.675}}{1+e^{3.675}} = 0.975$, and the probability that a war week is followed by collusion is $\Lambda(-2.641) = 0.067$ (p. 42). By Lemma 13.13, collusive spells last $\frac{1}{1-0.975} = 40$ weeks on average and wars $\frac{1}{0.067} = 15$ weeks. The long-run share of collusive weeks is $\frac{0.067}{0.025+0.067} = 0.73$ (our computation). The regimes are far from independent, which confirms the observation of Cosslett and Lee (1985).

Candidate triggers. To test for triggers, Ellison builds four share variables (p. 41). Let s_{it} measure the strength of firm i's demand, and let $\hat{s}_{it}$ be its predicted value. Each variable is the largest normalized deviation across firms, $\max_i \frac{s_{it}-\hat{s}_{it}}{\sigma_i}$, where σ_i is the sample standard deviation.

- *BIGSHARE1* uses $s_{it} = \log q_{it} - \frac{1}{N}\sum_j \log q_{jt}$, where N is the number of firms, with the average of the previous twelve weeks as $\hat{s}_{it}$. Using logs keeps the trade-off between the gain from a price cut and the loss from a war proportional across firms of different sizes.
- *BIGSHARE2* uses the ordinary market share, with the same prediction.
- *BIGSHAREQ* uses the log measure, with the assigned quota as the prediction. Quotas were often set unrealistically, so deviations from them measure adherence poorly. MacAvoy (1965) reports that the Chicago and Grand Trunk was admitted with a 10 percent quota while receiving only 2 to 7 percent of the traffic at the cartel price.
- *SMALLSHARE* is the largest shortfall of any firm's log measure below its prediction.

The demand innovation V_{1t} and the full demand shock U_{1t} serve as aggregate triggers. Under Green and Porter, unanticipated shocks start wars. Under Rotemberg and Saloner, wars are more likely when demand is high and expected to decline. Since $U_{1t} = \rho U_{1,t-1} + V_{1t}$, the two can be separated.

Table 13.9 reports the trigger coefficients. Only six wars are identified in the standard model, so high significance levels are not to be expected. BIGSHARE1 has the predicted negative sign and is significant at the 6 percent level in a one-tailed test. BIGSHARE2 and BIGSHAREQ are negative but smaller and insignificant. SMALLSHARE has the wrong sign. The aggregate innovation V_{1t} is large, negative and significant at the 6 percent level. In model 6 the innovation keeps its sign while the full shock U_{1t} enters with a positive, insignificant coefficient. The unanticipated component of demand predicts wars and the anticipated component does not. This separates the Green-Porter explanation from the Rotemberg-Saloner one, which Porter (1985) could not do with a two-step approach.

The timing of the estimated wars is uncertain, and the standard model does not match the onset date of Ulen's classification for any war (p. 43). Panel B of Table 13.9 therefore fits simple logits for the onset of a war in the reported regime series. The estimates are similar to Panel A, which supports a Green-Porter-type trigger.

Strength of the trigger. A trigger must also deter cheating. Ellison gives a rough calculation (p. 44). Suppose a firm offers a small secret price cut that raises its demand by 10 percent and its current profit by 8 to 10 percent. The cut raises its BIGSHARE1 measure by $\frac{\log 1.1}{\sigma_i}$ when it would otherwise have had the largest deviation. With the estimated coefficient, a simulation gives an increase in the probability of a war of about 0.001. If a war costs about 15 times the per-period profit, the expected future loss is about 0.001×15, roughly 1 to 2 percent of current profit. The estimated trigger is several times too weak to deter cheating, and the precision of the estimates does not allow it to be much stronger. Ellison offers two readings. The firms

Table 13.9: What started the price wars of the JEC?

Panel A. Estimated regimes, Markov model (Table 3)						
Model	1	2	3	4	5	6
Constant	4.63 (0.77)	4.36 (0.77)	3.95 (1.30)	2.96 (0.66)	4.43 (0.81)	4.35 (0.90)
BIGSHARE1	−0.77 (0.49)					
BIGSHARE2		−0.46 (0.39)				
BIGSHAREQ			−0.21 (1.06)			
SMALLSHARE				0.66 (0.89)		
V_{1t}					−4.15 (2.64)	−5.00 (3.15)
U_{1t}						1.17 (1.15)
Panel B. Reported regimes, logit for the onset of a war (Table 4)						
Model	1	2	3	4		
Constant	3.68 (0.65)	3.55 (0.65)	3.25 (0.61)	2.92 (0.57)		
BIGSHARE1	−0.71 (0.46)					
BIGSHARE2		−0.51 (0.39)				
BIGSHAREQ			−0.33 (0.44)			
SMALLSHARE				0.05 (0.37)		

Notes: From Ellison (1994, Tables 3 and 4). Standard errors in parentheses. Coefficients of the logit for $\mathbb{P}(I_{t+1} = 1 \mid I_t = 1, Z_t)$, so a negative coefficient raises the probability that a war begins. In Panel A each model contains all variables of the standard model. Panel B uses Ulen's reported regimes J_t. Means of BIGSHARE1, BIGSHARE2, BIGSHAREQ and SMALLSHARE are 1.09, 1.24, 1.17 and 1.23 (Ellison, 1994, Table 1).

may have reacted to information that the data miss, or to a true trigger that is only correlated with BIGSHARE1. Alternatively, the JEC's responses may have been too weak to sustain a noncooperative equilibrium.

Booms. The basic Rotemberg-Saloner model has perfect information and no regime shifts. It is a model of countercyclical collusion. With imperfect monitoring, its logic implies that a cartel facing a temporary peak in demand lowers its price or makes its trigger more sensitive (p. 45). A boom here is a period in which current demand is high relative to demand over the next fifteen weeks or so, the horizon of a war. Two sources create booms in the JEC data. Serially correlated shocks make a high shock raise demand today by more than in the future. Seasonality makes demand peak in winter, just before the lakes open. Ellison builds an index of the ratio of current demand to expected demand during a subsequent war (p. 46),

$$BOOM_t = K \frac{\exp\left(\alpha_2 LAKES_t + \sum_k \alpha_{2+k} SEAS_{kt} + \rho U_{1,t-1}\right)}{\sum_{s=1}^{52} \left(\hat{p}_{w,t+s} - \hat{p}_{c,t+s}\right) \exp\left(\alpha_2 LAKES_{t+s} + \sum_k \alpha_{2+k} SEAS_{k,t+s} + \rho^{s+1} U_{1,t-1}\right)} - 1. \tag{13.34}$$

Here $\hat{p}_{w,t+s} - \hat{p}_{c,t+s}$ is the additional probability of being in a war s weeks after one begins, taken from the standard model. K is a scaling constant. He adds $BOOM_t I_t$ to the supply relation and $BOOM_t$ to the transition logit. A seasonal-only version and the lagged shock $U_{1,t-1}$ separate the two sources.

The results are imprecise (Table 13.10). The coefficient on $BOOM_t I_t$ implies a collusive price about 3 percent lower when the incentive to deviate is one standard deviation above its mean. Its standard error is almost twice the estimate, so neither procyclical collusion nor a 12 percent reduction can be rejected (p. 47). The demand-shock decomposition is more precise but still insignificant. It implies a 5 percent lower price when $U_{1,t-1}$ is one standard deviation above its mean. The seasonal decomposition shows nothing. In the transition logit, $BOOM_t$

has the wrong sign. Controlling for the innovation V_{1t}, the predictable decline in demand after a positive shock does not cause wars. The seasonal effect has the right sign but is insignificant.

Table 13.10: Booms and collusion in the JEC

Panel A. Supply relation with boom interactions (Table 5)			
	Combined effect	Demand shocks	Seasonal
I_t	0.758 (0.416)	0.712 (0.195)	0.622 (0.119)
$BOOM_t \times I_t$	−0.233 (0.428)		
$U_{1,t-1} \times I_t$		−0.156 (0.164)	
$SEAS_t \times I_t$			0.041 (0.417)
log P in demand	−1.996 (2.055)	−1.594 (0.898)	−1.574 (1.459)
Log likelihood	186.2	187.1	181.2
Panel B. Logit for $\mathbb{P}(I_{t+1} = 1 \mid I_t = 1, Z_t)$ *(Table 6)*			
	Model 1	Model 2	Model 3
Constant	3.64 (0.49)	4.35 (0.90)	3.87 (0.71)
$BOOM_t$	0.36 (1.48)		
U_{1t}		1.17 (1.15)	
V_{1t}		−5.00 (3.15)	
$SEASONAL_t$			−2.51 (3.50)

Notes: From Ellison (1994, Tables 5 and 6). Standard errors in parentheses. Rotemberg and Saloner predict a negative coefficient on the boom interactions in Panel A and negative coefficients on the boom measures in Panel B. Panel A models also include boom terms in the transition logit. Model 2 of Panel B repeats model 6 of Table 13.9.

Ellison's verdict is cautious. The JEC does not support the view that wars occur during booms. The tests have little power, so a small degree of countercyclical pricing or a small rise in the frequency of wars cannot be ruled out. He also notes that a nineteenth-century railroad cartel is perhaps among the least likely places to apply the theory.

Secret price cuts. All the theories predict that members never cut prices in secret. The trade press of the time suggests that some did. The *Daily Commercial Bulletin* of June 16, 1881, for example, reported doubts that a quoted rate on grain to New York was being respected (p. 49). A one-week secret cut would be invisible to an econometrician, as to the JEC itself. If cutting and adherence were both common, however, secret cuts act like an omitted variable that shifts demand upward relative to the official price. Ellison looks for such shifts with hidden demand regimes.

Model 2 adds a dummy REGIME1 to demand (13.31). The high-demand regime occurs with probability r_1 in collusive weeks and never in wars, when firms already price competitively. Model 3 adds two dummies, REGIME1 and REGIME2, for three demand regimes. Under collusion they occur with probabilities r_1, r_2 and $1 - r_1 - r_2$. REGIME1 never occurs in wars, and the other two keep their relative probabilities in both conduct states (Figure 13.4). Ellison writes p_1 and p_2 for our r_1 and r_2. The low regime might reflect bad weather, labor problems or low steamship rates. Since the regimes enter demand, whose error is autocorrelated, the filter runs on pairs of consecutive states (Remark 13.12).

Table 13.11 reports the estimates. Ellison calls the fit almost unreasonably successful. The log likelihood rises from 181.0 to 529.0 and 582.5. Ellison likens the gain to Porter's when he added a second supply regime (p. 51). The comparison is loose, because Porter's figure is not a mixture log likelihood (Section 13.2.6). The t-statistics on REGIME1 are 12.1 and 26.7. In model 2, REGIME1 raises demand by about 55 percent ($e^{0.439} = 1.55$). In model 3, REGIME1

has demand 41 percent above REGIME2, and the low regime has demand 32 percent below REGIME2 ($e^{0.344} = 1.41$ and $e^{-0.384} = 0.68$).

Table 13.11: Hidden demand regimes in the JEC

	Model 2 (Table 7)	Model 3 (Table 7)	Model 3 with trigger test (Table 9)
Demand			
$\log P$ (α_1)	−1.354 (0.711)	−1.587 (0.092)	−1.57 (0.43)
LAKES	−0.222 (0.073)	−0.229 (0.092)	−0.23 (0.06)
REGIME1	0.439 (0.036)	0.728 (0.027)	0.73 (0.04)
REGIME2		0.384 (0.022)	0.38 (0.05)
Supply			
$\log Q$ (β_1)	0.220 (0.153)	0.242 (0.038)	0.24 (0.09)
I_t (β_3)	0.595 (0.079)	0.608 (0.047)	0.61 (0.07)

Collusion continues	0.979 (0.012)	0.976 (0.037)	logit below
War ends	0.061 (0.028)	0.070 (0.076)	0.07 (0.03)
r_1	0.650 (0.071)	0.256 (0.083)	0.26 (0.05)
r_2		0.519 (0.086)	0.52 (0.07)
Logit for collusion continuing			
Constant			5.65 (1.06)
V_{1t}			−3.17 (1.26)
$RSHIFT_t$			−0.48 (1.03)
Other			
$U_{1,t-1}$ (ρ)	0.888 (0.031)	0.947 (0.018)	0.947 (0.02)
Log likelihood	529.0	582.5	584.4

Notes: From Ellison (1994, Tables 7 and 9). Standard errors in parentheses. Seasonal dummies, the constants, the entry dummies and the error covariances are included and not shown. "Collusion continues" and "war ends" are Ellison's q_{123} (or q_{12}) and q_0. $RSHIFT_t = \alpha_{15} REGIME1_t + \alpha_{16}(REGIME2_t - 1)$ is the demand effect of the hidden regimes. Table 9 reports two decimals.

Interpreting the hidden regimes. Ellison warns that the regimes could reflect weather, irregular schedules, steamship competition, mechanical problems, or failures of the functional form (p. 52). He checks three kinds of evidence.

The first is the size and frequency of the implied cuts. Trade-press reports suggest that cuts of 10 to 25 percent were reasonable, and the cartel sometimes went two years between wars, so cuts were not very common (p. 53). In model 2, REGIME1 occurs in 65 percent of collusive weeks, and with an elasticity of 1.35 it would require price cuts of 25 to 30 percent. Ellison rejects it as a measure of secret cuts. In model 3, REGIME1 occurs in 26 percent of collusive weeks, and with an elasticity of 1.59 it requires a cut of about 20 percent. To check, solve $(1 - x)^{-1.587} = e^{0.344}$ for the cut x:

$$x = 1 - \exp\left(-\frac{0.344}{1.587}\right) = 1 - e^{-0.217} = 0.195$$

(our computation). A kernel density of the standard model's demand residuals $\hat{V}_{1t}$ has a second, smaller peak to the right, as occasional price cuts of similar size would produce (Ellison, 1994, Figure 2).

The second is historical evidence on cutting. Ellison codes two indicators from the *Daily Commercial Bulletin*. CUTREPORTED marks the 12 weeks in which an article reported rumors

of secret cuts. CUTLISTED marks the 18 weeks in which the average listed daily price was at least three cents below the official price. Overall, 26 percent of weeks fall in the high-demand regime. One and two weeks after a CUTREPORTED week, the shares are 57 and 66 percent, both significantly higher (Table 8, p. 54). Four weeks after a CUTLISTED week the share is 60 percent, and after a reported war it is 40 to 46 percent at lags of two to four weeks. The pattern fits retaliatory cutting after reports of cheating. About 15 percent of high-demand weeks are attributable to these excess occurrences.

The third is a test of observability. If the hidden regimes were invisible to the JEC, a Green-Porter trigger would respond to total unexpected demand, the innovation plus the regime effect $RSHIFT_t$, with equal coefficients. If the JEC observed the regimes, $RSHIFT_t$ should not matter. In the last column of Table 13.11, V_{1t} has coefficient −3.17 (1.26) and $RSHIFT_t$ has −0.48 (1.03). Equality is rejected at the 5 percent level (p. 56). The high-demand regime mostly reflects factors that the JEC recognized and that did not lead it to start wars. A by-product is that the demand innovation is now a clearly significant trigger, with a t-statistic of about 2.5.

Conclusions. Ellison draws four conclusions (p. 56). Price wars occurred, as earlier work found, but prices were much closer to the monopoly level than previously reported. A model that focuses on transition probabilities finds evidence of trigger strategies, and serially correlated demand lets the trigger be distinguished from the Rotemberg-Saloner prediction. Some secret price cutting occurred, contrary to the literal theory. It was not widespread, and secret cuts account for only a small fraction of the high-demand weeks. The JEC gives no support to the view that booms make wars more likely, although the tests have little power.

13.3.6 Assessment of the JEC evidence

What the JEC shows. Three findings have held up across specifications. First, regime switches are real and large. Prices in cooperative weeks were about 66 percent above war prices, holding demand and cost fixed (Table 13.5), and the estimated regimes match contemporary reports of wars. Second, the timing of wars fits imperfect monitoring. Wars were persistent, they followed unexpected demand innovations and possibly unusual shares, and they did not follow predictable booms. Third, cooperative prices stayed below the static monopoly level. With inelastic demand this follows from Corollary 13.5, and with Ellison's elastic demand it follows from comparing the estimated β_3 with (13.8). Both readings agree with Porter (1983b).

Limits. The evidence has limits, several of them general.

- *Observational equivalence.* By Proposition 13.9, prices and quantities alone cannot separate conduct regimes from cost regimes. The JEC evidence leans on outside information, the trade-press series, to read the regimes as conduct.
- *Measurement.* GR is a polled index that likely misses secret cuts, so the start of wars is measured with error. The prices of lake steamers are missing from demand, which weakens tests based on demand residuals.
- *The regime process.* Porter assumes i.i.d. regimes, which the data reject. Ellison's Markov model fixes this, but the trigger tests rest on six wars, and no specification identifies a trigger strong enough to deter cheating.
- *Functional form.* With latent regimes, identification comes from normality (Proposition 13.8). Ellison's hidden demand regimes show how easily the same machinery finds

additional "regimes" in non-normal residuals.

- *The meaning of θ.* The conduct index depends on the demand elasticity, which moves from 0.74 to 1.80 across specifications, and on the assumption that wars are Bertrand reversions. The collusive margin $1 - e^{-\beta_3}$ is more robust (Remarks 13.6 and 13.7).

Several papers extend the analysis. Lee and Porter (1984) combine the reported series with prices and quantities in a model with imperfect sample separation. Porter (1985) studies the incidence and duration of wars with a two-step approach. He finds no significant evidence that share deviations triggered wars. He does find that large aggregate demand did, but he cannot separate a trigger from a Rotemberg-Saloner effect (Ellison, 1994, p. 39). Hajivassiliou (1989) relates an index of grain production to the probability of being in a war. Berry and Briggs (1988) test the order of the regime process and find the JEC closer to Abreu, Pearce and Stacchetti than to Green and Porter. Together these studies made the JEC the reference case for the econometrics of collusion. The legal cartels of the next section show what records of internal deliberations add to such price-and-quantity evidence.

13.4 Rules, Communication and Price Wars in Other Legal Cartels

The Joint Executive Committee of Section 13.3 shows what prices and quantities can reveal about a legal cartel. Records of a cartel's internal deliberations reveal things that prices cannot. They show how firms designed rules, what they said to one another, how they judged accusations of cheating, and how they responded. This section studies two such records. The first is the Sugar Institute, a trade association of American cane sugar refiners that operated from 1927 to 1936 (Genesove and Mullin, 2001). The second is the bromine cartel of 1885–1914, whose contracts and correspondence survive in the papers of the Dow Chemical Company (Levenstein, 1997). Between the two we place a short link to the price wars of pre-1914 sugar refining. That link illustrates the observational-equivalence problem of Proposition 13.9 with real data.

The two cases speak to the predictions collected in Table 13.1. Theories of collusion under imperfect monitoring predict that firms punish on the basis of noisy public signals and that the punishment is the same whatever the deviation. Both cases agree with Stigler (1964) that detecting secret price cuts was the central problem of the cartel. Both cases disagree with the formal theory about how firms treated the cheating they found.

13.4.1 The Sugar Institute, 1927–1936

The question and the source. How does communication help firms collude? The repeated-game models of Chapter 12 give communication a narrow role. Firms may announce what they observed so that private histories become public, or they may coordinate on one of many equilibria. Genesove and Mullin (2001) study the private discussions of one cartel to see what firms said and why. Their source is unusual. Louis V. Place was vice president of McCahan, a midsize refinery in Philadelphia, "in charge of all activities of the company except production and raw sugar purchases." He wrote over 500 pages of single-spaced notes on the meetings of the Institute's Board of Directors, Executive Committee and Enforcement Committee from January 1929 through mid-1930 (p. 379). He also recorded the informal gatherings after the meetings and private conversations with other refiners. The memos circulated among only some six McCahan executives, so they are candid. Place testified at the trial that he regularly

destroyed them once he received the much less revealing official minutes. Genesove and Mullin supplement the memos with the record of *United States v. Sugar Institute*.

Setting. The Sugar Institute was a *trade association*, an organization of competing firms in one industry. It was formed in December 1927 by 14 firms that owned nearly all the cane sugar refining capacity of the United States. Several years of falling margins and excess capacity preceded it. It operated until 1936, when the Supreme Court ruled its practices illegal. The Institute never fixed prices or allocated market shares, and there was no legal finding that it did. It fixed rules instead. The main principles were stated in a Code of Ethics, and the details were issued as a series of Code Interpretations. The rules covered every aspect of the distribution and marketing of sugar other than the basis price itself. The refiners had the Code vetted by the Department of Justice, which nonetheless prosecuted them. The legal status of such associations was unclear in the 1920s. There were 150 "open price" associations in 1921, and over 400 operated under the National Recovery Administration when the Court decided the case (p. 385, fn. 20).

Measuring performance with direct cost data. Cane sugar refining has a fixed-proportions technology, which gives a direct measure of marginal cost (Section 3.7.3). One pound of refined sugar requires 1.075 pounds of raw sugar. All other variable costs amount to 0.60 cents per pound, or 60 cents per hundred pounds in December 1927 dollars. That is 26 cents in the 1898 dollars of Genesove and Mullin's earlier work.[1] Let p_t^{ref} and p_t^{raw} be the prices of refined and raw sugar in cents per pound. Marginal cost is

$$mc_t = 1.075\, p_t^{\text{raw}} + 0.60. \tag{13.35}$$

Genesove and Mullin define the *proper margin* as the refined price net of the raw sugar it contains,

$$PM_t = p_t^{\text{ref}} - 1.075\, p_t^{\text{raw}}. \tag{13.36}$$

Substituting (13.35) into the Lerner index of Equation (2.6) gives

$$L_t = \frac{p_t^{\text{ref}} - mc_t}{p_t^{\text{ref}}} = \frac{PM_t - 0.60}{p_t^{\text{ref}}}. \tag{13.37}$$

Table 13.12 reproduces their Table 1. Columns (2) to (6) are averages of weekly data from Willett and Gray's trade journal, and all prices are in December 1927 dollars.

The Institute coincided with a sharp rise in margins. Genesove and Mullin report that the proper margin rose by about 20 to 25 cents per hundred pounds over the preceding three years. In Table 13.12, the proper margin averaged 0.78 cents per pound in 1925–1927 and 1.01 cents in 1928–1930. The rise is 0.23 cents per pound, or 23 cents per hundred pounds (our computation). The Lerner index averaged 0.031 in 1925–1927 and 0.080 in 1928–1930, so it rose by a factor of about 2.6 (our computation). This is the "more than doubling" of the Lerner index in the text (p. 381). Figure 13.5 plots column (4) for all 28 years.

The Lerner index uses list prices, and secret discounts were the reason the Institute was founded. Genesove and Mullin argue that this bias strengthens their conclusion. The argument takes one line. Let the average transaction price be $p_t^a = p_t^{\text{ref}} - d_t$, where $d_t \geq 0$ is the average secret discount. Marginal cost is measured directly, so the change in the transaction margin is

$$\Delta\left(p_t^a - mc_t\right) = \Delta\left(p_t^{\text{ref}} - mc_t\right) - \Delta d_t \;\geq\; \Delta\left(p_t^{\text{ref}} - mc_t\right) \quad \text{whenever } \Delta d_t \leq 0. \tag{13.38}$$

[1] McCahan's internal documents put these costs at 63.6 cents per hundred pounds in 1927, against an industry average of 55.3 cents. Genesove and Mullin judge these differences across firms economically slight (p. 381, fn. 9).

Notes: Reproduced from Genesove and Mullin (2001), Table 1 (p. 382). Columns (2) to (6) are weekly averages. Column (2) is PM_t of (13.36) in cents per pound. Column (3) subtracts 0.60, the non-raw-sugar component of variable cost per pound. Column (4) is the ratio of column (3) to the refined price, (13.37). Column (5) is the output of the Atlantic refiners in millions of pounds. Column (6) is the sum of the variable profits of the Atlantic refiners in millions of dollars. Columns (7) and (8) are the annual shares (percent) of domestic beet sugar production and of imported refined sugar in total U.S. consumption. Prices are in December 1927 dollars. The rule marks the formation of the Institute in December 1927. Sources given by the authors: Willett and Gray's *Weekly Statistical Sugar Trade Journal*.

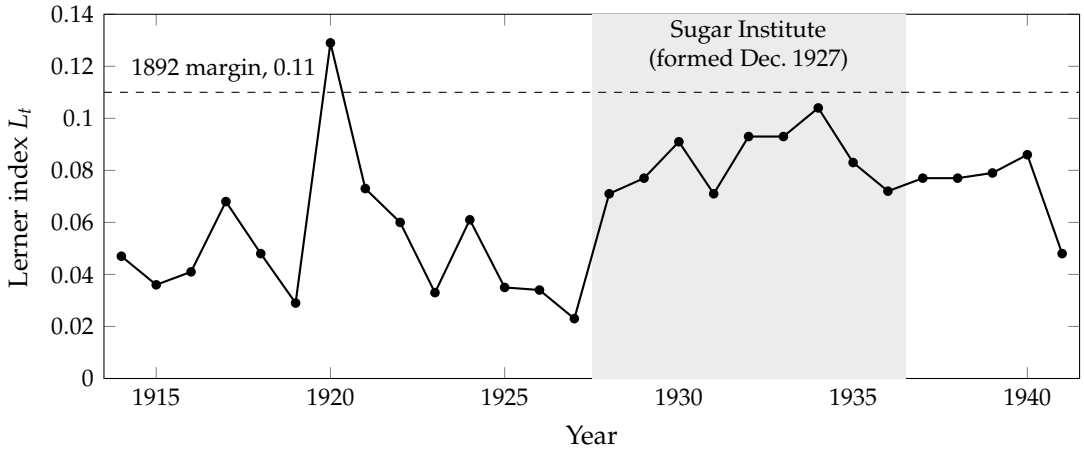

Figure 13.5: Lerner index of cane sugar refining, 1914–1941, computed from direct marginal cost, $L_t = \frac{p_t^{\text{ref}} - 1.075\, p_t^{\text{raw}} - 0.60}{p_t^{\text{ref}}}$. The shaded years are 1928–1936. The dashed line is the 1892 margin, which Genesove and Mullin (2001) propose as a realistic monopoly benchmark. Redrawn from Genesove and Mullin (2001), Table 1, column (4).

If the Institute eliminated secret concessions, or at least did not increase them, the rise in the list margin is a lower bound on the rise in the transaction margin.

How close did the refiners come to monopoly? The inverse elasticity rule of Section 2.2 gives a monopoly Lerner index of $\frac{1}{\varepsilon}$. With the demand elasticity of 1.75 that Genesove and Mullin estimated for 1890–1914, the monopoly Lerner index is $\frac{1}{1.75} = 0.57$, far above anything in Table 13.12. The authors give two reasons for the gap. The growth of beet sugar after the First World War raised the elasticity of demand facing cane refiners, and the refiners wanted to deter foreign and domestic entry. They propose 11 percent as a realistic benchmark. That was the margin in 1892, when both the margin and American Sugar Refining's market share (92 percent) reached their peaks. Over 1928–1935 the Lerner index averaged 0.085 (our computation), about three quarters of that benchmark, as the authors state. The benchmark has a structural reading. If 0.11 were the Lerner index of a firm pricing optimally against its residual demand, the inverse elasticity rule would put that residual elasticity at $\frac{1}{0.11} \approx 9$ (our computation). A perceived elasticity five times the market elasticity is consistent with pricing to limit entry and imports.

Quantities tell the same story more weakly. The output of the Atlantic refiners fell when the Institute began, though only a little, because sugar demand is inelastic. Output kept falling during the Great Depression, but much less than the 24 percent fall in total industrial output (p. 382). Rivals outside the agreement expanded. The share of imported refined sugar, almost all of it Cuban, rose from under half a percent to 6 percent in the Institute's first year and to almost 15 percent in 1933. The Sugar Act of 1934 then cut it to 11 percent by legislative fiat. Coca-Cola, the largest buyer of refined sugar, switched entirely to foreign suppliers. The beet share rose from an average of 15.4 percent in 1924–1927 to 17.7 percent in 1928–1931, but its year-to-year variability prevents a firm attribution to the Institute.

Collusion by rules. Genesove and Mullin describe the Institute as implicit collusion on price combined with explicit collusion on business practices (p. 383). Rule number one required "open prices and publicly announced terms." Prices were posted on the refiners' bulletin boards, the Institute was notified of every change in prices and pricing methods, and changes were announced by 3:00 p.m. These provisions continued existing practice. The more important

existing practice was the *moves system*. An announced price decrease took effect immediately, while an increase took effect only after a day. Buyers purchased a month's supply at a time, so they waited after a decrease until other refiners matched it, which they always did. Reactions often came within minutes. Price competition therefore preceded trade.

Remark 13.16 (Why the moves system leaves only secret deviations). Let N refiners sell a homogeneous good at a common list price p with $c < p \le p^m$, and let industry profit $\pi(p) = (p - c)D(p)$ be increasing on $[c, p^m]$. Suppose that a public price cut to $p' < p$ is matched by every rival before any buyer purchases. Buyers then split equally among the refiners, and the cutter earns $\frac{1}{N}\pi(p')$ in the period. Because π is increasing on $[c, p^m]$,

$$\frac{1}{N}\,\pi(p') < \frac{1}{N}\,\pi(p).$$

A public cut lowers the cutter's own profit. Only a concession that rivals cannot see, and hence cannot match, can raise a refiner's share. This is why the Institute worked to raise the probability of detecting secret concessions and did not try to shorten reaction times (Genesove and Mullin, 2001, pp. 383–384). The model of Section 13.5.1 formalizes this probability.

Almost every contractual term could hide a price cut, so the rules were wide-ranging and detailed. Table 13.13 lists the five rules that Genesove and Mullin examine, the concession each one closed, and the cost it imposed. The Institute also disallowed quantity discounts, allowances for returned sugar bags, long-term contracts and certain credit arrangements. It required refiners to report all sales of damaged sugar, drew up a list of permissible consignment points, and forbade downstream firms to combine brokerage and storage. Enforcing the last rule required private investigation and auditing.

The rules were costly. A monopolist could have discriminated among customers and exploited efficiencies that the rules forbade. When large buyers in Buffalo asked to receive sugar by water barge, even at the higher rail rate, the Institute refused for fear of creating an opportunity for discounts. The move to delivered pricing led refiners to replace brokers in barge transport. Between 1928 and 1931, barge shipments by refiners rose by 400 percent while those by customers fell by two thirds. Large customers denied quantity discounts threatened to integrate backward, as the grocery chain A&P did. The ban on long-term and tolling contracts also sacrificed efficiencies. Place was even prepared to forgo allocating production by cost. He feared that local differences in loading costs would lead to different rates, writing that "those enjoying more economical loading conditions can pocket the profits." The District Court judge put it succinctly (p. 384, fn. 14). The refiners "preferred to have all sugar sold in any given trade areas at precisely the same prices and terms" over economies in distribution.

Genesove and Mullin consider an alternative reading in which the rules suppressed nonprice competition directly. Contractual harmonization usually chose the lower "quality." The grace period was set at 7 days, and the number of consignment points was cut by half. They find this reading incomplete for three reasons. It does not explain many rules, such as the ban on quantity discounts or the notification rules discussed below. The number of sugar grades was never restricted, although grade proliferation was costly to small refiners. Most persuasively, the reading misses the stated intermediate goal of eliminating discrimination among customers, the first principle of the Code of Ethics. They conclude that suppressing nonprice competition complemented harmonization but was not its purpose.

An incomplete agreement and its governance. The initial agreement was incomplete in the sense of the theory of the firm. No one could foresee and enumerate all contingencies. The refiners told the court that the Code "could not be, self-operative" and required "interpretation and

Table 13.13: Sugar Institute rules, the hidden concessions they closed, and their costs

Rule	Concession it closed	Cost or side effect
Water-damaged or frozen sugar	Sound sugar shipped to a favored buyer and invoiced as damaged. Each sale now required "full details of amount, location, reason and price" to be circulated.	Discounts on truly damaged sugar became public.
Credit terms	Varying the grace period that qualified for the customary 2 percent cash discount.	Grace period fixed at 7 days rather than 14.
Storage	Brokers who ran warehouses cut storage charges in place of the sugar price.	Storage first banned in buyers' warehouses, then in broker-affiliated ones as refiners switched.
Delivery time	Letting favored buyers take delivery after the contract date, which saved storage and interest and was a price cut if the basis price rose.	Delivery dates enforced. Weekly reports of undelivered contracts. A secondhand market sold overbought sugar at discounts of 5 to 20 cents.
Freight	Rebates on freight rates that the Interstate Commerce Commission did not regulate, especially private water charters.	Charters registered, uniform rates required, written promises not to rebate. Then delivered pricing with a refusal to sell f.o.b. refinery.

Notes: Compiled from Genesove and Mullin (2001), Sections II, III and VI (pp. 383–387 and 390–392). The organization into columns is ours.

administration and consultation." The weekly meetings completed the contract in three ways. They answered minor questions the Code left open. May damaged sugar be sold under a price guarantee? No. Do 30-day contracts end on the 30th day or on the same day of the next month? The former. They modified rules that proved unworkable. The original policy charged the regulated all-rail rate whatever the mode of transport. This leveraged each refiner's power in its hinterland into contested markets such as the Great Lakes, and cheaper water routes offered too much arbitrage. A later regime of limited differential rates also failed. The refiners then moved to delivered prices with a refusal to sell f.o.b. refinery. The move was presented as independent action. The Place memos show that it was coordinated over several meetings in one week of April 1929. It had been delayed for over a year for fear of the antitrust authorities. Finally, the meetings closed loopholes. Each rule that shut one channel for secret concessions opened another, less effective one, much as taxpayers respond to a new tax rule.

The meetings formalized their decisions as Code Interpretations, which took on a quasi-judicial character. Participants spoke of evidence and precedent. Institute counsel called the Interpretations "absolutely indispensable," since "even national laws must be 'interpreted' by the Courts." Genesove and Mullin argue that legal principles helped complete the contract. One decision covered many later incidents, disputes were minimized, and participants could anticipate one another's responses.

A natural worry is that frequent meetings invite renegotiation out of punishments (McCutcheon, 1997). Genesove and Mullin see no sign of it. The refiners chose weekly meetings and no one proposed meeting less often. Threats were never retracted, and no firm bargained its way out of a punishment (p. 396).

Prior notification. Institute rules required a firm to notify the other members before selling damaged sugar, introducing new private brands, or changing any terms of trade. Firms also notified one another when no rule required it. Revere, a Boston refiner, told the Institute before it considered lowering its rail rates to the water rate. Arbuckle announced a cut in freight rates privately to the members before announcing it publicly. Notification served two purposes. First, it removed the lag before retaliation in nonprice dimensions, complementing open price announcements. Full collusion is possible when firms can respond to deviations before consumers act (Bhaskar, 1989). In the language of Section 13.5.1, notification makes a nonprice change visible with probability one before it can steal customers.

Second, notification served the individual interest of the notifying firm. Some actions are profitable once rivals have responded but steal market share if rivals do not anticipate them. Stealing share risks retaliation. A Godchaux representative praised Savannah, which explained its need to change its business methods at a Board meeting before announcing anything. As a result, its "subsequent announcements, because understood, did not cause any upheavals." Genesove and Mullin describe a two-level agreement. The lower level was a precise set of codes and resolutions. The higher level was an understanding that a refiner could withdraw from a lower-level rule if it first told the others. All the cases they record concern an easing of terms of trade. This distinguishes them from the familiar case of advance notice of price increases, where notice coordinates a move that is profitable only if all firms follow.

Ex post determination of fault. The meetings were also a forum for accusation and rebuttal. In March 1929, American charged Federal with secretly cutting prices by loading barges without charge. The dispute turned on what "f.o.b." meant, and Federal may have believed that other firms loaded barges the same way. As in Green and Porter (1984), the evidence of cheating was ambiguous. In their model the confounding factor is a fall in demand. Here it was a misunderstanding about the terms of the agreement. In other cases it was an external event, such as a shortage of barges or vacuum pans. An accusation could also be factually wrong. An Institute investigator once reported a concession on one barrel of caked sugar as a concession on a much larger amount of powdered sugar.

Genesove and Mullin give two reasons why firms investigated before retaliating. A firm may not have intended to break the agreement, and the Institute let an accused firm prove its innocence on factual or logical grounds. In their words, the Institute "raised the signal-to-noise ratio of indicators of cheating." An accuser acting alone also risked being accused of cheating itself. Evidence that only the accuser could observe was therefore insufficient, and accusers needed evidence that others could verify. In one case an investigator produced an invoice that seemed to show a sale from Godchaux to Edgar, a Detroit broker that also ran storage. Place examined the invoice and judged it part of Godchaux's bookkeeping, and the refiners were notified of "the error which apparently had been made." Corollary 13.20 below shows why lowering the rate of false accusations relaxes the incentive constraint.

Cheating and retaliation. In the theory of implicit collusion, every deviation by a player is treated the same way, whatever its nature or timing. Genesove and Mullin observe something quite different. Firms did cheat. A Detroit chain store received a secret concession when it switched from National to Spreckels. Spreckels overpaid truckers, who then worked a few hours "free" for certain customers. Arbuckle knowingly sold to a dummy corporation that fronted for Edgar. Cheating was worst in the South. Godchaux accepted a contract with a price guarantee for delivery by water barge whose movements it agreed not to trace. Texas City accepted a 42-day contract, and its owner offered to fire his top three executives over it. Colonial offered a 6-cent rebate to large buyers, and in Tampa postdated checks were used to

give credit (p. 390).

Outside the South, none of these violations led to competitive prices as in Green and Porter (1984), let alone to subcompetitive prices as in Abreu et al. (1986). The usual sequence was that fault was determined, the refiner confessed, justified itself or blamed its broker, and the practice stopped. Longer or open violations were matched. When one firm openly lowered its rail rate to the barge rate, the others lowered theirs to the same level. When the Pacific refiners gave a freight allowance, American announced that it would match it. Matching was in degree and in kind. The response stayed within the instrument of the violation, although Bernheim and Whinston (1990) show that punishing across all instruments strengthens collusion. When McCahan concluded that some refiners were not enforcing contract time limits, Place first threatened, and then with others carried out, a refusal to enforce McCahan's terms. Matching was even institutionalized. Each refiner reported its undelivered contracts for each price move, the reports circulated weekly, and an unannounced understanding let all refiners spread deliveries over as many days as the most delayed refiner.

Massive retaliation came only after large-scale cheating in several dimensions, and only in the South. As early as June 1929 an investigator reported the Code "dead in the water" in Texas. C&H refused to discuss any single violation there. It threatened to ask for "the entire suspension of the Code of Ethics in the Texas territory" so that all refiners could "fight fire with fire." Elsewhere in the South, Savannah was dissuaded from resigning by a resolution that allowed members to "meet the competition of Hershey," a Cuban refiner outside the Institute. The condition was that the competitor and the territory be announced to the Institute first. The agreement could be suspended, but only with prior notification.

Genesove and Mullin summarize the contrast in terms of statistical errors. In the Green and Porter equilibrium, firms accept punishing when no one has cheated so that cheating never occurs. The refiners chose the opposite end of the trade-off. They accepted some cheating so as not to punish inappropriately, and they sustained imperfect collusion because wholesale cheating did meet massive retaliation. Two features of the industry help explain this choice. Refiners sold through brokers, who often dealt exclusively with one refiner and earned a fixed commission on every sale. A broker gained much more from stealing a customer than its refiner did. Brokers' cheating added noise to demand and let refiners hide behind their brokers. The same agency relation made punishment costly, since selling agents cannot easily be told to follow one set of rules one day and another the next. Matching also has a known robustness, as in the "tit for tat" strategies of Axelrod (1984), and it fitted the ethic of nondiscrimination in the Code.

What the refiners did not do. In Green and Porter (1984) and its successors, firms infer cheating from movements in market shares, and some models transfer share to firms that lost it. Market-share data were available to the refiners at low frequency, but they rarely used them this way. Genesove and Mullin find only four such incidents in nearly a hundred meetings over 18 months (p. 394). In one, Arbuckle's low share was blamed on its strict contract enforcement, and the possibility that American's advertising was responsible was dismissed because others' sales had not fallen. The reason for a fall in share mattered, unlike in the theory. There was no mechanism for reallocating market shares. American twice proposed market-sharing schemes in 1929, but neither came with an enforcement mechanism and Institute counsel would not allow discussion that "could bring actual results." There were no mergers, and calls for coordinated market withdrawals went unfulfilled. The contrast with the quota-and-transfer cartels of Harrington and Skrzypacz (2011), discussed in Section 13.7, is sharp.

Interpretation, critiques and contribution. The Institute did more than host communication.

It was a neutral party that could audit members and aggregate self-reported statistics into confidential industry totals. Firms could also use it as a scapegoat or a commitment device in bargaining with brokers and buyers. Genesove and Mullin draw three lessons for theory. Collusive agreements are incomplete and need governance. Communication within the agreement is rich, with prior notification and ex post determination of fault. Retaliation is much more restrained than theory predicts, partly because of selling agents' high-powered incentives. They also stress that Stigler's basic insight survives. The rules were built by firms that knew each would later want to undermine them.

The evidence has limits. The notes come from one participant at a midsize refinery and cover 18 months of a nine-year cartel. The performance measures use list prices, so the transaction margin is bounded only from below by (13.38). There is no counterfactual for what prices would have been without the Institute in the Great Depression, and the rise in imports shows that the cartel's market power was limited. Inferring strategies from what participants said requires trusting that they described their reasoning accurately, a premise the authors defend. The forgone efficiencies are public, while those in Athey et al. (2004a) are private information, so that theory cannot explain why the refiners gave them up. Genesove and Mullin's own explanation is that exploiting the efficiencies would have destroyed the homogeneity of practices that made pricing transparent. The paper's contribution is to show that cartels can invest in detection itself, through rules that make contracts comparable and through a forum that judges evidence. It also poses the puzzle of tolerated cheating that Bernheim and Madsen (2017) later addressed (Section 13.7).

13.4.2 Price wars in pre-1914 sugar refining

The same industry provides a test of what price and cost data can say about conduct. Section 3.7.7 analyzes the two post-entry price wars of 1890–1914 studied by Genesove and Mullin (1998). They followed the entry of Spreckels (January 1890 to February 1892) and of Arbuckle and Doscher (September 1898 to April 1900). Conduct is $\theta_t = \theta_0 + (\theta_1 - \theta_0)WAR_t$. Direct cost data give $\theta_0 = 0.129$ and $\theta_1 - \theta_0 = -0.127$ in the published article (Genesove and Mullin, 1998, Table 10), so conduct in the wars was 0.002, essentially competitive. The NBER working paper on file reports 0.11 and -0.09 for the same direct measures (Genesove and Mullin, 1995, Table 14, column (9)). Holding marginal cost fixed across regimes, the nonlinear instrumental-variables estimates detect the fall. With linear demand, $\hat{\theta}_1 - \hat{\theta}_0 = -0.112$ (0.069) when k is estimated and -0.108 (0.051) when $k = 1.075$ is imposed (Table 3.15, Panel A). These two estimates are the same in both versions (working paper, Table 14, columns (3) and (4)).

When the cost intercept may also shift in the wars, the same estimator attributes the wars to falling cost. The estimated cost drop is 10 to 18 cents per hundred pounds and the fall in conduct only 0.015 to 0.024 across demand forms (Genesove and Mullin, 1995, Table 15). Neither difference is significant. This is Proposition 13.9 in real data. Prices and quantities alone cannot separate a switch in conduct from a switch in cost. Prior information that costs were stable, available here from the technology, breaks the tie. The Sugar Institute era of Section 13.4.1 is the same industry a generation later, when the refiners tried to avoid such wars by rules rather than by punishment.

13.4.3 The bromine cartel, 1885–1914

The question. Why do cartels fight price wars? In Green and Porter (1984) and Abreu et al. (1986) (APS hereafter), price wars are equilibrium punishments. Firms cannot see one another's

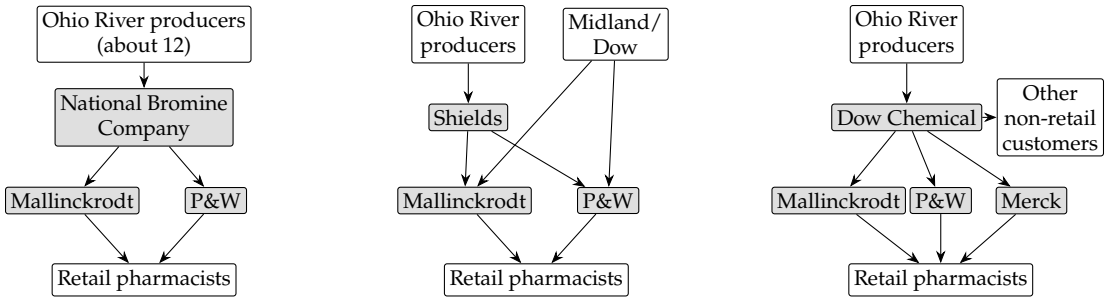
actions, so they punish after unfavorable public signals even though no one cheats (Chapter 12). An older view, associated with Stigler (1964), sees price wars as breakdowns caused by cheating or entry. Levenstein (1997) uses internal documents of the bromine industry, including contracts, correspondence and minutes of negotiations, to ask which view fits. She finds that both do, for different wars. Short, mild wars came from imperfect information. Long, severe wars were part of bargaining over the division of rents.

The industry. Bromine was first produced commercially in 1845. During the Civil War, army medics discovered the sedative properties of potassium bromide, which became a popular patent medicine for headaches and nervous disorders. In Europe bromine was used in aniline dyes, but this use was negligible in the United States until after the First World War. Before 1892 a dozen small firms near the Ohio River, in southeast Ohio and northwest West Virginia, produced all U.S. bromine by pumping and heating underground brine. They sold liquid bromine to *manufacturing chemists*, larger urban firms that converted it into potassium bromide powder and distributed it to pharmacies. The two most important were Powers & Weightman (P&W) and Mallinckrodt Chemical Works. The only other significant producers were German potash mines. They belonged to a bromine cartel allied with the German potash cartel, which had the active support of the German state.

The cartel's organization. Collusive institutions controlled the market for most of 1885–1914, and their form changed three times (Figure 13.6). In 1885 the National Bromine Company (NBC) contracted with the Ohio River firms to buy their entire output for five years at a specified price. The contracts forbade sales to anyone else. Mallinckrodt and P&W in turn agreed to buy all of the NBC's bromine, and they announced the price of potassium bromide in coordination. That price rose from 26.5 cents per pound at the end of 1884 to 34 cents right after the contracts were signed in March 1885. The NBC expired in March 1891. A new pool was not formed until October 1892. W. R. Shields of Columbus, Ohio then contracted with each producer to buy its entire output for five years, and he sold it to Mallinckrodt and P&W. These two firms agreed with the German cartel not to export, and the Germans agreed to buy $25,000 of bromine a year from them.

Herbert Dow's entry changed the industry. His Midland Chemical Company, incorporated in 1892 and merged with the Dow Chemical Company in 1900, used an electrolytic process. It produced bromine and bromide salts continuously and more cheaply, and its minimum efficient scale was at least ten times that of an Ohio River producer. Dow never joined the pool but sold its entire output to Mallinckrodt and P&W under a one-year contract in 1894. The contract limited Midland's output and forbade other sales. Two more one-year contracts followed, then a five-year contract in 1897. In the spring of 1902 Dow ended its cooperation and signed with two rival chemists, Rosengarten & Sons and George Merck & Company. Shields' contracts expired in October 1902 and were not renewed.

International relations followed a similar path. In September 1902 Dow and the German bromine combine agreed in writing that neither would export potassium bromide to the other's home market. Dow confirmed the agreement and soon began exporting to Europe in secret. In 1905 the Germans abrogated their side and entered the U.S. market. A detailed agreement at the end of 1908 ended the resulting war. Dow and the Germans set prices jointly in the United States, Europe and the rest of the world. Dow withdrew from Europe for a payment of $32,000 a year and received a one-third share of sales in the rest of the world, and the Germans withdrew from North America. Dow also signed ten-year contracts to supply all the bromine needs of three manufacturing chemists. It kept the price of potassium bromide below 20 cents for a year and a half, a price at which the Ohio River firms could not sell profitably. In May



(a) NBC pool, 1885–1891 **(b)** Shields pool, 1892–1902 **(c)** After 1910

Figure 13.6: Contractual relationships in the bromine industry. Arrows show the flow of bromine under the contracts. Shaded boxes reproduce the filled boxes of the original figures, which mark the firms at the center of each arrangement. In panel (c), P&W is Powers-Weightman-Rosengarten, as Dow's 1908 contracts name it. Redrawn from Levenstein (1997), Figures 2–4.

1910 it contracted to buy the entire output of all but one of them on a sliding scale tied to the published price. Prices then rose slowly but steadily until the First World War.

Evidence of success. The firms' account books have not survived, so Levenstein assembles indirect evidence. Midland paid its first dividend after its 1894 contract, followed by regular monthly dividends of two to five percent, when annual interest rates in the region averaged less than 6.5 percent. Dow, Shields, Mallinckrodt and the Germans made trans-Atlantic trips for no purpose other than negotiating collusive agreements. Shields supported his family for a decade on the rents he kept for organizing the pool.

Prices give stronger evidence. The price of bromine fell from six dollars a pound before the Civil War to 30 cents in 1875. It fell another 7 percent by 1880 and almost 30 percent more by 1884. The NBC reversed the trend. The average price of potassium bromide during the NBC pool, 34.08 cents, was almost 10 percent above the 31.07 cents of the preceding five years. When the NBC contracts ended in 1891, prices fell by almost 30 percent. The Shields pool averaged 40.88 cents, 65 percent above the 24.75 cents between the two pools (the paper says 60 percent) and 31.6 percent above the prices of 1880–1885. When the Shields contracts expired in 1902, the price fell 43.2 percent in one month. Between 1902 and 1914, the average price was 29.3 cents during cooperation and 16.8 cents otherwise, almost 75 percent higher. The price jumped from 13 to 19 cents on December 21, 1908, the day the Dow and German agreement took effect. The same comparisons hold for prices deflated by a wholesale chemical price index. For example, real prices after 1902 were 74 percent higher during cooperation (WP pp. 9–11, fns. 19–23).

Costs confirm that prices exceeded marginal cost. Dow estimated the marginal cost of a pound of bromine under the Ohio River process at 12 cents. Shields paid the Ohio River producers 16 cents in the first year of his contracts, rising by 2 cents a year to 22 cents. For potassium bromide, Levenstein estimates the cost of manufacture as

$$TC(Q) = Q\,(0.85\,P_{\mathrm{Br}} + 0.6\,P_{\mathrm{KOH}} + C_{\mathrm{mc}})\,. \tag{13.39}$$

Here P_{Br} is the contract price of bromine and P_{KOH} the market price of potash. The term $C_{\mathrm{mc}} = 4$ cents is the chemists' processing and distribution cost per pound. During the Shields pool the price averaged 40.9 cents and this cost 24.1 cents, a markup of almost 70 percent (WP Figure 5). The correlation between changes in price and changes in cost was -0.042. Dow's own cost of potassium bromide was about 8 cents before 1902, while its 1897–1902 contract paid 25 cents. Prices were also more stable under cooperation. They changed on average every

41.1 weeks during cooperation and every 11.5 weeks otherwise. Within the pool years the figures were 35 and 6.8 weeks, and after 1902 they were 64.7 and 17.5 weeks. Many firms announcing prices independently raise the chance that some price changes in a given week.

How close to monopoly. Levenstein compares the pool price with the prices that monopoly, Cournot and perfect competition would produce. She considers three linear inverse demand curves for potassium bromide. Each is consistent with aggregate data and is fitted through the average prices and outputs of two years:

$$\text{I: } P = 78 - 0.077\,Q, \qquad \text{II: } P = 67 - 0.038\,Q, \qquad \text{III: } P = 173 - 0.203\,Q. \tag{13.40}$$

Prices P are in cents per pound and quantities Q in thousands of pounds a year. Demand I uses 1895 and 1909, II uses 1896 and 1908, and III uses 1897 and 1909. Each firm's cost is (13.39) plus a fixed cost, evaluated at $P_{\text{Br}} = 12$ (Dow's marginal cost estimate) and $P_{\text{KOH}} = 4$ (the average potash price in the pool period). Marginal cost is therefore constant at

$$c = 0.85 \times 12 + 0.6 \times 4 + 4 = 10.2 + 2.4 + 4 = 16.6 \text{ cents}. \tag{13.41}$$

Example 13.17 (Reproducing Levenstein's Table 2)**.** Let inverse demand be $P = a - bQ$ and let N firms have constant marginal cost c. Firm i maximizes $(a - bQ - c)q_i$. Its first-order condition is

$$a - bQ - c - b\,q_i = 0.$$

In a symmetric equilibrium $q_i = \frac{Q}{N}$. Substituting,

$$a - c = bQ\left(1 + \frac{1}{N}\right) \quad \Longrightarrow \quad Q = \frac{N}{N+1}\,\frac{a-c}{b}, \qquad P = a - bQ = \frac{a + Nc}{N+1}.$$

For Demand I, $\frac{a-c}{b} = \frac{78-16.6}{0.077} = 797.4$ thousand pounds, the competitive output. Monopoly ($N = 1$) gives $Q = 398.7$ and $P = \frac{78+16.6}{2} = 47.3$ cents. Duopoly gives $Q = 531.6$ and $P = \frac{78+33.2}{3} = 37.1$. Twelve firms, about the number active in 1891, give $Q = 736.1$ and $P = \frac{78+199.2}{13} = 21.3$. Competition gives $P = c = 16.6$. These are exactly the entries of Table 13.14.

Table 13.14: Monopoly, Cournot and competitive outcomes for potassium bromide

	Demand I			Demand II	Demand III
Number of firms	q_i	Q	P	P	P
1 (joint maximum)	398.7	398.7	47.3	41.8	94.8
2	265.8	531.6	37.1	33.4	68.7
12	61.3	736.1	21.3	20.5	23.6
∞		797.4	16.6	16.6	16.6
Pool average price, 1885–1902, excluding price wars: 38.6 cents					

Notes: Reproduced from Levenstein (1997), NBER working-paper version, Table 2. Quantities in thousands of pounds a year, prices in cents per pound. Demand functions in (13.40), marginal cost 16.6 cents from (13.41). The Demand III entry for 12 firms is printed as 23.6. The printed quantity of 711.2 and the formula of Example 13.17 both give $P = \frac{173+199.2}{13} = 28.6$ (our computation), so 23.6 appears to be a misprint.

The pool average of 38.6 cents lies between the twelve-firm Cournot price of 21.3 and the monopoly price of 47.3 under Demand I. Levenstein concludes that the pool raised prices

above competitive and usually above Cournot levels, without reaching monopoly. Collusive prices ranged from 19 to 46 cents. The conduct parameter of Section 2.7 summarizes the pool price in one number. With linear demand the supply relation is $P = c + \theta bQ$, so $bQ = \frac{a-c}{1+\theta}$ and $P = \frac{\theta a+c}{1+\theta}$. Solving for θ at the pool price gives

$$\theta = \frac{P-c}{a-P} = \frac{38.6-16.6}{78-38.6} = \frac{22.0}{39.4} = 0.56$$

(our computation). This lies between symmetric Cournot duopoly ($\theta = \frac{1}{2}$) and joint profit maximization ($\theta = 1$).

Levenstein also measures the welfare cost of the pool. At 38.6 cents, Demand I gives an output of $\frac{78-38.6}{0.077} = 511.7$ thousand pounds and revenue of \$197,500 (our computation), matching the \$197,516 she reports. She reports a deadweight loss of \$44,568 a year, less than six hundredths of a cent per person in 1900. The loss is about 23 percent of industry revenue (our computation), although the paper says about 25 percent. The triangle between Demand I and the marginal cost of (13.41) is smaller. It equals $\frac{1}{2}(38.6-16.6)(797.4-511.7) = 3{,}143$ thousand cent-pounds, or about \$31,400 (our computation).[2]

Testing the order of the regime process. Green and Porter's trigger strategies imply wars of fixed length $T-1$, so the regime process is Markov of order $T-1$. In APS the length of a war is random and the regime follows a first-order Markov process. Levenstein applies the test of Berry and Briggs (1988), described in Section 13.2.6, to two regime series for 1885–1914, one weekly and one monthly. Each series sets $I_t = 1$ when the firms collude and $I_t = 0$ otherwise. The series come from reports of collusive activity in the *Oil, Paint and Drug Reporter* and from Dow's papers, and prices were not used to build them. She did not estimate regimes by switching regressions, as Porter (1983a) did. Demand shifted with regime changes because buyers speculated on whether a break in prices would last, so the supply relation was not stable across regimes (WP p. 16, fn. 35).

The statistic is W of (13.28), which compares the conditional frequencies $\hat{p}_h$ across histories h that share the same last period. With a single restriction it reduces to a squared t-statistic for the difference of two frequencies. In the monthly two-period test, the histories $(I_{t-2}, I_{t-1}) = (0,0)$ and $(1,0)$ have $\hat{p} = 0.068$ with $N = 73$ and $\hat{p} = 0.167$ with $N = 6$. (Levenstein's tables list histories in the order $(t-1, t-2)$.) The statistic for their equality is

$$W = \frac{(0.068-0.167)^2}{\frac{0.068\times 0.932}{73} + \frac{0.167\times 0.833}{6}} = \frac{0.00980}{0.00087 + 0.02318} = 0.408,$$

which reproduces her Table 3 (our computation). Levenstein treats a restriction as untestable when one of its cells has $\hat{p}_h \in \{0,1\}$, and hence zero estimated variance (WP p. 17). She drops such restrictions. In the monthly series this leaves one restriction, hence one degree of freedom. In the weekly series every restriction involves a degenerate cell, so she reports no statistic. For those cells she computes instead the probability, under the first-order null, of the run that occurred. For example, six continued weeks of collusion after a collusive week have probability $0.994^6 = 0.965$ when the continuation probability is 0.994. No such probability falls below 0.68.

Table 13.15 collects the results. First order cannot be rejected against two- or three-period alternatives, with p-values of 0.52 and 0.55. History independence is rejected overwhelmingly against a one-period alternative. A second test compares the distribution of war durations with

[2] Her figure is matched by a marginal cost of about 12.4 cents (our computation). The paper does not state which cost benchmark the deadweight loss uses.

Table 13.15: The regime process of the bromine cartel

	Weekly series	Monthly series
Panel A. Transition probabilities (Table 5)		
$\mathbb{P}(I_t = 1 \mid I_{t-1} = 1)$	0.995	0.978
periods with $I_{t-1} = 1$	1,195	275
$\mathbb{P}(I_t = 1 \mid I_{t-1} = 0)$	0.017	0.076
periods with $I_{t-1} = 0$	394	79
W for history independence, 1 df	18,139.1	844.0
Implied mean collusive spell (our computation)	200 weeks	45.5 months
Implied mean price war (our computation)	58.8 weeks	13.2 months
Panel B. First order against higher order (Tables 3 and 4)		
Two-period alternative, W (p-value)	not computable	0.408 (0.52)
Three-period alternative, W (p-value)	not computable	0.358 (0.55)
Panel C. Kolmogorov-Smirnov test of war durations (Table 6)		
Statistic d_6	0.352	0.340
Rejection threshold at the 20 percent level	0.41	0.41

Notes: From Levenstein (1997), NBER working-paper version, Tables 3–6. Levenstein drops every restriction that involves a cell with zero estimated variance. In the weekly series every restriction does, so the weekly two- and three-period tests are not computable. Levenstein reports "significance" levels of 0.477 and 0.450, which are one minus the p-values shown. Mean spells use Lemma 13.13, for example $\frac{1}{1-0.995} = 200$ and $\frac{1}{0.017} = 58.8$.

the geometric distribution implied by a first-order process. With the weekly exit probability 0.017, the probability that a war has ended within t weeks is $F(t) = 1 - (1 - 0.017)^t$. The six wars lasted 6, 12, 21, 22, 82 and 201 weeks. The Kolmogorov-Smirnov statistic is the largest gap between this F and the empirical distribution. It occurs at $t = 22$, where four of six wars have ended,

$$d_6 = \frac{4}{6} - \left[1 - (0.983)^{22}\right] = 0.667 - 0.314 = 0.352$$

(our computation reproduces her statistic). This is below the 20 percent threshold of 0.41, so the first-order model is not rejected. The mean of the six durations, 57.3 weeks, is close to the predicted 58.8 weeks.

These tests have little power. Six wars cannot distinguish a geometric distribution from many alternatives, and the mean duration is driven by one war of 201 weeks. A geometric distribution with mean 58.8 weeks has a median of about 40 weeks, against an observed median of 21.5 weeks (our computation). Levenstein's conclusion from the statistics is modest. Like Berry and Briggs (1988) for the Joint Executive Committee, she finds the bromine regimes closer to APS than to Green and Porter. The historical record then raises serious doubts about both.

The six price wars. The trade press announced six price wars, three before Dow's entry and three after it. Table 13.16 reproduces Levenstein's comparison. An optimal APS punishment is the same after any history, prescribes the same behavior in every punishment period, and is the worst equilibrium punishment. None of these holds. The initial drop ranged from 0 to 15 cents, or 0 to 50 percent (1 to 15 cents in the five wars with an initial drop). Prices stayed flat in the first two wars but spiralled down for 73 and 149 weeks in Pool III and Dow III. The lowest prices ranged from 32.5 to 13 cents. Only Pool III and Dow III reached the one-shot Cournot level of Table 13.14, and no war pushed price below marginal cost.[3]

[3] In Dow III the price fell to 13 cents, below the twelve-firm Cournot prices of Table 13.14. By 1905 Dow produced

Table 13.16: Characteristics of the bromine price wars

	Pool I 1886–1887	Pool II 1888	Pool III 1891–1892	Dow I 1902	Dow II 1903	Dow III 1905–1908
Initial drop (cents)	2	1.5	1	4	0	15
Initial drop (%)	6.0	4.4	3.0	9.1	0	50
Total drop (cents)	2	1.5	13	19	0	17
Total drop (%)	6.0	4.4	39.4	43.2	0	56.7
Duration (weeks)	22	12	82	6	21	201
Weeks to trough	1	1	73	6	0	149
Low price (cents)	32	32.5	20	25	25	13
Initial cause	Germans cut price to force U.S. firms out of Europe	Germans believe U.S. firms export to Europe	NBC expires, dispute over new pool terms	Dow signs with non-pool distributors	Dow tries to raise price, pool distributors refuse	Germans respond to Dow's entry into Europe
Central cause	Coordination	Information	Coordination	Both	Unclear	Both

Notes: Reproduced from Levenstein (1997), NBER working-paper version, Table 7. All prices are for potassium bromide from the *Oil, Paint and Drug Reporter*. Price-war periods were determined from reports in that journal and internal documents, independently of prices. "Unclear" renders the table's question mark.

Two kinds of price war. Levenstein attributes the differences to different causes. Pool War II and Dow War I came from imperfect information. In 1888 the Germans saw bromides imported into their markets and took them as a sign that Mallinckrodt and P&W had exported in violation of their agreement. It is not clear whether the Germans were mistaken or whether customers outside the agreement resold bromine. In 1902 Mallinckrodt and P&W read Dow's contracts with Rosengarten and Merck as a sign that Dow would undercut the pool. They cut their price as soon as the Shields contracts expired. Both wars were short and ended after an exchange of letters reaffirming the commitment not to compete on price. After Dow War I the firms adopted a new device, pricing at the price announced in the *Oil, Paint and Drug Reporter*, to prevent further misunderstandings. Neither war took prices to Cournot levels.

Levenstein explains why these wars were mild. More severe punishments would not have been renegotiation-proof. Members discounted threats to price below marginal cost. Dow's executives assessed the credibility of each threat and demanded verification of the inventories that Mallinckrodt and P&W claimed to hold. Threats nonetheless mattered. In December 1892 Shields wrote to Dow that his contracts gave him the right to annul them "should a new producer of bromine appear." Midland then agreed to restrict its output and sell only to Mallinckrodt and P&W. Between 1894 and 1896 Midland's quota rose from 150,000 to 200,000 pounds a year, while its capacity exceeded 350,000 pounds. Midland accepted a five-year contract limiting it to 200,000 pounds in 1897. It accepted largely because it believed the chemists held 800,000 pounds of bromine, which they threatened to sell if Midland did not cooperate.

Pool War III and Dow War III were different. They were prolonged by information problems, such as the Germans' ignorance of Dow's costs, but did not result from them. Firms publicly announced that they would sell below the old collusive price, and everyone understood the announcements as moves in a renegotiation of the division of rents. In Dow War III the Germans offered bromides in New York at 15 cents, half the market price. Dow withdrew from the U.S. market and sold its entire output abroad, a response the Germans had not anticipated. The war lasted until prices reached all-time lows and Dow's representatives had made three trans-Atlantic trips. Dow learned the German "Queensbury rules" of commercial warfare during the negotiations. One rule gave "the firm that shows their ability to get the market in a fight" the same share in the next truce (WP p. 24). With shares in the next truce tied to shares during the war, prices spiralled down. In these wars the price war itself shaped the next collusive equilibrium. It was not a punishment that restored the old one.

Learning to avoid price wars. The 1908 agreement between Dow and the Germans included price-war punishments, but they were never used. When cheating was suspected, the parties identified the most likely culprit, sometimes by chemical analysis of the bromide. The culprit then made a cash side payment based on a low estimate of its gain. Such firm-specific transfers sustain more profitable equilibria than common price wars when outcomes reveal who deviated (Abreu et al., 1990; Fudenberg et al., 1994). Levenstein offers two reasons for the change. The firms learned, having started from the price-war punishments common in other pools of the period. The number of parties also fell and their identities stabilized, which made it easier to identify a cheater and more worthwhile to invest in information. Genesove and Mullin cite the tit-for-tat clause in the Dow and German agreement as a parallel to the Sugar Institute's matching. The transfers anticipate those of Harrington and Skrzypacz (2011).

Assessment. Figure 13.7 shows the episodes. The study's strength is its sources. The

more than half of U.S. output at a marginal cost below 10 cents, so the table's Ohio River costs no longer applied (WP fns. 38–39).

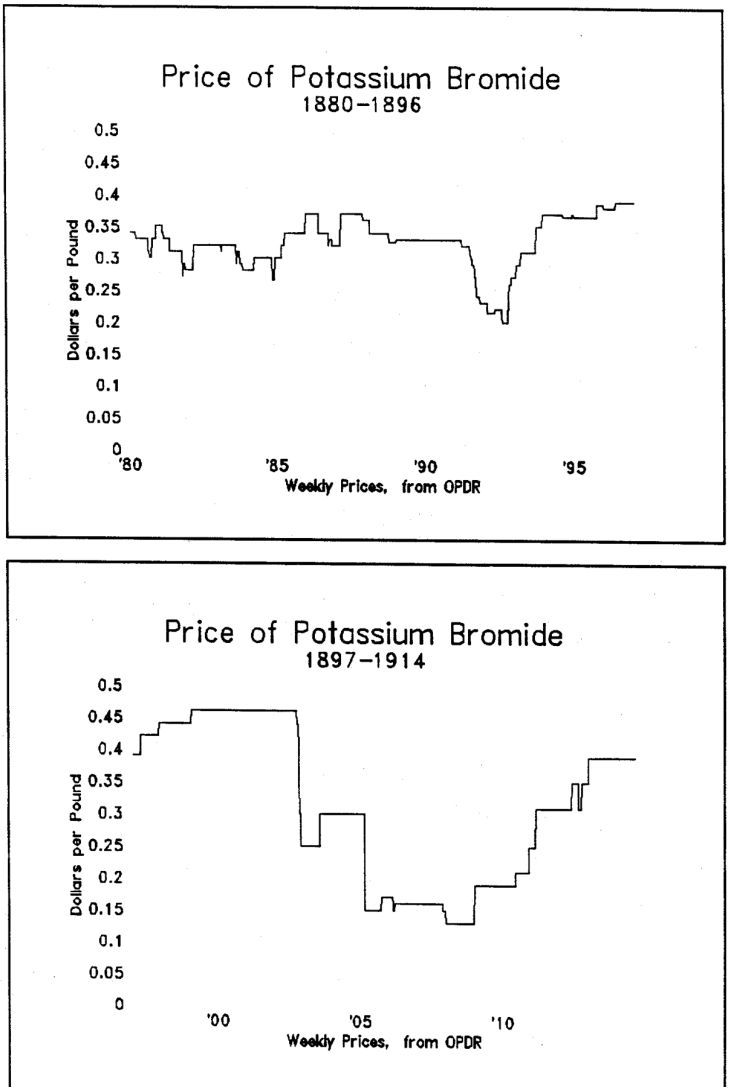


Figure 13.7: Weekly price of potassium bromide in dollars per pound, 1880–1896 (top) and 1897–1914 (bottom), from the *Oil, Paint and Drug Reporter*. The drop of 1891–1892 is Pool War III, the collapse of 1902 is Dow War I, and the long trough of 1905–1908 is Dow War III. Source: Levenstein (1997), Figure 1 (NBER working-paper version).

regime series and the causes of each war come from documents written by the participants, independently of prices. Its quantitative parts are weaker. Each demand curve is fitted through two years of aggregate data. Costs come from Dow's estimates of Ohio River costs, and the deadweight-loss figure cannot be reproduced from the stated cost. The statistical tests rest on six wars. The paper's contribution is conceptual. Some price wars fit equilibrium punishment under imperfect monitoring, but they were mild because severe punishments are not credible. Other price wars were bargaining over the terms of the next agreement, and their severity reflected the stakes of that bargaining.

13.5 Information, Transparency and Coordination

The Sugar Institute shows firms investing in the detection of secret price cuts. This section asks the same question from the policy side. What happens when an outside body makes prices more transparent, or when firms use an information system to signal intentions? We first derive the basic theoretical result, which formalizes Stigler (1964). We then study three cases. Danish authorities published firm-specific concrete prices and prices rose (Albæk et al., 1997). The U.S. Department of Justice restricted how airlines could communicate through their fare-publishing system, with temporary effects (Miller, 2010). Universities agreed on financial aid formulas, and their average prices did not change (Carlton et al., 1995).

13.5.1 Transparency and the incentive constraint

We embed imperfect detection in the Bertrand supergame of Chapter 12. The detection probability is a reduced-form summary of everything that lets firms infer secret price cuts, such as their own sales, the trade press, published prices or audits.

Assumption 13.18 (Bertrand supergame with imperfect detection)**.**

(i) There are $N \geq 2$ firms selling a homogeneous good at constant marginal cost c. Industry profit $\pi(p) = (p - c)D(p)$ is maximized at p^m, and $\pi^m = \pi(p^m) > 0$.

(ii) In each period $t = 1, 2, \ldots$ firms set prices simultaneously. The lowest price serves the whole market, and tied firms split it equally. Firms maximize discounted profit with discount factor $\delta \in (0, 1)$.

(iii) Prices are not publicly observed. At the end of each period a public signal $z_t \in \{0, 1\}$ is realized. If some firm priced below p^m, then $z_t = 1$ with probability $\mu \in (0, 1]$. If all firms priced at p^m, then $z_t = 1$ with probability $\mu_0 \in [0, \mu)$.

(iv) A firm's information about rivals' prices is summarized by the history of public signals.

We call μ the *detection probability* and μ_0 the *false-alarm probability*. Consider the *public grim-trigger strategy*: charge p^m in period t if $z_s = 0$ for all $s < t$, and charge c otherwise. Pricing at c forever is a Nash equilibrium of every subgame that follows a signal, because each period's static Bertrand game has the equilibrium $p = c$ with zero profit.

Proposition 13.19 (Transparency facilitates collusion)**.** *Under Assumption 13.18 with $\mu_0 = 0$, the public grim-trigger strategy is a subgame perfect equilibrium if and only if*

$$\delta \;\geq\; \underline{\delta}(\mu) = \frac{N - 1}{N - 1 + \mu}. \tag{13.42}$$

The threshold $\underline{\delta}(\mu)$ is strictly decreasing in μ and strictly increasing in N. It equals $1 - \frac{1}{N}$ when $\mu = 1$ and tends to 1 as $\mu \to 0$.

Proof. After a signal, the strategies prescribe static Nash play forever, which is subgame perfect. On the collusive path we use the one-shot deviation principle (Chapter 12). On the path each firm earns $\frac{\pi^m}{N}$ per period, so the value of collusion is

$$V = \frac{\pi^m}{N(1-\delta)}.$$

A one-shot deviation to a price above p^m earns zero today and does not change the signal, so it is not profitable. A deviation to $p < p^m$ captures the market and earns $\pi(p)$, whose supremum over $p < p^m$ is π^m. Tomorrow the signal reveals the deviation with probability μ, after which the deviator earns zero forever. With probability $1 - \mu$ the deviation goes unnoticed and collusion continues with value V. Since the supremum of deviation payoffs is approached but not attained, no deviation is profitable if and only if

$$V \;\geq\; \pi^m + \delta(1-\mu)\,V.$$

Substitute V:

$$\frac{\pi^m}{N(1-\delta)} \;\geq\; \pi^m + \delta(1-\mu)\,\frac{\pi^m}{N(1-\delta)}.$$

Multiply both sides by $\frac{N(1-\delta)}{\pi^m} > 0$:

$$1 \;\geq\; N(1-\delta) + \delta(1-\mu).$$

Rearrange:

$$1 - \delta + \delta\mu \;\geq\; N - N\delta \quad\Longleftrightarrow\quad \delta\,(N - 1 + \mu) \;\geq\; N - 1.$$

Since $N - 1 + \mu > 0$, this is (13.42). Differentiating, $\frac{\partial \underline{\delta}}{\partial \mu} = -\frac{N-1}{(N-1+\mu)^2} < 0$ and $\frac{\partial \underline{\delta}}{\partial N} = \frac{\mu}{(N-1+\mu)^2} > 0$. The limits follow by substitution. □

Figure 13.8 plots the threshold. Detection matters most when it is poor. With $N = 2$, raising μ from 0.2 to 0.4 lowers the threshold from 0.83 to 0.71, while raising it from 0.8 to 1 lowers it only from 0.56 to 0.50.

False alarms make collusion harder because they end collusion on the equilibrium path. This lowers the value of colluding, and with it the loss that a deviator suffers when caught.

Corollary 13.20 (False alarms)**.** *Under Assumption 13.18 with $\mu_0 \in [0, \mu)$, the public grim-trigger strategy is a subgame perfect equilibrium if and only if*

$$\delta\,(N - 1 + \mu - N\mu_0) \;\geq\; N - 1. \tag{13.43}$$

Collusion at p^m is therefore sustainable for some $\delta < 1$ if and only if $\mu > N\mu_0$, and then the threshold is $\frac{N-1}{N-1+\mu-N\mu_0}$. When $\mu_0 > 0$, collusion on the equilibrium path lasts a geometric number of periods with mean $\frac{1}{\mu_0}$.

Proof. On the path a false alarm occurs with probability μ_0 each period. The value of collusion solves $V = \frac{\pi^m}{N} + \delta(1-\mu_0)V$, so

$$V = \frac{\pi^m}{N\left(1 - \delta + \delta\mu_0\right)}.$$

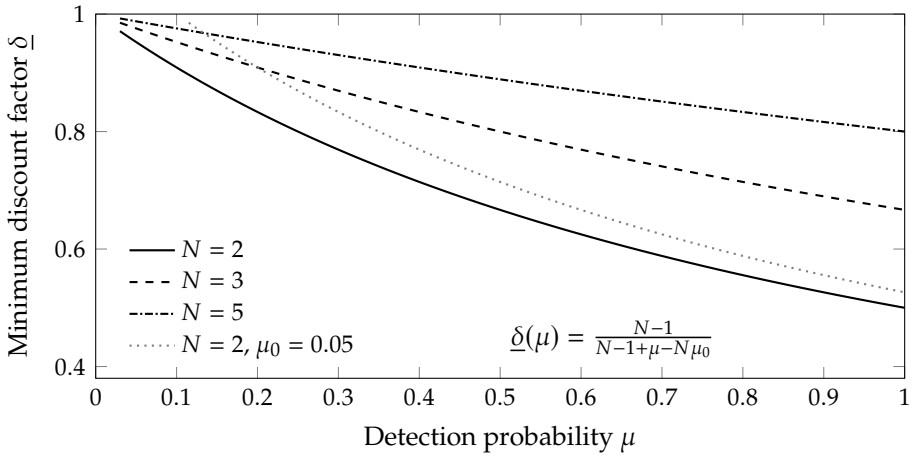

Figure 13.8: The minimum discount factor that sustains collusion at the monopoly price as a function of the detection probability μ, from Proposition 13.19 ($\mu_0 = 0$) and Corollary 13.20 (gray dotted curve, $\mu_0 = 0.05$). With $\mu = 1$ and $\mu_0 = 0$ the threshold is $1 - \frac{1}{N}$. False alarms shift the curve up, and with $N = 2$ collusion is impossible unless $\mu > 2\mu_0 = 0.1$.

A deviation earns at most π^m today and V tomorrow with probability $1 - \mu$. The incentive constraint is $V \geq \pi^m + \delta(1-\mu)V$, or $V(1 - \delta + \delta\mu) \geq \pi^m$. Substituting V and multiplying by $\frac{N(1-\delta+\delta\mu_0)}{\pi^m}$ gives

$$1 - \delta + \delta\mu \;\geq\; N\left(1 - \delta + \delta\mu_0\right) \quad\Longleftrightarrow\quad \delta\left(N - 1 + \mu - N\mu_0\right) \;\geq\; N - 1,$$

which is (13.43). If $\mu > N\mu_0$, the coefficient on δ exceeds $N - 1 > 0$, and the threshold lies below 1. If $\mu \leq N\mu_0$, the left side is at most $\delta(N-1) < N - 1$ for every $\delta < 1$, so no discount factor works. The duration statement follows from Lemma 13.13 with a per-period exit probability of μ_0. □

Remark 13.21 (Relation to Green and Porter). Set $N = 2$ and $\mu = 1$, and let μ_0 be the probability of a zero-demand period in the Bertrand version of Green and Porter (1984). A firm then always sees zero sales after a rival's undercut, and sees zero sales with probability μ_0 on the path. Condition (13.43) becomes $\delta(2 - 2\mu_0) \geq 1$, or $\delta(1 - \mu_0) \geq \frac{1}{2}$. This is the condition for collusion with permanent reversion in that model (Chapter 12). Profits there are scaled by the probability of positive demand, and the scale cancels from the incentive constraint. There the optimal cartel shortens punishments to limit the cost of false alarms. The Sugar Institute lowered μ_0 directly, by verifying accusations before anyone retaliated.

Remark 13.22 (Transparency to buyers). Publication informs buyers as well as sellers. Better-informed buyers move faster to a price cutter, which raises the payoff from a secret cut. Suppose a secret cut captures only a fraction $\omega \in [\frac{1}{N}, 1]$ of the market, so a deviator earns $\omega\pi^m$. With $\mu_0 = 0$ the incentive constraint becomes $\frac{\pi^m}{N(1-\delta)} \geq \omega\pi^m + \delta(1-\mu)\frac{\pi^m}{N(1-\delta)}$. The same algebra as in the proof of Proposition 13.19 gives

$$\delta \;\geq\; \frac{N\omega - 1}{N\omega - 1 + \mu}.$$

This threshold rises with ω and falls with μ. A policy that raises both ω and μ has an ambiguous effect, so whether transparency raises or lowers prices is an empirical question. Stigler (1964)

made the same point. The more buyers know about prices, the more customers a secret cut attracts and the faster it is detected. Transparency can also help firms agree on a focal price, as the bromine firms did when they adopted the trade-journal price after Dow War I.

13.5.2 Government-assisted coordination: Danish ready-mixed concrete

The question. Albæk et al. (1997) study a natural experiment in transparency. Did the publication of firm-specific transaction prices by a competition authority lower prices, as the authority intended, or did it help firms coordinate?

The policy. The Danish Competition Act of 1990 stated its purpose as promoting competition "through the largest possible transparency of competitive conditions." Unlike U.S. and EU law, the Act rested on abuse control. It had no per se prohibitions, and the authority intervened case by case. A *per se* prohibition makes conduct illegal without any inquiry into its effects. Under the *rule of reason*, a court weighs the conduct's harm to competition against its claimed benefits. The Competition Council interpreted the Act to mean that suspected abuses such as oligopolistic coordination should be countered by more transparency. The premise was that firm-specific price information lets buyers shop around and so pushes prices down.

The product and the market. Ready-mixed concrete is a mixture of cement, gravel, sand and water, and its strength is measured in megapascals (MPa). A given grade is homogeneous, and different grades are imperfect substitutes. The study covers a weak grade (10 MPa), used for foundations of single-family houses, and a strong grade (25 MPa), used for staircases. Concrete travels in mixer lorries holding at most six cubic metres. It can stay in a lorry for only about two hours, so it normally travels at most about twenty miles. Denmark had 115 production sites. The two main producers were Unicon, owned by the only Danish cement producer, and 4K, and the remaining capacity belonged to independent local firms. In 1987 the national four-firm concentration ratio was 57 percent, with Unicon at 37 percent and 4K at 11 percent. Two years later Unicon's share reached 43 percent after it acquired the third-largest firm. Within a radius of 20 km of a plant, many local markets were monopolies, and the average share of the largest firm was about 70 percent. Typically fewer than five sites could serve a given customer. Pricing combined rigid, publicly posted list prices with large confidential discounts.

The intervention and the data. In October 1993 the Council decided to sample invoice prices from 18 sites and publish them in its newsletter, roughly once a quarter. The sites were in three regions, Copenhagen (7 sites), Aarhus (6) and Northern Jutland (5). For each site and grade the Council published the list price, the average price and the average of the five lowest prices in the first month of a quarter. Prices appeared with a lag of about three months. The data cover the four quarters of 1994 and the first three of 1995, seven observations per site. Table 13.17 gives the timeline. The two dominant firms had almost identical list prices in each region. They set the highest list prices and gave the largest discounts. Average discounts were 25 to 26 percent of list for 10 MPa and 27 to 31 percent for 25 MPa. Maximum discounts ranged from 25 percent in Northern Jutland to 38 percent in Aarhus.

The main finding. Figure 13.9 shows the national indices of average transaction prices for the two grades, weighted by the firms' turnover. Prices rose sharply over the first two to three quarters of 1994. According to the Council's reports, the weighted average increase across the two grades was 19 percent between January and October 1994. Prices then levelled off. Over the first three quarters of 1994, consumer prices rose 1.9 percent, wholesale prices 1.6 percent, and import prices of unprocessed raw materials 1.1 percent. An index of residential

Table 13.17: Timeline of the Danish concrete price publication

Date	Event
1990	Competition Act adopts the transparency principle
October 1993	Competition Council decides to collect and publish invoice prices
April 8, 1994	January 1994 prices published
July 5, 1994	April 1994 prices published
January to October 1994	Weighted average price of the two grades rises 19 percent
April 1996	Last publication (November 1995 prices)
December 1996	Council decides to publish no more concrete prices
May 30, 1997	New competition law drops the emphasis on transparency

Notes: From Albæk et al. (1997), pp. 430–433 and 440–441.

construction costs barely moved. The unit value of all concrete produced and the unit value of cement, the main input, show nothing like the rise in the published prices.

The comparison is a before-after design with an aggregate benchmark. Let p_t be the published price index and p_t^{b} a benchmark index that captures costs and general inflation. The implicit estimate of the effect of publication is

$$\hat{\tau} = \left(\ln p_1 - \ln p_0\right) - \left(\ln p_1^{\mathrm{b}} - \ln p_0^{\mathrm{b}}\right), \tag{13.44}$$

with period 0 in January 1994 and period 1 in October 1994. With a 19 percent price rise and consumer prices as the benchmark, $\hat{\tau} \approx \ln 1.19 - \ln 1.019 = 0.155$, or about 17 percent (our computation). Interpreting $\hat{\tau}$ as a causal effect requires that, without publication, concrete prices would have moved with the benchmark. The rest of the paper defends this assumption.

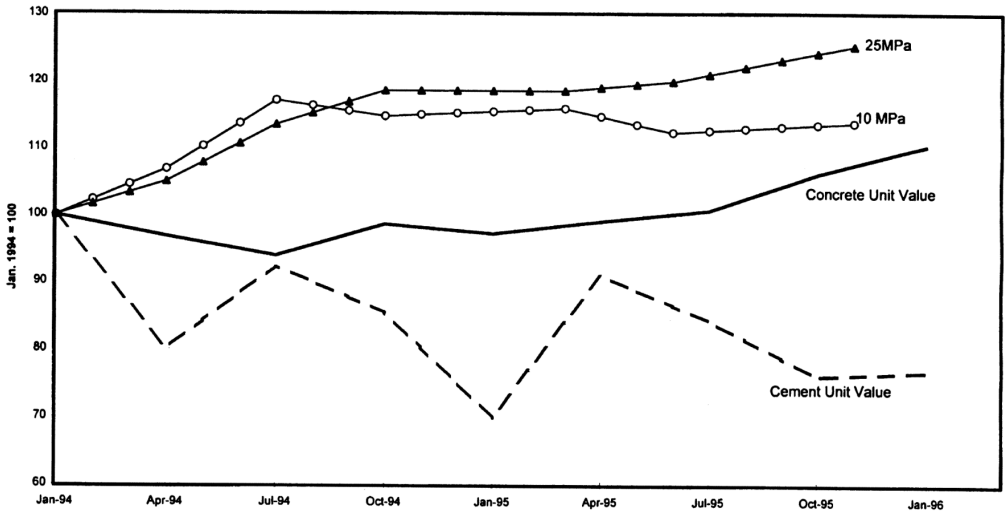

Figure 13.9: National price indices for ready-mixed concrete (January 1994 = 100). The marked lines are the published average transaction prices of 10 MPa and 25 MPa concrete. The solid line is the unit value of all concrete produced and the dashed line the unit value of cement. Source: Albæk et al. (1997), Figure 1 (unit values from Danmarks Statistik, published prices from the Competition Council).

Ruling out competitive explanations. In a price-setting oligopoly with capacity constraints, prices

could rise because demand grew, capacity fell or input prices rose. The authors examine each. A deep construction recession bottomed out in the summer of 1993. By February 1994 construction employment was back at its low 1992 level. By November 1994 seasonally adjusted employment had risen 4.4 percent and unadjusted employment 17.6 percent. Production of concrete at the end of 1993 was as low as at the trough ten years earlier. Production in 1994 was almost 20 percent above 1993 but still below 1991.

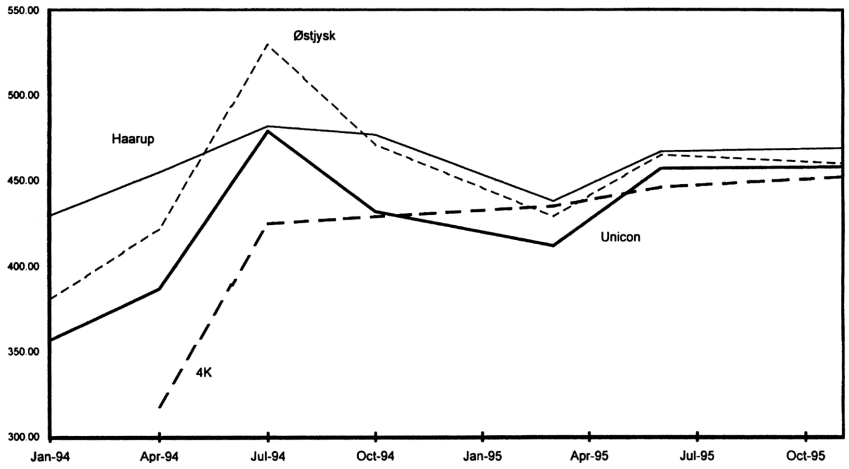
Capacity was not binding. In 1987 production was more than 50 percent above its 1994 level. Even then, capacity utilization was about 41 percent in production and 62 percent in distribution, and productive capacity had not fallen much since. If capacity was unchanged, utilization in 1994 was at most $\frac{62}{1.5} \approx 41$ percent in distribution and $\frac{41}{1.5} \approx 27$ percent in production (our computation). Distribution capacity is the number of mixer lorries, which firms could import or move between regions. Input costs did not rise either. Wages and energy prices were flat from 1993 to 1994, and the unit value of cement fell. The cement supplier, which owned Unicon, charged uniform delivered prices to all concrete producers.

A closer look at Aarhus. The authors then focus on Aarhus. Its six sampled firms carried about 70 percent of the weight in the national indices, and price increases in the other two regions were much more moderate. Copenhagen is large, and only half of its sites were sampled. Northern Jutland is sparsely populated, its sampled firms are local monopolies, and its discounts were smaller at the outset. Within Aarhus the authors drop a plant on a peninsula more than 60 km away and a Unicon plant 40 km away in Randers. The remaining four are plants of 4K and Unicon about 2 km apart in the city, and two commonly owned local plants (Haarup and Østjysk) 25 km and 40 km away. Together they carried about 60 percent of the national index weight and had a combined local share close to one.

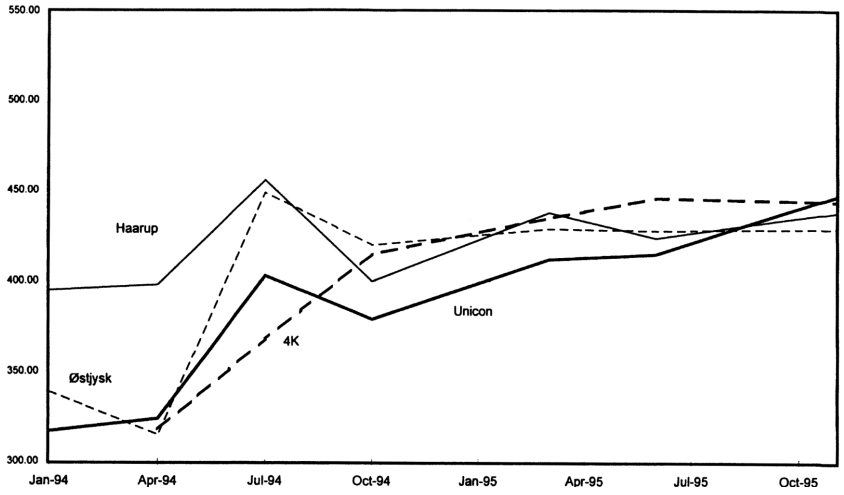
Figure 13.10 shows the prices of these four plants. From January to April 1994, low prices were roughly constant while average prices rose a little. From April to July 1994, prices jumped by 20 to 25 percent and then stayed at the new level. The timing fits the flow of information. The January prices were published on April 8, 1994, so April transactions could at best partly reflect them. The April prices were published on July 5, so by July every firm had two quarters of reliable information on rivals' formerly secret discounts. Prices also converged. By the end of the sample, the four plants' prices varied by only 2 to 4 percent around their mean, against up to 30 percent early in 1994. Low prices rose toward average prices, so the largest discounts disappeared. The authors see no explanation for a 25 percent rise in tandem by two major producers 2 km apart, other than reduced competition after secret discounts became public.

Interpretation. In terms of Proposition 13.19, publication raised the detection probability μ of secret discounts. The publication lag also mattered for Remark 13.22. Prices for the first month of a quarter appeared about three months later. That told each firm what its rivals had charged, but told a buyer little about the prices it could get today (our reading). The authors ask why a trade association had not supplied the same information. The association said it received no price reports from members. They suggest that unverified reports would not be credible, since a firm that gives secret discounts also gains by misreporting. The Council would also have frowned on industry price reporting (p. 440, fn. 12). The Council itself stopped publishing at the end of 1996. It noted that the convergence of actual and list prices since January 1994 had come entirely from a rise in actual prices (p. 430, fn. 4). The authors also point to related evidence from U.S. railroad freight. After Congress mandated the disclosure of firm-specific rail contract terms, grain rates rose. Fuller et al. (1990) and Schmitz and Fuller (1995) attribute the rise to the improved scope for tacit collusion (p. 441).

Limitations. The authors list the main weaknesses. There is no control group, either regions



(a) Figure 2 of the paper



(b) Figure 3 of the paper

Figure 13.10: Published 10-MPa prices of the four Aarhus plants, January 1994 to October 1995. The journal titles both panels "Low 10-MPa Prices in Aarhus." The text describes both average and low prices. Panel (b) is flat from January to April 1994, as the text says of low prices, and lies below panel (a). We therefore read panel (a) as average prices and panel (b) as low prices. Source: Albæk et al. (1997), Figures 2 and 3 (data from the Competition Council).

without publication or the same regions before publication. The Council had some data from before January 1994 but refused access. There are no data on firms' costs or capacities, and the sample has seven quarterly observations. There is no structural model and no standard error. One alternative they do not discuss is seasonality. The gap between adjusted and unadjusted construction employment shows strong seasonal demand, and the jump between April and July coincides with the building season. A seasonal rise would have reversed, however, and published prices stayed high through 1995 (our observation). Despite its limits, the paper is the cleanest evidence in this chapter that transparency can raise prices. It also shows that a policy can harm competition through the mechanism of Proposition 13.19.

13.5.3 Signaling through a fare-publishing system: the Airline Tariff Publishing case

The question. Firms may also use an information system to communicate intentions directly. Miller (2010) asks whether an antitrust case against such communication among U.S. airlines changed their prices and output. The airline industry is described in Chapter 9.

Setting. The Airline Tariff Publishing (ATP) Company, owned by the airlines, is the clearinghouse for airline fares. It collects and disseminates over 100,000 fare updates a day to airlines and to the computer reservation systems of travel agents. Each entry contains a fare basis code, a dollar amount, a route, fare rules and footnotes, typically first or last ticket dates. Airlines monitor the updates with sophisticated software. Travel agents can view only one market at a time and do not see the footnote designators. In December 1992 the Department of Justice sued the eight major domestic airlines and ATP, alleging that they used the system to communicate and to enforce price coordination (Civil Action No. 92-2854). The alleged channels were rapid monitoring, enforcement, signaling an intent to raise fares without shifting market shares (Holt and Scheffman, 1987), bargaining over fares and restrictions, and linking fares across markets (Bernheim and Whinston, 1990; Evans and Kessides, 1994). In a widely cited example, airlines punished fare cuts by America West with fare codes containing "HP," America West's industry code, and withdrew them once America West retracted its cuts. The case contrasts with an earlier and blunter invitation to collude. In 1982 Robert Crandall, chief executive of American Airlines, telephoned Howard Putnam of Braniff, a rival on routes out of Dallas-Fort Worth. He proposed that Braniff raise its fares by twenty percent and promised to raise his own the next morning (Asker and Nocke, 2021, pp. 188–189). Putnam recorded the call and turned it over to the Department of Justice, which filed a complaint against American and Crandall. Such explicit, private communication is easy to condemn. The ATP case concerned coded, public signals, which serve the same purpose and are harder to prohibit (Section 12.7.1).

Without admitting guilt, United and US Airways settled on November 1, 1993, and the other six defendants on August 10, 1994. For ten years the airlines agreed to three restrictions. They would not use footnote indicators or fare basis codes to convey extraneous information, or special codes linking different fares. They would not preannounce price changes except for widely publicized sales. A facilitating practice is judged under the rule of reason (Miller, 2010, p. 570), and the airlines defended ATP as an efficient business tool. Hay (2000) called a related defense "we're naturally bad." It holds that the industry's rapid monitoring alone explains supracompetitive profits, so restricting ATP would not help. The theoretical prediction is thus ambiguous.

Data. Miller uses the Department of Transportation's DB1A database, a 10 percent sample of domestic tickets, from the second quarter of 1991 to the first quarter of 1995. Fares below

$10 (presumed frequent-flyer redemptions) and above ten times the Standard Industry Fare Level (presumed errors) are dropped, which removes less than 1 percent of fares. The unit of observation is an airline, city-pair market and quarter. There are 411,726 such cells, with a mean of 229 sampled tickets and a mean fare of $209.70. Both vary widely across cells, with standard deviations of 933.16 tickets and $129.80, and the mean distance of a market is 1,056 miles (Table 1). The average market has 4.7 airlines, a Herfindahl index of 5,341 points and a four-firm concentration ratio of 97 percent.

Design and estimating equation. The identification strategy compares markets that the case should have affected with markets it should not have affected. If ATP facilitated collusion among the defendants, the remedy should matter only where several defendants compete. *Affected* markets are city pairs served by more than two defendant airlines in every quarter. *Control* markets are city pairs where the number of major airlines is always below two. Let Y_{ijt} be tickets sold or the average fare of airline i in city pair j in quarter t. Let $ATP1_t$ equal one from the second quarter of 1992, after the investigation intensified with the first depositions in March 1992. Let $ATP2_t$ equal one from the first quarter of 1994, after the settlements began. The probe itself had been announced in June 1990, and Miller dates the treatment from its intensification. An event study finds no response of defendants' stock prices to the 1990 announcement and a significant negative response to the intensification on March 18, 1992 (p. 574, note 9). The estimating equation is

$$Y_{ijt} = \beta_0 + \sum_{k=1}^{2} \beta_k^A \, ATPk_t \cdot Aff_j + \sum_{k=1}^{2} \beta_k \, ATPk_t + x_{jt}\beta_X + a_i + g_j + e_{ijt}. \tag{13.45}$$

Here Aff_j marks affected markets, and a_i and g_j are airline and city-pair fixed effects. The controls x_{jt} are the Standard Industry Fare Level, a cost measure, and the geometric means of the endpoint states' populations and gross state products, which shift demand. Richer versions replace $\beta_k ATPk_t$ with quarter effects or with airline-by-quarter effects. Standard errors are clustered by city pair.

The two indicators are cumulative steps. The coefficient β_1^A is the effect during the investigation, and $\beta_1^A + \beta_2^A$ is the effect after the settlement. A lasting effect of the remedy requires $\beta_1^A + \beta_2^A \neq 0$, which Miller tests with an F test. Identification rests on parallel trends. Affected and control markets would have evolved alike absent the case, conditional on the controls. The model is identified even with airline-by-quarter effects, because each airline serves both kinds of market before and after the case. Affected and control markets differ in fares and distance. Miller therefore repeats the analysis with a second control group of dominated markets, in which one airline sells over 90 percent of tickets in every quarter.

Miller also checks the results on several restricted samples (pp. 575–577). They keep flights within the continental United States, markets with distances between 250 and 2,000 miles, and markets with stable numbers of defendant and other airlines. One restriction counts an airline as present only if it has at least 10 sampled tickets in the market, about 100 passengers a quarter. Another reassigns the tickets of commuter carriers to the defendants with which they had operating agreements (p. 577, note 14). Combining all of these restrictions leaves 736 city-pair markets, the sample of columns (3) and (6) of Table 13.18.

Results. Table 13.18 reproduces the main estimates. Tickets rose in affected markets after the case, but they rose more in control markets. In column (1) the relative change after the settlement is $-91.983 - 40.318 = -132.3$ sampled tickets per airline, market and quarter, significant at the 8 percent level. Multiplying by 10 to undo the sampling gives about 1,300 tickets, the "over 1,000

Table 13.18: Quantity and price effects of the Airline Tariff Publishing case

	Number of tickets			Average fare (dollars)

City-pair markets	4,825	4,825	736	4,825	4,825	736
R^2	0.05	0.05	0.22	0.04	0.05	0.34

Notes: Reproduced from Miller (2010), Table 2. The unit is an airline, market and quarter in the 10 percent ticket sample. All regressions include city-pair and airline fixed effects and the controls described in the text. Standard errors clustered by city pair in parentheses. Columns (3) and (6) combine the sample restrictions listed in the text, which leave 736 markets.

tickets per quarter" in the text (our reconstruction). Column (3) gives $10 \times (4.361 + 59.948) = 643$, matching the reported postsettlement decline of 640 tickets, significant at the 5 percent level. Lower relative traffic contradicts a lasting increase in competition and fits the airlines' claim that the restrictions made travel planning harder.

Fares fell and then recovered. In column (4), affected-market fares fell \$13.57 relative to control markets during the investigation and rose \$12.71 after the settlement. The net effect of −\$0.86 is insignificant ($p = 0.81$). With the average fare near \$210, the initial fall is about 6.5 percent (our computation). In logs, the two coefficients are −0.088 and 0.035, both significant. The pattern holds across the fare distribution. With quarter effects, the investigation lowered the 10th percentile, median and 90th percentile fares by \$9.08, \$10.98 and \$28.93, and the settlement raised them by \$9.51, \$14.76 and \$21.24 (Table 3). Price dispersion therefore fell and then rose, and only the 90th percentile shows a net decline, significant at the 10 percent level.

Figure 13.11 plots the implied fare paths. Two further results support the reading of a temporary effect. Separate regressions for defendants and other airlines show that the fall and rise in fares came from the defendants, whose relative fares fell \$8.71 and then rose \$10.49 (Table 4). Their relative ticket sales rose during the investigation, while other airlines lost traffic. The defendants' fare cuts mostly shifted passengers from other carriers. Miller also re-estimates the multimarket-contact regression of Evans and Kessides (1994):

$$\ln Price_{ijt} = x_{ijt}\beta_X + \beta_Z Z_{jt} + \sum_{k=1}^{2} \beta_{Zk}\, ATPk_t \cdot Z_{jt} + a_i + g_j + \tau_t + e_{ijt}. \tag{13.46}$$

Here Z_{jt} is the average number of routes that the airlines serving market j have in common, divided by 1,000. The controls x_{ijt} include the airline's route and airport shares and the route

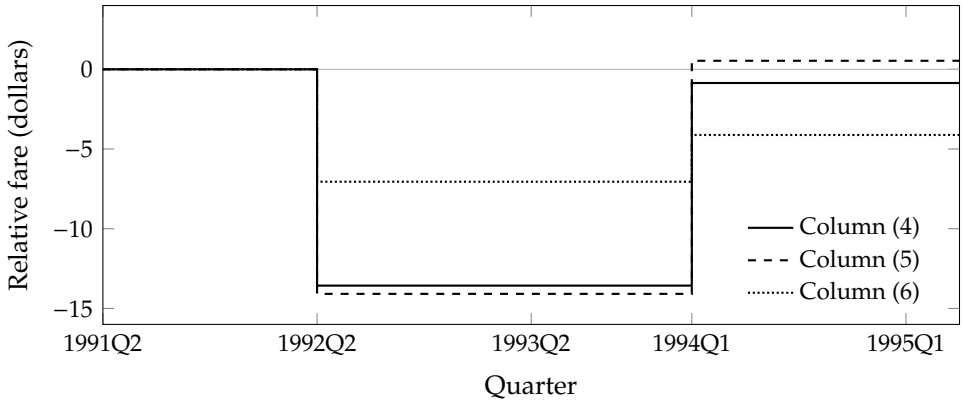

Figure 13.11: Average fares in affected markets relative to control markets implied by Miller (2010), Table 2. The path is 0 before the second quarter of 1992, β_1^A during the investigation, and $\beta_1^A + \beta_2^A$ from the first quarter of 1994. Our construction from the reported coefficients.

Herfindahl index. In the Evans-Kessides sample, the contact coefficient is 0.269 (0.043). It falls by 0.104 (0.030) during the investigation and rises by 0.107 (0.033) after the settlement, with a p-value of 0.96 for no net change (Table 5). The contact effect vanished while the case was active and then returned. Finally, the hub premium, which should have risen if collusion in contested markets broke down, fell by about 8 percent during the investigation and by another 13 percent after the settlement.

Interpretation and critiques. The defendants lowered fares under the scrutiny of the investigation and raised them once the settlement was in place. The settlement left the system largely intact, including the rapid fare monitoring that lets airlines detect and match fare cuts. In terms of Proposition 13.19, the remedy removed some signaling devices but left the detection probability μ high. The business press described weekend fare changes as a near substitute for the forbidden preannouncements. American Airlines was later accused of violating the decree and accepted a new seven-year decree in 2004. Alternatively, the airlines may never have used ATP as alleged. Borenstein (2004) reports relative price increases after the settlement on 387 routes likely to be affected, consistent with Miller.

The design has weaknesses that Miller discusses. Group membership depends on entry and exit, which are outcomes. She treats it as predetermined over four years and drops markets whose group changes. Southwest's entry was more frequent in affected markets, and the results survive dropping markets that Southwest entered or left. Affected and control markets differ in fares, distances and traffic, which weakens parallel trends, so she repeats the analysis with dominated markets as controls. The timing of treatment is also uncertain. The probe was announced in June 1990, the suit filed in December 1992, and the settlements signed in 1993 and 1994. The paper does not report pre-trends, so the identifying assumption cannot be checked directly (our observation). The case connects to the retrospective methods of Section 13.10. Its broader lesson is that remedies against facilitating practices must remove the monitoring capacity as well as the most visible signals.

13.5.4 Rules among nonprofits: the Overlap group and financial aid

The question. Can an agreement on rules among nonprofit institutions raise prices? Carlton et al. (1995) study the antitrust case against the Overlap group of universities. They ask whether

the schools' agreement on financial aid raised the average price that students paid. They also ask how antitrust law should treat collective action by nonprofits. The study grew out of work by Lexecon for MIT, and Carlton testified as MIT's expert witness, as the paper discloses.

The agreement. In the 1950s the Ivy League schools met to stop bidding for star athletes. They agreed that no athlete would receive aid beyond financial need, and soon applied the same idea to star students. By the 1970s the Overlap meetings included the eight Ivy League schools, MIT and 14 other selective colleges, 23 schools in all. Their combined undergraduate enrollment of about 60,000 was less than one percent of the national total. Figure 13.12 shows the accounting. Let $\bar{p}$ be the gross charge for tuition, room, board and fees. A student covers it with grants G, self help H (loans and jobs) and a family contribution F. In this subsection G, H and F are local symbols for these three sources, not distribution functions:

$$\bar{p} = G + H + F, \qquad \text{aid package} = G + H, \qquad \text{payment to the school} = H + F = \bar{p} - G. \quad (13.47)$$

The Overlap schools agreed to give aid only on the basis of need and to use a common method to define need. They also met to discuss individual students admitted by more than one school. A printout of commonly admitted students listed each school's proposed family contribution. When proposals differed by more than several hundred dollars, the schools discussed them and usually agreed on a common figure. Disagreements arose for 10 to 20 percent of the commonly admitted students who applied for aid. Regardless of which Overlap school admitted a student, the family contribution F was the same. Some schools also agreed on the split of the aid package between H and G.

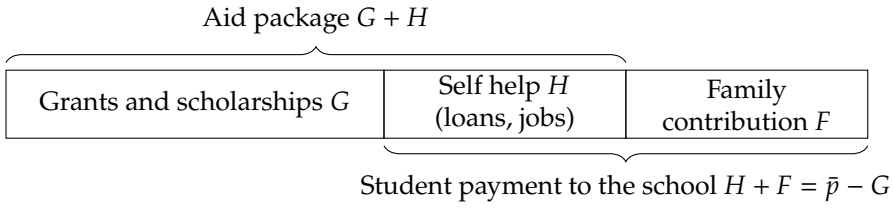

Figure 13.12: The components of the gross charge $\bar{p}$ for a student receiving aid. The Overlap schools agreed on the family contribution F of commonly admitted aid applicants. Redrawn from Carlton et al. (1995), Figure 1.

The schools justified the agreement as a way to concentrate scarce aid on needy students, supporting need-blind admission with a guarantee of full aid for every admitted student. Few schools outside Overlap made both commitments. Federal aid policy had the same logic, since federal money generally goes only to needy students.

The case. In 1991 the Antitrust Division sued MIT and the eight Ivy League schools under Section 1 of the Sherman Act. It called the agreement "garden variety price fixing" on the number and size of discounts from list price. By limiting discounts, it claimed, the schools raised the prices paid by meritorious high-income students and the average price paid by all. There was no allegation that enrollment fell, and enrollment growth at Overlap and non-Overlap private schools was similar in 1984–1990. The Government asked for per se condemnation. The Ivy League schools signed a consent decree, and MIT went to trial. In July 1992 Congress passed the Higher Education Act of 1992. It gave prospective antitrust immunity to much Overlap-type conduct but not to discussions of individual students. In September 1992 the District Court found MIT guilty of price fixing. In September 1993 the Court of Appeals overturned the verdict and ordered a full rule-of-reason analysis that weighed

the social benefits claimed by MIT. In December 1993 the Government settled. MIT and other schools could agree not to give merit aid, use common principles to assess need, pool student information and audit departures, but could not discuss individual awards.

Theory. The authors argue that the Government's claim that average prices must rise is wrong as a matter of theory for nonprofits. A university's objective has many attributes, including the quality of education, the welfare of students, faculty and administrators, research, innovation and donors' preferences. At MIT, student charges covered only about half the full cost of education. Schools erect barriers to trade that a profit maximizer would not. They do not sell admission, and the authors suspect that Harvard or MIT could profitably auction its last five places. Raising the average price would raise revenue for valued uses but would harm students, who are part of the objective. The authors also ask why schools colluding to raise revenue would target needy students rather than rich ones, and why they would keep need-blind admission. These facts raise doubts but cannot rule out a price effect, so the question is empirical.

The accounting identity (13.47) shows what the data can test. Let n students attend a school and let G_s be student s's institutional grant. Average net revenue per student is

$$p = \bar{p} - \frac{1}{n}\sum_{s=1}^{n} G_s. \tag{13.48}$$

The Government's theory implies that Overlap lowered total grants $\sum_s G_s$ and so raised p. The schools' theory implies that Overlap reallocated grants from merit to need, changing the distribution of G_s without changing their sum. Average net price p discriminates between the two theories. It is silent on how the agreement redistributed aid.

Data. A before-and-after comparison is infeasible. Overlap had met for over 30 years, and it stopped after the 1991–1992 academic year, leaving only two years of data contaminated by the lawsuit. The authors therefore compare schools. The 23 Overlap schools fall into five 1987 Carnegie classifications, and annual data for 1984–1990 cover about 225 private and public schools in these classes. The dependent variable is the real average price per student. It equals gross tuition plus room and board plus mandatory fees minus the average institutionally administered grant per student, deflated to 1990 dollars by the consumer price index. Institutional grants are the school's own money plus small federal SEOG grants of about $50 per undergraduate. For the 162 private schools in the pooled sample, the average net price is $12,366 with a standard deviation of $2,420 (Table 4).

The regressors in their Table 2 are an Ivy-plus-MIT Overlap dummy *IVY* and an other-Overlap dummy *NONIVY*. Carnegie dummies are *RSRCH1*, *RSRCH2*, *DOCTOR1* and *DOCTOR2*, with Liberal Arts I omitted. Quality is measured by the percent of applicants accepted (*PCTACC*), the percent scoring above 700 on the verbal or mathematics SAT (*SAT*) and the percent completing a degree (*COMPDEG*). Financial capacity is measured by real endowment per full-time-equivalent student in thousands (*ENDOW*) and by the percent of students not receiving need-based aid (*PCTNOAID*, a wealth proxy). Real state per capita disposable income (*YDPC*) proxies both income and costs. Further dummies mark non-religious schools (*NONRELIG*), public schools (*PUBLIC*) and missing fee data (*FEEMISS*).

Estimating equations. For school i in year t, the annual cross-section model is

$$p_{it} = x_{it}\beta_t + e_{it}, \tag{13.49}$$

estimated separately for each year by least squares. Here i indexes schools, a local use. Because the regressors change slowly within a school, a pooled regression essentially uses cross-school variation. The authors therefore also estimate a school-average model. Let N_i be the number of years with data for school i and let $d_{it} = \frac{1}{N_i}$ for those years. Averaging (13.49) with a common β gives

$$\bar{p}_i = \sum_t d_{it} p_{it} = \Big(\sum_t d_{it} x_{it} \Big) \beta + \sum_t d_{it} e_{it}. \tag{13.50}$$

If the e_{it} are uncorrelated over time with common variance σ^2, the averaged error has variance $\text{Var}\left(\sum_t d_{it} e_{it} \right) = \frac{\sigma^2}{N_i}$. Multiplying (13.50) by $\sqrt{N_i}$ makes the error homoskedastic, and least squares on the transformed equation is generalized least squares. This is why the authors weight by $\sqrt{N_i}$ (WP p. 19, fn. 22). They also report White standard errors, which are similar.

Table 13.19: Determinants of the average net price per student at private colleges

Panel A. School averages, 1984–1990, weighted by $\sqrt{N_i}$ (Table 6)					
Variable	Coef.	(s.e.)	Variable	Coef.	(s.e.)
Intercept	2299.47	(2429.07)	*PCTACC*	−27.89	(11.97)
IVY	−322.42	(678.72)	*PCTNOAID*	43.58	(9.44)
NONIVY	130.37	(463.81)	*SAT*	2.31	(11.16)

	(468.39)	(529.46)	(517.53)	(658.66)	(650.61)
N	130	137	136	106	105

Notes: Reproduced from Carlton et al. (1995), NBER working-paper version, Tables 5 and 6. Dependent variable: real gross tuition, room, board and mandatory fees minus the average institutional grant per student, in 1990 dollars. Standard errors in parentheses. Panel B also has a 1990 column, with *IVY* −2.22 (1681.46), *NONIVY* 422.67 (1092.78) and $N = 53$. No Ivy Overlap school reported complete data for 1988.

Results. Table 13.19 reproduces the results for private schools. In no annual regression is either Overlap coefficient positive and significant. In the pooled average regression, *IVY* is −322 dollars with a standard error of 679, and *NONIVY* is 130 dollars with a standard error of 464. If anything, Overlap schools charged less, though not significantly so. With gross charges as the dependent variable, the Overlap coefficient is −376 dollars and insignificant (fn. 24). The authors also display the fit school by school (their Figures 2 and 3). Equation (13.50) overpredicts the average price of four of the seven Ivy-plus-MIT schools with data and underpredicts it for the other three. Their residuals are small and average close to zero. The other coefficients are sensible. Schools with richer students charge more, and non-religious schools charge about $1,500 more than religious ones in the annual regressions. Including public schools gives about 225 schools and a significant public-school effect of about −$8,400.

The quality premium is modest. Compare a selective school (*PCTACC* = 25, *COMPDEG* = 80) with a less selective one (*PCTACC* = 75, *COMPDEG* = 40). The predicted difference is

$$-27.89\,(25-75)+45.68\,(80-40)=1{,}394.5+1{,}827.2=3{,}222 \text{ dollars}$$

(our computation), the "roughly $3000" of the text and about a quarter of the average price. The authors compare it with the return to an elite education. James et al. (1989) find that graduates of elite schools earn 3 to 5 percent more. With a base income of $50,000, a 5 percent premium and a 10 percent real interest rate, the premium is worth about $\frac{0.05\times 50{,}000}{0.10}=25{,}000$ dollars as a perpetuity.

Robustness. The finding survives several checks. Generalized least squares on the panel with equicorrelated errors within a school gives a correlation of about 0.8 and results like those in Table 13.19. A random-effects model cannot be distinguished from a fixed-effects model by a Hausman (1978) test. The fixed-effects model cannot identify the Overlap effect, but its other coefficients match. Results are unchanged with public schools included, with suspect duplicate observations dropped, with quadratic terms in *PCTACC*, *COMPDEG* and *ENDOW*, and with logs. Dropping the wealth variable, which is the regressor most likely to be endogenous, or lagging it, leaves the Overlap coefficients unchanged. To address the endogeneity of Overlap membership itself, the authors estimate the model on non-Overlap schools only and test whether it fits the excluded schools. An F test never rejects, and the model predicts the Overlap schools' average prices well.

The case for collective action. The authors argue that without Overlap, competition for star students would have diverted aid from needy to meritorious students. Merit aid was growing as a share of institutional aid. Across 72 schools, the ratio of merit aid to need aid rose from 0.134 in 1984 to 0.180 in 1989, and among Liberal Arts I colleges from 0.076 to 0.131 (Table 7). To test whether Overlap raised access, they regress the log odds of the black or Hispanic share of students on the same variables (Table 8). One regressor is added, the state's minority share of the college-age population. For black students the Overlap coefficient is 0.451 (0.172). Splitting it, *IVY* is 0.396 (0.268) and *NONIVY* 0.478 (0.198). For Hispanic students the coefficient is 0.183 (0.146), with *IVY* 0.025 (0.227) and *NONIVY* 0.258 (0.167). A log-odds effect of 0.451 raises a 3 percent share to $\frac{0.0309\times e^{0.451}}{1+0.0309\times e^{0.451}}=4.6$ percent (our computation), close to the authors' "about five rather than about three percent." They note that Overlap schools may simply have recruited black students harder.

The Court of Appeals distinguished the case from *National Society of Professional Engineers*, where the Supreme Court struck down a quality-motivated bidding restriction by an association of profit-maximizing members. It noted "the absence of any finding of adverse effects such as higher price or lower output" and that the agreement was not intended to raise revenue. The authors support this reasoning. Institutions granted 501(c)(3) status pursue social goals that competition among profit maximizers does not achieve. If such goals could never justify collective action, no collective action by nonprofits would be legal.

Critiques. Identification is by selection on observables in a cross-section. Overlap membership is not random, and the Ivy-plus-MIT coefficient rests on seven schools with data (Dartmouth and Cornell are missing), all at the extremes of selectivity and wealth. Some controls may themselves respond to Overlap. The share of students not receiving need-based aid, *PCTNOAID*, depends on aid policy, and conditioning on it can absorb part of the effect being measured (our observation). The test concerns the mean of the price distribution, while the schools' own account implies a change in its shape, a transfer from meritorious high-income students to

others. The authors' conclusion says exactly this. Finally, the test has limited power. The 95 percent confidence interval for *IVY* is

$$-322.42 \pm 1.96 \times 678.72 = [-1{,}653,\ 1{,}008] \text{ dollars}$$

(our computation). The data cannot rule out an Overlap price effect of about $1,000, or 8 percent of the average price. A finding of no significant effect is a statement about precision. The contrast with Danish concrete is instructive. There the outcome moved by 20 percent within two quarters, and even a crude design could detect it.

13.5.5 What the information cases show

The three cases fit the logic of Proposition 13.19 and Remark 13.22. Publishing past transaction prices raised the detection probability of secret discounts more than it informed buyers, and concrete prices rose. The airline remedy removed signaling codes but left rapid monitoring in place, and fares returned to their earlier relative level. The Overlap agreement concerned the allocation of aid among students. It had no detectable effect on average prices, and its likely effects were distributional. Together with the Sugar Institute and bromine, these cases show that information is a strategic variable. Firms invest in detection, outside bodies can supply it, and the effect of any change depends on who learns what and how fast.

13.6 Retail Gasoline: Dynamic Pricing, Price Cycles and a Prosecuted Cartel

Each case so far had a dated institution to study: a legal cartel, an agreement among firms, or a change in what firms could observe. Detection usually faces a harder problem, which is to infer conduct from prices when no such institution is documented. Retail gasoline has produced some of the most detailed and most contested evidence on this problem. The product is close to homogeneous, prices are posted on large signs, wholesale costs are observed at high frequency, and demand follows a predictable seasonal pattern. These features make gasoline a convenient laboratory. Four papers use it to reach three different conclusions about similar price patterns, and a fifth shows how tacit coordination emerged. Borenstein and Shepard (1996) find that margins in United States cities move with expected future demand and cost, as tacit dynamic collusion predicts. Noel (2007) argues that the sawtooth price cycles of Toronto are competitive Edgeworth cycles. Clark and Houde (2013) show that an explicit cartel in Quebec also produced asymmetric cycles, and Erutku and Hildebrand (2010) measure what happened to prices when that cartel was exposed. Byrne and de Roos (2019) trace how stations in Perth learned to coordinate through price leadership. The lesson for detection runs through the whole section: a price pattern alone rarely identifies conduct.

Throughout the section a market is a city or a station, indexed by i or j. The period t is a month, a week or half a day, depending on the data. The *retail margin* M_{it} is the retail price minus a measure of the wholesale cost of gasoline. The wholesale cost is the *terminal* or *rack price*, the posted price at which refiners sell gasoline at the city terminal to distributors and stations. We keep each paper's variable names in italics (for example *MARGIN* and *NVOLUME*) so that the reader can match our equations to the originals.

13.6.1 Theory: collusive margins and expected future conditions

The repeated-game models of Chapter 12 tie the highest sustainable collusive price to the balance between the gain from cheating today and the loss from punishment tomorrow. In the model of Rotemberg and Saloner (1986), demand is drawn independently each period, so the future loss does not depend on today's state. With N firms, Bertrand reversion and industry profit $\pi_s(p)$ in demand state s, the incentive constraint in state s reads

$$\frac{N-1}{N}\,\pi_s(p_s) \le \frac{\delta}{1-\delta}\,\frac{1}{N}\,\mathbb{E}\big[\pi(p)\big], \tag{13.51}$$

whose right side is the same in every state. The temptation is largest when current demand is high, so margins are lowest in booms. Haltiwanger and Harrington (1991) replace the independent draws with a deterministic demand cycle, and Bagwell and Staiger (1997) with persistent Markov growth states. Once demand is predictable, the future loss depends on where the market is heading. The test of Borenstein and Shepard (1996) rests on this version, which we now develop with time-varying costs.

Assumption 13.23 (Collusion along a predictable path)**.**

(i) $N \ge 2$ symmetric firms sell a homogeneous good at a common constant marginal cost c_t.

(ii) Market demand is $D_t(p) = A_t\, d(p)$, where $A_t > 0$ is a demand shifter and d is decreasing. The sequences $\{A_t\}$ and $\{c_t\}$ are known to all firms in advance and are bounded.

(iii) Industry profit $\pi_t(p) = (p - c_t)D_t(p)$ is strictly increasing in p on $[c_t, p_t^m]$, where p_t^m is the monopoly price, and $\pi_t^m = \pi_t(p_t^m)$ denotes monopoly profit.

(iv) Firms set prices each period with common discount factor $\delta \in (0,1)$. On the collusive path they charge a common price p_t and split demand equally.

(v) A deviation is observed at the end of the period. It is followed by $T \le \infty$ periods of Bertrand pricing at $p = c$, after which the firms return to the collusive path.

The punishment in (v) is credible because each punishment period is a static Nash equilibrium. We now derive the incentive constraint at date t. Let V_t be a firm's value on the collusive path from date t on. Collusion yields

$$V_t = \frac{1}{N}\pi_t(p_t) + \sum_{s=1}^{T} \delta^s \frac{1}{N}\pi_{t+s}(p_{t+s}) + \delta^{T+1} V_{t+T+1}.$$

The best deviation undercuts p_t by an arbitrarily small amount and serves the whole market for one period. The deviator then earns zero for T periods and returns to the path at $t+T+1$. Its value is

$$\pi_t(p_t) + 0 + \delta^{T+1} V_{t+T+1}.$$

Collusion is optimal at t if V_t is at least the deviation value. The term $\delta^{T+1}V_{t+T+1}$ appears on both sides and cancels. Multiplying by N gives

$$\pi_t(p_t) + \sum_{s=1}^{T} \delta^s \pi_{t+s}(p_{t+s}) \ge N\pi_t(p_t),$$

so the incentive constraint is

$$(N-1)\,\pi_t(p_t) \;\le\; \Phi_t \equiv \sum_{s=1}^{T} \delta^s\, \pi_{t+s}(p_{t+s}). \tag{13.52}$$

The left side is the temptation, which depends on current demand and cost. The right side Φ_t is the discounted collusive profit that a deviation destroys, which depends only on the future.

It is convenient to work with profit levels instead of prices. On $[c_t, p_t^m]$ the map $p \mapsto \pi_t(p)$ is a strictly increasing bijection onto $[0, \pi_t^m]$. A price above p_t^m is never needed, because a lower price gives the same profit and hence the same constraints. Let $v_t = \pi_t(p_t) \in [0, \pi_t^m]$ denote collusive industry profit at t. A profit path $v = \{v_t\}$ is *sustainable* if it satisfies $(N-1)v_t \le \sum_{s=1}^{T} \delta^s v_{t+s}$ at every date.

Lemma 13.24 (Most collusive path)**.** *Under Assumption 13.23 there is a sustainable path $\bar{v}$ with $\bar{v}_t \ge v_t$ for every date and every sustainable path v. It is the greatest solution of*

$$\bar{v}_t = \min\left\{\pi_t^m,\; \frac{1}{N-1}\sum_{s=1}^{T} \delta^s\, \bar{v}_{t+s}\right\} \qquad \text{for all } t. \tag{13.53}$$

At each date either the cartel charges the monopoly price or the incentive constraint binds.

Proof. Let v and v' be sustainable and let $w_t = \max\{v_t, v'_t\}$. Fix t and suppose $w_t = v_t$. Then $(N-1)w_t = (N-1)v_t \le \sum_s \delta^s v_{t+s} \le \sum_s \delta^s w_{t+s}$, and the same argument applies when $w_t = v'_t$. Hence the set of sustainable paths is closed under pointwise maxima. Define $\bar{v}_t = \sup\{v_t : v \text{ sustainable}\} \le \pi_t^m$. Enumerate the dates and start from any sustainable path $v^{(0)}$. For each $k \ge 1$, let $v^{(k)}$ be the pointwise maximum of $v^{(k-1)}$ and of k sustainable paths that come within $\frac{1}{k}$ of $\bar{v}_t$ at the first k dates. These paths are sustainable, nondecreasing in k and converge pointwise to $\bar{v}$. The constraint passes to the limit by monotone convergence, so $\bar{v}$ is sustainable and is the greatest sustainable path.

Sustainability and the cap give $\bar{v}_t \le \min\{\pi_t^m, \frac{1}{N-1}\sum_s \delta^s \bar{v}_{t+s}\}$. Suppose the inequality were strict at some t. Raising $\bar{v}_t$ slightly keeps the constraint at t satisfied. It only enlarges the right sides of the constraints at earlier dates and leaves later dates unchanged. The new path is sustainable and exceeds $\bar{v}$, a contradiction. So $\bar{v}$ solves (13.53). Every solution of (13.53) is sustainable, so $\bar{v}$ is the greatest solution. □

The most collusive path maximizes profit at every date at once, so it is also the path that maximizes the cartel's discounted profit. We write $\bar{p}_t$ for the price that delivers $\bar{v}_t$. The recursion (13.53) involves only future profits and the cap π_t^m. That simple structure delivers the comparative statics behind the empirical test.

Proposition 13.25 (Collusive margins and the expected future)**.** *Suppose Assumption 13.23 holds.*

(a) Better futures raise current margins. *Compare two dates t_1 and t_2 with the same current demand and cost. If $\pi_{t_1+s}^m \ge \pi_{t_2+s}^m$ for every $s \ge 1$, then $\bar{p}_{t_1} \ge \bar{p}_{t_2}$. Higher future demand or lower future cost raises future monopoly profits and so weakly raises the current collusive margin.*

(b) Higher current demand lowers margins at a binding date. *If the constraint binds at t, then holding the future fixed, $\bar{p}_t$ falls when A_t rises.*

(c) Static benchmark. *In a static Nash equilibrium the price at t depends only on (A_t, c_t). Expected future demand and cost have no effect on current prices once current conditions are controlled for.*

Proof. (a) The value $\bar{v}_t$ depends only on $\{\pi^m_{t+s}\}_{s\geq 0}$. Constraints at dates after t involve only later dates, and constraints at earlier dates never restrict later profits, because raising later profits only relaxes them. So $\bar{v}_{t_1}$ and $\bar{v}_{t_2}$ are the first elements of the greatest solutions of two forward problems with caps $\{\pi^m_{t_1+s}\}$ and $\{\pi^m_{t_2+s}\}$, which differ only in the caps. The greatest solution of the second problem satisfies the constraints of the first problem, because the constraints are identical and its caps are lower. It is therefore sustainable in the first problem and lies below that problem's greatest path, so $\bar{v}_{t_1} \geq \bar{v}_{t_2}$. Current demand and cost are the same, so $\pi_{t_1} = \pi_{t_2}$ is increasing on the relevant interval and $\bar{p}_{t_1} \geq \bar{p}_{t_2}$.

(b) At a binding date $\bar{v}_t = \frac{\Phi_t}{N-1}$, which does not depend on A_t. Writing $\pi_t(p) = A_t(p - c_t)d(p)$, the price solves

$$(\bar{p}_t - c_t)\, d(\bar{p}_t) = \frac{\Phi_t}{(N-1)A_t}.$$

The right side falls in A_t and the left side increases in $\bar{p}_t$ on $[c_t, p^m_t]$, so $\bar{p}_t$ falls.

(c) A static equilibrium price solves first-order conditions that contain only date-t demand and cost. □

Part (b) is the effect of Rotemberg and Saloner (1986): holding the future fixed, a firm is more tempted to cheat when today's market is large. Part (a) is the effect that Haltiwanger and Harrington (1991) emphasize. Its premise compares whole future paths, which a seasonal cycle does not deliver at every horizon. A week on the rising side of the cycle faces higher demand over the next months but lower demand half a year later. When punishments are short or discounting is strong, the near future dominates, and the conclusion holds. Figure 13.13 computes the most collusive path for a linear-demand example. The cartel sustains the monopoly price while demand rises. It cuts its price below monopoly as soon as demand starts to fall. At dates t_1 and t_2 current demand is the same, yet the sustainable price is much higher at t_1. The cartel returns to the monopoly price before the demand trough. By then demand falls slowly, so current monopoly profit is no longer large relative to profit over the punishment horizon.

From the incentive constraint to a margin regression. To motivate an estimating equation we linearize the binding constraint. Let $M_t = \bar{p}_t - c_t$ be the collusive margin, $L_t = \frac{M_t}{\bar{p}_t}$ the Lerner index (a local use of L_t, which denotes the lakes dummy in Section 13.3), and $\varepsilon_t = -\frac{d'(\bar{p}_t)\bar{p}_t}{d(\bar{p}_t)}$ the industry demand elasticity. At a binding date, taking logs of $(N-1)A_t M_t d(c_t + M_t) = \Phi_t$ gives

$$\ln A_t + \ln M_t + \ln d(c_t + M_t) = \ln \Phi_t - \ln(N-1).$$

Differentiate, using $\frac{d'}{d} = -\frac{\varepsilon_t}{\bar{p}_t}$:

$$\left(\frac{1}{M_t} - \frac{\varepsilon_t}{\bar{p}_t}\right) \mathrm{d}M_t = \mathrm{d}\ln\Phi_t - \mathrm{d}\ln A_t + \frac{\varepsilon_t}{\bar{p}_t}\,\mathrm{d}c_t.$$

The bracket equals $\frac{1-\varepsilon_t L_t}{M_t}$. It is positive below the monopoly price, because there profit rises with price: $\frac{\mathrm{d}}{\mathrm{d}p}\big[(p-c_t)d(p)\big] = d(p)\,(1-\varepsilon_t L_t) > 0$. Near a stationary point the weights $\omega_s = \frac{\delta^s}{\sum_{r=1}^{T}\delta^r}$ give $\mathrm{d}\ln\Phi_t = \sum_s \omega_s\,\mathrm{d}\ln\bar{v}_{t+s}$. Hold future margins at their stationary values, so that future profits move only through demand and cost: $\mathrm{d}\ln\bar{v}_{t+s} = \mathrm{d}\ln A_{t+s} - \frac{\varepsilon}{\bar{p}}\mathrm{d}c_{t+s}$. Substituting and collecting terms,

$$\mathrm{d}M_t = \frac{M}{1-\varepsilon L}\sum_{s=1}^{T}\omega_s\big(\mathrm{d}\ln A_{t+s} - \mathrm{d}\ln A_t\big) - \frac{\varepsilon L}{1-\varepsilon L}\sum_{s=1}^{T}\omega_s\big(\mathrm{d}c_{t+s} - \mathrm{d}c_t\big). \tag{13.54}$$

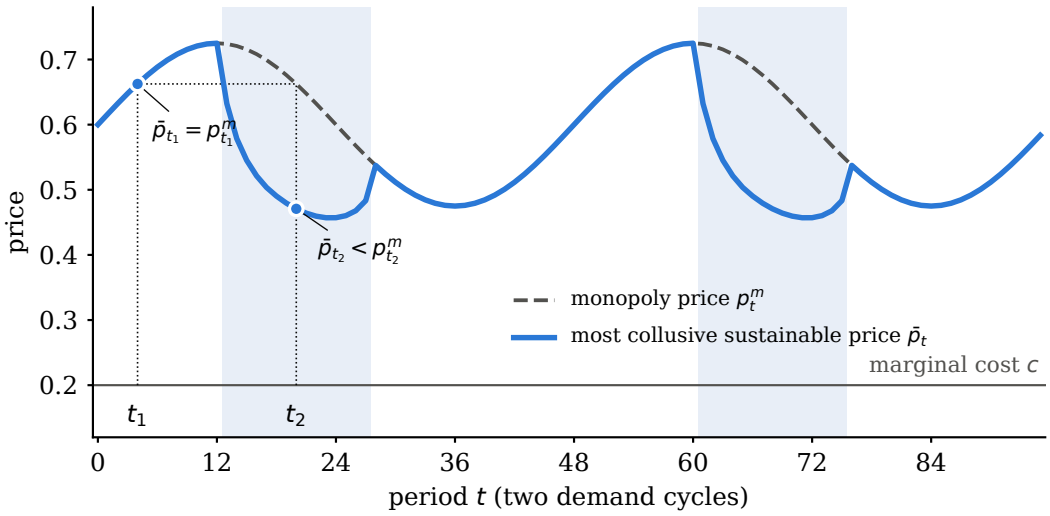

Figure 13.13: Most collusive sustainable price over a deterministic demand cycle. Linear demand $D_t(p) = a_t - p$ with $a_t = 1 + 0.25 \sin\left(\frac{2\pi t}{48}\right)$, marginal cost $c = 0.2$, $N = 8$ firms, $\delta = 0.99$ per period and a ten-period Bertrand punishment. Shaded periods are those in which the incentive constraint (13.52) binds. Demand is the same at t_1 (rising) and t_2 (falling), yet $\bar{p}_{t_1} = p^m_{t_1} = 0.66$ while $\bar{p}_{t_2} = 0.47$. The path solves (13.53) by iteration (script `bs_cycle.py`).

The current levels of demand and cost enter only through their expected changes. With a one-period horizon and expectations formed at t, the margin equation becomes

$$M_t \approx \alpha_0 + \alpha_2 \, \mathbb{E}_t\left[\Delta \ln A_{t+1}\right] + \alpha_3 \, \mathbb{E}_t\left[\Delta c_{t+1}\right], \qquad \alpha_2 = \frac{M}{1 - \varepsilon L} > 0, \quad \alpha_3 = -\frac{\varepsilon L}{1 - \varepsilon L} < 0. \tag{13.55}$$

The coefficients α_2 and α_3 are local to this section and have nothing to do with the logit price coefficient. Under the static benchmark of Proposition 13.25(c), $\alpha_2 = \alpha_3 = 0$. This is the null hypothesis that Borenstein and Shepard (1996) test. If punishments last longer than one period, the one-period expected change measures the relevant weighted change in (13.54) with error. The estimates of α_2 and α_3 are then biased toward zero, so the test is conservative.

Remark 13.26 (Why level and change can be separated). With independent draws, $\mathbb{E}_t[\ln A_{t+1}]$ is a constant, so $\mathbb{E}_t[\Delta \ln A_{t+1}] = \text{const} - \ln A_t$. The level of demand and its expected change are then perfectly collinear, and a high level always signals an expected fall. A seasonal cycle breaks the collinearity. Two weeks with the same demand, one before and one after the seasonal peak, have opposite expected changes. That is why the test needs predictable movements in demand and cost.

Competing explanations and the sign of the cost effect. Two non-collusive mechanisms could also tie current margins to expected future conditions. Both predict the opposite sign for the cost effect. The first is inventories. Suppose a supplier prices off its replacement cost, the terminal price w_{t+1} expected at its next purchase, and adds a constant margin m°. Then $p_t = \mathbb{E}_t[w_{t+1}] + m^\circ$, and the observed margin is

$$M_t = p_t - w_t = m^\circ + \mathbb{E}_t\left[\Delta w_{t+1}\right]. \tag{13.56}$$

The coefficient on the expected cost change is +1, while collusion predicts $\alpha_3 < 0$. The second mechanism is a cost of changing prices. A firm facing such costs moves its price toward the

price it expects to want in the future. An anticipated cost increase then raises today's price and today's margin, again a positive sign. A negative coefficient on expected cost changes is therefore a distinctive prediction of dynamic collusion. Inventory motives tied to demand require a risk of stockouts, which Borenstein and Shepard (1996) rule out because wholesale purchases were never constrained in their sample.

13.6.2 Margins and expected demand in U.S. cities: Borenstein and Shepard (1996)

Question. Earlier tests of collusion used contemporaneous prices, quantities and costs, as in the conduct-parameter studies of Chapter 3. Bresnahan (1989) stressed that such tests rest on functional-form assumptions, because static non-cooperative prices can move either way with demand. Borenstein and Shepard (1996) ask whether current retail gasoline margins respond to *expected* changes in demand and wholesale cost. Under static pricing they should not respond at all, so a response is evidence of dynamic collusion that does not depend on the shape of demand or cost. The question matters because gasoline retailing is far from a tight oligopoly. Most metropolitan areas have more than ten wholesale suppliers and many more stations.

Setting. Crude oil is refined and shipped by pipeline or barge to city terminals. From the terminal, gasoline is trucked to stations either by independent wholesalers, called *jobbers*, or by refiners. Jobbers distribute about 55 percent of U.S. retail gasoline and pay the posted terminal price (working paper, pp. 8–10). Refiners sell to independently operated stations at the *dealer tankwagon* price, which is subject to widespread unobserved discounts. Borenstein and Shepard therefore measure marginal cost by the terminal price. It is the only observed wholesale price for jobbers, it is the opportunity cost of gasoline sold at refiner-supplied stations, and it is rarely discounted. The margin they study is the gap between the retail price and the terminal price. It mixes decisions of refiners, jobbers and station operators.

Data. The panel covers 59 cities in 43 states over the 72 months from 1986 to 1991. *RETAIL* is the Lundberg Survey average price of regular unleaded self-service gasoline, net of all taxes, on one Friday each month. *TERM* is the average branded terminal price posted on the same Friday, so the two prices match exactly and $MARGIN = RETAIL - TERM$. Volume comes from monthly state sales reported by the Federal Highway Administration. Daily volume in adjacent months is interpolated linearly to the survey day, giving *VOLUME*. Because over 99 percent of the variance of *VOLUME* is between states, volume is normalized by its state mean: $NVOLUME_{it} = \frac{VOLUME_{it}}{\overline{VOLUME}_i}$. Table 13.20 reports the summary statistics. Demand peaks in August at about 20 percent above the January trough. Short-run demand elasticities lie between -0.1 and -0.2 (Dahl and Sterner, 1991). Retail prices would then have to swing by 100–200 percent to generate such a cycle, so the seasonal pattern reflects shifts of demand rather than movements along it. Over half of the monthly crude oil price changes exceed 5 percent in absolute value.

The estimating equation. Retail prices adjust to terminal prices with lags, and increases pass through faster than decreases. The authors start from an error-correction model with

Table 13.20: Retail gasoline in 59 U.S. cities, 1986–1991: summary statistics

Variable	Mean	Std. dev.	Min	Max
RETAIL (cents per gallon)	72.83	12.41	43.18	126.57
TERM (cents per gallon)	62.28	11.82	36.00	111.88
CRUDE (cents per gallon)	46.38	10.77	25.83	87.98
MARGIN (cents per gallon)	10.57	5.12	−8.91	34.90
VOLUME (100,000 gallons per day)	10.43	10.48	0.38	38.12
NVOLUME	1.005	0.087	0.570	1.617
EXP VOLCHG, $\hat{\eta} = -0.1$	0.000	0.050	−0.403	0.287
EXP TERMCHG (cents per gallon)	0.139	4.172	−17.313	13.959

Notes: 3,838 city-month observations. Prices exclude sales and excise taxes and are in current cents. *EXP VOLCHG* and *EXP TERMCHG* are the expected one-month changes in normalized volume and in the terminal price defined in the text. Source: Borenstein and Shepard (1996), working-paper version, Table 1.

asymmetric adjustment (working paper, eq. (1)):

$$\begin{aligned} RETAIL_{it} - RETAIL_{i,t-1} = {} & \beta_1 \Delta TERM^{+}_{it} + \beta_2 \Delta TERM^{+}_{i,t-1} + \beta_3 \Delta TERM^{+}_{i,t-2} \\ & + \beta_4 \Delta TERM^{-}_{it} + \beta_5 \Delta TERM^{-}_{i,t-1} + \beta_6 \Delta TERM^{-}_{i,t-2} \\ & + \beta_7 \Delta RETAIL^{+}_{i,t-1} + \beta_8 \Delta RETAIL^{+}_{i,t-2} \\ & + \beta_9 \Delta RETAIL^{-}_{i,t-1} + \beta_{10} \Delta RETAIL^{-}_{i,t-2} \\ & + \beta_{11} RETAIL_{i,t-1} + \beta_{12} TERM_{i,t-1} + e_{it}. \end{aligned} \tag{13.57}$$

Here $\Delta X_{it} = X_{it} - X_{i,t-1}$, and ΔX^{+} and ΔX^{-} are the positive and negative parts of the change. The lagged levels form the error-correction term. If the long-run relation is $RETAIL = \gamma_0 + \gamma_1 TERM$ and the gap closes at rate $\kappa > 0$, the correction $-\kappa(RETAIL_{t-1} - \gamma_0 - \gamma_1 TERM_{t-1})$ produces the two lagged levels, with $\beta_{11} = -\kappa$ and $\beta_{12} = \kappa\gamma_1$. The constant is absorbed by fixed effects.

To put the margin on the left, add $RETAIL_{i,t-1}$ to both sides and subtract $TERM_{it}$. The left side becomes $MARGIN_{it}$. On the right, $TERM_{it} = \Delta TERM^{+}_{it} + \Delta TERM^{-}_{it} + TERM_{i,t-1}$, so subtracting it lowers the coefficients on $\Delta TERM^{+}_{it}$ and $\Delta TERM^{-}_{it}$ by one and the coefficient on $TERM_{i,t-1}$ by one. Adding $RETAIL_{i,t-1}$ raises its coefficient by one. The margin form (working paper, eq. (2)) is therefore (13.57) with $\beta_1 - 1$, $\beta_4 - 1$, $\beta_{11} + 1$ and $\beta_{12} - 1$ in place of β_1, β_4, β_{11} and β_{12}. Adding current volume and the two expectation terms gives the estimating equation (working paper, eq. (3)), in which the coefficient adjustments are left implicit:

$$\begin{aligned} MARGIN_{it} = {} & \alpha_1 NVOLUME_{it} + \alpha_2 EXP\ VOLCHG_{it} + \alpha_3 EXP\ TERMCHG_{it} \\ & + \sum_{k=0}^{2} \left(\beta^{+}_{k} \Delta TERM^{+}_{i,t-k} + \beta^{-}_{k} \Delta TERM^{-}_{i,t-k} \right) \\ & + \sum_{k=1}^{2} \left(\phi^{+}_{k} \Delta RETAIL^{+}_{i,t-k} + \phi^{-}_{k} \Delta RETAIL^{-}_{i,t-k} \right) \\ & + \beta_{11} RETAIL_{i,t-1} + \beta_{12} TERM_{i,t-1} + \mu_i + \lambda_t + e_{it}. \end{aligned} \tag{13.58}$$

We have relabeled the twelve β's of the original to show the pattern. The terms μ_i and λ_t (local symbols here) are city fixed effects and 72 month fixed effects, which absorb cross-city

correlation of the errors at a point in time. Current volume α_1 captures any static effect of demand on margins, such as changes in the mix of customers or peak-load pricing. The coefficients of interest are α_2 and α_3, the empirical counterparts of (13.55). The effect of current volume holding expected next-month volume fixed is $\alpha_1 - \alpha_2$, because *EXP VOLCHG* is expected next-month volume minus current volume.

Endogeneity of volume: an instrument built from an assumed elasticity. Volume depends on the retail price and hence on the margin, so OLS is inconsistent, and no excluded demand shifters are available. The authors resolve the problem with a constructed instrument. Write the system (working paper, eqs. (4) and (5))

$$M = a\,Q + X^{\top} g + e, \qquad \ln Q = Z\beta + \eta \ln P + v. \tag{13.59}$$

Here M is the margin, Q volume, P the retail price and X the exogenous variables in the margin equation. Z collects demand shifters, $\eta < 0$ is the industry demand elasticity, and e and v are uncorrelated errors. If η were known, the variable

$$\ln Q' = \ln Q + \ln k - \eta \ln P = Z\beta + \ln k + v \tag{13.60}$$

would be volume purged of the direct price effect. It depends on Z and v only, so it is uncorrelated with e. It is correlated with Q, so it is a valid instrument. Some demand shifters may themselves respond to P, for example prices of other goods that rise with transport costs. Partition $Z = (Z_1, Z_2)$ with $Z_1 = \theta_0 + \theta_1 \ln P$ and Z_2 independent of P. Then

$$\ln Q = (\theta_0 + \theta_1 \ln P)\beta_1 + Z_2\beta_2 + \eta \ln P + v,$$

and the variable

$$\ln Q'' = \ln Q + \ln k - \tilde{\eta} \ln P = \theta_0\beta_1 + Z_2\beta_2 + \ln k + v, \qquad \tilde{\eta} \equiv \eta + \theta_1\beta_1, \tag{13.61}$$

is again a valid instrument. Published estimates of gasoline demand elasticities ignore such indirect effects, so they are best read as estimates of $\tilde{\eta}$.

The implementation multiplies daily volume by $kP^{-\hat{\eta}}$ with $k = \frac{\bar{P}^{\hat{\eta}}}{\bar{Q}}$, where $\bar{P}$ is the city's mean retail price and $\bar{Q}$ the mean of the corrected series. The result, $TNVOLUME = \frac{VOLUME}{\bar{Q}} \left(\frac{P}{\bar{P}}\right)^{-\hat{\eta}}$, instruments *NVOLUME* in two-stage least squares. Since $\hat{\eta}$ is unknown, the regression is repeated for $\hat{\eta} \in \{0, -0.1, -0.2, -0.3\}$, a range slightly wider than the -0.1 to -0.2 found with monthly and quarterly data. With $\hat{\eta} = 0$ the correction is void and *NVOLUME* is treated as exogenous. The correction is small: a price 20 percent above the city mean raises *TNVOLUME* relative to *NVOLUME* by $1.2^{0.3} - 1 = 5.6$ percent when $\hat{\eta} = -0.3$ and by $1.2^{0.1} - 1 = 1.8$ percent when $\hat{\eta} = -0.1$.

The contemporaneous terminal price could also be endogenous if the marginal cost of supplying a city rises with its volume. The authors argue that the feedback is small, because terminals have ten or more refiners and supply can shift across regions. A Hausman test nonetheless rejects exogeneity of the current terminal price and of the expected terminal-price change. The current price is therefore instrumented with the residual from a regression of *TERM* on *NVOLUME*. The expected change is instrumented with a forecast built from that orthogonalized series. Instrumenting does not change the results in an economically or statistically meaningful way. The residuals of (13.58) are not serially correlated, so the lagged dependent variables raise no endogeneity problem.

Measuring expectations. Expected volume comes from a forecasting regression estimated state by state (working paper, eq. (8)):

$$NVOLUME_{it} = a_0 + a_1 NVOLUME_{i,t-1} + a_2 NVOLUME_{i,t-2} + \sum_{j=2}^{12} \varsigma_j MONTH_j + a_3 t + a_4 t^2 + a_5 t^3 + e_{it}. \tag{13.62}$$

The R^2 lies between 0.80 and 0.95 for nearly all states. The one-period lead of the fitted values gives $EXP\ VOLCHG_{it} = \widehat{NVOLUME}_{i,t+1} - NVOLUME_{it}$. The instrument for *EXP VOLCHG* uses the same regression estimated with *TNVOLUME*. Expected terminal prices come from a city-level error-correction autoregression with crude oil prices (working paper, eq. (9)):

$$\begin{aligned}\Delta TERM_{it} = b_0 + \sum_{k=1}^{2} \left(b_k^+ \Delta TERM_{i,t-k}^+ + b_k^- \Delta TERM_{i,t-k}^- + d_k^+ \Delta CRUDE_{i,t-k}^+ + d_k^- \Delta CRUDE_{i,t-k}^- \right) \\ + b_9 TERM_{i,t-1} + b_{10} CRUDE_{i,t-1} + \sum_{j=2}^{12} \varsigma_j' MONTH_j + e_{it}.\end{aligned} \tag{13.63}$$

The current crude price is excluded because it would not be known when the forecast is made. The R^2 ranges from 0.30 to 0.60, lower than for volume because crude prices behave roughly like a random walk. Then $EXP\ TERMCHG_{it} = \widehat{\Delta TERM}_{i,t+1}$. The forecasting coefficients use the whole sample, which in principle includes information the firms did not have. Forecasts from rolling regressions with volume data back to 1982 change neither the predictions nor the final coefficients substantively.

Identification. The month fixed effects absorb any national seasonal pattern, including the common August peak. The coefficient on *EXP VOLCHG* is therefore identified from differences in seasonal patterns across states and from state-specific trends. These differences are large. The peak-to-trough swing is 51 percent of mean volume in Wyoming and 7 percent in Arizona. August demand is below the state mean in Florida, and January demand is above it in Colorado and Hawaii (working paper, p. 27). The coefficient on *EXP TERMCHG* is identified from city-specific terminal-price dynamics. Cold-weather cities, for instance, see winter declines in gasoline terminal prices when refiners produce heating oil and gasoline jointly. The expectation terms are functions of lagged variables and deterministic seasonals, so they are predetermined with respect to the current margin shock.

Results. Table 13.21 reproduces the two-stage least squares estimates. The coefficient on *EXP VOLCHG* is positive and significant at the 1 percent level for every assumed elasticity, and it changes little with $\hat{\eta}$. The coefficient on *EXP TERMCHG* is negative and significant at the 1 percent level throughout. Both signs are those of (13.55). The negative cost coefficient is the opposite of the inventory prediction (13.56).

Example 13.27 (Reading the magnitudes)**.** Take the column $\hat{\eta} = -0.1$, which the authors regard as closest to the true elasticity. Raise expected next-month volume by 1 percent of its mean, that is by 0.01005 units of *NVOLUME*, holding current volume fixed. *EXP VOLCHG* rises by the same amount, so the margin rises by $3.860 \times 0.01005 = 0.039$ cents, which is $\frac{0.039}{10.57} = 0.37$ percent of the mean margin. The elasticity of the margin with respect to expected next-month volume is therefore 0.37. Raise the expected next-month terminal price by 1 percent of its mean, or 0.623 cents. The margin falls by $0.062 \times 0.623 = 0.039$ cents, an elasticity of -0.37.

Table 13.21: Retail margins and expected changes in demand and cost (dependent variable *MARGIN*)

Assumed elasticity	$\hat{\eta} = 0$	$\hat{\eta} = -0.1$	$\hat{\eta} = -0.2$	$\hat{\eta} = -0.3$
$NVOLUME_t$	3.397 (0.754)	5.563 (0.758)	7.926 (0.768)	10.455 (0.785)

Observations	3,838	3,838	3,838	3,838

Notes: Two-stage least squares estimates of (13.58) with city and month fixed effects (not reported). Asymptotic standard errors in parentheses. *NVOLUME* is instrumented with the elasticity-corrected series for the assumed $\hat{\eta}$. Source: Borenstein and Shepard (1996), working-paper version, Table 2.

These are the two elasticities in the authors' abstract. A one-standard-deviation increase in *EXP VOLCHG* (0.050) adds $3.860 \times 0.050 = 0.19$ cents to the margin. A one-standard-deviation increase in *EXP TERMCHG* (4.172 cents) subtracts $0.062 \times 4.172 = 0.26$ cents.

The seasonal peak shows how the two volume terms combine. July volume averages 8.3 percent above the sample mean, which adds $5.563 \times 0.083 = 0.46$ cents to the July margin. August volume is 8.8 percent above the mean, so the expected July-to-August change of 0.5 percent adds $3.860 \times 0.005 = 0.02$ cents, for a total of 0.48 cents. In August, current volume adds $5.563 \times 0.088 = 0.49$ cents. The expected fall of 4.6 percent into September subtracts $3.860 \times 0.046 = 0.18$ cents, so August margins are only 0.31 cents above average. Margins are higher on the way up to the peak than at the peak itself, as Figure 13.13 predicts.

The rest of the table describes price adjustment. A one-cent rise in the terminal price lowers the margin in the same month by 0.305 cents, so the retail price rises by $1 - 0.305 = 0.70$ cents within the month. A one-cent fall raises the margin by 0.584 cents, so the retail price falls by only $1 - 0.584 = 0.42$ cents. Increases pass through faster than decreases. The long-run pass-through follows from the lagged levels. Setting all changes to zero in (13.58) gives $RETAIL(1 - \beta_{11}) = TERM(1 + \beta_{12}) + \text{const}$, so

$$\left.\frac{\partial\, RETAIL}{\partial\, TERM}\right|_{\text{long run}} = \frac{1 + \beta_{12}}{1 - \beta_{11}} = \frac{1 - 0.660}{1 - 0.619} = 0.89.$$

This matches the authors' statement that terminal price changes are passed through about 90 percent in the long run, a rate they cannot distinguish statistically from 100 percent.

Example 13.28 (How large should the effects be?)**.** The linearized constraint (13.55) gives a benchmark for the coefficients. Take the sample means $M = 10.57$ and $\bar{p} = 72.83$ cents, so $L = 0.145$, and an industry elasticity between 0.1 and 0.3. Then εL lies between 0.015 and

0.044. The benchmark is $\alpha_2 = \frac{M}{1-\varepsilon L}$, between 10.7 and 11.1 cents per unit change in $\ln A$, and $\alpha_3 = -\frac{\varepsilon L}{1-\varepsilon L}$, between -0.015 and -0.045. The estimates of 3.86 and -0.062 are of the same order of magnitude. The comparison is only indicative. The benchmark assumes that the constraint always binds, that punishments last one month, that the whole measured margin is collusive and that future margins do not move.

Robustness: expected versus unexpected changes. The main threat is measurement error. Monthly state volumes are matched to a single day's city prices. If current volume is measured with error and next month's volume contains information about current volume, then *EXP VOLCHG* could proxy for the true current volume. Since current volume raises margins, this would mimic the collusive effect. The two explanations differ in their predictions for *unexpected* future changes. Firms cannot respond to changes they do not foresee, so under collusion unexpected changes have zero coefficients. Under measurement error, unexpected changes would carry information about current volume as well. The authors estimate (working paper, eq. (3′))

$$\begin{aligned} MARGIN_{it} = {} & \alpha_1 EXP\ VOL_{it} + \alpha_1' UNX\ VOL_{it} + \alpha_2 EXP\ VOLCHG_{it} + \alpha_2' UNX\ VOLCHG_{it} \\ & + \alpha_3 EXP\ TERMCHG_{it} + \alpha_3' UNX\ TERMCHG_{it} \\ & + (\text{price-adjustment terms and fixed effects of (13.58)}) + e_{it}. \end{aligned} \tag{13.64}$$

Here *UNX VOLCHG* is next month's actual volume change minus its expected value. The terms *EXP VOL* and *UNX VOL* split current volume into the part predicted a month earlier and the surprise. Table 13.22 reports the key rows. Unexpected future volume changes are never significantly positive, and they differ significantly from expected changes for every nonzero $\hat{\eta}$. Unexpected terminal changes have coefficients near zero, significantly different from the expected ones. Unexpected *current* volume raises margins significantly for every nonzero $\hat{\eta}$. Margins therefore do respond to current surprises. Their failure to respond to future surprises is informative.

Table 13.22: Expected versus unexpected changes (dependent variable *MARGIN*)

Assumed elasticity	$\hat{\eta} = 0$	$\hat{\eta} = -0.1$	$\hat{\eta} = -0.2$	$\hat{\eta} = -0.3$
$EXP\ NVOLUME_t$	4.116 (0.824)	5.150 (0.830)	6.273 (0.846)	7.478 (0.871)
$UNX\ NVOLUME_t$	0.926 (1.388)	7.003 (1.402)	13.347 (1.447)	19.751 (1.518)

$UNX\ VOLCHG_t$	1.178 (1.292)	0.146 (1.309)	−1.478 (1.355)	−3.532 (1.425)
$EXP\ TERMCHG_t$	−0.059 (0.018)	−0.059 (0.018)	−0.057 (0.018)	−0.054 (0.018)
$UNX\ TERMCHG_t$	0.013 (0.016)	0.011 (0.016)	0.009 (0.016)	0.006 (0.016)
Observations	3,838	3,838	3,838	3,838

Notes: Estimates of (13.64). The price-adjustment terms, city and month fixed effects are included and not shown. Standard errors in parentheses. Source: Borenstein and Shepard (1996), working-paper version, Table 3.

Interpretation. Borenstein and Shepard read the evidence as consistent with tacit collusion in the sense of Rotemberg and Saloner (1986) and Haltiwanger and Harrington (1991). They stress what the test does not show. Collusion here need not mean prices near monopoly. With an industry elasticity between -0.1 and -0.3, demand is inelastic at observed prices, so an industry monopolist would raise prices far above them. The authors conclude that actual margins fall far short of the monopoly level. Nor does the test measure the level of collusion.

The measured margin includes delivery and other short-run variable costs, so the collusive part is smaller than 10.6 cents, and the data cannot isolate it. What the test detects is the dynamic signature of an incentive constraint. A mild form of tacit coordination fits the market: a station that cuts its price provokes nearby stations to retaliate, and the retaliation is costlier when future margins are high.

Critiques. Five limitations deserve mention. First, expectations are the econometrician's forecasts. Their coefficients are estimated on the full sample, and the true information sets of station managers are unknown. Second, volume is measured at the state level, prices at the city level, and prices only on one day per month. Third, the one-month horizon is arbitrary. Longer punishments would make the measured expectation a noisy proxy and attenuate the estimates, which the authors acknowledge. Fourth, the test rejects static pricing, but other dynamic non-cooperative models could generate forward-looking prices. Section 13.6.3 shows that Edgeworth cycles are one such model, although its mechanism differs from the one tested here. Fifth, the margin mixes the decisions of refiners, jobbers and station operators, so the colluding agents are not identified.

Contribution. The paper moved the empirical study of collusion from tight oligopolies to an unconcentrated industry with many differentiated sellers. It replaced contemporaneous price-cost relations, which require functional-form assumptions, with a dynamic implication of the incentive constraint. It also showed how to build a test that distinguishes collusion from inventory behavior and from measurement error through sign restrictions and a placebo on unforecastable changes.

13.6.3 Edgeworth cycles in Toronto: Noel (2007)

Question. In many Canadian cities retail gasoline prices follow a fast asymmetric cycle. A large, sudden price increase is followed by many small decreases until margins are thin, and then prices jump again. Consumer groups and governments have often read the synchronized jumps as collusion. Noel (2007) asks whether the cycle is instead a competitive *Edgeworth cycle*, the Markov equilibrium of dynamic price competition introduced by Maskin and Tirole (1988). The answer matters for policy, because evidence of Edgeworth cycles argues against costly investigations of covert collusion.

Theory. In the model of Maskin and Tirole (1988), two firms sell a homogeneous good and set prices alternately, each price fixed for two periods. Strategies are Markov: the moving firm conditions only on the rival's current price (and, in the extension of Noel (2007), on the current cost). With demand D^i for firm i and cost c_t, firm i earns $\pi_t^i(p_t^1, p_t^2, c_t) = D^i(p_t^1, p_t^2)(p_t^i - c_t)$. When firm 1 moves after firm 2 has set p_{t-1}^2, its values are

$$V^1(p_{t-1}^2) = \mathbb{E}_c\left[\max_{p_t}\left\{\pi_t^1(p_t, p_{t-1}^2, c_t) + \delta_1 W^1(p_t)\right\}\right], \tag{13.65}$$

$$W^1(p_{s-1}^1) = \mathbb{E}_c\left[\mathbb{E}_{p_s}\left[\pi_s^1(p_{s-1}^1, p_s, c_s) + \delta_1 V^1(p_s)\right]\right]. \tag{13.66}$$

Here W^1 is firm 1's value in a period in which firm 2 moves, and p_s is firm 2's reply. The game has two kinds of Markov perfect equilibria, focal-price equilibria and Edgeworth-cycle equilibria. The incentives behind a cycle are as follows. At a high rival price, undercutting by one step captures the whole market for a period, roughly twice what matching yields. Prices therefore fall step by step in the *undercutting phase*. Near marginal cost an undercut earns

nothing. Raising the price is costly for the firm that moves first, because the rival keeps the low price and serves the market for a period. Each firm prefers the other to restore prices, so the bottom of the cycle is a war of attrition in which firms randomize between staying low and jumping up. The firm that moves jumps all the way to the top in a single *relenting phase*. A gradual increase would be undercut at once and would not repay its cost. Figure 13.14 draws the resulting sawtooth.

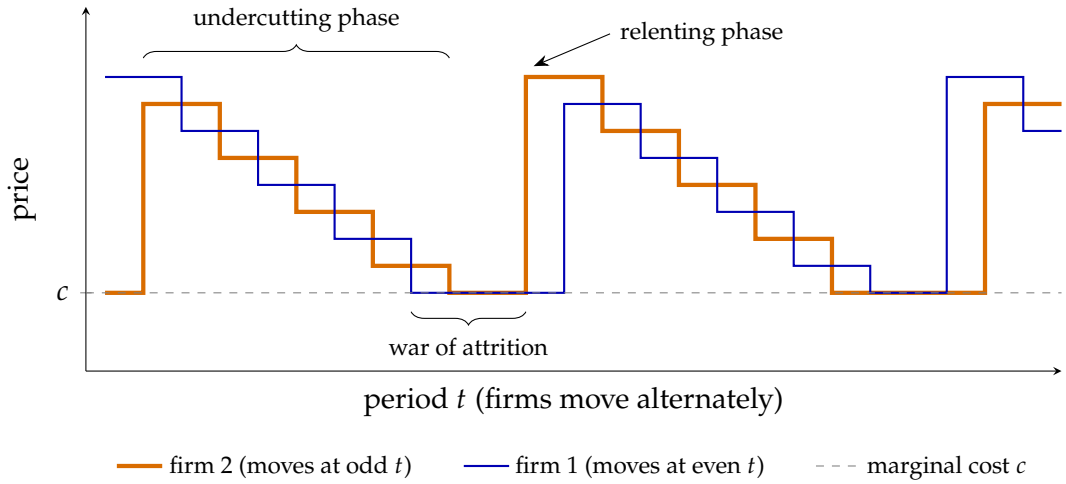

Figure 13.14: A stylized Edgeworth cycle with two symmetric firms. Each firm's price is fixed for two periods and firms move in turn. Prices fall by one step per move until they reach marginal cost c. After a war of attrition one firm relents to the top in a single jump, the rival undercuts it at once, and the cycle restarts. Where the two prices coincide, the thin line lies on the thick one. Drawn by us after the logic of Maskin and Tirole (1988) and Figure 2 of Noel (2007).

Firm asymmetries sharpen the predictions. Eckert (2003) lets firms split the market unequally at equal prices. The firm with the smaller share at equal prices gains more from undercutting, since it gives up less of the shared market, so small firms lead prices down. Large firms, which control many stations and coordinate them easily, are better placed to restart the cycle. The theory thus makes one structural prediction and three behavioral ones. The structural prediction is that each station raises its price by the full height of the cycle in one period and then lowers it in small consecutive steps. The behavioral predictions are (1) fast but not simultaneous reactions, (2) small firms lead prices down, and (3) large firms lead prices up. Edgeworth cycles survive cost fluctuations and mild spatial differentiation, so the predictions carry over to retail gasoline.

Data. Noel collected retail prices every twelve hours at 22 Toronto stations on major routes over 131 consecutive days, February 12 to June 22, 2001. Thirteen stations belong to major integrated firms and nine to independents, twelve firms in all, spread over 17 miles. The price is for regular unleaded self-service gasoline in Canadian cents per liter (cpl). The rack price is the daily spot price of the largest wholesaler at the Toronto rack, which can be treated as exogenous because U.S. wholesale supply is readily available. Excise taxes are 24.7 cpl and the sales tax is 7 percent. The average price before tax is 43.09 cpl (standard deviation 4.44), and after tax 72.53 (4.75). The rack price averages 39.77 (4.00). The lagged retail price exceeds the rack price by 3.31 cpl (2.08) on average (Table I). Figure 13.15 shows a major and an independent station against the rack price. The retail cycle is evident, and the rack price has none.

Model. For station s in period t, the regime $I_{st} \in \{R, U\}$ is either relenting or undercutting.

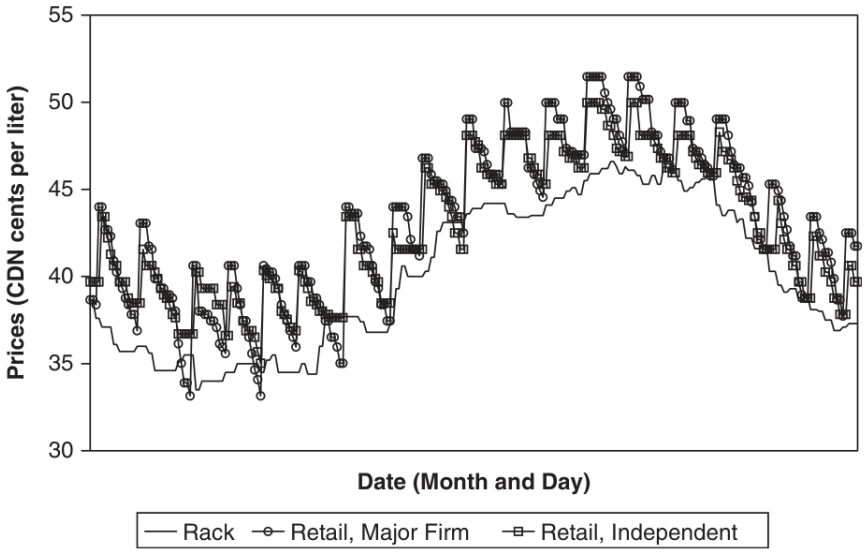

Figure 13.15: Twelve-hourly retail prices at a major-firm station and an independent station in Toronto, February to June 2001, with the rack price. Prices exclude taxes. Source: Noel (2007), Figure 1.

The regime is latent, because a zero or small change can belong to either phase. Within regime i, the price change Δp_{st} follows (Noel's eq. (4))

$$\Delta p_{st} = \begin{cases} X_{st}^{i}\beta^{i} + \epsilon_{st}^{i}, & \text{with probability } 1-\gamma_{st}^{i}, \\ 0, & \text{with probability } \gamma_{st}^{i}, \end{cases} \qquad \epsilon_{st}^{i} \sim N(0,\sigma_{i}^{2}). \tag{13.67}$$

The mass point at zero allows for stations that skip a period, since the twelve-hour sampling need not match the true length of a pricing period. The *sticky-price probability* γ_{st}^{i} and the regime transition probabilities are logits (Noel's eqs. (5)–(6)):

$$\begin{aligned} \lambda_{st}^{iR} &= \mathbb{P}\big(I_{st}=R \mid I_{s,t-1}=i, W_{st}^{i}\big) = \frac{\exp(W_{st}^{i}\vartheta^{i})}{1+\exp(W_{st}^{i}\vartheta^{i})}, \qquad \lambda_{st}^{iU} = 1-\lambda_{st}^{iR}, \\ \gamma_{st}^{i} &= \frac{\exp(V_{st}^{i}\zeta^{i})}{1+\exp(V_{st}^{i}\zeta^{i})}. \end{aligned} \tag{13.68}$$

In this subsection λ and γ are local symbols, and $a_i = \mathbb{E}[\Delta p \mid \Delta p \neq 0, \text{regime } i]$ denotes the expected nonzero price change, which Noel writes α^{i}. The density of an observed change in regime i mixes a point mass and a normal density:

$$g_i(\Delta p_{st}) = \gamma_{st}^{i}\,\mathbf{1}\{\Delta p_{st}=0\} + (1-\gamma_{st}^{i})\,\frac{1}{\sigma_i}\,\phi\!\left(\frac{\Delta p_{st}-X_{st}^{i}\beta^{i}}{\sigma_i}\right)\mathbf{1}\{\Delta p_{st}\neq 0\}, \tag{13.69}$$

where ϕ is the standard normal density. The likelihood is computed with the filter of Section 13.2.5, following Cosslett and Lee (1985) as in Ellison (1994). Let $\xi_{t|t-1}(j)$ be the probability of regime j given past price changes. Then

$$\xi_{t|t-1}(j) = \sum_{i\in\{R,U\}} \lambda_{st}^{ij}\,\xi_{t-1|t-1}(i), \qquad f(\Delta p_{st}\mid \text{past}) = \sum_{j}\xi_{t|t-1}(j)\,g_j(\Delta p_{st}),$$

$$\xi_{t|t}(j) = \frac{\xi_{t|t-1}(j)\,g_j(\Delta p_{st})}{f(\Delta p_{st}\mid \text{past})}, \qquad \ell = \sum_{s}\sum_{t}\ln f(\Delta p_{st}\mid \text{past}).$$

The parameters are estimated by maximum likelihood with Newey-West standard errors.

The cycle's characteristics follow from the switching probabilities. With constant probabilities the length of a spell in regime i is geometric, so its expected duration is $\frac{1}{1-\lambda^{ii}}$ (Lemma 13.13). The expected period of the cycle is the sum of the two expected durations. The total price increase during a relenting spell is the sum of a random number of independent price changes, each with mean $(1-\gamma^R)a_R$. By Wald's identity its expectation is the product of the mean duration and the mean change:

$$\mathbb{E}[\text{amplitude}] = \frac{(1-\gamma^R)\,a_R}{1-\lambda^{RR}}, \qquad \mathbb{E}[\text{period}] = \frac{1}{1-\lambda^{RR}} + \frac{1}{1-\lambda^{UU}}, \qquad \text{asymmetry} = \frac{1-\lambda^{RR}}{1-\lambda^{UU}}. \tag{13.70}$$

The asymmetry measure is the ratio of the undercutting duration to the relenting duration. Standard errors come from the delta method.

The anatomy of the cycle. Table 13.23 reproduces the estimates with constant parameters. The relenting phase lasts 1.008 half-days, which confirms the structural prediction: each station completes its increase within one twelve-hour period. The undercutting phase lasts 12.78 half-days, so the cycle repeats about once a week. The amplitude is 5.62 cpl, or 13 percent of the average pre-tax price and 170 percent of the average markup. Increases of 10 cpl in one step were common in the sample.

Table 13.23: Regime estimates and cycle characteristics, Toronto 2001

	(1) All firms	(2) Major firms	(2) Independents
Relenting phase			
a_R (expected nonzero change, cpl)	5.576 (0.083)	5.782 (0.101)	5.192 (0.142)
σ_R	1.650 (0.066)	1.610 (0.085)	1.655 (0.100)
γ^R (sticky share)	4.0E-5 (4.6E-4)	4.1E-5 (4.8E-4)	3.8E-5 (4.9E-4)
Undercutting phase			
a_U (expected nonzero change, cpl)	−0.751 (0.008)	−0.767 (0.010)	−0.720 (0.015)
σ_U	0.459 (0.009)	0.467 (0.012)	0.441 (0.012)
γ^U (sticky share)	0.429 (0.007)	0.422 (0.008)	0.441 (0.014)
Switching probabilities			
λ^{RR}	0.008 (0.004)	0.008 (0.005)	0.007 (0.007)
λ^{RU}	0.992 (0.004)	0.992 (0.005)	0.993 (0.007)
λ^{UR}	0.078 (0.001)	0.078 (0.002)	0.078 (0.003)
λ^{UU}	0.921 (0.001)	0.921 (0.002)	0.921 (0.003)
Cycle characteristics			
Relenting duration (half-days)	1.008 (0.004)	1.008 (0.007)	1.007 (0.007)
Undercutting duration (half-days)	12.780 (0.291)	12.779 (0.358)	12.784 (0.484)
Cycle period (half-days)	13.788 (0.291)	13.787 (0.358)	13.792 (0.485)
Asymmetry	12.680 (0.291)	12.677 (0.363)	12.687 (0.491)
Amplitude (cpl)	5.619 (0.082)	5.828 (0.098)	5.232 (0.144)

Notes: Specification (1) has no firm-type dummies. Specification (2) adds major and independent dummies to a_i, λ^{ij} and γ^i. Standard errors from the delta method in parentheses. Source: Noel (2007), Tables II and III.

Example 13.29 (Checking the cycle arithmetic)**.** From (13.70), the relenting duration is $\frac{1}{1-0.008} = 1.008$. The undercutting duration of 12.780 implies an unrounded $\lambda^{UU} = 1 - \frac{1}{12.780} = 0.9218$, which the table rounds to 0.921. The period is $1.008 + 12.780 = 13.788$ half-days and the asymmetry is $\frac{12.780}{1.008} = 12.68$. The amplitude is $(1 - 0.00004) \times 5.576 \times 1.008 = 5.62$ cpl, equal to

the reported 5.619 up to rounding. The descent can be checked the same way. The expected change per half-day in the undercutting phase is $(1 - 0.429) \times (-0.751) = -0.43$ cpl, and over 12.78 half-days prices fall by $0.43 \times 12.78 = 5.48$ cpl. Up and down movements nearly balance over a cycle, as they must when prices show no strong trend over the sample.

Small versus large firms. To test the behavioral predictions, Noel lets the parameters depend on two variables, interacted with firm type. The first, $POSITION_{st} = RETAIL_{s,t-1} - RACK_{st} - TAX_{st}$, measures how far the station's pre-tax price is above the bottom of the cycle. The second, $FOLLOW_{st}$, equals one if some other station has already relented and station s has not. The probability of switching from undercutting to relenting rises steeply as margins shrink. For majors it is 0.046 at the mean *POSITION* of 3.31 cpl and 0.110 at 1.53, the mean just before a relent. It reaches 0.272 at zero and 0.803 at the minimum of −3.24 (Table IV). At *POSITION* = 1.53 the derivative $\frac{\partial \lambda^{UR}}{\partial\, POSITION}$ is −0.065 (0.006) for majors and −0.051 (0.006) for independents.

Prediction (2) holds. Near the top of the cycle independents undercut more often and majors keep sticky prices. Near the bottom the roles reverse. The derivative of the sticky-price probability with respect to *POSITION* is 0.036 (0.002) for majors and −0.034 (0.005) for independents (Table V). Large firms try to hold high prices for a while, then chase the small firms down. Just before a relent majors are often cheaper than independents.

Prediction (3) holds as well, and Table 13.24 shows it. When no station has yet relented, a major relents in a given half-day with probability 0.091 and an independent with probability 0.026. Once some station has relented, a major follows within half a day with probability 0.925 and an independent with probability 0.720. Both probabilities are high, which confirms prediction (1): reactions are fast but not simultaneous. With data sampled every two days or less often, the increases would look perfectly synchronous. A major that follows raises its price by 0.200 cents less than if it had led, which is the predicted undercut of the leader by the follower. The relenting jump falls almost one for one with *POSITION* (derivatives −0.897 for majors and −0.873 for independents), so stations restore a nearly standard markup.

Table 13.24: Leaders and followers: probability of switching from undercutting to relenting in a half-day

	Leaders (no station has relented)		Followers (some station has relented)	
	Majors	Independents	Majors	Independents
POSITION = 1.53	0.091 (0.006)	0.026 (0.003)	0.925 (0.045)	0.720 (0.045)
POSITION = 0	0.235 (0.020)	0.066 (0.011)	0.974 (0.016)	0.868 (0.030)

Notes: Entries are λ^{UR} from specification (4), in which the relenting jump and the switching probability depend on firm type, *FOLLOW*, *POSITION* and their interactions. Delta-method standard errors in parentheses. A *POSITION* of 1.53 cpl is the average just before a relent. Source: Noel (2007), Table V.

Competing hypotheses. Noel rejects four alternatives to Edgeworth cycles. A day-of-the-week demand cycle cannot produce one large jump followed by daily declines. The jump falls on different weekdays, and periods range from four to ten days. Relents do cluster early in the week. The first relent of a round comes on Monday 18 percent of the time, Tuesday 32, Wednesday 22, Thursday 18, Friday 10 and never at weekends. Differences in menu or monitoring costs cannot explain why majors move faster upward but not downward. Inventory depletion would require station managers to misforecast their sales in the same direction every period, and deliveries occur on different days for different stations. Rack-price discounts are below 1 cpl, against an amplitude of 5.6 cpl, and do not vary over time.

The fifth alternative, covert collusion, cannot be excluded by any price pattern, since the folk theorem (Chapter 12) admits many collusive paths. Noel argues that a cycle is an implausible collusive scheme. Simple rules such as a constant markup are easier to agree on and to monitor. Cycles require fast, differentiated price moves at hundreds of stations, and their large jumps attract complaints. The data also show no single price leader: different firms lead the relents, and the ranking of stations changes often during the descent.

Interpretation and critiques. The evidence supports a competitive reading of the Toronto cycle. Its price wars are not punishments: prices fall repeatedly and predictably as firms compete, and informed consumers can lower what they pay by timing purchases. An informal poll of 58 residents found that they expected 58 percent of price changes to be increases, whereas 86 percent of actual changes were decreases. The study has clear limits. It has no quantity data, so it cannot measure welfare or the station-level elasticity behind the fast undercutting. The sample is 22 stations over 131 days. The tests are consistency tests, since the theory leaves the amplitude and the top price undetermined. The main caveat for detection comes from Quebec. Section 13.6.4 shows that a documented cartel there also produced asymmetric cycles. The shape of the cycle cannot by itself separate competition from collusion. The role assignments of small and large firms carry more of the evidential weight than the shape. Later work exploits sharper variation, for example a regulation of the timing of price changes in Perth studied by Wang (2009).

13.6.4 A prosecuted cartel with asymmetric retailers: Clark and Houde (2013)

Question. Repeated-game theory has long recognized that firms with different costs or sizes need side payments to collude (Jacquemin and Slade, 1989). Upstream cartels can assign quotas or territories. In a retail market with posted prices, however, a cartel cannot tell consumers where to shop. At a common price, market shares follow locations and amenities. They need not match what each firm requires to stay in the cartel. Clark and Houde (2013) ask how a cartel of heterogeneous gasoline retailers solved this problem, using the record of a prosecuted case.

Setting and data. The cartel came to light after a Victoriaville newspaper published, on June 6, 2004, an interview with station owner Christian Goulet. He claimed he was harassed for refusing to go along with price fixing. The Canadian Competition Bureau began recording phone conversations on March 3, 2005 and executed search warrants from May 29, 2006. Charges were announced on June 12, 2008, with later rounds in 2010 and 2012, against fourteen companies and thirty-nine individuals in total. By September 2012 seven companies and 27 individuals had pleaded guilty, with company fines from $90,000 to $1,850,000. The case covers 128 stations and 64 firms in Victoriaville, Thetford Mines, Sherbrooke and Magog.

Three sources are combined. The Competition Bureau's court documents summarize or quote the recorded calls for each price change, with caller, receiver and time. A weekly station-level survey by the Quebec energy board (the Régie de l'énergie) covers 2002–2005. A quarterly survey by Kent Marketing reports volumes, characteristics and the full cross-section of prices. The key players differ sharply. Bilodeau (Shell) organized the cartel in Victoriaville and Thetford Mines and Bourassa (Olco) in Sherbrooke. Both run the largest networks of lessee stations. Ultramar, the only refiner in eastern Quebec, sets prices centrally and runs a low-price guarantee that commits its stations to post the lowest price in each neighborhood. Two big-box retailers, Canadian Tire and Maxi, run high-volume stations as loss leaders. Couche-Tard, the largest convenience-store chain, sets prices through one regional representative.

Heterogeneous costs. Station sizes vary widely. The average Sherbrooke station sells 48.67 thousand liters a week with a standard deviation of 24.56 (Table 2). Following Houde (2012), marginal cost is additive in the *minimum estimated price* (MEP), a weekly price floor published by the Régie that stations may not undercut:

$$mc_{jt} = MEP_t + c_j. \tag{13.71}$$

The station cost differential c_j comes from Houde (2012). He recovers station marginal costs by inverting the multi-product Bertrand first-order conditions of a spatial demand model (Chapter 4) and regresses them on station characteristics. Stations with more pumps, a convenience store or a car wash have lower costs. The differentials range from −0.05 to −1.98 cpl in Sherbrooke and from −0.02 to −2.03 cpl in Victoriaville. Ultramar's stations are on average 1.6 cpl below the MEP.

Price patterns. Weekly price changes in the cartel cities from 2002 to 2005 form an asymmetric cycle (Figure 13.16). Increases are spread symmetrically around 4 cpl, with an interquartile range of 2 cpl. Cuts cluster at 1 or 2 cpl, and 70 percent are at most 2 cpl. Floor changes are much more symmetric, so prices rise faster than they fall. Prices were unchanged two weeks in a row 48 percent of the time in Victoriaville, 57 percent in Thetford Mines and 36 percent in Sherbrooke. The floor was constant only 1.2 percent of the time. In Victoriaville and Thetford Mines, 95 percent of price changes kept the ending digit fixed. The cross-section of prices was concentrated. In Victoriaville the suggested price was 2 cpl above the minimum, and two fringe stations were allowed to post up to 2 cpl below it. In Thetford Mines self-service stations posted half a cent below full-service ones.

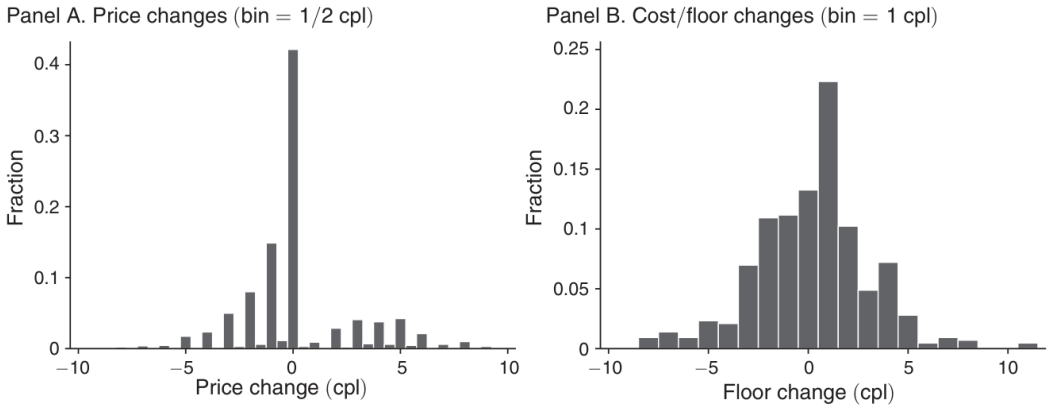

Figure 13.16: Distribution of weekly price changes (panel A) and of price-floor changes (panel B) in the cartel cities, 2002–2005. Source: Clark and Houde (2013), Figure 1.

Why asymmetry is a problem: a two-firm model. The authors illustrate the enforcement problem with two retailers of a homogeneous good facing inelastic unit demand. Firm H has marginal cost $c > 0$ and firm L has cost 0. At the cartel price $\bar{p}$ they hold shares s_H and $s_L = 1 - s_H$. After a deviation they play static Bertrand forever, in which H earns zero and L serves the market at price c. The incentive constraints are

$$IC^H: \ \frac{s_H(\bar{p} - c)}{1 - \delta} \geq p_H^d - c, \qquad IC^L: \ \frac{s_L \bar{p}}{1 - \delta} \geq p_L^d + \delta \frac{c}{1 - \delta}, \tag{13.72}$$

where p_j^d is the deviation price. The low-cost firm loses less from the punishment, because it keeps the whole market at price c.

Proposition 13.30 (Collusion needs an unequal split)**.** *In the two-firm model, let deviations undercut $\bar{p}$ by an arbitrarily small amount. Collusion at $\bar{p}$ is sustainable if and only if*

$$\delta \geq \underline{\delta}(s_L) \equiv \max\left\{s_L,\ \frac{(1-s_L)\,\bar{p}}{\bar{p}-c}\right\}.$$

The threshold is minimized at $s_L^* = \frac{\bar{p}}{2\bar{p}-c} > \frac{1}{2}$, where $\underline{\delta}(s_L^*) = \frac{\bar{p}}{2\bar{p}-c}$. With equal shares the threshold is $\frac{\bar{p}}{2(\bar{p}-c)}$, which is at least one when $c \geq \frac{\bar{p}}{2}$, so collusion with equal shares is then impossible for every $\delta < 1$.

Proof. Let $p_H^d, p_L^d \to \bar{p}$. Multiplying IC^H by $1-\delta$ gives $s_H(\bar{p}-c) \geq (1-\delta)(\bar{p}-c)$, or $\delta \geq 1-s_H = s_L$. Multiplying IC^L by $1-\delta$ gives

$$s_L\bar{p} \geq (1-\delta)\bar{p} + \delta c,$$

which rearranges to $\delta(\bar{p}-c) \geq (1-s_L)\bar{p}$, or $\delta \geq \frac{(1-s_L)\bar{p}}{\bar{p}-c}$. Both must hold, which gives the maximum. The first term increases in s_L and the second decreases, so the maximum is smallest where they are equal: $s_L(\bar{p}-c) = (1-s_L)\bar{p}$, or $s_L^* = \frac{\bar{p}}{2\bar{p}-c}$. Since $c > 0$, $s_L^* > \frac{1}{2}$. Substituting $s_L = \frac{1}{2}$ gives $\max\{\frac{1}{2}, \frac{\bar{p}}{2(\bar{p}-c)}\} = \frac{\bar{p}}{2(\bar{p}-c)}$, which is at least one when $\bar{p} \leq 2c$. □

The proposition is our formalization of the authors' example. With a large cost gap, collusion on equal shares is impossible at any discount factor, while a split that favors the low-cost firm sustains it for δ close to one. The cartel thus faces an *enforcement problem*, which requires shifting market share toward low-cost and small-network firms. It also faces a *coordination problem*, because firms with different deviation gains disagree about the price. In posted-price retail the cartel cannot set s_L directly. It has to create temporary price differences that move volume toward the firms it needs to keep on board.

The mechanism: a coordinated order of play. The court documents show how. A price increase works like a negotiation. The leader first agrees with Couche-Tard and the active followers on a target price and a time t_0 at which most stations raise their prices. The leader then contacts Ultramar and the big-box retailers and proposes a later time $t_1 \geq t_0$ for their increase. Dissident stations, which are independents with large capacity or outlying locations, are told of the increase directly or indirectly. A typical Victoriaville increase involved about 65 calls, many between the leader and Couche-Tard (Table 3). Low-cost stations and dissidents received far more calls than they made. The delay was explicit. When a station owner said he would wait for the neighboring Ultramar station, Bilodeau replied: "I know that, I'm not worried, it's always the same thing." An Ultramar manager described the arrangement in these words. "We built the system seven years ago, the competitors know that the program belongs to us and we want to be sure that we are the last one to move [up]."

Most stations raise their prices at once, while a group delays by up to four hours in Victoriaville and 80 minutes in Thetford Mines (Figure 3). Table 13.25 regresses each station's delay on station categories and episode characteristics. Relative to the leader's stations, Ultramar and the big-box stations raise their prices about two and a half hours later in Victoriaville and about an hour later in Thetford Mines. Larger proposed increases shorten the delays. A larger increase makes the delay more costly for early movers and more valuable for late movers, so the cartel grants less time. Delays are longer when more than 20 days have passed since the

last increase, because the transfer then accumulates over a longer interval. Price decreases are different. Ultramar initiates them without warning, nine of the ten documented decreases in Victoriaville and three of the four in Thetford Mines. Others match quickly without retaliation, and a decrease involves about 26 calls. The low-price guarantee makes Ultramar the natural leader of cuts and saves the cartel the cost of coordinating them. The leader's role on the way down is to warn followers quickly, so that they stay competitive and do not cut on their own. A linear probability model of who receives such a warning (Table 6 of the paper) shows that the low-cost chains are rarely called, because they start the cuts. In the pooled sample, followers are 25 percent less likely to be warned than the leader's own stations.

Table 13.25: Price-increase delays (minutes after the leader's stations) and station characteristics

	(1) Victoriaville	(2) Thetford Mines
Dissident stations	157.6*** (37.88)	
Low-cost chains (Ultramar, big-box)	149.4*** (21.33)	64.70*** (9.206)
Follower stations	37.41** (15.75)	13.71* (7.019)
Couche-Tard stations	23.68 (23.50)	−13.74*** (4.879)

Observations	122	83
R^2	0.657	0.535

Notes: OLS, robust standard errors in parentheses. The reference group is the leader's network. Delays of dissidents are observed only when they cooperated, and the actions of the two Thetford Mines dissidents are never observed. ***, **, *: significant at 1, 5, 10 percent. Source: Clark and Houde (2013), Table 4 (the regression of delays).

The value of delay: demand model. To measure the transfer, the authors model a firm that may raise its price late, or cut it early. It receives a fraction τ_t of the week's demand at the initial price vector. The paper writes α_t for this share and γ for the price coefficient. We use τ_t and α to keep the book's notation, in which α is the price coefficient. The documents suggest delays of about half a day on increases and thirty minutes on decreases, at most once a week. With uniform demand over twelve open hours a day, this would be $\frac{1}{14}$ and $\frac{1}{168}$ of weekly sales. Predictable increases and the price dispersion they create make consumers time their purchases, so the authors set $\tau = \frac{1}{7}$ for increases and $\tau = \frac{1}{140}$ for decreases. Three firms (Ultramar, Maxi and Canadian Tire) may delay increases and only Ultramar may lead cuts.

Two demand models bracket the truth. In the homogeneous model consumers buy at the cheapest station, shares are $\frac{1}{N}$ at equal prices, and low-price stations serve the whole market during a delay. The market size is the population of Victoriaville times three liters a day. The logit model (Chapter 7) gives station j the demand

$$D_j(\mathbf{p}_t) = M \, \frac{\exp(X_{jt}\beta + \xi_q - \alpha p_{jt})}{\exp(-\alpha p_{0t}) + \sum_k \exp(X_{kt}\beta + \xi_q - \alpha p_{kt})}. \tag{13.73}$$

Mean quality $X_{jt}\beta + \xi_q$ depends on size and amenities X_{jt} and on a quarter effect ξ_q. The paper writes it as δ_{jt}, a symbol that this chapter reserves for the discount factor. The price p_{0t} is the

average price in neighboring markets, and M is market size. Let $\tilde{\mathbf{p}}_t$ be the price vector at the start of the week, before late movers adjust, and let $\mathcal{T}_t$ be the set of firms receiving a transfer. Demand with delays is

$$D_{j,t}(\mathbf{p}_t, \tau_t) = \begin{cases} \tau_t D_j(p_{j,t-1}, \tilde{\mathbf{p}}_{-j,t}) + (1-\tau_t) D_j(\mathbf{p}_t), & j \in \mathcal{T}_t, \\ \tau_t D_j(p_{j,t}, \tilde{\mathbf{p}}_{-j,t}) + (1-\tau_t) D_j(\mathbf{p}_t), & j \notin \mathcal{T}_t. \end{cases} \tag{13.74}$$

During an increase a receiver keeps its old, lower price for the fraction τ_t of the week while the others have already moved. The demand parameters $\Theta^{\mathrm{d}} = (\alpha, \beta, \xi)$ are estimated by nonlinear least squares on quarterly Kent volumes $\hat{Q}_{jq}$ for Victoriaville, 2001–2007:

$$\min_{\Theta^{\mathrm{d}}} \sum_{j} \sum_{q} \left(\log \hat{Q}_{jq} - \log Q_{jq}(\Theta^{\mathrm{d}}) \right)^2, \qquad Q_{jq}(\Theta^{\mathrm{d}}) = \sum_{t \in q} D_{j,t}(\mathbf{p}_t, \tau_t \mid \Theta^{\mathrm{d}}). \tag{13.75}$$

The estimated coefficient on price in utility is -0.409, with prices in cents per liter, so $\hat{\alpha} = 0.409$. It implies a store-level elasticity of about -30. In the logit model the own elasticity is $-\alpha p_j (1 - s_j)$, and shares are only 0.01–0.03 (Table 2). An elasticity of -30 therefore corresponds to $p_j(1 - s_j) \approx \frac{30}{0.409} = 73$ cents per liter (our computation). Identification comes mostly from the two dissident stations that priced 2 cpl below the cartel price and from the collapse of price dispersion after the cartel ended. One of these stations lost half of its market share after the collapse. Prices are treated as exogenous given quarter effects and characteristics. The authors note that the dissidents were not randomly assigned, so $\hat{\alpha}$ may be biased. Houde (2012) obtains a lower average elasticity of -15 with bimonthly Quebec data.

Results: volume transfers. Table 13.26 reports the simulated change in each group's sales when the delays are switched on. Increases occur in only 16–23 percent of weeks but are large, so they generate sizable transfers. The low-cost firms gain about 4 percent of volume in Victoriaville and about 6 percent in Sherbrooke and Thetford Mines. The two demand models give similar answers except in Victoriaville. There the homogeneous model ignores the unequal shares created by location and amenities and predicts larger gains.

Table 13.26: Simulated change in sales volume from the delay scheme

		Share of weeks with		Logit demand		Homogeneous demand	
Market	Players	increase	decrease	Percent	1,000 l.	Percent	1,000 l.
Sherbrooke	Ultramar	0.225	0.373	0.061	6,759.584	0.055	733.012
	Big-box	0.224	0.372	0.059	773.265	0.047	651.790
	Other	0.223	0.370	−0.014	−275.124	−0.035	−442.205
Thetford Mines	Ultramar	0.169	0.350	0.064	895.420	0.056	763.006
	Other	0.168	0.349	−0.009	−52.570	−0.027	−337.746
Victoriaville	Ultramar	0.164	0.284	0.040	522.315	0.079	752.152
	Big-box	0.164	0.284	0.038	366.553	0.054	515.890
	Other	0.161	0.288	−0.010	−79.329	−0.025	−215.419

Notes: "Percent" entries are proportional changes (0.061 is 6.1 percent) in total sales volume over the collusive period when the delay scheme is added to the simulation. The entry 6,759.584 is reproduced as printed, although it is about ten times the neighboring entries. Source: Clark and Houde (2013), Table 7.

Results: delays and cartel stability. To study stability, the authors take the observed price path from January 2002 to October 2004 as the collusive path, with one common price p_t per week.

Information is perfect, so price wars occur only off the path. Punishment sets prices at a floor for T weeks, either the MEP or the "long-run" floor of MEP plus 3 cpl, after which collusion resumes. The big-box stations receive an extra 2 cpl cost advantage to capture their loss-leader motive, which puts their differential near -3 cpl against Ultramar's -2.03. Firm f, owning stations $\mathcal{J}_f$, earns in week t

$$\Pi_{f,t} = \begin{cases} \sum_{j \in \mathcal{J}_f} \left[\tau_t \pi_j(p_{j,t-1}, \tilde{\mathbf{p}}_{-j,t}) + (1-\tau_t)\pi_j(\mathbf{p}_t) \right], & f \in \mathcal{T}_t, \\ \sum_{j \in \mathcal{J}_f} \left[\tau_t \pi_j(p_{j,t}, \tilde{\mathbf{p}}_{-j,t}) + (1-\tau_t)\pi_j(\mathbf{p}_t) \right], & f \notin \mathcal{T}_t, \end{cases} \qquad \pi_j(\mathbf{p}) = D_j(\mathbf{p})\,(p_j - mc_{jt}).$$

An agreement $\mathcal{A} = \{p_t, \tau_t, \mathcal{T}_t, T\}_{t \geq 0}$ is enforceable if every firm prefers cooperation at every date:

$$V^{c}_{f,t}(\mathcal{A}) - V^{d}_{f,t}(\mathcal{A}) = \sum_{s=0}^{T} \delta^s \, \Pi_{f,t+s} - \left[\Pi^{d}_{f,t} + \sum_{s=1}^{T} \delta^s \, \Pi^{p}_{f,t+s} \right] \geq 0. \tag{13.76}$$

Collusion resumes after the punishment, so the cooperation and deviation paths coincide from $t+T+1$ on and the comparison stops at T. The deviation profit $\Pi^{d}_{f,t}$ is the best one-week profit from undercutting all of the firm's stations by a whole number of cents, and $\Pi^{p}_{f,t} = \sum_{j \in \mathcal{J}_f} \pi_j(\mathbf{p}^{f}_{t})$ is profit at the floor. The weekly discount factor is 0.99. The deviation frequency is the share of firm-weeks at which (13.76) fails. The minimum punishment T^{*} is the shortest war that prevents every deviation in the sample.

Table 13.27 shows that delays matter at intermediate punishment lengths. With very short or very long wars the deviation frequency is one or zero with or without transfers. In between, the delays lower it. They also shorten the war needed to deter all deviations. In the homogeneous model the saving is 27 weeks with the high floor and 9 weeks with the low floor. In the logit model it is 6 weeks with the high floor and zero with the low floor. A higher floor weakens punishments, and less differentiation raises the gain from undercutting. In both cases the cartel is less stable, and transfers become more valuable.

Table 13.27: Deviation frequencies and minimum punishment lengths, Victoriaville

Specification		Deviation frequency				Minimum punishment T^{*}	
Floor	Demand	$T=4$	$T=8$	$T=32$	$T=52$	Delays	No delays
$MEP_t + 3$	logit	0.868 (0.017)	0.516 (0.085)	0.009	0.000	35	41
MEP_t	logit	0.460 (0.073)	0.078 (0.004)	0.000	0.000	15	15
$MEP_t + 3$	homogeneous	1.000 (0.000)	0.981 (0.016)	0.636 (0.104)	0.394 (0.406)	144	171
MEP_t	homogeneous	1.000 (0.000)	0.956 (0.022)	0.340 (0.435)	0.071 (0.286)	67	76

Notes: Share of firm-weeks, January 2002 to November 2004, in which the incentive constraint (13.76) fails, with the delay transfers. Numbers in parentheses are the proportional change in that frequency when the transfers are removed. T^{*} is the shortest punishment, in weeks, with no deviation in the sample. Source: Clark and Houde (2013), Table 8.

Table 13.28 measures who gains. With logit demand the delays raise the net value of collusion for the three receivers by 3 to 13 percent. With homogeneous demand the gains range

from 17 to 53 percent. The early movers, 88 percent of firms, lose between 1 and 5 percent on average. Ultramar gains least, because its two-station network already gains less from deviating. Network size, more than cost, emerges as the main source of asymmetry, partly because the floor limits the effect of cost differences.

Table 13.28: Net value of the delay transfers, Victoriaville (thousands of dollars)

Floor	Demand	Canadian Tire	Maxi	Ultramar	Others
$MEP_t + 3$	logit	14.956 (0.129)	17.000 (0.127)	7.373 (0.075)	−1.685 (−0.025)
MEP_t	logit	15.424 (0.049)	17.471 (0.048)	7.478 (0.032)	−1.577 (−0.011)
$MEP_t + 3$	homogeneous	41.892 (0.523)	42.195 (0.531)	46.386 (0.273)	−4.528 (−0.051)
MEP_t	homogeneous	44.420 (0.290)	44.736 (0.294)	47.985 (0.168)	−5.695 (−0.032)

Notes: Change in the net value of cooperation $V^c_{f,t} - V^d_{f,t}$ when the delays are added, evaluated at the minimum punishment T^* without delays (last column of Table 13.27). Proportional changes in parentheses. "Others" is the average over the firms that move early. Source: Clark and Houde (2013), Table 9.

Interpretation. The Quebec cartel solved its enforcement problem with intertemporal transfers implemented through the order of play. The transfers resemble the sales-based payments of Harrington and Skrzypacz (2011) (Chapter 12) and the sidepayments of Asker's bidding ring (Section 13.8). Their currency is time, and the timing is predictable and agreed in advance. The pricing rule of large, infrequent increases followed by small cuts or constant prices resembles an (s, S) rule. It economizes on the costly and risky communication needed to coordinate increases, while a constant-markup rule would require frequent coordinated changes as costs move. The two signatures that antitrust authorities usually look for, parallel price changes and stable margins, are both absent. Sequential moves and asymmetric cycles can be part of a collusive agreement. Clark and Houde (2013, p. 25) report that their companion paper (Clark and Houde, 2014) finds a substantial fall in price asymmetry in all four cities after the search warrants were executed. The fall stems largely from larger price cuts, once the cartel could no longer prevent firms from undercutting their rivals.

Critiques. The analysis relies on summaries of conversations selected by investigators. Only a few price increases are common to all stations, so the standard errors of the episode variables are understated, as the authors note. The price coefficient comes from non-random variation. The stability exercise assumes perfect information and immediate punishment, whereas the two documented deviations were met with weeks of threats and negotiation before a price war began. The model treats the delay as given. A full account would let firms bargain over delays and prices (Harrington, 1991). The price floor regulation is specific to Quebec, and it shapes both the cost function and the punishment.

Contribution. The paper is among the first to document the internal organization of a retail cartel. It identifies a transfer mechanism suited to posted-price markets, quantifies it with demand models, and shows through a structural incentive-constraint exercise when it matters for stability. Its main message for detection is that collusion and competitive Edgeworth cycles can generate similar price paths.

13.6.5 The end of the cartel as a natural experiment: Erutku and Hildebrand (2010)

Question and setting. When an investigation becomes public, a cartel may collapse. Erutku and Hildebrand (2010) use the public announcement of the Quebec investigation to estimate

the overcharge in Sherbrooke, the largest of the four cities. Sherbrooke has close to 150,000 residents and about 60 stations (Table 1). Court documents report 16 price increases or attempted increases between April 1, 2005 and April 18, 2006. The Bureau's documents give different counts of the participants (p. 224, note 2). The number of conspirators in Sherbrooke is 53, 54 or 63, and the number of stations 64, 65 or 66. With 53 participants and 66 stations, at least 80 percent of the stations took part at some point. On May 29, 2006 the Bureau's officers raided stations in the Sherbrooke-Victoriaville area, and on June 2 the Commissioner of Competition publicly confirmed the investigation. The authors treat these events together as the announcement. On June 12, 2008 the Commissioner announced criminal charges against 13 individuals and 11 companies in the four cities. Fines on the parties that pleaded guilty totaled over $2 million, and the Bureau's immunity program offered protection to the first party to disclose the offense (p. 224).

The market structure is unusual for a prosecuted cartel. In the price-fixing cases brought by the U.S. Department of Justice from 1963 to 1972, 49 of 62 cases had ten or fewer conspirators. The four-firm concentration ratio exceeded 50 percent in 38 of the 50 cases with data (our tabulation of Hay and Kelley's table as reproduced in Erutku and Hildebrand, 2010, Table 2). In Sherbrooke at least 50 different individuals coordinated price increases (p. 227). The market was not concentrated, with a Herfindahl index below 1,800. Ultramar, the largest retailer with 14 outlets, came close to being a maverick. Its Value Plus program promised prices no higher than competitors' lowest prices in each price zone, so Ultramar followed an increase only after every other station had raised its price. Sometimes it waited so long that the agreed increase collapsed (p. 227). Demand followed a seesaw, with each high-volume quarter followed by a low-volume quarter, which made fluctuations deterministic (p. 228). The authors score the market against eight items of the antitrust checklist derived from Stigler (1964) (their Table 3). Only three point toward collusion: buyers who make frequent small purchases, price transparency and multimarket contact. The others, such as a small number of sellers and high entry barriers, are absent. Section 13.9.1 returns to what the case implies for the weight of such checklists.

Data. Weekly city-average retail prices net of taxes come from MJ Ervin, which surveys stations by telephone every Tuesday morning. They cover Sherbrooke, Montreal and Quebec City from May 31, 2005 to May 22, 2007, which gives 52 weeks before and 52 weeks after the announcement. Weekly wholesale prices in Montreal and Quebec City are identical and serve as marginal cost. Average retail prices were 64.8 cpl before and 64.0 after the announcement in Sherbrooke, 65.1 and 64.1 in Quebec City, and 62.0 and 62.9 in Montreal (Table 4). The average wholesale price rose from 58.1 to 58.8 cpl (Table 5). The raw difference in differences against Montreal is $(64.0-64.8)-(62.9-62.0) = -1.7$ cpl. Against Quebec City it is $(64.0-64.8)-(64.1-65.1) = 0.2$ cpl.

Estimating equation. With i indexing the treated city and one control city, the regression is (their eq. (1), our notation)

$$P_{it} = a_0 + a_1 S_i + a_2 Post_t + \tau^{\mathrm{DD}}\big(Post_t \times S_i\big) + \sum_{l=0}^{2} b_l\, w_{i,t-l} + \mu_{q(t)} + e_{it}. \tag{13.77}$$

Here P_{it} is the retail price, S_i indicates Sherbrooke and $Post_t$ indicates weeks after the announcement. The $w_{i,t-l}$ are current and lagged wholesale prices, and $\mu_{q(t)}$ are quarter effects. The paper writes the four dummy coefficients as $\gamma_0, \ldots, \gamma_3$. The coefficient τ^{DD} is the change in Sherbrooke's price relative to the control after the announcement. Under the

parallel-trends assumption of difference in differences (Appendix A), and if the cartel ended at the announcement, $-\tau^{DD}$ measures the overcharge. The equation is estimated by OLS with White standard errors and then by the Hildreth-Lu method, which corrects for first-order serial correlation ρ in the errors. Results with one to four wholesale lags are similar, and the table reports two. Each regression uses the control city's wholesale price for both cities (p. 231).

Table 13.29: Difference-in-differences estimates of the announcement effect on Sherbrooke retail prices

	Control: Montreal		Control: Quebec City	
	Coefficient	t-statistic	Coefficient	t-statistic
Constant	1.35 (1.94)	0.70	2.58 (1.95)	1.32
S_i (Sherbrooke)	2.80 (0.57)	4.94**	−0.32 (0.58)	−0.55
$Post_t$	0.21 (0.56)	0.37	−1.84 (0.58)	−3.17**
$Post_t \times S_i$	−1.75 (0.80)	−2.19*	0.26 (0.82)	0.31
w_{it}	0.73 (0.05)	16.19**	0.62 (0.04)	15.08**
$w_{i,t-1}$	0.30 (0.05)	5.87**	0.35 (0.04)	7.83**
$w_{i,t-2}$	0.01 (0.04)	0.31	0.12 (0.04)	2.81
ρ	0.09 (0.07)	1.25	0.20 (0.07)	2.68**
R^2	0.91		0.92	
Durbin-Watson	2.00		2.03	

Notes: Estimates of (13.77) with Sherbrooke as the treated city. $N = 208$ city-weeks in each regression. Quarter effects not reported. Standard errors in parentheses. * significant at 5 percent, ** at 1 percent. Source: Erutku and Hildebrand (2010), Table 6.

Results. Table 13.29 reports the estimates. Before the announcement Sherbrooke's prices exceeded Montreal's by 2.80 cpl, controlling for wholesale prices, and were indistinguishable from Quebec City's. Against Montreal, $\hat{\tau}^{DD} = -1.75$ (0.80), significant at 5 percent. Against Quebec City the estimate is 0.26 (0.82), while the common post-announcement term is −1.84 (0.58). Sherbrooke and Quebec City prices fell together after the announcement (Figure 13.17 shows Sherbrooke against Montreal). Moving the assumed announcement date by one to four weeks in either direction leaves the Montreal estimate negative, significant at 10 percent and above 1.34 cpl in absolute value. With Quebec City as the control no shift produces a meaningful effect.

The authors read the Montreal estimate as an overcharge of 1.75 cpl. Relative to the post-announcement Sherbrooke price, this is $\frac{1.75}{64.0} = 2.7$ percent of the retail price. Relative to the post-announcement margin over wholesale cost, it is $\frac{1.75}{64.0-58.8} = 34$ percent. About 135 million liters were sold in Sherbrooke between May 2005 and May 2006, so damages in the year before the announcement exceed $2 million ($0.0175 \times 135$ million = $2.4 million, our arithmetic). The 2.7 percent overcharge is small next to surveys of cartel overcharges (their Table 7, reproduced in Table 13.49), but the increase in the markup is large. The authors compare it with Ohio school milk (p. 235). There Porter and Zona (1999) estimate an average price effect of 6.5 percent, which they translate into a rise of roughly 30 percent in the markup (Section 13.9.4). A cartel under investigation may also keep prices high to reduce estimated damages (Harrington, 2004), so the estimate could understate the effect.

Critiques. The design rests on the choice of control. Quebec City matched Sherbrooke in levels before the announcement and moved with it after. Either Quebec City prices were also affected by the investigation, or the Montreal estimate reflects Montreal-specific shocks. The data cannot tell these apart. Parallel trends are checked only visually. There is one treated city

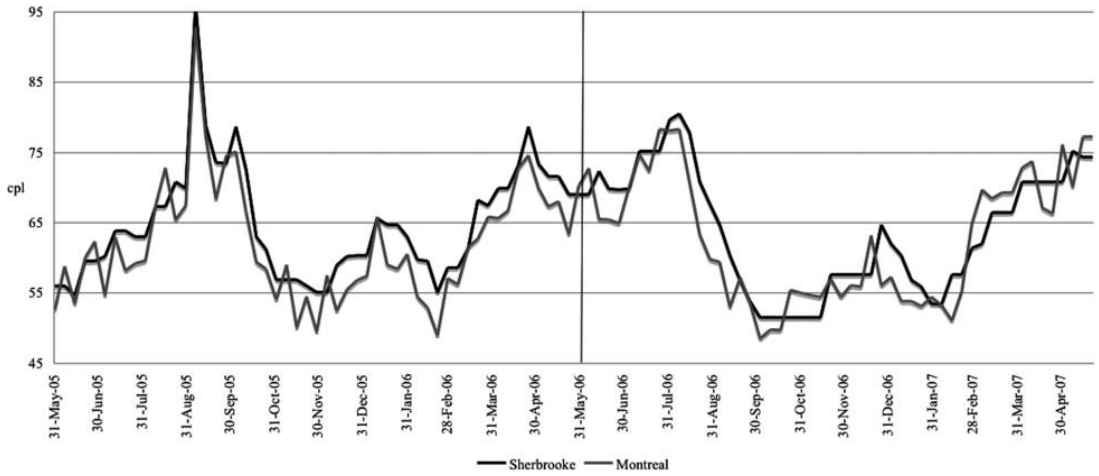

Figure 13.17: Weekly retail prices net of taxes in Sherbrooke (black) and Montreal (gray), June 2005 to May 2007, in cents per liter. The vertical line marks the announcement of the investigation at the end of May 2006. Source: Erutku and Hildebrand (2010), Figure 2.

and one control city in each regression, so inference treats the weekly observations of a single pair as independent apart from an AR(1) correction. The general problems of difference in differences with a single treated unit apply (Appendix A). The cartel's end date is uncertain, because cooperation may have weakened when the wiretaps or raids began. Prices at the end of a cartel need not return at once to the competitive level. Clark and Houde (2013, p. 25) report that their companion paper (Clark and Houde, 2014) finds larger price cuts after the collapse, which suggests a complementary reading. The cartel's main effect may have been on the shape of the cycle more than on the average price.

13.6.6 Learning to coordinate in Perth: Byrne and de Roos (2019)

The Quebec cartel coordinated by telephone. Coordinating a price increase took on average 65 calls among its members and a price decrease 26 (Asker and Nocke, 2021, pp. 195–196). Theory allows firms to reach the same outcome tacitly, but it says little about how independent firms would arrive at a common understanding (p. 189). Byrne and de Roos (2019) document such a process in retail gasoline in Perth, Australia, from 2001 to 2015, as summarized by Asker and Nocke (2021, pp. 189–191). During this period, stations in Perth had to commit to their prices a day ahead and post them on Fuelwatch, a government website. Its purpose was to help consumers find cheap gasoline. The same transparency let stations monitor one another, which makes Fuelwatch a form of government-assisted information sharing like the Danish publication of concrete prices (Section 13.5.2).

Perth prices follow cycles of sudden jumps and gradual declines, like those of Toronto (Section 13.6.3). Before 2009, price jumps occurred on various days of the week. From 2009, BP, the largest chain, led jumps on Wednesdays. Most of its remaining stations jumped on Thursdays. Caltex, the next-largest chain, gradually adopted the pattern, and by mid-2010 it followed BP's Wednesday jump with a jump on Thursday. BP then reduced the share of its stations that jumped on Wednesday and raised the share that jumped on Thursday. It thus scaled back its price leadership, and with it the sales it lost by leading. In several periods BP stopped leading on Wednesday to test whether the market would coordinate on Thursday without it. By 2013 the market had settled on Thursday jumps of 2 cents per liter, better

synchronized adjustments and higher margins (pp. 189–191, Figure 3).

The episode is a third kind of conduct behind similar price cycles. In Toronto the cycles were consistent with competitive Edgeworth cycles. In Quebec an explicit cartel ran them by telephone. In Perth, price leadership under a transparency regime produced tacit coordination, with market interaction as the only communication. In terms of Proposition 13.19, Fuelwatch raised the probability that a deviation would be seen. The transition took about four years, which shows how slow tacit coordination can be. A simple rule, such as a fixed day and a fixed jump, makes deviations easy to detect. It also leaves the firms less able to respond to fluctuations in demand (Asker and Nocke, 2021, p. 194). Section 12.7.1 discusses the case as evidence on how agreements start.

13.6.7 What the gasoline evidence shows

Table 13.30 summarizes the five studies. They share an industry, high-frequency prices and an observed wholesale cost. They differ in what lets them speak about conduct. Borenstein and Shepard use a dynamic implication of the incentive constraint, the response of margins to expected future demand and cost. Sign restrictions and a placebo separate collusion from inventories and from measurement error. Noel uses the roles that theory assigns to small and large firms within a cycle. Clark and Houde use wiretaps, which reveal the conduct directly, and then use structural models to measure what the observed mechanism achieved. Erutku and Hildebrand use the end of the cartel as an event. Byrne and de Roos follow the emergence of price leadership over time.

Three lessons follow. First, price patterns alone do not identify conduct. Asymmetric cycles appear in competitive Toronto and in the Quebec cartel, and parallel, synchronized increases arise in both. Perth adds cycles produced by tacit coordination. Screens based on asymmetry, stickiness or low price variance (Abrantes-Metz et al., 2006) can flag markets for scrutiny, but they cannot separate the two. Second, evidence becomes informative when it tests a prediction specific to one theory. Examples are the expected-future effects of an incentive constraint, the role assignments of the Maskin-Tirole equilibrium, or the transfers needed when firms are asymmetric. Third, direct evidence remains decisive in prosecutions. The Quebec case rested on wiretaps and guilty pleas, and economic analysis then measured the mechanism and its effects. Section 13.10 returns to these methods for measuring damages.

13.7 Imperfect Cartels: Tolerated Cheating and Business Stealing

The Quebec cartel of Section 13.6.4 had to shift market share toward the members it needed to keep on board. The Sugar Institute of Section 13.4.1 met much of the cheating it detected with forbearance. Both features recur in the records of prosecuted industrial cartels. The repeated-game theory of Chapter 12 explains how the threat of punishment keeps cartel members in line. Its simplest versions make sharp predictions about the records that cartels leave behind. With perfect monitoring, no member cheats and no punishment occurs on the equilibrium path. With imperfect public monitoring (Green and Porter, 1984), punishments do occur. They are triggered by events that no member controls, however, and a detected deviation would always be punished. The case records of prosecuted cartels fit neither prediction. Members cut prices below agreed targets and took customers allocated to others. The other members knew it, and often nothing followed.

This section documents these facts and recalls the sales-reporting and transfer schemes

Table 13.30: Retail gasoline studies of conduct

Study	Market and data	Price pattern	Method	Conclusion about conduct
Borenstein and Shepard (1996)	59 U.S. cities, monthly, 1986–1991	Margins rise ahead of seasonal demand peaks and fall ahead of cost increases	2SLS margin regression with forecast demand and cost, elasticity-corrected instrument, placebo on unexpected changes	Tacit dynamic collusion: margin elasticities of 0.37 to expected demand and −0.37 to expected cost (Table 2)
Noel (2007)	22 Toronto stations, twelve-hourly, 131 days in 2001	Asymmetric weekly cycle: one-step jumps of 5.6 cpl, then 12.8 half-days of small cuts	Markov-switching regression with sticky prices, leader and follower roles by firm type	Competitive Edgeworth cycles: small firms lead cuts, large firms lead relents (Tables II–V)
Clark and Houde (2013)	128 stations in four Quebec cities, wiretaps 2005–2006, weekly prices 2002–2005	Asymmetric cycle: increases near 4 cpl, cuts of 1–2 cpl, sticky prices	Coded court documents, delay regressions, logit and homogeneous demand, simulated incentive constraints	Explicit cartel using timed delays as transfers to low-cost firms: 4–6 percent volume gains (Table 7), shorter required punishments (Table 8)
Erutku and Hildebrand (2010)	Sherbrooke versus Montreal and Quebec City, weekly, 2005–2007	Price drop after the announcement of the investigation	Difference in differences with wholesale-price controls and AR(1) errors	Overcharge of 1.75 cpl against Montreal, none against Quebec City (Table 6)

that cartels used to contain them (Section 13.7.1). It then develops the model of Bernheim and Madsen (2017), in which deliberate and unpunished business stealing is part of the optimal cartel agreement (Section 13.7.2). The model is the one piece of collusion theory that this chapter develops in full, because its testable implications concern the internal records of cartels.

13.7.1 Evidence from prosecuted industrial cartels

The prevalence of discord. Marshall et al. (2013) classify the European Commission decisions on major industrial cartels from 2000 to 2005. Throughout this section, page, footnote and theorem numbers for Bernheim and Madsen (2017) refer to the working-paper version (NBER Working Paper 19993, 2014). As summarized by Bernheim and Madsen (2017, footnote 2), Marshall, Marx and Samkharadze label 9 of 22 rulings *discordant*. In a discordant cartel the decision records frequent bargaining problems and deviations by members throughout the cartel period. Only 6 rulings are *fully concordant*, meaning that the cartel functioned smoothly while it lasted. The sample is selected toward cartels effective enough to attract enforcement. Discord in the population of cartels is therefore probably more common still. Levenstein and Suslow (2006) survey the coordination problems of many cartels and stress the same selection problem (Chapter 12).

Marshall and Marx (2012, ch. 6) offer a first-hand reading of the twenty-two Commission decisions on industrial-product cartels issued from 2000 through 2005. Following Stigler (1964), they describe every cartel as solving the problem of secret deviations with three complementary structures. *Pricing structures* implement price increases. *Allocation structures* divide the collusive gain and correct deviations through redistributions. *Enforcement structures* monitor compliance and threaten punishment (pp. 105–106). Their Table 6.1 records the paragraphs of each decision that describe the cartel's allocation structure and any role of a third-party facilitator (pp. 125–127). By our count from that table, 17 of the 22 cartels used a market-share allocation, 10 a customer allocation and 7 a geographic allocation. Nineteen used at least one of the three, and 10 combined market shares with customers or territories. Eleven decisions mention a facilitator, such as a trade association or a consulting or accounting firm, which can verify the sales on which a market-share agreement depends (pp. 125 and 128). The vitamins cartel corrected deviations through "true-ups". A firm that sold more than its allotted share had to buy product at the cartel price from a firm that sold less (p. 128). Asker and Nocke (2021, p. 198, note 53) conclude from the same review that almost all of the decisions feature customer, geographic or market-share allocation.

Three cartels in the record. The global lysine cartel operated at least from 1992 through 1995. Lysine is an amino acid added to animal feed. Throughout 1993 and 1994 its members discussed a persistent and substantial gap between target and actual prices in Europe. They first attributed the gap to arbitrage by commodity traders and to exchange rates, and eventually to undercutting by particular members. The difficulties culminated in a "reset", in which the members briefly suspended sales to drive the price back up to the target. The record shows no punishment of the deviators (Bernheim and Madsen, 2017, pp. 2–3). At an April 30, 1993 meeting, the president of Archer Daniels Midland (ADM) told executives of a Japanese producer that "our competitors are our friends and our customers are our enemies."

A cartel of nucleotide producers (food flavor enhancers) operated in Europe from 1988 to 1999. It tried to allocate several large customers among its members. At meetings from 1991 to 1996, members complained repeatedly about low prices and about customers who asked them to match lower quotes from other members. Bernheim and Madsen (2017, p. 3) find no sign

that punishments were considered or carried out. Each time, the cartel set a new price and urged its members to respect it.

The citric acid cartel in western Europe (1991–1995) suspected one member, Jungbunzlauer, of undercutting during the second half of its life. The members held special sessions alongside the regular meetings to monitor and discuss Jungbunzlauer's conduct. They never changed the arrangement in response. The cartel collapsed abruptly in early 1995. Bernheim and Madsen read the collapse as a general breakdown of coordination and consider a delayed, coordinated punishment the less likely reading. The Sugar Institute of Section 13.4.1 shows the same pattern. Members skirted its rules with indirect price cuts or kickbacks, apologized when caught, and stopped. The Institute then banned the specific practice, and this forbearance does not seem to have undermined the cartel (Genesove and Mullin, 2001).

Cheating as a defense. The pattern matters for enforcement. Defendants often present price cuts, business stealing and the absence of retaliation as proof that a cartel was ineffective. In the criminal trial of ADM executives over lysine, a defense attorney argued that ADM had been "stealing customers" and "undercutting competitors" (Bernheim and Madsen, 2017, footnote 10). In European proceedings, firms in the citric acid, food flavor enhancer, industrial tube, lysine and zinc phosphate cases argued that agreed prices were not respected and that non-compliance went unpunished (Bernheim and Madsen, 2017, footnote 11). A theory in which tolerated cheating coexists with effective collusion bears directly on how courts should weigh such evidence.

Quotas, sales reports and transfers. Where prices and sales were private, many of these cartels set sales quotas, monitored them through self-reported sales and settled deviations with interfirm transfers. Section 12.7.3 documents these schemes, following Harrington and Skrzypacz (2011), and Table 12.12 reproduces the quotas of the lysine, citric acid and 1926 steel cartels. One feature of these schemes matters for the model that follows. In lysine, monthly "scorecards" compared each member's reported sales with its quota, and a member above quota had to buy output from members below it. Some members underreported their sales, yet the agreement was largely successful (Harrington and Skrzypacz, 2011, p. 2426). Deviations from quota were thus recorded and compensated, and they did not end the cartel.

Transfer schemes explain how cartels monitor when sales are private. They do not explain why a cartel would leave detected cheating unpunished. That is the question Bernheim and Madsen answer.

13.7.2 A model of imperfect collusion with business stealing

As before, theorem numbers refer to the working-paper version of Bernheim and Madsen (2017). We write ϕ for the fixed cost of quoting, Ψ_H and Ψ_A for the price distributions of the home and away firms, and p^{fl} for the cartel's price floor. Profits are written Π, as in the paper.

Environment

Assumption 13.31 (Environment)**.**

(i) Two risk-neutral firms interact in periods $t = 1, 2, \ldots$ with common discount factor $\delta \in (0, 1)$. There are two markets.

(ii) Firm i is the *home firm* in market i and the *away firm* in the other market. Its marginal cost is c_H at home and c_A away, with $\Delta c \equiv c_A - c_H > 0$.

(iii) A firm that quotes a price in a market in a period pays a fixed cost $\phi > 0$, whether or not it makes the sale. The cost stands for a local office, relationships with clients or bid preparation.

(iv) Each market contains a unit mass of customers with unit demand and reservation values distributed with CDF F. Customers buy from the lowest quote that does not exceed their value, with ties broken at random. Demand at price p is

$$D(p) = 1 - \lim_{\hat{p} \uparrow p} F(\hat{p}). \tag{13.78}$$

(v) In each market and period, each firm chooses simultaneously a probability of quoting and a CDF for its price conditional on quoting. All quotes become public at the end of the period.

Two prices summarize each firm's position. The *break-even price* $\underline{p}_i$, for $i \in \{H, A\}$, is the lowest price at which a firm that sells to the whole market covers its costs:

$$\underline{p}_i = \inf\{p : \; D(p)(p - c_i) \geq \phi\}. \tag{13.79}$$

The monopoly price is $p_i^* = \arg\max_p D(p)(p - c_i)$. Bernheim and Madsen assume that these prices are unique and that single-firm profit $D(p)(p - c_i)$ rises strictly between c_i and p_i^*. They also assume $\underline{p}_A < p_H^*$. Under this condition the low-cost firm cannot blockade entry by charging its monopoly price. Since $c_A > c_H$, we have $\underline{p}_H < \underline{p}_A$ and $p_H^* \leq p_A^*$.

Two profit levels serve as benchmarks. The stage profit of a home firm that monopolizes its market at p_H^* is

$$\Pi^M \equiv D(p_H^*)(p_H^* - c_H) - \phi. \tag{13.80}$$

The *competitive profit* is what a home firm earns when it sells to the whole market at the away firm's break-even price. Since $D(\underline{p}_A)(\underline{p}_A - c_A) = \phi$,

$$\Pi^C \equiv D(\underline{p}_A)(\underline{p}_A - c_H) - \phi = D(\underline{p}_A)(\underline{p}_A - c_A) + \Delta c \, D(\underline{p}_A) - \phi = \Delta c \, D(\underline{p}_A). \tag{13.81}$$

For $\Pi \in [\Pi^C, \Pi^M]$, let $\tilde{p}(\Pi)$ be the price in $[\underline{p}_A, p_H^*]$ at which a home monopolist earns Π, so that $D(\tilde{p})(\tilde{p} - c_H) - \phi = \Pi$. The map is continuous and strictly increasing. A final identity links the two firms' profits at the same price. The away firm's single-firm profit is

$$D(p)(p - c_A) - \phi = \big[D(p)(p - c_H) - \phi\big] - \Delta c \, D(p). \tag{13.82}$$

At the price $\tilde{p}(\Pi)$, an away firm that takes the whole market earns $\Pi - \Delta c \, D(\tilde{p}(\Pi))$.

The stage game

We first characterize behavior in a single market in which prices below some floor p_f are never quoted. The same construction delivers both the one-shot equilibrium and, later, optimal collusion.

Lemma 13.32 (Indifference construction)**.** *Fix $p_f \in [\underline{p}_A, p_H^*)$. Suppose that in one market the home firm always quotes, with CDF Ψ_H on $[p_f, p_H^*]$. The away firm quotes with probability λ_A, with an*

atomless CDF Ψ_A on $[p_f, p_H^*]$. Suppose further that (a) the away firm earns zero at every price in (p_f, p_H^*) and (b) the home firm earns the same profit at every price in $[p_f, p_H^*]$. Then

$$\Psi_H(p) = 1 - \frac{\phi}{D(p)(p - c_A)} \quad \text{for } p \in (p_f, p_H^*), \qquad \Psi_H(p_H^*) = 1, \tag{13.83}$$

$$\lambda_A \Psi_A(p) = 1 - \frac{D(p_f)(p_f - c_H)}{D(p)(p - c_H)} \quad \text{for } p \in [p_f, p_H^*], \tag{13.84}$$

$$\lambda_A = 1 - \frac{D(p_f)(p_f - c_H)}{D(p_H^*)(p_H^* - c_H)}. \tag{13.85}$$

The home firm places an atom of mass $1 - \frac{\phi}{D(p_f)(p_f - c_A)}$ at p_f and an atom of mass $\frac{\phi}{D(p_H^*)(p_H^* - c_A)}$ at p_H^*. It earns $D(p_f)(p_f - c_H) - \phi$ per period, and the away firm earns zero.

Proof. An away quote $p \in (p_f, p_H^*)$ wins when the home price exceeds p, which has probability $1 - \Psi_H(p)$. Condition (a) reads

$$\big[1 - \Psi_H(p)\big] D(p)(p - c_A) - \phi = 0.$$

Solving for Ψ_H gives (13.83). Letting $p \downarrow p_f$, the probability that the home price is at most p_f is $1 - \frac{\phi}{D(p_f)(p_f - c_A)}$. Since the home firm never quotes below p_f, this is the mass of its atom at p_f. Letting $p \uparrow p_H^*$, the probability that the home price is below p_H^* is $1 - \frac{\phi}{D(p_H^*)(p_H^* - c_A)}$. The remaining mass sits at p_H^*.

The away firm never quotes p_f or less on this support, so a home quote of p_f wins for sure and earns $D(p_f)(p_f - c_H) - \phi$. A home quote $p \in (p_f, p_H^*]$ wins unless the away firm quotes and its price is lower, which has probability $\lambda_A \Psi_A(p)$ because Ψ_A has no atoms. Condition (b) reads

$$\big[1 - \lambda_A \Psi_A(p)\big] D(p)(p - c_H) - \phi = D(p_f)(p_f - c_H) - \phi.$$

Solving gives (13.84). At $p = p_H^*$ the left side of (13.84) must equal λ_A, because $\Psi_A(p_H^*) = 1$. This gives (13.85). Both CDFs are nondecreasing because $D(p)(p - c_A)$ and $D(p)(p - c_H)$ rise on $[\underline{p}_A, p_H^*]$. The value λ_A lies in $[0, 1)$ because $D(p_f)(p_f - c_H) \le D(p_H^*)(p_H^* - c_H)$. □

The probability of *business stealing*, the event that the away firm makes the sale, follows directly. An away quote p wins with probability $1 - \Psi_H(p) = \frac{\phi}{D(p)(p - c_A)}$, so

$$\mathbb{P}(\text{away firm sells}) = \int_{[p_f, p_H^*)} \frac{\phi}{D(p)(p - c_A)} \, \mathrm{d}\big[\lambda_A \Psi_A(p)\big]. \tag{13.86}$$

Theorem 13.33 (Bernheim and Madsen, Theorem 1)**.** *The stage game has a unique Nash equilibrium. In each market:*

(i) The home firm always quotes. The away firm quotes with probability strictly between 0 and 1.

(ii) The home firm earns $\Pi^C = \Delta c \, D(\underline{p}_A) > 0$, and the away firm earns zero.

(iii) Prices lie in $[\underline{p}_A, p_H^*]$. Each firm's price distribution has full support on this interval and is atomless, except for an atom of the home firm at p_H^*.

The equilibrium distributions are those of Lemma 13.32 with $p_f = \underline{p}_A$.

Proof of equilibrium, with uniqueness in outline. Set $p_f = \underline{p}_A$ in Lemma 13.32. The home atom at $\underline{p}_A$ has mass $1 - \frac{\phi}{D(\underline{p}_A)(\underline{p}_A - c_A)} = 0$, and the home profit is $D(\underline{p}_A)(\underline{p}_A - c_H) - \phi = \Pi^C$ by (13.81). We check that neither firm gains by leaving its support.

Consider the away firm. It earns zero at every price in $[\underline{p}_A, p_H^*)$. A price above p_H^* never wins and costs ϕ. A price below $\underline{p}_A$ yields at most $D(p)(p - c_A) - \phi < 0$. Staying out yields zero. Mixing between quoting and staying out is therefore optimal.

Consider the home firm. It earns Π^C at every price in $[\underline{p}_A, p_H^*]$. A price below $\underline{p}_A$ also wins for sure but earns less, since $D(p)(p - c_H)$ rises below p_H^*. A price $p > p_H^*$ wins only if the away firm stays out and earns $(1 - \lambda_A)D(p)(p - c_H) - \phi < (1 - \lambda_A)D(p_H^*)(p_H^* - c_H) - \phi = \Pi^C$. Staying out earns $0 < \Pi^C$.

Uniqueness is proved in Appendix B of the working paper (Theorem B.1 and Lemmas B.1 to B.7). The steps show that both firms' supports end at p_H^*, that equilibrium prices lie in $[\underline{p}_A, p_H^*]$, and that the only possible atom is the home firm's atom at p_H^*. Given these facts, conditions (a) and (b) of Lemma 13.32 must hold, and they pin down the distributions. □

Three features of this equilibrium stand out (Bernheim and Madsen, 2017, p. 9). First, customers always pay strictly more than $\underline{p}_A$, the lowest price the high-cost firm would ever accept. Expected profits are the same as if both firms quoted $\underline{p}_A$ and the home firm sold, yet prices are higher, because both firms pay fixed costs. Second, prices have full support up to p_H^*, so an ex post outcome can look arbitrarily collusive. Third, business stealing occurs with positive probability even though there is no cartel.

Example 13.34 (Uniform values)**.** Let $v \sim U[0,1]$, so $D(p) = 1 - p$, with $c_H = 0.1$, $c_A = 0.2$ and $\phi = 0.05$. The home monopoly price solves $\frac{\mathrm{d}}{\mathrm{d}p}(1-p)(p-0.1) = 1.1 - 2p = 0$, so $p_H^* = 0.55$. The away break-even price is the lower root of

$$(1-p)(p-0.2) = 0.05 \iff p^2 - 1.2p + 0.25 = 0,$$

which gives $\underline{p}_A = \frac{1.2 - \sqrt{0.44}}{2} \approx 0.2683$. The assumption $\underline{p}_A < p_H^*$ holds. The benchmarks are $\Pi^C = 0.1 \times (1 - 0.2683) = 0.0732$ and $\Pi^M = 0.45 \times 0.45 - 0.05 = 0.1525$. By (13.83), $\Psi_H(p) = 1 - \frac{0.05}{(1-p)(p-0.2)}$, with an atom of $\frac{0.05}{0.45 \times 0.35} = 0.3175$ at p_H^*. The numerator of (13.84) is $D(\underline{p}_A)(\underline{p}_A - c_H) = \Pi^C + \phi = 0.1232$, so

$$\lambda_A \Psi_A(p) = 1 - \frac{0.1232}{(1-p)(p-0.1)}, \qquad \lambda_A = 1 - \frac{0.1232}{0.2025} = 0.3918.$$

Evaluating (13.86) numerically, the away firm makes the sale with probability 0.238. The expected lowest quote is 0.368, against a break-even price of 0.268. Panel (a) of Figure 13.18 plots the two distributions.

Stationary collusion

Industry profit is highest when each home firm monopolizes its market at p_H^* and the away firm stays out. We call this *perfect collusion*. An equilibrium with profits above the stage-game level and below perfect collusion is an *imperfectly collusive* arrangement. Lifetime profits are normalized as $(1 - \delta) \sum_{t \geq 1} \delta^{t-1} \pi_t$, so that a constant stream π is worth π. Characterizing the whole equilibrium payoff set of a repeated game with mixed strategies and continuous actions is hard. Bernheim and Madsen therefore restrict attention to the following class.

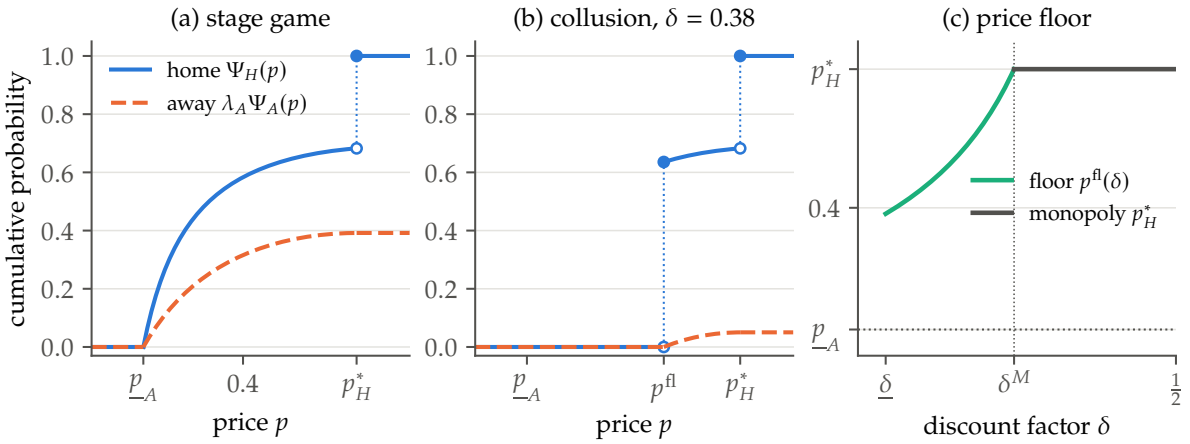

Figure 13.18: The model of Bernheim and Madsen (2017) with $v \sim U[0,1]$, $c_H = 0.1$, $c_A = 0.2$ and $\phi = 0.05$. Panels (a) and (b) show the home firm's price CDF Ψ_H as a solid line, with atoms marked by dots. The dashed line is the away firm's unconditional CDF of quotes $\lambda_A \Psi_A$, which ends at the entry probability λ_A. Panel (a) is the stage-game equilibrium. Panel (b) is the optimal stationary collusive equilibrium at $\delta = 0.38$, with floor $p^{\text{fl}} = 0.449$. Panel (c) shows the floor $p^{\text{fl}}(\delta)$ over $[\underline{\delta}, \delta^M] = [0.345, 0.413]$, where $\underline{\delta} = \delta^0$ is the threshold of Theorem 13.38. Above δ^M the cartel achieves the monopoly price. Source: our calculations (`bm_static.py`).

Definition 13.35 (Stationary equilibrium)**.** A subgame perfect equilibrium is *stationary* if there is a stage-game strategy profile τ such that τ is played after every history on the equilibrium path. Behavior off the path is unrestricted beyond subgame perfection.

Off-path behavior can be nonstationary, so optimal penal codes in the sense of Abreu (1988) are allowed. On the path, lifetime profits equal stage profits. Let $\underline{\Pi}(\delta)$ be the infimum of a firm's lifetime profits over all subgame perfect equilibria, and let δ^M be the lowest discount factor at which perfect collusion is sustainable.

Theorem 13.36 (Bernheim and Madsen, Theorem 2)**.** *For each $\delta \le \delta^M$, the unique Pareto-optimal stationary equilibrium profit vector $(\bar{\Pi}, \bar{\Pi})$ satisfies*

$$\bar{\Pi} = (1-\delta)\Big[2\bar{\Pi} - \Delta c\, D\big(\tilde{p}(\bar{\Pi})\big)\Big] + \delta\, \underline{\Pi}(\delta). \tag{13.87}$$

Moreover, $\bar{\Pi} > \Pi^C$ if and only if $\underline{\Pi}(\delta) < \Pi^C$, and $\bar{\Pi}$ is strictly increasing in δ whenever $\underline{\Pi}(\cdot)$ is nonincreasing.

We derive the incentive constraint behind (13.87). Consider an agreement that divides the markets along cost lines and gives each firm stage profit Π in its home market. The rival's lowest home price $p_{\min}$ must satisfy $D(p_{\min})(p_{\min} - c_H) - \phi \ge \Pi$, since even a sure sale at the lowest price must deliver Π. Hence $p_{\min} \ge \tilde{p}(\Pi)$. Consider a firm that keeps its home strategy and slightly undercuts $p_{\min}$ in the away market for one period.

Step 1. By (13.82), undercutting $p_{\min}$ in the away market earns

$$D(p_{\min})(p_{\min} - c_A) - \phi = \big[D(p_{\min})(p_{\min} - c_H) - \phi\big] - \Delta c\, D(p_{\min}) \ge \Pi - \Delta c\, D\big(\tilde{p}(\Pi)\big),$$

because the bracket is at least Π and $D(p_{\min}) \le D(\tilde{p}(\Pi))$.

Step 2. Adding the home profit Π, the deviation earns at least $2\Pi - \Delta c\, D(\tilde{p}(\Pi))$ in the deviation period.

Step 3. The worst the cartel can do afterwards is to impose $\underline{\Pi}(\delta)$. The deviator's lifetime payoff is at least
$$(1-\delta)\Big[2\Pi - \Delta c\, D\big(\tilde{p}(\Pi)\big)\Big] + \delta\,\underline{\Pi}(\delta).$$

Step 4. The agreement survives only if the on-path payoff is at least this large:
$$\Pi \;\geq\; (1-\delta)\Big[2\Pi - \Delta c\, D\big(\tilde{p}(\Pi)\big)\Big] + \delta\,\underline{\Pi}(\delta). \tag{13.88}$$

Step 5. The firms pick the largest Π that satisfies (13.88). At that Π the constraint binds, which is (13.87). The equilibrium of Theorem 13.40 below attains it.

Both firms agree on the best scheme, so the Pareto frontier of stationary equilibria is a single symmetric point.

Remark 13.37 (Nash reversion supports no collusion). Collusion in this model requires punishments harsher than reversion to the stage game (Bernheim and Madsen, 2017, footnote 22). To see why, set $\underline{\Pi} = \Pi^C$ in (13.88) and subtract Π^C from both sides:
$$\Pi - \Pi^C \;\geq\; (1-\delta)\Big[2\Pi - \Delta c\, D(\tilde{p}) - \Pi^C\Big] = (1-\delta)\big[(\Pi - \Pi^C) + a(\tilde{p})\big],$$
where $a(p) \equiv D(p)(p - c_A) - \phi = \Pi - \Delta c\, D(\tilde{p})$ at $p = \tilde{p}(\Pi)$ is the away firm's single-firm profit. Rearranging gives $\delta(\Pi - \Pi^C) \geq (1-\delta)\, a(\tilde{p})$. Now $\Pi - \Pi^C = a(\tilde{p}) - \Delta c\big[D(\underline{p}_A) - D(\tilde{p})\big] \leq a(\tilde{p})$. The constraint therefore requires $\delta\, a(\tilde{p}) \geq (1-\delta)\, a(\tilde{p})$, that is, $\delta \geq \tfrac{1}{2}$. Since $\delta^M < \tfrac{1}{2}$ (Theorem 13.39), Nash reversion sustains no profit above Π^C in the whole range where imperfect collusion is the relevant case.

Theorem 13.38 (Bernheim and Madsen, Theorem 3)**.** *Suppose*
$$\delta \;\geq\; \delta^0 \equiv \frac{1}{2 + \frac{\Delta c\, D(p_H^*)}{\phi}}.$$
Then a subgame perfect equilibrium gives both firms zero lifetime profits, so $\underline{\Pi}(\delta) = 0$.

Zero is the harshest conceivable punishment, because a firm can always stay out of both markets. The punishment is a one-period price war followed by a return to optimal collusion. In the war period both firms enter both markets. The home firm quotes some $p^{PW} \leq \underline{p}_H$ and serves its market at a loss. The away firm mixes over $(p^{PW}, \underline{p}_H]$, never sells, and loses its fixed cost. Its presence ensures that a home firm that raises its price cannot profit. If both firms take part, play returns to the collusive phase worth $\bar{\Pi}$. If either refuses, the war restarts. The war price is set so that
$$(1-\delta)\Big[D(p^{PW})(p^{PW} - c_H) - 2\phi\Big] + \delta\bar{\Pi} = 0.$$
The bound on δ guarantees $p^{PW} \leq \underline{p}_H$. A deviator's best option in the war period is then to exit both markets, which yields zero today and a restarted war, so it gains nothing.

Theorem 13.39 (Bernheim and Madsen, Theorem 4)**.** *Suppose* $\Pi^M > \phi + \Delta c\, D(p_H^*)$. *Then* $\delta^0 < \delta^M$, *and for each* $\delta \in [\delta^0, \delta^M]$ *the optimal stationary profit satisfies*
$$\bar{\Pi} = (1-\delta)\Big[2\bar{\Pi} - \Delta c\, D\big(\tilde{p}(\bar{\Pi})\big)\Big]. \tag{13.89}$$

The profit $\bar{\Pi}$ is continuous, strictly greater than Π^C, and strictly increasing in δ. Perfect collusion is sustainable for all $\delta \geq \delta^M$, where

$$\delta^M = \frac{\Pi^M - \Delta c\, D(p_H^*)}{2\Pi^M - \Delta c\, D(p_H^*)}. \tag{13.90}$$

The threshold (13.90) follows from (13.88). Perfect collusion sets $\Pi = \Pi^M$, so $\tilde{p}(\Pi^M) = p_H^*$, and the harshest punishment is zero:

$$\begin{aligned} \Pi^M &\geq (1-\delta)\left[2\Pi^M - \Delta c\, D(p_H^*)\right] \\ 1-\delta &\leq \frac{\Pi^M}{2\Pi^M - \Delta c\, D(p_H^*)} \\ \delta &\geq 1 - \frac{\Pi^M}{2\Pi^M - \Delta c\, D(p_H^*)} = \frac{\Pi^M - \Delta c\, D(p_H^*)}{2\Pi^M - \Delta c\, D(p_H^*)}. \end{aligned}$$

The numerator is the away firm's profit at p_H^*, which is positive because $p_H^* > \underline{p}_A$. Twice the numerator, $2\Pi^M - 2\Delta c\, D(p_H^*)$, is smaller than the denominator, so $\delta^M < \frac{1}{2}$. In the symmetric Bertrand duopoly without fixed costs the threshold is exactly $\frac{1}{2}$ (Chapter 12). Here a raid on the other market earns less than the home firm's profit, because the raider has the higher cost. The temptation is smaller, so perfect collusion is easier.

For $\delta \in [\delta^0, \delta^M)$, equation (13.89) pins down the floor $p^{\text{fl}}(\delta) \equiv \tilde{p}(\bar{\Pi}(\delta))$. Collecting terms in (13.89) gives $(1-2\delta)\bar{\Pi} = (1-\delta)\Delta c\, D(\tilde{p}(\bar{\Pi}))$, which in terms of the floor reads

$$(1-2\delta)\Big[D(p^{\text{fl}})(p^{\text{fl}} - c_H) - \phi\Big] = (1-\delta)\,\Delta c\, D(p^{\text{fl}}). \tag{13.91}$$

The left side rises in p^{fl} and the right side falls. At $\underline{p}_A$ the left side minus the right side equals $(1-2\delta)\Pi^C - (1-\delta)\Pi^C = -\delta\Pi^C < 0$. At p_H^* it equals $(1-2\delta)\Pi^M - (1-\delta)\Delta c\, D(p_H^*)$, which is positive exactly when $\delta < \delta^M$. A unique floor therefore lies strictly between $\underline{p}_A$ and p_H^*. Differentiating the difference with respect to δ gives $-2\Pi + \Delta c\, D(p) = -[\Pi + a(p)] < 0$. By the implicit function theorem the floor rises with δ and reaches p_H^* at δ^M.

Theorem 13.40 (Bernheim and Madsen, Theorem 5)**.** *When $\delta < \delta^M$, the profits $(\bar{\Pi}, \bar{\Pi})$ are supported by a stationary equilibrium with the following on-path properties:*

(i) The home firm's strategy is the same in each market, and so is the away firm's.

(ii) The home firm always enters. The away firm enters with probability strictly between 0 and 1.

(iii) The home firm earns stage profit $\bar{\Pi}$, and the away firm earns zero.

(iv) Each firm's price distribution has full support on $[p^{\text{fl}}, p_H^*]$. The home firm places atoms at p^{fl} and at p_H^*. The away firm's distribution is continuous.

(v) The away firm sells with positive probability, which decreases in $\bar{\Pi}$.

(vi) An away quote at or below p^{fl} triggers a punishment worth $\underline{\Pi}(\delta)$ to the deviator.

These on-path strategies are unique among stationary equilibria whose price distributions have full support on $[p^{\text{fl}}, p_H^*]$.

The on-path strategies are exactly those of Lemma 13.32 with $p_f = p^{\text{fl}}$, as the proof of Theorem B.4 in the working paper confirms. The equilibrium check is short. The away firm earns zero at every price in (p^{fl}, p_H^*) and is never punished there. Its best one-period deviation is to undercut the home atom at p^{fl}, which earns $\bar{\Pi} - \Delta c\, D(p^{\text{fl}})$ by (13.82). The home firm earns $\bar{\Pi}$ at every price it quotes, so it cannot gain at home. A firm that combines both moves earns $2\bar{\Pi} - \Delta c\, D(p^{\text{fl}})$ for one period and then $\underline{\Pi}(\delta)$. Condition (13.87) says that this deviation exactly breaks even. The stage equilibrium of Theorem 13.33 is the special case $p^{\text{fl}} = \underline{p}_A$, in which the home atom at the floor vanishes.

Example 13.41 (Uniform values, continued)**.** In Example 13.34, $\Delta c\, D(p_H^*) = 0.1 \times 0.45 = 0.045$ and $\Pi^M = 0.1525 > \phi + 0.045 = 0.095$, so Theorem 13.39 applies. The thresholds are

$$\delta^0 = \frac{1}{2 + \frac{0.045}{0.05}} = \frac{1}{2.9} = 0.345, \qquad \delta^M = \frac{0.1525 - 0.045}{0.305 - 0.045} = \frac{0.1075}{0.26} = 0.413.$$

At $\delta = 0.38$, equation (13.91) gives $p^{\text{fl}} = 0.449$ and $\bar{\Pi} = 0.142$. The home firm quotes the floor with probability 0.636 and the monopoly price with probability 0.317. The away firm enters with probability $\lambda_A = 0.050$ and makes the sale with probability 0.017, down from 0.238 in the stage game. The expected lowest quote is 0.482. A clean split of the markets at the floor would give the same profits with a price of 0.449, so the tolerated raids cost consumers money. Panels (b) and (c) of Figure 13.18 show the distributions and the floor as a function of δ.

Why the cartel tolerates raids

Why do the firms not agree on the simpler plan of a clean split at the floor? Under a clean split the away firm stays out, and the home firm sells at p^{fl}. A firm could then raise its home price to p_H^* and raid the other market at the same time. If no business stealing ever occurs on the path, the best deviation earns Π^M at home plus $\Pi - \Delta c\, D(\tilde{p}(\Pi))$ away. The agreement is incentive compatible only if

$$\Pi \;\geq\; (1-\delta)\Big[\Pi - \Delta c\, D\big(\tilde{p}(\Pi)\big) + \Pi^M\Big] + \delta\, \underline{\Pi}(\delta). \tag{13.92}$$

The deviation payoff here exceeds the one in (13.88) by $(1-\delta)(\Pi^M - \Pi) > 0$. At $\Pi = \bar{\Pi}$ the constraint (13.88) binds, so (13.92) fails. All punishment power is already used to deter raids, so none is left to deter the home price increase. The cartel must instead make a high home price unattractive directly. It does so by letting the away firm enter at prices above the floor. Entry costs ϕ, so the away firm enters only if it sometimes wins. The home firm cedes those sales by charging the monopoly price part of the time. Equilibrium thus combines occasional price escalation at home with unpunished business stealing away (Bernheim and Madsen, 2017, pp. 15–17).

Theorem 13.42 (Bernheim and Madsen, Theorems 6 and 7)**.** *Let $\delta < \delta^M$.*

(i) All stationary equilibria with profits $(\bar{\Pi}, \bar{\Pi})$ share the same minimum price, maximum price and entry probabilities. Among them, the equilibrium of Theorem 13.40 uniquely minimizes the probability that an away firm wins.

(ii) There exists $\tilde{\Pi} < \bar{\Pi}$ such that in any stationary equilibrium with profits $(\Pi_1, \Pi_2) > (\tilde{\Pi}, \tilde{\Pi})$, the away firm captures each market with strictly positive probability on the equilibrium path.

Part (ii) follows from (13.92) by continuity. The constraint fails at $\bar{\Pi}$, and both sides are continuous in Π, so it fails on an interval of profits below $\bar{\Pi}$. Business stealing is therefore a feature of every nearly optimal cartel. It is not an artifact of a particular equilibrium.

Remark 13.43 (Why tolerate deliberate cheating?). The model resolves the puzzle posed by the lysine, nucleotide and citric acid records. When perfect collusion is out of reach, every member knows that the aspirational price cannot hold. Members protect their home markets by occasionally cutting price to the floor, and they raid each other at prices above it. The raids are anticipated and serve a purpose. Their threat keeps home prices from drifting up to levels that would make the cartel unstable. Punishing them would remove that discipline. Only raids at or below the floor, which the home firm could have prevented by quoting the floor, would be punished.

Testable implication. The cleanest prediction is that business stolen at prices above the floor goes unpunished, while stealing below the floor triggers punishment. The floor is rarely known with precision. The average price is no proxy for it, because some stealing occurs at below-average prices. Bernheim and Madsen therefore propose a more robust implication: the higher the price at which business is stolen, the less likely the theft is to trigger punishment. They leave the test to future work (Bernheim and Madsen, 2017, p. 7).

Many firms and comparative statics. With $N+1$ firms and $N+1$ markets, the stage game has many equilibria. For each nonempty set of away firms there is a unique equilibrium in which exactly those firms enter (Theorem 8). Bernheim and Madsen then restrict attention to *market-symmetric* equilibria, in which all away firms in a market play alike. Under mild conditions on N and Π^M they obtain analogues of the duopoly results (Theorems 9 to 13). Optimal profits satisfy $\bar{\Pi} = (1-\delta)\big[(N+1)\bar{\Pi} - \Delta c\, N\, D(\tilde{p}(\bar{\Pi}))\big] + \delta\, \underline{\Pi}(\delta; N)$, because a deviator keeps its home profit and raids all N other markets. The perfect-collusion threshold is

$$\delta^M(N) = 1 - \frac{1}{N+1}\left(\frac{N}{N+1}\,\frac{\tilde{\Pi}^M}{\Pi^M} + \frac{1}{N+1}\right)^{-1},$$

where $\tilde{\Pi}^M = \Pi^M - \Delta c\, D(p_H^*)$ is a high-cost firm's profit at p_H^*. With $N = 1$ the formula reduces to (13.90). The threshold lies below $1 - \frac{1}{N+1}$, rises with N and tends to one (Theorem 14). Large cartels can therefore hope only for imperfect collusion, even when their members are very patient. The two frictions are both needed. As $c_A \to c_H$, collusion becomes all or nothing: $\bar{\Pi} \to \Pi^C$ for $\delta < \frac{N}{N+1}$ and $\bar{\Pi} \to \Pi^M$ for $\delta \geq \frac{N}{N+1}$ (Theorem 15). As $\phi \to 0$, business stealing vanishes and the home firm sells at $\underline{p}_A$ with probability one (Theorem 16).

Assessment. The model explains two facts that standard theory does not, deliberate cheating and its toleration, without any monitoring noise. Several features limit its reach. The analysis is confined to stationary equilibria, and the authors cannot rule out that nonstationary schemes do better. In the duopoly $\delta^M < \frac{1}{2}$, so with literal discounting perfect collusion would be easy. Bernheim and Madsen therefore read δ as a reduced form for impatience from agency problems, turnover or the number of rivals, and the many-firm results support that reading. The sharp divide between tolerated and punished stealing would blur with imperfect monitoring, for example with rogue salespeople who do not know about the cartel. The theory's main empirical implication has not yet been tested. Read together, Harrington and Skrzypacz (2011) and Bernheim and Madsen (2017) show that the internal records of cartels contain more than evidence of agreement. Quotas, reports, transfers and tolerated raids are equilibrium objects with testable structure. The next section studies a cartel whose internal records are complete enough to estimate such structure.

13.8 Inside a Bidding Ring: Asker's Stamp Cartel

A bidding ring is a cartel of bidders. Section 14.12 shows that in an English auction a ring whose members know each other's values is self-enforcing (Proposition 14.87). Real rings do not know their members' values. They must elicit them and divide the gains, and the mechanism they use shapes both bidding and damages. Asker (2010) studies a ring of stamp dealers whose internal records survive in full. His questions are how the ring organized itself, what incentives its mechanism created, and who bore the costs: sellers, bidders outside the ring, or the ring itself. The answers matter for antitrust damages, for the efficiency costs of collusion, and for detection, which relies on understanding how rings behave in practice.

13.8.1 Question and institutions

Until July 1997, 11 wholesale stamp dealers belonged to the ring. It bid in auctions of collectible stamps, typically collections, held mainly at New York auction houses. These houses ran open outcry ascending auctions, that is, English auctions. The ring began in the late 1970s or early 1980s and lasted 15 to 20 years, with very few changes in membership after its first five years. It collapsed when a stamp dealer outside the ring brought it to the attention of antitrust enforcers (Asker, 2010, p. 725). The data come from the resulting case, *New York et al. v. Feldman et al.* in the Southern District of New York.

The knockout. The ring coordinated through a *knockout*, a private auction held before each *target auction*. Members sent sealed bids on the lots they wanted, by fax or in writing, to an agent: a New York taxi and limousine driver employed by the ring. The agent determined the winner of each lot and notified the members. He sent the bids to another member, who computed the sidepayments after the target auction. Sidepayments were aggregated and settled quarterly. In the target auction the agent, or another agent he arranged, bid for the knockout winner up to the winning knockout bid. The winning bid thus set the ring's bidding limit. Because the ring's own agent did the bidding, compliance with the limit was easy to monitor. The coordinating member paid the agent $30 an hour, and each member paid him $50 for every target auction in which it was active. Depositions state that the agent never revealed bids before a knockout closed. Ties were resolved by the agent, who tried "as much as possible to be fair" (Asker, 2010, pp. 727–728).

Enforcement. Evidence on enforcement is thin. In the ring's early years at least two members were expelled, one for not meeting his financial obligations and one for being interested only in sidepayments. The records show no member who lost a knockout and then bid against the ring, and no temporary suspensions. One auction house signaled that it knew a ring was active, and the ring stopped operating there. In its final years the ring hid its activity by also bidding through other professional agents and through its own members (Asker, 2010, p. 728).

Knockouts of the kind this ring used have a long history in markets for rare books, art, rugs, stamps, coins and antiques. In the 1919 sale of the library of Ruxley Lodge in England, 81 London booksellers formed a ring. Their knockouts after the sale ran in rounds of 81, 24, 15 and finally 8 members. These rounds raised £10,292 on top of the £3,161 paid in the sale itself. Rings were legal in the United Kingdom before 1927 (Asker, 2010, p. 726).

The sidepayment rule. Sidepayments compensated members for not competing when the ring won. Let P be the target price paid by the ring. Order the knockout bids from highest to lowest as $b_{(1)} \geq b_{(2)} \geq \cdots \geq b_{(n)}$. Here the subscript counts from the top, unlike the order statistics of Chapter 14. Let m be the number of bids at or above P, and set $b_{(m+1)} \equiv P$.

Definition 13.44 (Incremental sidepayment rule)**.** For $j = 2, \dots, m$, let $\Delta_j = b_{(j)} - b_{(j+1)}$ be the increment between consecutive eligible bids. The knockout winner keeps half of each increment. The other half is split equally among the $j-1$ losing bidders whose bids are at least $b_{(j)}$. Bidders with bids below P receive nothing.

Proposition 13.45 (Properties of the rule)**.** *Under Definition 13.44:*

(i) The loser ranked $k \in \{2, \dots, m\}$ receives $s_{(k)} = \sum_{j=k}^{m} \frac{\Delta_j}{2(j-1)}$.

(ii) The winner pays $\frac{1}{2}\big(b_{(2)} - P\big)$ in total. Its outlay for the lot is $P + \frac{1}{2}(b_{(2)} - P) = \frac{1}{2}(P + b_{(2)})$.

(iii) Payments balance.

(iv) Holding ranks fixed, a loser's receipt rises by $\frac{1}{2(k-1)}$ per dollar of its own bid whenever its bid exceeds P.

(v) With two knockout bidders, the loser receives $\frac{1}{2}(b_{(2)} - P)^+$.

Proof. Part (i) restates the rule: the loser ranked k shares in increments $j = k, \dots, m$, each among $j-1$ losers. For (ii), the winner pays half of every increment, and the sum telescopes:

$$\sum_{j=2}^{m} \frac{\Delta_j}{2} = \frac{1}{2}\big(b_{(2)} - b_{(m+1)}\big) = \frac{1}{2}\big(b_{(2)} - P\big).$$

For (iii), exchange the order of summation in the losers' receipts:

$$\sum_{k=2}^{m} s_{(k)} = \sum_{j=2}^{m} \sum_{k=2}^{j} \frac{\Delta_j}{2(j-1)} = \sum_{j=2}^{m} \frac{\Delta_j}{2} = \frac{1}{2}\big(b_{(2)} - P\big).$$

For (iv), the own bid $b_{(k)}$ enters $s_{(k)}$ only through $\Delta_k = b_{(k)} - b_{(k+1)}$, with weight $\frac{1}{2(k-1)}$. Part (v) is the case $m = 2$. □

Remark 13.46 (The rule for any number of eligible reports). Marshall and Marx (2012, pp. 192–194, Table 9.1) state the ring's payments for any number of eligible reports. They rank the reports as $r_1 > r_2 > \cdots > r_k > p > r_{k+1} > \cdots > r_n$, where p is the price paid at the auction. In our notation $r_j = b_{(j)}$, $p = P$ and $k = m$. Members $k+1, \dots, n$ receive nothing. Member k receives $\frac{r_k - p}{2} \cdot \frac{1}{k-1}$, member 2 receives

$$\frac{r_k - p}{2} \cdot \frac{1}{k-1} + \frac{r_{k-1} - r_k}{2} \cdot \frac{1}{k-2} + \cdots + \frac{r_2 - r_3}{2},$$

and member 1, the winner, pays the sum of the half-increments, $\frac{r_k - p}{2} + \frac{r_{k-1} - r_k}{2} + \cdots + \frac{r_2 - r_3}{2}$. Since $r_j - r_{j+1} = \Delta_j$, these are parts (i) and (ii) of Proposition 13.45. Their verbal summary is Asker's description of Definition 13.44, and they call the mechanism a variant of the one described by Graham et al. (1990) (p. 193, note 15). They also note that members have an incentive to overreport, which the ring accepted as a cost of doing business, much as cartels accept some misreporting of sales (p. 194).

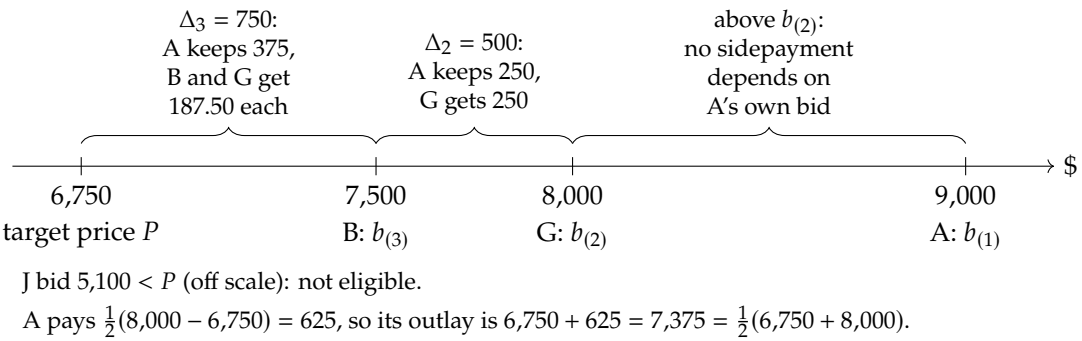
Example 13.47 (Sotheby's, June 24, 1997, Lot 49)**.** Table 13.31 reproduces Asker's Example 1. Bidder J's \$5,100 lies below the target price of \$6,750, so J is not eligible and $m = 3$. The increments are $\Delta_3 = 7{,}500 - 6{,}750 = 750$ and $\Delta_2 = 8{,}000 - 7{,}500 = 500$. Bidder A keeps \$375 of

the first increment and gives \$187.50 each to B and G. A keeps \$250 of the second increment and gives \$250 to G, the only loser whose bid reaches \$8,000. A pays $\frac{1}{2}(8{,}000 - 6{,}750) = 625$, which equals 437.50 + 187.50. A's outlay is \$7,375 for a lot bought at \$6,750. Figure 13.19 shows the increments.

Table 13.31: Sidepayments after a successful acquisition: Sotheby's, June 24, 1997, Lot 49

Knockout auction	Bid (\$)	Sidepayment (\$)
Bidder A	9,000	$-\left(\frac{7{,}500-6{,}750}{2}\right) - \left(\frac{8{,}000-7{,}500}{2}\right) = -625$
Bidder G	8,000	$+\left(\frac{7{,}500-6{,}750}{2}\right) \times \frac{1}{2} + \left(\frac{8{,}000-7{,}500}{2}\right) = 437.50$
Bidder B	7,500	$+\left(\frac{7{,}500-6{,}750}{2}\right) \times \frac{1}{2} = 187.50$
Bidder J	5,100	0
Target auction price	6,750	

Source: Asker (2010, Example 1).



J bid 5,100 < P (off scale): not eligible.

A pays $\frac{1}{2}(8{,}000 - 6{,}750) = 625$, so its outlay is $6{,}750 + 625 = 7{,}375 = \frac{1}{2}(6{,}750 + 8{,}000)$.

Figure 13.19: The incremental sidepayment rule in Example 13.47. Each increment runs from one eligible knockout bid to the next, between the target price and the second-highest bid. The winner keeps half of it. The losers whose bids reach its top share the other half equally. Source: drawn from Asker (2010, Example 1).

An older rule. Before the late 1980s the ring split each increment equally among all eligible bidders, the winner included. Under that rule the loser ranked k receives $\sum_{j=k}^{m} \frac{\Delta_j}{j}$. In the example, the \$750 increment would have been shared three ways, giving \$250 each to A, G and B, and the \$500 increment two ways. G would have received \$500 and B \$250, and A would have paid \$750. Treating bids as true willingness to pay, the older rule gives each member its imputed Shapley value, a point Graham and Marshall (1987) make in their analysis of nested knockouts. The *Shapley value* gives each member its marginal contribution to the coalition's surplus, averaged over all orders in which the members could join. Graham et al. (1990) first studied this class of mechanisms, in which a member's sidepayment rises with its own bid. With two knockout bidders the old and new rules coincide, since each splits the single increment equally between winner and loser.

13.8.2 The theory of the knockout

Asker adapts the model of Graham et al. (1990). We write ω_j for member j's participation probability (Asker writes α_j, a symbol this book uses for coefficients). G and g denote the distribution and density of a rival member's knockout bid. H_r and h_r denote the distribution and density of the highest value among bidders outside the ring.

Assumption 13.48 (Knockout environment)**.**

(i) Private values: member i's value v_i is drawn from F_i on $[\underline{v}_i, \bar{v}_i]$, independently across members, and is private information.

(ii) Members know how many members bid in the knockout but not who they are. Member j participates with known probability ω_j.

(iii) Bidders outside the ring bid up to their values in the English target auction, which is weakly dominant (Section 14.4.2). The highest outside value r has CDF H_r and density h_r and is independent of members' values. Here r denotes the highest outside value, not a reserve price.

(iv) Members use increasing, differentiable bid functions β_j with inverses β_j^{-1}. The ring's agent bids up to the winning knockout bid $b_{(1)}$.

Under (iii) and (iv) the ring wins the target auction exactly when $r < b_{(1)}$, and it then pays $P = r$. Every lot carried a secret reserve price, but Asker finds no evidence that reserves ever bound, so the model omits them (Asker, 2010, footnote 12).

The two-bidder objective. Consider a member with value v who faces one rival. The rival's bid y has CDF

$$G(y) = \frac{\sum_{j \neq i} \omega_j F_j\big(\beta_j^{-1}(y)\big)}{\sum_{j \neq i} \omega_j},$$

a mixture over the rival's unknown identity, with density g. Define the target surplus and sidepayment integrals

$$A(b) \equiv \int_{-\infty}^{b} (v - x)\, h_r(x)\, \mathrm{d}x, \qquad S(z) \equiv \int_{-\infty}^{z} (z - x)\, h_r(x)\, \mathrm{d}x. \tag{13.93}$$

If the member bids b and wins the knockout ($y < b$), the ring bids up to b. The member gains $v - r$ when $r < b$, and pays the loser $\frac{1}{2}(y - r)$ when $r < y$. Its expected payoff is $A(b) - \frac{1}{2}S(y)$. If it loses the knockout ($y > b$), the ring bids up to y, and the member receives $\frac{1}{2}(b - r)$ when $r < b$. Its expected payoff is $\frac{1}{2}S(b)$. Averaging over y,

$$U(b) = \int_{-\infty}^{b} g(y)\Big[A(b) - \tfrac{1}{2}S(y)\Big]\mathrm{d}y + \big[1 - G(b)\big]\tfrac{1}{2}S(b). \tag{13.94}$$

This is equation (1) of Asker (2010) after exchanging the order of integration in the sidepayment term.

The first-order condition. We differentiate term by term. By Leibniz's rule, $A'(b) = (v - b)h_r(b)$ and $S'(z) = (z - z)h_r(z) + \int_{-\infty}^{z} h_r(x)\,\mathrm{d}x = H_r(z)$. The first term of (13.94) splits into $G(b)A(b)$

and $-\frac{1}{2}\int_{-\infty}^{b} g(y)S(y)\,\mathrm{d}y$. Their derivatives are

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}b}\big[G(b)A(b)\big] &= g(b)A(b) + G(b)(v-b)h_r(b),\\ \frac{\mathrm{d}}{\mathrm{d}b}\Big[-\tfrac{1}{2}\textstyle\int_{-\infty}^{b} g(y)S(y)\,\mathrm{d}y\Big] &= -\tfrac{1}{2}g(b)S(b),\\ \frac{\mathrm{d}}{\mathrm{d}b}\Big[\tfrac{1}{2}\big(1-G(b)\big)S(b)\Big] &= -\tfrac{1}{2}g(b)S(b) + \tfrac{1}{2}\big[1-G(b)\big]H_r(b).\end{aligned}$$

Adding the three lines,

$$U'(b) = g(b)\big[A(b)-S(b)\big] + G(b)(v-b)h_r(b) + \tfrac{1}{2}\big[1-G(b)\big]H_r(b).$$

Since $A(b)-S(b) = \int_{-\infty}^{b}(v-x-b+x)h_r(x)\,\mathrm{d}x = (v-b)H_r(b)$, we obtain

$$U'(b) = (v-b)\Big[g(b)H_r(b) + G(b)h_r(b)\Big] + \tfrac{1}{2}H_r(b)\big[1-G(b)\big]. \tag{13.95}$$

The first term is the familiar trade-off of a second-price auction. A higher bid wins the knockout more often (at rate gH_r) and wins the target more often after a knockout win (at rate Gh_r), each worth $v-b$ at the margin. The second term is new. When the member loses the knockout and the ring wins below its bid, each extra dollar of bid brings an extra half dollar of sidepayment.

Lemma 13.49 (Asker, Lemma 1)**.** *At $b=v$, $U'(v) = \frac{1}{2}H_r(v)\big[1-G(v)\big] \geq 0$.*

Proposition 13.50 (Overbidding (Asker, Result 1))**.** *A member bids strictly above its value whenever $H_r(v) > 0$ and $G(v) < 1$, and bids its value when v is at the top of the rival's bid support.*

Proof. For $b < v$ both terms of (13.95) are nonnegative, so U is nondecreasing on $(-\infty, v]$ and no bid below v beats $b=v$. At $b=v$, Lemma 13.49 gives $U'(v) > 0$ when $H_r(v) > 0$ and $G(v) < 1$, so some bid above v does strictly better. If $G(v) = 1$, then for $b > v$ we have $G(b) = 1$ and $g(b) = 0$, so $U'(b) = (v-b)h_r(b) \leq 0$, and the optimal bid is v. □

Asker states the result for any number of knockout bidders. For bids below v the usual dominance argument for second-price and English auctions applies, and the sidepayment term pushes bids above v.

Remark 13.51 (Overbidding without sidepayments). Overbidding does not depend on sidepayments (Asker, 2010, footnote 15). Remove them, so the payoff is $U^0(b) = G(b)A(b)$. Then $U^{0\prime}(v) = g(v)A(v) > 0$ whenever the expected target surplus $A(v)$ is positive. A knockout win removes a rival from the target auction, which has an option value, and a higher bid buys more of it. In (13.95) the sidepayment terms cancel this option value at $b=v$, because $A(v) = S(v)$, and replace it with the sidepayment motive $\frac{1}{2}H_r(1-G)$.

The inverse bid function. Setting (13.95) to zero and solving for v gives equation (2) of Asker (2010):

$$v = b - \frac{\frac{1}{2}H_r(b)\big[1-G(b)\big]}{h_r(b)G(b) + H_r(b)g(b)}. \tag{13.96}$$

The equation maps each observed bid to a unique value, given the distribution of rival bids and the distribution of the highest outside value. It plays the role that the inversion of Guerre et al. (2000) plays for first-price auctions, $v = b + \frac{G(b)}{(n-1)g(b)}$ (Equation (14.34), Chapter 15). The

signs differ: first-price bidders shade below value, while knockout bidders inflate above it. In both cases identification requires the inverse bid function to be strictly increasing. Asker also derives three- and four-bidder analogues (his footnote 13). They involve integrals of H_r against the rival bid distribution, and the structural analysis uses only two-bidder knockouts.

Corollary 13.52 (Inefficiency (Asker, Corollary 1))**.** *The knockout can lead to an inefficient allocation in the English target auction.*

Suppose the highest outside value r lies between the top member's value $v_{(1)}$ and that member's knockout bid $b_{(1)}$. The ring wins and pays $r > v_{(1)}$, although an outside bidder values the lot more. The ring then harms itself. The seller can gain, because under competition the price would be the second-highest value overall, which is at most r. Outside bidders lose in two ways. They lose the lot they would have won, and when they do win, the ring's inflated limit $b_{(1)}$ can push their price above the competitive level. Asymmetries among members add a further inefficiency, because the knockout need not allocate the lot to the member with the highest value (Asker, 2010, footnote 16).

Lemma 13.53 (Asker, Lemma 2)**.** *The inverse bid function* (13.96) *can have regions where* $\frac{\mathrm{d}v}{\mathrm{d}b} < 0$.

Asker's example sets H_r lognormal with $\mu = -2$ and $\sigma^2 = 0.08$, and G lognormal with $\mu = -1$ and $\sigma^2 = 1$. Figure 13.20 confirms the claim: $v(b)$ falls for $b \in [0.161, 0.220]$. On that region some stationary points of the first-order condition are local minima. An estimator could then map observed bids to values through the wrong branch, which contradicts optimal bidding. Asker therefore maintains that the population inverse bid function is strictly increasing, and he imposes it through the choice of smoothing parameters (Section 13.8.4). With a more dispersed outside value ($\sigma^2 = 0.5$), the same G yields a monotone inverse. Both curves lie below the 45° line, which is overbidding.

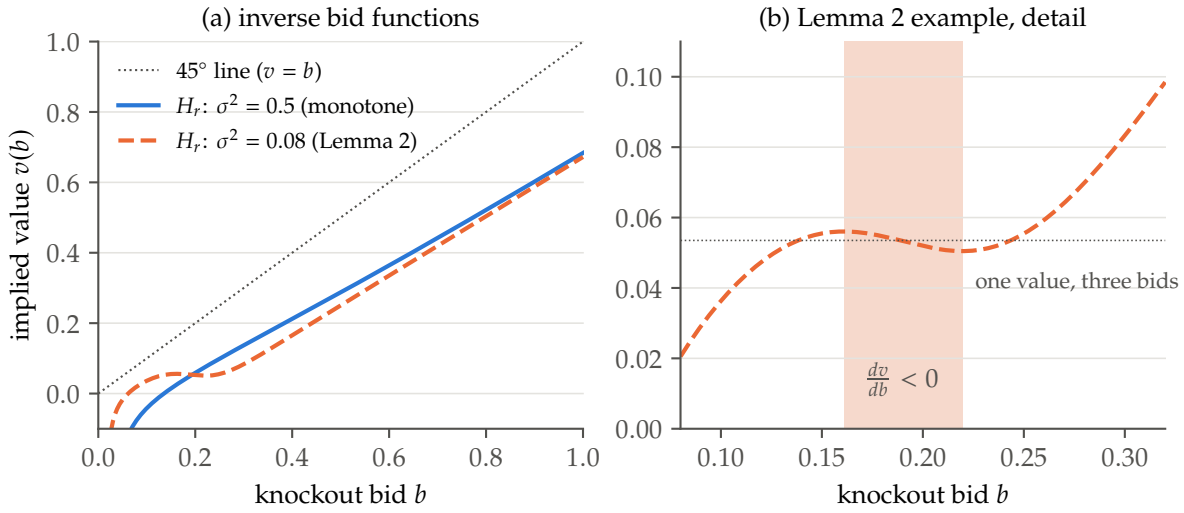


Figure 13.20: The inverse bid function (13.96) with G lognormal ($\mu = -1$, $\sigma^2 = 1$) and H_r lognormal with $\mu = -2$. Panel (a): Asker's Lemma 2 example ($\sigma^2 = 0.08$, dashed) and a monotone case ($\sigma^2 = 0.5$, solid). Implied values lie below the 45° line, so bids exceed values. Panel (b): detail of the Lemma 2 example. On the shaded region $v(b)$ decreases, so one value is consistent with three bids. Source: our calculations (`asker_inverse_bid.py`).

Why this mechanism?

The ring's design looks puzzling. It induces overbidding, misallocation and occasional losses for the ring itself. Asker's Section II.A explains why simpler designs were unattractive.

Mailath and Zemsky (1991) show that with independent private values drawn from different distributions, a mechanism exists that achieves efficient collusion at second-price auctions. It balances the budget ex post and no subcoalition wants to break away. The mechanism depends heavily on the value distributions, however, and Asker knows of no game form that implements it. With symmetric bidders a simple mechanism is optimal. The ring holds a first-price sealed-bid knockout, the winner bids in the target, and the winner's knockout bid is split equally among the losers. With asymmetric bidders that simple design fails. If the ring cannot discriminate in sidepayments, it may do better to exclude a weak member whose expected contribution to the collusive surplus is smaller than his share. McAfee and McMillan (1992) analyze rings at first-price auctions and introduce the notion of an insincere bidder, an extreme form of weakness. Lopomo et al. (2005) show that when the knockout follows the target auction and the budget must balance ex post, no scheme at all can implement an efficient allocation at English auctions. A ring with asymmetric members thus faces a choice. It can exclude its weak members or accept some inefficiency. The stamp ring kept its weak members.

Remark 13.54 (Why tie the target limit to the knockout bid?). Consider an alternative in which the knockout winner chooses its own limit in the target auction, with sidepayments computed as before. Suppose two members bid and the bids become known. Let the winner's value be v_1 and the loser's bid k_2. If $k_2 < v_1$, the standard English auction argument gives a limit of v_1. If $k_2 > v_1$, the winner chooses a limit $\bar{b} \le k_2$ to maximize

$$\int_{-\infty}^{\bar{b}} (v_1 - x)\, h_r(x)\, \mathrm{d}x - \frac{1}{2} \int_{-\infty}^{\bar{b}} (k_2 - x)\, h_r(x)\, \mathrm{d}x.$$

The first-order condition is $(v_1 - \bar{b})h_r(\bar{b}) - \frac{1}{2}(k_2 - \bar{b})h_r(\bar{b}) = 0$, so

$$v_1 - \bar{b} = \tfrac{1}{2}(k_2 - \bar{b}) \quad \Longrightarrow \quad \bar{b} = 2v_1 - k_2 < v_1.$$

The winner would underbid, to avoid winning lots whose sidepayment exceeds its profit (Asker, 2010, p. 734 and footnote 19). Underbidding would leave profitable lots unbought and invite members to defect and bid secretly against the ring. It would also attract outside bidders. Tying the limit to the knockout bid makes the ring aggressive instead. No member wants to be outside a ring that overbids, and outsiders are deterred from entering. On this account the design traded some allocative efficiency for stability.

13.8.3 Data and descriptive evidence

The data cover the knockouts before 11 target sales between June 5, 1996 and June 26, 1997. A sale is a collection of lot auctions that often runs over several days. The New York Attorney General's office collected the records during its investigation. They were transcribed from faxes and written records kept by one member, who was known in the ring for worrying about not being paid what he was owed. For each lot the data give the date, auction house, lot number, target price, all sidepayments, and the identities and bids of the knockout bidders. Fewer than 3 percent of observations are incomplete, for reasons such as faxes faded by sunlight. The records are matched to auction catalogs, which report estimated minimum and maximum values or a book value, condition grades, origin and number of stamps. The main shortcoming

is that the number of bidders in the target auction is unknown, and only the winning target price is recorded (Asker, 2010, pp. 734–735).

The analysis excludes the Harmer-Schau sale (189 lots, 87 percent won by the ring), where the ring used an informal arrangement and the target price almost always equaled the second-highest knockout bid. In the remaining 1,781 lots the ring won 58 percent of the lots on which it was active, or 66 percent by estimated value. The lots it won raised $6,377,284, against $10,034,754 across all lots on which it was active. The pooled mean knockout bid was $2,142 and the pooled mean winning target bid $2,042 (Asker, 2010, Table 1).

Table 13.32 organizes the lots by the number of members in the knockout. A single member bid on 623 lots, and eight members bid on 26. The ring's win rate rises steeply with participation, from 19 percent to 96 percent. Either outside participation grew more slowly than ring participation, or overbidding grew with the number of members, or both. Mean winning target bids rise weakly with participation and are roughly flat between three and six bidders.

Table 13.32: Bidding by number of bidders in the knockout

Number of	Target auction (winning bid)		Knockout (median bid)		% of lots	Total
bidders	Mean	SD	Mean	SD	won by ring	lots
1	733	1,262	616	1,134	19	623
2	1,314	2,016	1,066	2,048	36	367
3	2,014	3,246	1,750	3,029	48	260
4	2,217	3,492	2,293	4,082	69	196
5	2,249	3,419	2,092	3,322	68	144
6	2,098	2,628	2,163	3,014	74	91
7	2,979	3,425	3,655	4,116	86	74
8	4,790	4,904	6,233	7,726	96	26

Notes: Amounts in dollars. Excludes the Harmer-Schau sale. The lot counts sum to 1,781. Weighting the win rates by lots gives about 43 percent, below the 58 percent of Asker's Table 1, so the two figures are computed on different bases. Source: Asker (2010, Table 2).

Participation and win rates. Asker's Table 3 regresses the number of members in each knockout on lot characteristics by OLS. A second column uses a transformed logit, whose dependent variable is the log share of members participating minus the log share not participating. In the logit, participation rises with the spread of the catalog estimate, $E_{\max} - E_{\min}$ in thousands of dollars (coefficient 0.196, standard error 0.103), much more than with its midpoint (0.031, standard error 0.024). It also rises with the spread of condition grades (0.198, standard error 0.022) and falls when no grade is given (−0.492, standard error 0.074). Both regressions use 1,781 lots, with an R^2 of 0.261 for OLS and 0.255 for the logit. Participation is always incomplete: at most 8 of the 11 members ever bid on a lot. Since entering a very low knockout bid costs little and can earn a sidepayment, Asker suggests a dynamic enforcement rule or a small participation cost as explanations (Asker, 2010, pp. 737–738).

Table 4 of Asker (2010) reports a logit of a ring win on the same covariates. The number of members raises the win probability, with a coefficient of 0.854 (standard error 0.127) and a marginal effect of 0.208 per member. The effect diminishes, with a coefficient of −0.046 (0.017)

on the square. Higher average grades raise the win probability (0.313, standard error 0.069). The estimated value and its spread have no significant effect once these are controlled for. Auction house dummies remain significant, perhaps because outside competition differed across houses.

Weak members. Table 13.33 reports knockout outcomes by member. Members D, G and H rarely submit the high bid: 14, 11 and 14 percent of the knockouts they enter, and 10, 10 and 4 percent when at least two members bid. Yet they receive sidepayments at least as often as the others (20, 34 and 34 percent) and almost never pay them (3, 5 and 0 percent). In an independent private values model, a member's strength comes from its value distribution. A weak member's distribution places more mass on low values. Asker notes that distributions with a similar mean but a much lower variance fit the pattern. Such members lose more often, but their losing bids sit close to the winning bid and so earn sidepayments (Asker, 2010, footnote 30). Member D was explicit in his deposition. His objective, he said, was to "make money from these people" rather than to buy the stamps (Asker, 2010, p. 738).

Table 13.33: Knockout outcomes, by ring member

	All knockouts ($n \geq 1$)		Knockouts with at least two members ($n \geq 2$)			
Member	% high bid	Knockouts	% high bid	% receives	% pays	Knockouts
A	40	675	33	22	12	607
B	57	196	52	21	16	175
C	34	449	20	23	5	368
D	14	715	10	20	3	686
E	39	353	38	24	21	348
F	31	120	28	28	4	116
G	11	186	10	34	5	184
H	14	56	4	34	0	50
I	44	210	44	17	20	209
J	45	878	30	22	9	686
K	42	1,075	28	21	9	861

Notes: "% high bid" is the share of a member's knockouts in which it submitted the highest bid. "% receives" and "% pays" are the shares in which it received or paid sidepayments. Source: Asker (2010, Table 5).

Figure 13.21 shows net sidepayments by member. Over all auctions, E was the largest net payer, with \$74,418 paid into the ring. D and G were the largest net recipients, with \$22,251 and \$21,574, although G took part in only 186 knockouts against D's 715. Excluding the 25 lots with target prices above \$10,000 reduces E's role. E was active in 18 of them and paid \$38,000 net on them. Its largest single payment was \$15,500, on a lot acquired for \$26,000. The ability of D and H to extract sidepayments is unchanged by the exclusion (Asker, 2010, p. 740 and footnote 28).

Naive damages. A naive measure of the seller's loss treats knockout bids as true values. In an English auction without the ring, the price would be the second-highest value among all bidders. When the ring wins, the target price is the highest outside value. The naive damage on a lot the ring won is therefore

$$\text{naive damage}_k = \max\{b_{(2),k} - P_k,\, 0\}. \tag{13.97}$$

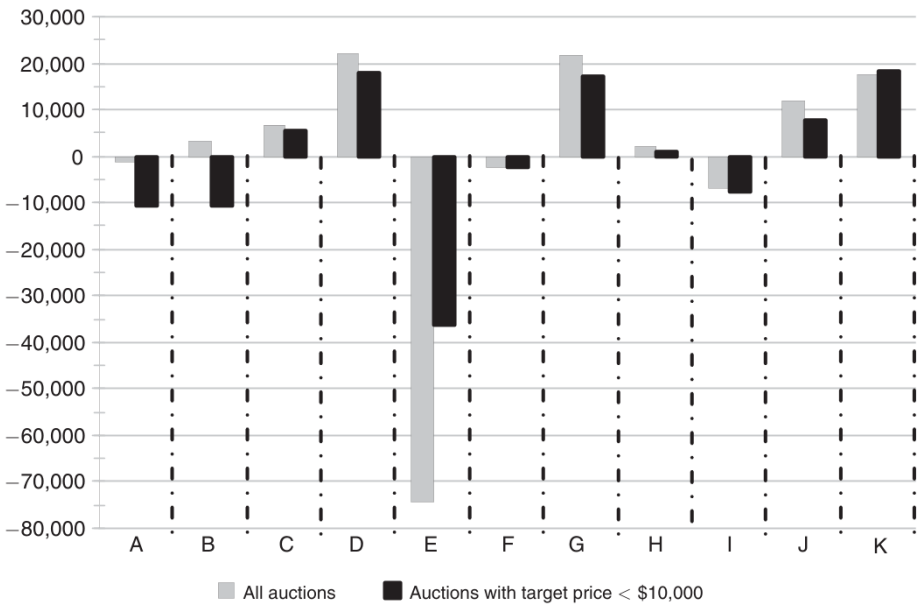

Figure 13.21: Net sidepayments from the ring, by member, in dollars. Positive values are net receipts. Grey bars cover all auctions, and black bars cover auctions with target prices below $10,000. Source: Asker (2010), Figure 1.

Table 13.34 reports the measure for the 1,158 lots with at least two members in the knockout, which are the 1,781 lots minus the 623 single-member lots. Total naive damages are $514,900. The mean of $445 per lot divides by all 1,158 lots, including the 509 the ring did not win. Naive damages rise with the target price, reaching $3,820 per lot above $10,000, and with the number of members, reaching $3,796 per lot in eight-member knockouts. By auction house, Matthew Bennett, a stamp specialist, bears the largest total, $283,200 (Asker, 2010, Table 6). The measure overstates true damages, because Proposition 13.50 implies that $b_{(2)}$ exceeds the second-highest member's value. Measuring true damages requires the structural model.

13.8.4 Structural estimation

The structural model recovers the distributions of members' values and of the highest outside value from bids. With these distributions, damages, efficiency losses and the ring's returns can be simulated. The estimator adapts Guerre et al. (2000) and is closest to Krasnokutskaya's treatment of unobserved heterogeneity (Krasnokutskaya, 2011), which Asker cites in its 2004 working-paper form.

Primitives. Member i's value for lot k is

$$u_{ik} = \Gamma(x_k)\, v_{ik}\, \kappa_k, \qquad \Gamma(x_k) = e^{x_k \gamma}. \tag{13.98}$$

The row vector x_k holds the catalog's estimated minimum and maximum values and a catalog value if one is provided. It also holds the minimum and maximum condition grades, a dummy for lots of exclusively US stamps, and a dummy for lots without value estimates. The factor κ_k is lot heterogeneity that bidders observe and the econometrician does not, such as information from inspecting the stamps. The private component v_{ik} reflects a dealer's clients,

Table 13.34: Naive damages in target auctions with two or more ring members active in the knockout

By final price in target auction ($)	0–500	501–1,000	1,001–2,000	2,001–3,000	3,001–5,000	5,001–7,000	7,001–10,000	10,000+	Aggregate
Mean target price	314	745	1,483	2,527	3,929	5,940	8,514	17,180	1,986
Mean highest knockout bid	471	1,066	1,996	3,187	5,918	8,041	10,428	23,840	2,718
Mean total sidepayments	42	92	154	245	622	697	526	1,910	222
Total naive damages	28,390	53,460	68,000	51,950	113,150	65,500	38,950	95,500	514,900
Mean naive damages	83	184	308	490	1,243	1,394	1,053	3,820	445
Lots won by ring	203	162	112	50	55	29	23	15	649
Total lots	341	290	221	106	91	47	37	25	1,158
By number of ring members in knockout	2	3	4	5	6	7	8		Aggregate
Mean target price	1,314	2,014	2,217	2,249	2,098	2,979	4,790		1,986
Mean highest knockout bid	1,281	2,327	3,197	3,282	3,301	5,750	9,496		2,718
Mean total sidepayments	12	96	249	211	365	895	1,898		222
Total naive damages	8,920	50,095	97,540	60,760	66,415	132,470	98,700		514,900
Mean naive damages	24	193	498	422	730	1,790	3,796		445
Lots won by ring	133	126	136	98	67	64	25		649
Total lots	367	260	196	144	91	74	26		1,158

Notes: Amounts in dollars. Naive damages are the second-highest knockout bid minus the target price on lots the ring won. Mean naive damages divide total naive damages by total lots (for example, $\frac{514,900}{1,158} = 445$). The source also reports a panel by auction house. Source: Asker (2010, Table 6).

its cost of capital and its private information about the market. In the basic model $\kappa_k = 1$. The multiplicative form lets both the mean and the variance of values move with observed characteristics. Only two-bidder knockouts are used. Members D, G and H form a weak type and the others a strong type, with a common value distribution within each type. Each bidder knows that it faces one rival of unknown type, and the empirical participation frequencies serve as the probabilities ω_j.

Lemma 13.55 (Homogeneity (Asker, Lemma 3))**.** *In a two-bidder knockout, suppose b is an optimal bid at value v when all values are as given. If every member's value and the highest outside value are multiplied by $\Gamma > 0$, there is an equilibrium in which the optimal bid at value Γv is Γb.*

Proof. We mark objects of the scaled game with a superscript Γ. Let every member use $\beta_j^{\Gamma}(u) = \Gamma \beta_j(\frac{u}{\Gamma})$ in the scaled game. The rival's bid then has CDF $G^{\Gamma}(y) = G(\frac{y}{\Gamma})$ and density $g^{\Gamma}(y) = \frac{1}{\Gamma} g(\frac{y}{\Gamma})$. The highest outside value has $H_r^{\Gamma}(x) = H_r(\frac{x}{\Gamma})$ and $h_r^{\Gamma}(x) = \frac{1}{\Gamma} h_r(\frac{x}{\Gamma})$. Substitute $x = \Gamma \tilde{x}$ and $y = \Gamma \tilde{y}$ in each integral of (13.94). For example,

$$\int_{-\infty}^{\Gamma \tilde{b}} (\Gamma v - x)\, h_r^{\Gamma}(x)\, \mathrm{d}x = \int_{-\infty}^{\tilde{b}} \Gamma (v - \tilde{x})\, \frac{1}{\Gamma} h_r(\tilde{x})\, \Gamma\, \mathrm{d}\tilde{x} = \Gamma \int_{-\infty}^{\tilde{b}} (v - \tilde{x})\, h_r(\tilde{x})\, \mathrm{d}\tilde{x},$$

and $g^{\Gamma}(y)\,\mathrm{d}y = g(\tilde{y})\,\mathrm{d}\tilde{y}$. Every term scales in the same way. The scaled objective U^{Γ} therefore satisfies $U^{\Gamma}(\Gamma \tilde{b}; \Gamma v) = \Gamma\, U(\tilde{b}; v)$ for every bid $\tilde{b}$. A positive multiple of an objective has the same maximizers, so $\tilde{b}$ is optimal at v if and only if $\Gamma \tilde{b}$ is optimal at Γv. The argument applies to each member, so the scaled profile is an equilibrium. □

Asker proves the lemma from the first-order conditions in his appendix. He reports that it does not hold for knockouts with three or more bidders, which is why only two-bidder

knockouts enter the structural analysis. For three-bidder knockouts he estimated an additive version, whose results he judged explicable only by strong misspecification (Asker, 2010, footnote 34). Applying the lemma with $\Gamma = \Gamma(x_k)\kappa_k$ gives log bids of the form

$$\ln b_{ik} = x_k \gamma + \ln \kappa_k + \ln \beta(v_{ik}), \tag{13.99}$$

where β is the bid function at normalized values. By the dominant strategy argument the same scaling holds for outside bidders, so the target price on a lot the ring wins is $\ln P_k = x_k \gamma + \ln \kappa_k + \ln r_k$.

Step 1: observed heterogeneity. Following Haile et al. (2003), Asker runs the first-stage regression

$$\ln b_{ik} = x_k \gamma + a_i + e_{ik}, \tag{13.100}$$

which is his equation (3). The sample pools the knockout bids and the target prices, so that i ranges over the members and the target. The terms a_i are dummies for each member and for the target price, and e_{ik} is an error. Pooling preserves the relative ordering of bids within a lot. The normalized bids are $\ln \hat{b}_{ik} = \ln b_{ik} - x_k \hat{\gamma}$. The first stage removes much of the heterogeneity across lots. The standard deviation of lot-mean bids falls from 1,367 before the normalization to 370 after it (Asker, 2010, footnote 45).

Step 2: unobserved heterogeneity. After normalization, the two bids on a lot share the common component $\ln \kappa_k$:

$$\ln \hat{b}_{1k} = \ln \kappa_k + \ln \beta(v_{1k}), \qquad \ln \hat{b}_{2k} = \ln \kappa_k + \ln \beta(v_{2k}). \tag{13.101}$$

This is a measurement-error structure with two indicators of a common factor. Li and Vuong (1998) showed how to estimate it nonparametrically, building on an identification result of Kotlarski (1966). The same result underlies Krasnokutskaya's estimator (Chapter 15).

We state the result in the notation of Lemma B.124, which proves it. There $\psi_X(t) = \mathbb{E}[e^{itX}]$ is the *characteristic function* of a random variable X, and ψ_Q is the joint characteristic function of a pair (Q_1, Q_2).

Theorem 13.56 (Kotlarski 1966)**.** *Let Y_1, Y_2 and Y_3 be mutually independent with nonvanishing characteristic functions, with $\mathbb{E}\lvert Y_1\rvert < \infty$, $\mathbb{E}\lvert Y_3\rvert < \infty$ and $\mathbb{E}[Y_1] = 0$. Then the joint distribution of $Q_1 = Y_1 + Y_3$ and $Q_2 = Y_2 + Y_3$ determines the distributions of Y_1, Y_2 and Y_3 through* (B.87) *(Lemma B.124).*

Each assumption has a role. Independence delivers the factorization on which the proof rests,

$$\psi_Q(t_1, t_2) = \psi_{Y_1}(t_1)\, \psi_{Y_2}(t_2)\, \psi_{Y_3}(t_1 + t_2).$$

The nonvanishing condition allows the divisions and the logarithm in (B.87). The zero mean of Y_1 is a location normalization. Without it, a constant could be moved freely between Y_3 and the idiosyncratic components.

In Asker's application $Q_j = \ln \hat{b}_{jk}$, $Y_3 = \ln \kappa_k$ and $Y_j = \ln \beta(v_{jk})$ for $j = 1, 2$, where bidder 1 is always a strong member (Asker, 2010, footnote 35). When both bidders are strong, Y_1 and Y_2 share a distribution. The estimator replaces ψ_Q by the empirical characteristic function over the K lots,

$$\hat{\psi}_Q(z_1, z_2) = \frac{1}{K} \sum_{k=1}^{K} \exp\!\left(\mathrm{i} z_1 \ln \hat{b}_{1k} + \mathrm{i} z_2 \ln \hat{b}_{2k}\right), \tag{13.102}$$

plugs it into (B.87), and recovers each density by a damped inverse Fourier transform (Asker's equation (5)):

$$\hat{g}_X(x) = \frac{1}{2\pi} \int_{-T_n}^{T_n} d(t)\, e^{-\mathrm{i}tx}\, \hat{\psi}_X(t)\, \mathrm{d}t, \qquad X \in \big\{\ln \kappa, \ln \beta(v_1), \ln \beta(v_2)\big\}. \tag{13.103}$$

Here $d(t)$ is a damping function and T_n a smoothing parameter.

Assumption 13.57 (Asker's Assumption U)**.** (a) The normalized bids satisfy (13.101) with $\mathbb{E}[\ln \beta(v_1)] = 0$. (b) The components $\ln \kappa$, $\ln \beta(v_1)$ and $\ln \beta(v_2)$ are mutually independent. (c) Their characteristic functions never vanish. Regularity conditions on smoothness and integrability follow Li and Vuong (1998).

Part (b) rests on the independence of private information across bidders. Part (a) is the normalization of Theorem 13.56. Within-lot variation identifies the private components only up to location, so their position is fixed by the mean of the strong component. A practical consequence follows. Unlike the estimator of Guerre et al. (2000), this approach identifies only distributions. It cannot recover the value behind any particular bid.

The target price adds a third measurement. On lots the ring wins, $\ln r_k^* \equiv \ln \hat{P}_k = \ln \kappa_k + \ln r_k$. Asker applies the procedure to both pairs $\{\ln \beta(v_2), \ln \beta(v_1)\}$ and $\{\ln r^*, \ln \beta(v_1)\}$, setting aside for the moment that target prices are observed only when the ring wins. Each pair yields an estimate of $\psi_{\ln \kappa}$, and the two are averaged with weights equal to the number of observations, as Li and Vuong (1998) suggest. Variation across lots identifies the distribution of $\ln \kappa$, and variation within lots identifies the distributions of the private components (Asker, 2010, pp. 745–746).

Step 3: selection in the target price. The target price reveals the highest outside value only when the ring wins, that is, when r falls below the highest knockout bid $b_{\max}$. Let G_m and g_m be the distribution and density of $b_{\max}$, and let $\tilde{h}_r$ be the density of r among lots the ring wins.

Proposition 13.58 (Selection correction)**.** *Suppose r is independent of $b_{\max}$ and the support of r lies within that of $b_{\max}$. Then*

$$h_r(r) = \mathcal{A}\, \frac{\tilde{h}_r(r)}{1 - G_m(r)}, \qquad H_r(r) = \mathcal{A} \int_{-\infty}^{r} \frac{\tilde{h}_r(x)}{1 - G_m(x)}\, \mathrm{d}x, \qquad \mathcal{A} = \left[\int_{-\infty}^{\infty} \frac{\tilde{h}_r(x)}{1 - G_m(x)}\, \mathrm{d}x \right]^{-1}. \tag{13.104}$$

Proof. By independence, the selected distribution is

$$\tilde{H}_r(\rho) = \mathbb{P}(r \le \rho \mid r < b_{\max}) = \frac{\int_{-\infty}^{\rho} h_r(x) \mathbb{P}(b_{\max} > x)\, \mathrm{d}x}{\mathbb{P}(r < b_{\max})} = \frac{1}{\mathcal{A}} \int_{-\infty}^{\rho} h_r(x) \big[1 - G_m(x)\big] \mathrm{d}x,$$

with $\mathcal{A} = \int h_r(x)[1 - G_m(x)]\, \mathrm{d}x = \mathbb{P}(r < b_{\max})$. Differentiating gives $\mathcal{A}\, \tilde{h}_r(r) = h_r(r)[1 - G_m(r)]$. The support condition ensures $1 - G_m(r) > 0$ wherever $h_r(r) > 0$, so we can divide. This gives the first formula. Integrating gives the second. Requiring $H_r(\infty) = 1$ gives the third. □

Both $\tilde{h}_r$ and G_m can be estimated from the data. The support condition says that the highest knockout bid can reach at least as high as the highest outside value. Given overbidding, Asker judges it unrestrictive (Asker, 2010, p. 747).

Step 4: from bids to values. The densities of $\beta(v_1)$, $\beta(v_2)$ and r are estimated with the triweight kernel $K(u) = \frac{35}{32}(1 - u^2)^3 \mathbf{1}(|u| < 1)$, and their distribution functions by empirical distribution

functions. Combined with the participation frequencies, these estimates form G, g, H_r and h_r. Equation (13.96) then maps bids to values, separately for the strong and weak types.

Step 5: simulated auctions. Asker draws from the estimated distributions of κ, $\beta(v_1)$, $\beta(v_2)$ and r, converts bids into values with Step 4, and recombines the pieces into 100,000 pseudo-auctions. Observed heterogeneity is added by drawing from the empirical joint distribution of x_k. The two percent of draws with bids outside the observed bid range are dropped. Confidence intervals come from a bootstrap that resamples auctions, with 5,000 replications.

Practical choices. The damping function is $d(t) = \max\left[1 - \frac{|t|}{\sqrt{2}\,T_n}, 0\right]$, following Diggle and Hall (1993). The smoothing parameter T_n is chosen in two stages. A linear extrapolation rule of Diggle and Hall gives a range. Within it Asker minimizes

$$\left(\frac{\widehat{ND} - ND}{ND}\right)^2 + \left(\frac{\widehat{PW} - PW}{PW}\right)^2 + P\,\mathbf{1}\{\text{nonmonotonic}\},$$

where ND is mean naive damages, PW the probability that the ring wins, hats denote simulated values, and the last term penalizes nonmonotone inverse bid functions (Lemma 13.53). The common component is well identified and insensitive to T_n, so $T_n = 50$ for $\ln \kappa$. The search gives $T_n = 12.0$, 3.0 and 8.3 for the strong component, the weak component and $\ln r$. Deconvolution estimates are imprecise in the tails, which makes the ratio in (13.104) unstable, so supports are trimmed using the largest within-lot differences between bids. Kernel bandwidths follow the rule of thumb $h = 1.06\,\hat{\sigma} n^{-\frac{1}{6}}$, and smoothed distribution functions use $h = 1.06\,\hat{\sigma} n^{-\frac{1}{5}}$. One outlier is dropped. Its knockout bids were \$42,500 and \$18,000 and its target price \$18,000, while the next highest bid in any two-bidder knockout was \$13,500 (Asker, 2010, pp. 748–749).

Identification and counterfactuals. The argument has three layers. Variation across lots identifies the distribution of the common component. Variation within lots identifies the private components. The first-order condition (13.96) maps the bid distribution into the value distribution, provided the population inverse is increasing. The argument also needs a single equilibrium in the data and knowledge of the number of knockout bidders. Damages compare the ring's outcome with a competitive English auction in which all bidders bid their values. When the ring wins, it pays $P_r = r$. The competitive price P_c is the second-highest value among all bidders, which depends on the second-highest outside value $r_{(2)}$. The data do not identify it, so Asker brackets it with two assumptions.

- U.B. (upper bound on damages): $r_{(2)} = r$. Then $P_c \geq r = P_r$, so sellers never gain, and the competitive price takes its highest model-consistent value.
- L.B. (lower bound on damages): $r_{(2)} = \min\{r, v_{(1)}\}$, with $v_{(1)}$ the highest member value. If the ring won with $r > v_{(1)}$, a misallocation, then $P_c = v_{(1)} < P_r$ and the seller gains. Otherwise P_c is as under U.B.

Under both assumptions the seller loses exactly when the second-highest member value exceeds r. The share of ring wins in which sellers gain under L.B. therefore equals the share of misallocations.

13.8.5 Results

Figure 13.22 shows the estimated bid function of a strong member, evaluated at a common component of 520 and a 70 percent chance of facing another strong member. Bids lie above the

45° line throughout. Overbidding is roughly constant at low values and declines once values exceed about $750, as the chance of winning the target rises. A member with a value of $800 would win the target with probability 0.44 if it bid its value. It bids $877, which raises that probability to 0.446. The bid function of a weak member is very similar (Asker, 2010, p. 750).

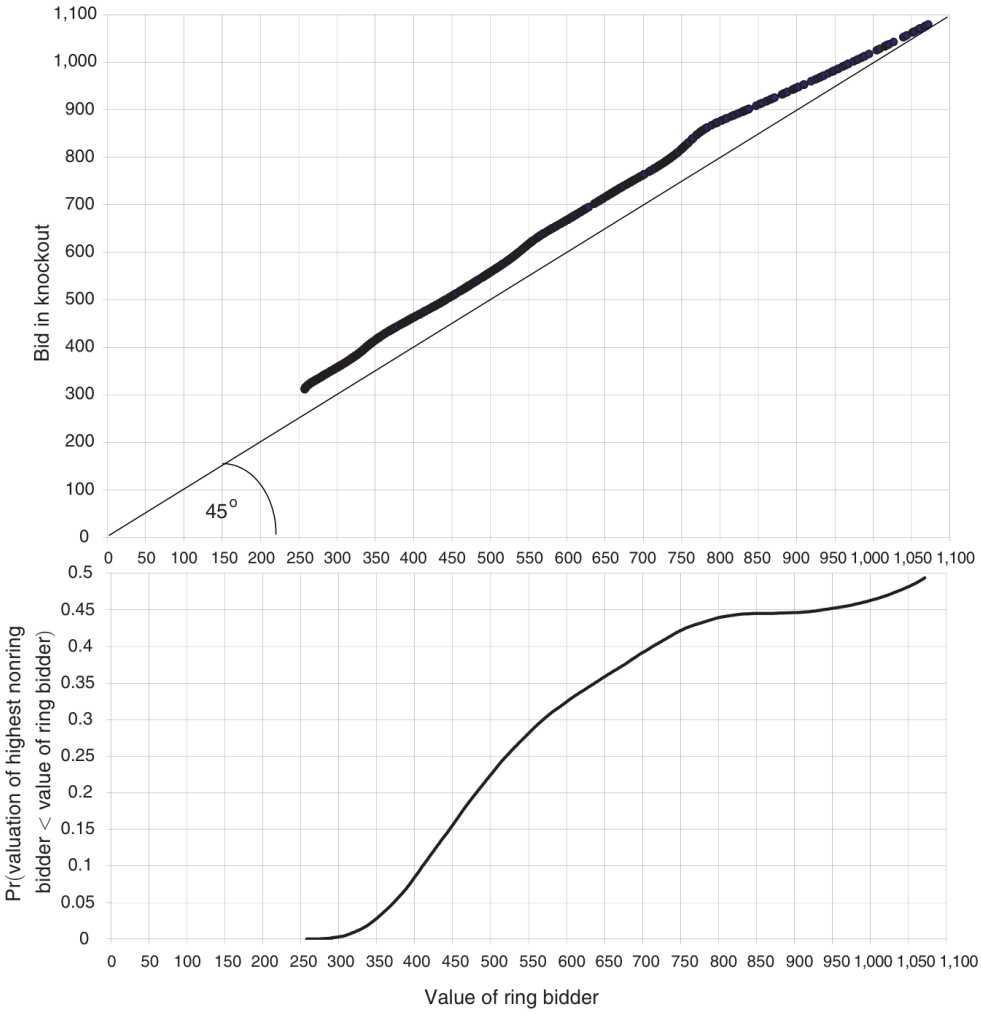

Figure 13.22: Estimated knockout bid function of a strong member in the model with unobserved lot heterogeneity (top), and the probability that the highest outside value lies below the member's value (bottom). The bid function is constructed with a common component of 520 and a 70 percent chance of facing another strong member. Source: Asker (2010), Figure 2.

Damages to sellers. Table 13.35 reproduces Asker's Table 7. In the data, mean naive damages on lots the ring won are $67 among two-bidder knockouts. The model with unobserved heterogeneity predicts $74, and the model without it predicts $150. Without a common component, simulated bids vary too much within lots. Both models match the ring's win rate well, at 0.34 and 0.37 against 0.36 in the data, although the intervals are wide. With unobserved heterogeneity, mean true damages per ring win are $36.99 under U.B. and $26.50 under L.B. These are about half and about a third of the model's naive damages of $74.21. The 90 percent confidence intervals for the ratio of true to naive damages are $[0.38, 0.69]$ under U.B. and $[0.25, 0.63]$ under L.B. (Asker, 2010, footnote 47). Ignoring unobserved heterogeneity raises

true damages to $105.74 and $99.15.

Share of target auctions won		0.34	0.08	0.49	0.37	0.18	0.45

Notes: Means are over target auctions the ring won unless further conditioned. The damage ratio is the price the seller receives with the ring, P_r, divided by the competitive price, P_c. U.B. and L.B. are the upper- and lower-bound assumptions on the second-highest outside value. Each model uses 100,000 simulated auctions. Intervals are bootstrapped with 5,000 replications. Source: Asker (2010, Table 7).

The rest of the table decomposes the ring's wins. Sellers were harmed in 27 percent of them, and in those cases the ring lowered the price by 17 percent on average. These figures are the same under both assumptions, as the counterfactual analysis implies. Under L.B., sellers gained in 19 percent of ring wins, with prices 7 percent higher. In those auctions the overbidding in the knockout carried into the target auction. There is also an unmeasured benefit to sellers. When an outside bidder wins, the ring's inflated limit can raise the price it pays, so the damage estimates overstate sellers' losses.

Damages to bidders outside the ring. Table 13.36 collects Asker's Tables 8 to 10. Under L.B., 19 percent of ring wins misallocate the lot to the ring. Damages from misallocation average $10.48 per ring win, 40 percent of the sellers' L.B. damages. Price inflation costs outside winners $104.20 per auction the ring loses. That figure is an upper bound, since L.B. imposes the damage in every lost auction. In the raw data, the target price equals the highest knockout bid in 11.5 percent of the auctions the ring loses. The ring also loses about twice as often as it wins. Asker therefore deflates the $104.20 by a factor of five, to a little over $20 per ring win. Adding misallocation, he concludes that outside bidders' damages are likely at least as large as sellers'. Price inflation is a transfer from outside bidders to sellers, so it lowers sellers' damages by the same amount it raises outside bidders' (Asker, 2010, pp. 753–754).

Efficiency. An English auction with private values allocates efficiently, and a ring that colluded efficiently would only change transfers (Graham and Marshall, 1987). This ring creates inefficiency, which is an additional economic reason for enforcement. The loss is small. When

Table 13.36: Damages to outside bidders, efficiency and returns to the ring

Mean proportional price discount	0.96	0.91	0.98	0.88	0.84	0.93

Notes: "Lower" and "Upper" bound the 90 percent bootstrap interval (5,000 replications). Efficiency losses in dollars are conditional on a ring win. Proportional losses average over all auctions and compare the realized allocation with the efficient one, with a seller value of zero. "No ring bidders" and "only ring bidders" remove the ring members or the outside bidders from the auction. Returns average over ring wins. Each model uses 100,000 simulated auctions. Source: Asker (2010, Tables 8–10).

the ring wins, the average efficiency loss is $10.56, less than 1 percent of the value of the efficient allocation. For comparison, removing the ring members from the auction would lower efficiency by 8 percent, and removing the outside bidders by 29 percent. The difference between the $10.56 and the $10.48 of misallocation damages reflects lots won by the ring but assigned to the wrong member (Asker, 2010, footnote 49). If outside bidders' damages are as large as L.B. suggests, the ring may discourage their participation. The comparison suggests that such participation effects could cost much more than the misallocation itself, but the data cannot measure them.

Returns to the ring. The ring harmed itself in 19 percent of the auctions it won, by paying more than its value. The average harm is $10.48 per win. The benefit from suppressing competition among members averages $36.91, so the net return is $26.42 per win, and prices averaged 96 percent of the competitive level. The benefit is what an ideal cartel would capture. By that yardstick the ring captured about 72 percent of the available surplus, since $\frac{26.42}{36.91} = 0.72$. A deposition confirms the cost: a member who left the ring in the late 1980s felt that ring prices were so inflated that a buyer through the ring paid too much.

Strong members as a group capture $4.64 and weak members $21.95 of the roughly $27 the ring earns per win (Asker, 2010, p. 756). The weak members' disproportionate share matches the raw sidepayment data of Figure 13.21. Why did the strong members not expel them? Asker suggests a hold-up problem. An expelled member could inform the antitrust authorities and benefit from leniency for informants (Section 13.10).

Fit and robustness. Asker compares simulated and observed densities with the integrated absolute error $\int |f(x) - \hat{f}(x)|\,dx \in [0, 2]$. For the density of knockout bids it is 0.192 with unobserved heterogeneity and 0.280 without. For the ratio of the target price to the highest knockout bid it is 0.611 (0.922 without). For the ratio to the second-highest bid it is 0.480 (0.899). For the ratio of the highest to the second-highest strong bid it is 0.194 (0.506). For the ratio of weak to strong bids it is 0.238 (0.401). The model fits worst near the point where the target price approaches the highest knockout bid. Asker attributes the misfit to estimating from marginal distributions and to the strong independence assumptions. A second concern is that two-bidder knockouts are a selected sample. Asker therefore re-estimates the model on the half of two-bidder knockouts with the highest propensity score for having two bidders. Damages are higher in that sample, but each point estimate lies within the other sample's 90 percent interval (Asker, 2010, pp. 756–758).

13.8.6 Interpretation, critiques and contribution

Interpretation. The ring's gains were modest per lot, and its design gave much of them away to weak members and to overpayment. Damages to sellers were about half of what naive comparisons suggest, because overbidding sometimes raised prices. If the ratio of true to naive damages is used to extrapolate, sellers lost between $207,000 and $269,000 in total on the lots the ring won (Asker, 2010, footnote 54). Outside bidders were harmed at least as much as sellers. This finding has a legal implication. Under the Sherman and Clayton Acts any person injured by an antitrust violation may sue for treble damages. Asker knows of no claim against a ring brought by outside bidders, and his estimates suggest that such claims could be large and proximate enough to succeed.

Critiques. The results rest on strong assumptions, several of which Asker discusses.

- Values are independent and private. A common-value component could change the extent of overbidding in ways that are hard to sign.
- Only two-bidder knockouts are used, because Lemma 13.55 and the closed-form inversion apply there. Extrapolating to larger knockouts is uncertain. Damages there could be larger, since a member is more likely to hold the second-highest value, or smaller, since overbidding and outside entry may rise.
- Members are assumed to know the number of knockout bidders. Uncertainty about it would make bids a mixture of two-, three- and more-bidder optimal bids (Asker, 2010, footnote 52).
- Target-auction participation is unobserved, which forces the U.B. and L.B. bounds and the assumption that the distribution of the highest outside value does not vary with lot heterogeneity (Asker, 2010, footnote 41).
- Monotonicity of the inverse bid function is imposed through the choice of T_n. That choice also targets naive damages and the win rate, which are close to the outcomes of interest.
- The model treats each knockout as a static game. It ignores the repeated interaction that sustained the ring for 15 to 20 years, the expulsions, and the incomplete participation that may reflect dynamic enforcement.
- The link between the English target price and the highest outside value ignores jump bidding and bid increments, which Haile and Tamer (2003) show can break it. Asker reports that jump bidding was rare and bid increments small in the auctions he attended.

Ring design and auction design. Marshall and Marx (2012, chs. 9–10) place the stamp ring among the rings that operate in different auction formats. In a sealed-bid procurement, a ring must police secret deviations. Members told to bid high could otherwise undercut the designated bidder. The cast-iron pipe ring of the 1890s held a knockout before each procurement and had the losers submit deliberately losing bids. It could monitor them because bids and bidders' identities were read out in public (pp. 189–192). At an ascending auction where bidders see who holds the high bid, a ring needs little more than a list of its members. Members do not bid against one another, and items won are reallocated in a knockout after the sale. The antiques, machinery and real estate rings prosecuted in U.S. courts worked this way (pp. 194–196). The stamp auctions did not reveal identities in this way, so the stamp ring collected reports before each auction and sent a third-party agent to bid (p. 190). Records also differ across formats. A sealed-bid auction leaves a written record of every bid, including close pairs of losing bids that may signal collusion. An ascending auction often leaves no record of who took part or what they bid (pp. 206–207).

These differences suggest remedies (ch. 10). The more an auctioneer reveals about bidders' identities, bids and outcomes, the easier a ring finds it to monitor its members (p. 200). Transparency rules meant to prevent favoritism by officials can therefore help rings. In early spectrum auctions of the Federal Communications Commission, bidders used the last digits of their bids to signal to one another. Later designs fixed the bid increments and hid identities until the auction ended (pp. 201–202). A right of last refusal for an incumbent supplier lets it watch rivals' bids and is pro-collusive (p. 202). Allowing bidders to register several identities, or to bid as shills, makes deviations from a ring harder to detect (pp. 202–203). Registration that does not reveal identities disrupts rings at ascending auctions where the identity of the high bidder is hidden (pp. 203–205). Marshall and Marx list six measures (p. 207). Auctioneers

can use sealed bids, limit the information they release and deny incumbents a right of last refusal. They can also allow multiple bids under disguised identities, disclose information about the item with collusion in mind, and hold auctions at long and irregular intervals. The stamp ring's response to one auction house shows that rings react to such signals. When the house made clear that it knew of a ring, the ring stopped bidding there (Section 13.8.1).

Contribution. Asker (2010) offers the first detailed look at the internal mechanism of a long-lived ring with complete records of its private auctions. Earlier studies of known cartels, such as Pesendorfer (2000) on school milk, had rich data on target auctions but could only infer the ring's workings from outcomes. The paper shows that the overbidding incentive identified by Graham et al. (1990) is quantitatively important, that it makes naive damages misleading, and that it shifts damages from sellers to other bidders. Methodologically, it extends the inversion logic of Guerre et al. (2000) to a new mechanism and combines it with Kotlarski deconvolution and a selection correction. It also connects the theory of ring design (Graham and Marshall, 1987; Mailath and Zemsky, 1991; McAfee and McMillan, 1992) with evidence on how a real ring traded efficiency for stability. Like the Sugar Institute and the cartels of Section 13.7, the stamp ring tolerated behavior that a frictionless theory would rule out, here the extraction of rents by weak members. Statistical methods that detect rings from bids alone are the subject of Section 13.9.

13.9 Detecting Collusion: Market Evidence and Tests for Bid Rigging

An outsider who suspects collusion usually sees prices, quantities or bids, and little else. This section asks what such evidence can reveal. Section 13.9.1 reviews the kinds of evidence on which a finding of collusion can rest. They are pricing patterns, measures of price elevation, facilitating practices, structural conditions, internal records, and the plus factors of cartels and bidding rings. The remaining subsections develop formal tests for public procurement.

Public procurement is among the settings in which collusion is most often prosecuted, and statistical detection methods are most developed there. A buyer, such as a highway department or a school district, solicits sealed bids for a contract and awards it to the lowest bidder. In procurement, bid rigging (Section 13.1) takes the form of an agreement among bidders about who will win a contract and at what price. Porter and Zona (1993, p. 1) show how common it is. Between 1982 and 1988, bid rigging or price fixing in auction markets accounted for more than half of the criminal antitrust cases filed by the U.S. Department of Justice. In school milk alone, Porter and Zona (1999, p. 1) count investigations in more than twenty states and guilty pleas in at least a dozen. They also report fines above $90 million and about ninety people sent to jail.

The buyer observes the bids and the identities of the bidders. It does not observe their costs. A ring that knows this can choose bids that look competitive. Detection therefore follows the strategy of the rest of this chapter. We write down a model of noncooperative bidding, derive restrictions on observable bids, and ask whether a group of suspected firms violates restrictions that other firms satisfy. A rejection shows that the suspected group behaves differently. It does not by itself prove an agreement, because the model may be misspecified for that group alone. Section 13.9.2 develops the theory of such tests. Sections 13.9.3 and 13.9.4 apply it to highway paving on Long Island and to school milk in Ohio. Detection based on the comparison of auction formats, as in the test for mill collusion of Athey et al. (2011), is treated in Chapter 15. Page and table references to the two papers of Porter and Zona are to their NBER working-paper versions, and "WP p." denotes a working-paper page.

13.9.1 Market evidence, plus factors and screens

Detection is the central challenge in the control of coordinated price elevation (Kaplow, 2013, p. 256). Firms hide conduct that may be illegal, and an aggressive search for it produces false positives that chill competitive behavior. This subsection asks what an outsider can infer from market evidence before we turn to the specialized tests for procurement. It draws on two book-length treatments. Kaplow (2013, chs. 10–11) classifies the evidence on which a finding of coordination can rest. Marshall and Marx (2012, chs. 11–12) catalog the plus factors of cartels and bidding rings. A plus factor is economic circumstantial evidence of collusion beyond the parallel movement of prices (p. 213). Section 12.7.1 introduces the concept and its legal background. Here we ask how strong each kind of evidence is and how the kinds combine.

Parallel prices are not evidence. Parallel movement of prices is the weakest evidence of all, because competitive markets produce it too. When the costs of competing firms rise, their prices rise together and their quantities fall. When demand rises, prices and quantities rise together. Competitors react alike to new technology, new regulations and shifts in tastes (Kaplow, 2013, p. 260). Kaplow compares parallel pricing to breathing. Every patient breathes, so no doctor treats breathing as a symptom of bronchitis. Useful evidence is behavior that is consistent with coordination and inconsistent with competition, or the reverse (p. 261). Kaplow groups such evidence into pricing patterns, measures of price elevation and facilitating practices. We take these in turn and then consider structural conditions, internal records and communications.

Three phases of a collusive episode. Kaplow separates three phases: the initiation of elevated prices, their maintenance and their breakdown (p. 261). Each phase leaves a different pattern. At initiation, a sharp price increase is suspicious only if no concurrent change in cost or demand can explain it. Any proposed explanation must also match the movement of quantities, as the next proposition shows. It uses a simple competitive benchmark with price-taking firms.

Proposition 13.59 (Sign restrictions on a price increase)**.** *Let industry demand be $Q = D(p, y)$, with $D_p < 0$ and a demand shifter y with $D_y > 0$ (D and y are local symbols). Firm $i = 1, \dots, N$, with $N \geq 2$, has marginal cost $c_i(q_i) + \kappa_i$, where $c_i' > 0$ and κ_i is a cost shifter. Under competition each firm takes the price as given and supplies $q_i = s_i(p - \kappa_i)$, where s_i is the inverse of c_i and $s_i' = \frac{1}{c_i'} > 0$. Let $S' = \sum_i s_i'$. Then, for small changes, the following hold.*

(i) A demand increase raises the price, total output and the output of every firm.

(ii) A common cost increase $d\kappa$ raises the price by less than $d\kappa$ and lowers total output and the output of every firm.

(iii) A cost increase at firm j alone raises the price and lowers total output and the output of firm j. It raises the output of every other firm.

(iv) A coordinated price increase with y and every κ_i unchanged lowers total output. The division of output among firms is whatever the agreement sets.

Proof. Market clearing requires

$$D(p, y) = \sum_{i=1}^{N} s_i(p - \kappa_i).$$

Differentiate both sides totally:

$$D_p\, dp + D_y\, dy = \sum_i s_i'\,(dp - d\kappa_i).$$

Collect the terms in dp and divide by $S' - D_p > 0$:

$$dp = \frac{D_y\, dy + \sum_i s_i'\, d\kappa_i}{S' - D_p}. \tag{13.105}$$

(i) With $d\kappa_i = 0$ for all i, (13.105) gives $dp = \frac{D_y\, dy}{S' - D_p} > 0$, and then $dq_i = s_i'\, dp > 0$ for every i. (ii) With $d\kappa_i = d\kappa > 0$ for all i, $dp = \frac{S'}{S' - D_p}\, d\kappa$. The factor lies strictly between 0 and 1 because $-D_p > 0$, so $0 < dp < d\kappa$. Then $dq_i = s_i'(dp - d\kappa) < 0$ for every i. (iii) With only $d\kappa_j > 0$, $dp = \frac{s_j'}{S' - D_p}\, d\kappa_j$. The factor lies strictly between 0 and 1 because $s_j' < S' - D_p$. Hence $dq_j = s_j'(dp - d\kappa_j) < 0$ and $dq_i = s_i'\, dp > 0$ for $i \neq j$. In (ii) and (iii) total output changes by $dQ = D_p\, dp < 0$. (iv) Demand slopes down, so $D(p^1, y) < D(p^0, y)$ for any $p^1 > p^0$. □

Table 13.37 collects the predictions. The limit of constant marginal cost, $s_i' \to \infty$, sharpens them. A demand increase then leaves the price unchanged, and a common cost increase passes through in full. These are the predictions behind the conduct tests of Chapter 3 (Kaplow, 2013, pp. 273–274). A common cost shock is the hardest alternative to rule out, because it moves price and output in the same directions as coordination. Two checks remain. Cost increases can be measured in input markets, and cost shocks that hit firms unequally reallocate output under competition (p. 262). Under coordination, firm-specific cost shocks reallocate less output, because the agreement fixes shares (p. 274).

Table 13.37: What a price increase implies for quantities under competition and under coordination

Source of the increase	Price	Industry output	Output across firms	Check that separates it from coordination
Demand increase	Rises (unchanged if marginal cost is constant)	Rises	Every firm expands	Output rises
Common cost increase	Rises by less than the cost (by the full cost if marginal cost is constant)	Falls	Every firm contracts	Measured input prices
Cost increase at one firm	Rises a little	Falls	Output shifts away from the affected firm	Reallocation of output
Coordinated elevation	Rises	Falls	Set by the agreement, little reallocation	No matching change in cost or demand

Notes: Our summary of Proposition 13.59 and of Kaplow (2013, pp. 260–262 and 273–274).

Initiation. Coordinated increases need not be sudden. Firms that do not fully trust one another may raise prices in small steps, and a leader may move cautiously while it waits for rivals to follow. Kaplow argues that such signaling can make coordination easier to infer (pp. 262–263). A sequence of announced moves that cost and demand cannot explain is more telling than a single jump. Sophisticated firms can also spread increases over time, or time them to coincide with cost events that are hard to measure (pp. 263–264). The price announcements of the vitamins cartel show both sides. Compared with the period before 1985, the cartel's announcements were more frequent, came at regular intervals and involved modest individual increases (Marshall and Marx, 2012, pp. 221–222). They were usually joint, with one firm

leading and the others matching within about a week. Firms other than the market leader, Roche, often led joint announcements after 1985 and rarely did before. About 50 percent of the cartel's announcements came well before the effective date of the increase, against 5 percent in the earlier benchmark period (p. 222). Long lead times let the cartel test buyers' acceptance and withdraw a resisted increase before shares were disturbed.

Maintenance. Coordinated prices, and perhaps market shares, tend to be stickier than competitive ones (Kaplow, 2013, pp. 264–265). Frequent adjustment requires either negotiation, which raises the risk of detection, or signaling, which risks being misread. A firm that cuts its price because it sees demand softening may be taken for a cheater and start a war. Competitors, by contrast, respond to changes promptly. Menu costs, the costs of changing prices as such, also produce stickiness. They differ from coordination frictions in two ways. Menu costs apply symmetrically to increases and decreases, and they lead firms to change prices at different times. Sluggishness caused by coordination has neither feature (p. 265). The bromine record fits this account. Prices changed on average every 41.1 weeks during cooperation and every 11.5 weeks otherwise (Section 13.4.3). The variance screen of Abrantes-Metz et al. (2006), which flags periods in which prices vary unusually little, rests on the same logic. Pesendorfer (2000) finds more stable market shares in a bidding ring that did not use sidepayments than in one that did (Kaplow, 2013, p. 264, note 17).

Breakdown. Sudden, sharp price cuts are as suspicious as sudden increases. If prices fall steeply without an exogenous change of matching size, the earlier price was a coordinated one (Kaplow, 2013, p. 265). Price wars thus reveal past collusion, as the railroad and bromine records showed (Sections 13.3 and 13.4.3). Using wars as evidence creates a danger that the targeting of increases does not. A penalty for price cuts may deter the cuts themselves and so raise prices. Kaplow replies that the threat of punishment is a necessary condition for collusion, so a policy that makes wars costly can deter collusion itself (p. 266). Kaplow adds that the problem is more complicated still (p. 266). Firms might respond with less sensitive triggers or shorter wars, which leave prices elevated and give buyers rarer relief. Kaplow therefore suggests leniency, immunity or even rewards for the first price cutter, with full sanctions for the firms that retaliate (pp. 266–267). The next example shows why one proposal of this kind would fail.

Example 13.60 (How large must a price cut be to pay?)**.** Kaplow (2013, pp. 267–268, note 22) discusses a proposal by Sagi. In selected industries, a price cut of at least 20 percent would trigger a six-month freeze of all prices, and a cut of at least 10 percent a three-month freeze. Rivals could not retaliate during the freeze, so the first price cutter would gain. Kaplow's arithmetic shows how much capacity such a gain requires. Let marginal cost be a constant c and the collusive price $(1+m)c$, so that m is the elevation of price above marginal cost. A member sells q at the collusive price and earns $\pi = mcq$ per period. It cuts its price by the fraction x and multiplies its output by k. Its profit becomes

$$\pi^{\text{cut}} = k\,q\,\big[(1-x)(1+m)-1\big]\,c.$$

Suppose the cut must recover R periods of collusive profit, so that it breaks even when $\pi^{\text{cut}} = R\pi$. Dividing both sides by cq gives the break-even condition

$$k\big[(1-x)(1+m)-1\big] = Rm. \tag{13.106}$$

In the short run, $R = 1$. Expand the left side of (13.106) and collect the terms in m:

$$\begin{aligned} k(1-x)(1+m) - k &= m, \\ m\big[k(1-x)-1\big] &= k - k(1-x) = kx, \\ m &= \frac{kx}{k(1-x)-1}. \end{aligned}$$

With $k = 2$ and $x = 0.2$, $m = \frac{0.4}{1.6-1} = \frac{2}{3}$. A firm that can double its output at once breaks even on a 20 percent cut only if the collusive price exceeds marginal cost by two thirds. The cut takes the price from $\frac{5}{3}c$ to $\frac{4}{3}c$, which halves the margin while output doubles. With $k = 1.5$, the same formula gives $m = \frac{0.3}{1.2-1} = 1.5$, so the price must exceed marginal cost by 150 percent.

Now suppose a 10 percent cut triggers a three-month freeze, after which collusion collapses and eight quarters of elevated prices are lost. Kaplow ignores discounting and requires the profit of the freeze quarter to cover the eight lost quarters, so $R = 8$ and $x = 0.1$. Solving (13.106) for k gives

$$k = \frac{8m}{0.9(1+m)-1} = \frac{8m}{0.9m - 0.1}.$$

The required factor falls as m rises and approaches $\frac{8}{0.9} \approx 8.9$ as m grows large. Kaplow's "almost ninefold" output increase is this limit (our reading). The limit treats the margin as falling by the same 10 percent as the price. For finite m the margin falls by more, so the limit is a lower bound. At $m = \frac{2}{3}$ the requirement is 10.7 (our computation). A firm with a 25 percent share would need a share above 200 percent. Kaplow concludes that the proposal provides nowhere near the desired incentive to cut prices, and that generous treatment of the first price cutter under ordinary enforcement is more promising.

Evidence of price elevation. A second family of evidence asks whether current prices exceed marginal cost (Kaplow, 2013, pp. 269–275). Elevation alone does not show coordination, because a single firm with market power also prices above cost (p. 269). A direct comparison of price with measured marginal cost is simple in logic and hard in practice. The analyst must decide which costs are variable and how to allocate joint costs, and average cost is easier to measure than marginal cost. Capacity creates a trap. Suppose marginal cost is low over most of a firm's output range and rises steeply near capacity. A firm producing near capacity and pricing at marginal cost then sets a price well above average cost, and it appears to elevate price when it does not (p. 270). Such errors produce false positives. Kaplow suggests that enforcers treat more costs as variable and require a larger measured gap.

Comparisons across markets avoid measuring the level of marginal cost. Price is at least marginal cost in every market, so a higher price in one market is supracompetitive to the extent that cost differences do not explain it (p. 271). Price discrimination gives a sharper bound, as the next remark shows.

Remark 13.61 (Price discrimination bounds the margin). Suppose a seller with marginal cost mc sells the same good to two groups of buyers at prices $p_L < p_H$, and serving the two groups costs the same. The seller would not sell to the low-price group below cost, so $p_L \geq mc$. Subtract both sides from p_H and divide by p_H:

$$p_H - mc \;\geq\; p_H - p_L, \qquad \frac{p_H - mc}{p_H} \;\geq\; \frac{p_H - p_L}{p_H}.$$

The Lerner index of the high-price sale is at least the proportional price gap (Kaplow, 2013, pp. 271–272). The bound applies to negotiated discounts as well as to posted prices. Buyers

who obtain large discounts reveal that other buyers pay well above marginal cost (p. 272, note 33). Two caveats apply. Some price dispersion arises from buyers' imperfect information, and a highly successful cartel may even reduce dispersion by suppressing secret discounts (p. 272, note 34).

Two further sources complete the list. Econometric conduct tests ask whether prices respond to shifts in demand and cost as competition or as monopoly would predict (pp. 273–274). Chapter 3 develops these tests, and Proposition 13.9 states their main limit. Entry also carries information (pp. 274–275). If fringe firms enter or expand while incumbents have unused capacity, prices are probably elevated. A steep fall in price and a rise in output after entry reveal earlier supracompetitive pricing, much as a price war does. A failure of price to fall when a key patent expires may also indicate coordination (p. 275, note 45).

Facilitating practices. A facilitating practice (Section 13.1) can matter in two ways (Kaplow, 2013, pp. 276–277). Its use supports an inference of coordination when no other plausible explanation for it exists. The practice can also be prohibited itself, which punishes attempts when success is hard to prove. Kaplow examines three groups of practices (pp. 277–285). The first improves mutual understanding through advance price announcements, exchanges of prices through trade associations and audits of invoices. More than 150 price-exchange agreements arose in Britain within a few years after overt price fixing was declared illegal (p. 278, note 53). Kaplow stresses the firms' own incentives. Helping buyers find discounts would undercut a cartel, while helping sellers spot cheaters would sustain it. If firms in an industry conducive to coordination make prices more open, the second motive is the likely one (p. 279). Exchanges of demand forecasts deserve similar scrutiny where transaction prices are secret, because demand uncertainty is then the main threat to a cartel (p. 281). The second group standardizes products, for example through basing-point pricing (p. 282). The third changes the payoffs from cutting prices. It includes cross-ownership, sidepayments, purchases from rivals that sold less than their share, most-favored-customer clauses, resale price maintenance and meeting-competition clauses (pp. 283–285). Section 12.7.2 analyzes several of these practices. The publication of concrete prices in Section 13.5.2, the fare-publishing system of Section 13.5.3 and the interfirm purchases of Section 13.7.1 are cases in point.

Conducive conditions. Evidence on whether market conditions favor coordination sharpens inference in both directions (Kaplow, 2013, pp. 286–288). Conduciveness is roughly a necessary condition for success. If conditions make coordination nearly impossible, it is probably not taking place. The enforcer may misjudge the conditions, however, and the firms usually understand their industry better. Strong evidence of successful coordination should therefore override a judgment that conditions are unfavorable (p. 287). Conduciveness is not sufficient either. If deterrence works, coordination is rare even where conditions are ideal (p. 288). Kaplow reviews the familiar conditions briefly (pp. 289–292). A larger number of firms makes it harder to agree on a price and a punishment and harder to detect cheating by small firms. In most prosecuted cases the firms were few and concentration high. Spare capacity raises both the gain from cheating and the ability to punish, while asymmetric capacities hinder coordination. Many small buyers facing public prices make cheating easy to detect. A few large buyers who place infrequent, privately negotiated orders make it hard. Public procurement usually publishes winning bids, which may explain why so many prosecutions involve bid rigging (p. 290). Uncertain demand hides cheating when prices are secret, and anticipated changes in demand alter the ratio of current gains from cheating to future losses (Section 12.4). Product heterogeneity complicates agreement and the policing of quality and terms, and most prosecuted cases involve homogeneous products. Similar costs, horizons and managerial

backgrounds ease agreement, and multimarket contact enlarges the scope for punishment. Finally, coordination pays only if the industry demand elasticity and the supply response of fringe firms leave room to raise price.

The empirical basis for these factors is weaker than their familiarity suggests (pp. 292–294). Cross-section studies find little relation between concentration and profitability. Studies within an industry find a more robust positive relation between concentration and price, although cost differences and endogeneity complicate them. Structural screens have a poor record. Scherer described a Federal Trade Commission effort to find price-fixing cases from structural indicators alone as "a resounding flop" (pp. 294–295, note 26). Kaplow concludes that highly unconducive conditions strongly negate success, that strong evidence of success should usually convince, and that high conduciveness alone is a weak basis for inferring coordination (pp. 294–295). This ranking differs from that of a rule based on communications. Under such a rule, highly conducive conditions can lower the inference that prohibited communications were used, because the firms needed them less (p. 286, note 1). Section 12.8.4 calls this the paradox of proof.

The Sherbrooke cartel of Section 13.6.5 shows why the checklist deserves limited weight. Erutku and Hildebrand (2010, Table 3) score the market against eight items derived from Stigler (1964), and only three point toward collusion. The market had about 60 stations and a Herfindahl index below 1,800. Yet at least 80 percent of the stations took part in the cartel. In Kaplow's terms, the wiretaps supplied strong evidence of success, which outweighed an unfavorable reading of the conditions. The case fits his warning that outsiders misjudge conditions that the firms themselves understand (p. 287).

Internal evidence and communications. For almost every market-based indicator there is matching evidence inside the firm (Kaplow, 2013, pp. 295–302). Invoices record prices and quantities. Cost and marketing data reveal what the firm believes about marginal cost and demand. Strategy memos and notes of meetings explain why prices moved. Omissions are informative too. If a firm's files contain no new data or discussion about demand, a demand shift is an unlikely explanation for its price increase (p. 299). Internal evidence has two limits. A large firm's knowledge is spread over many people who may disagree, and lawyers who anticipate litigation can sanitize records (pp. 299–300). Kaplow doubts that sanitizing can go far. Several firms would have to fabricate consistent records of a cost shock that never occurred, quickly and without leaving traces, and their story would have to match external data (p. 301).

Communications among firms are internal evidence of a special kind (pp. 302–306). Explicit and reliable records of them can be decisive, especially when they refer to earlier successful price increases. Public communications, such as sequences of advance announcements that converge on a common price, can be as revealing as secret ones (p. 303). The absence of such records proves little, because firms hide their communications and need them least where conditions are most conducive (p. 305). Kaplow also argues that inferring secret communications from circumstantial evidence adds nothing. Let C denote successful coordination, E the observed evidence and M an unobserved communication (local symbols). By the law of total probability,

$$\mathbb{P}(C \mid E) = \mathbb{P}(C \mid E, M)\,\mathbb{P}(M \mid E) + \mathbb{P}(C \mid E, \text{not } M)\,\mathbb{P}(\text{not } M \mid E).$$

Any inference about M drawn from E is already part of $\mathbb{P}(C \mid E)$. Only direct evidence of M, which enlarges E, can strengthen the conclusion (p. 305, note 41).

What decided the cases of this chapter. Kaplow's categories classify the evidence behind the cases of Table 13.48. The legal cartels, namely the Joint Executive Committee, the Sugar Institute and the bromine pools, left internal records and open communications. Wiretapped

communications and guilty pleas proved the Quebec gasoline cartel. The lysine and citric acid cartels were proved in criminal prosecutions and Commission decisions resting on documents and testimony, and the lysine investigation recorded cartel meetings on video (Asker and Nocke, 2021, p. 197, note 46). The stamp ring's knockout records were internal evidence, found after a complaint. The Overlap and fare-publishing cases targeted the agreements and information systems themselves. The Danish concrete episode is the one case in which market-based evidence carried the main weight, and there the authority itself had created the transparency. Statistical tests decided none of the prosecutions. On Long Island and in Ohio they corroborated convictions and confessions after the fact. Porter and Zona call their tests "poor substitutes for a wiretap or a disclosure by a dissident ring member" (Asker and Nocke, 2021, p. 210, note 78).

Plus factors. Courts that require proof of an agreement look for plus factors (Section 12.7.1). A plus factor that delivers a strong inference of collusion is a *super-plus factor* (Marshall and Marx, 2012, p. 213). Marshall and Marx organize plus factors by the cartel conduct that produces them, in nine groups (pp. 213–214). Pricing structures produce price elevation, quantity restriction, steps to reduce buyers' resistance to price increases and changes in incentives within firms. Allocation structures produce an allocation of the collusive gain and redistributions among members. Enforcement structures produce communication and monitoring and a readiness to abandon collusion if cheating persists. A cartel that has suppressed rivalry may finally engage in dominant-firm conduct. Marshall and Marx measure the strength of a plus factor F by the likelihood ratio $S = \frac{\mathbb{P}[F|C]}{\mathbb{P}[F|\text{not } C]}$, where C is again the event that the firms collude (p. 235). The next remark derives the posterior probability of collusion and extends it to several plus factors.

Remark 13.62 (Combining plus factors). Let $O = \frac{\mathbb{P}[\text{not } C]}{\mathbb{P}[C]}$ be the prior odds against collusion. Bayes' rule gives the posterior odds in favor of collusion, which we then invert:

$$\frac{\mathbb{P}[C \mid F]}{\mathbb{P}[\text{not } C \mid F]} = \frac{\mathbb{P}[F \mid C]}{\mathbb{P}[F \mid \text{not } C]} \cdot \frac{\mathbb{P}[C]}{\mathbb{P}[\text{not } C]} = \frac{S}{O},$$

$$\mathbb{P}[C \mid F] = \frac{\frac{S}{O}}{1 + \frac{S}{O}} = \frac{1}{1 + \frac{O}{S}}.$$

This is the formula of Marshall and Marx (2012, p. 235, note 42), derived as (12.105) in Chapter 12. Now suppose that K plus factors $F_1, \ldots, F_K$ are independent conditional on C and conditional on not C. The likelihood ratio of the joint event is then the product of the individual ratios, $S = \prod_{k=1}^{K} S_k$. As an illustration with our own numbers, let each plus factor have $\mathbb{P}[F_k \mid C] = 0.6$ and $\mathbb{P}[F_k \mid \text{not } C] = 0.2$, so that $S_k = 3$, and let $\mathbb{P}[C] = 0.1$, so that $O = 9$. One plus factor gives $\mathbb{P}[C \mid F] = \frac{1}{1+3} = 0.25$. Two give $\frac{1}{1+1} = 0.5$, and three give $\frac{1}{1+\frac{1}{3}} = 0.75$. Plus factors that are weak alone can thus be strong together, as Marshall and Marx note (p. 235). Conditional independence is a strong assumption, however. Plus factors that share a cause, such as a concentrated market structure, carry less joint information than the product suggests. Market structure belongs in the prior odds O, which is where Kaplow's conducive conditions enter.

Marshall and Marx list six super-plus factors (pp. 235–236), which Section 12.7.1 reproduces. Two of them concern market data directly. The first is a path of transaction prices that departs from the predictions of a reliable econometric model fitted to noncollusive benchmark data. The sixth is stable market shares, customer incumbency or geographic dominance in the face of excess capacity, while prices and profits rise. The others are communication and information sharing, interfirm transfers, synchronized changes in sales-force incentives, and dominant-firm

conduct by firms that lack dominance. Cartels respond to detection by avoiding super-plus factors, and avoidance is costly (pp. 236–237). A market-share cartel that forgoes year-end transfers must police shares more tightly. One that fakes volatility in its shares can destabilize itself.

Plus factors for bidding rings. Marshall and Marx (2012, ch. 12) adapt the analysis to auctions and procurements. Two cautions come first (pp. 241–243). An auctioneer or procurement officer who is bribed, or who simply favors one bidder, can produce depressed prices and skewed awards that look like collusion among bidders. A lone bidder can also enlist shill bidders to satisfy a rule that requires a minimum number of bids. Next, a ring with n_{ring} of the n bidders has $n_{\text{ring}} - 1$ free bids to use as it wishes. Screens that look for identical bids therefore presume a careless ring (p. 243). Two super-plus factors apply to both auction formats (p. 244). One is transfers among bidders, such as knockout payments, or subcontracting and joint ownership that were not declared before the auction. The other is a divergence between realized prices and the predictions of a model fitted to periods without a ring.

Other plus factors depend on the format. At an ascending auction, a ring's simplest rule is that members do not bid against an active member (pp. 244–246). The winner and the last underbidder are then never both members. A group of bidders who never bid against one another at meaningful prices is suspicious, although many auctions are needed to see the pattern. Resale of the item soon after the auction to another bidder who was present signals a post-auction knockout. An ascending auction allocates efficiently, so a ring would have to change its mechanism to avoid this footprint. Light attendance is no super-plus factor, because some rings require members to attend. At a sealed-bid auction, post-auction resale is weak evidence, since asymmetric bidders make the auction inefficient even without a ring (p. 246). Losing bids unrelated to costs are evidence that a ring can avoid. The ring can ask its members to submit rescaled versions of their noncollusive bids, all below the designated bid (pp. 246–247). This is the adaptation that Section 13.9.3 discusses for the rank test.

Close pairs of bids are harder to avoid (p. 247). A designated bidder who bids far below its noncollusive bid tempts other members to win secretly through a shill. In the example of Marshall and Marx, the highest-valuing member values the item at $100,000 and would bid $90,000 alone, but the ring wants it to bid $50,000. A member with value $60,000 whose share of the collusive gain is below $10,000 would then gain by bidding about $50,001 through a shill. The ring therefore instructs the designated member to bid more, say $65,000, and has another member bid just below that amount. The second bid ensures that the designated member complies, because a lower bid would lose to it. Frequent close pairs of bids then point to collusion, a pattern related to the clustering of Example 13.67. Finally, a switch from ascending to sealed bidding that raises prices sharply indicates a ring at the ascending auctions. Risk aversion also raises sealed-bid prices, but by much less (p. 248).

Example 13.63 (Shill bidders in Russian oil and gas auctions)**.** Russian ascending auctions for oil and gas leases required at least two registered bidders (Marshall and Marx, 2012, pp. 248–255). The government set a reserve price and the bid increment, and the lowest feasible bid was one increment above the reserve. Marshall and Marx have data on 620 auctions from 2004 to 2007, complete for 121 of them. Five of these were canceled and one used criteria other than price, which leaves 115. Table 13.38 reproduces their Table 12.2. Auctions with two participants look different from the rest. Of the 43 such auctions, 34 (79 percent) ended one or two increments above the reserve. With six or more participants, every winning bid was at least 20 increments above the reserve. The average reserve price of the 34 low-priced two-bidder auctions was 27,515,294 rubles, about half the average over all 620 auctions. The authors write "less than

half" (p. 250). Their averages on p. 249 put the ratio at 51 percent (our computation). Small licenses of only regional interest could explain part of the pattern. The identities of the losers suggest more (their Table 12.3). The 34 auctions have 24 distinct winners and 26 distinct losers. Bidder Y won six of them, each time against bidder 1Y, which never won any of the 620 auctions. Marshall and Marx classify 13 losers as pure shills, which bid at most once, never won a lease and never took part in an auction without their winning partner. Two losers rotated as winner and loser, and the remaining 11 are occasional shills. The evidence fits single real bidders who registered agents to satisfy the two-bidder rule (pp. 251–253).

Table 13.38: Winning bids in Russian oil and gas lease auctions, by number of participants

	Increments of the winning bid above the reserve					
Participants	1	2	3–19	20–99	100 or more	Auctions
2	53%	26%	9%	7%	5%	43
3	3%	9%	26%	41%	21%	34
4	8%	0%	15%	15%	62%	13
5	10%	10%	20%	10%	50%	10
6 or more	0%	0%	0%	33%	67%	15
All	23%	13%	15%	22%	28%	115

Notes: Shares of the 115 auctions with complete data, 2004–2007. Rows sum to 100 percent up to rounding. Source: Marshall and Marx (2012), Table 12.2.

The remainder of this section turns some of these plus factors into formal statistical procedures for procurement.

13.9.2 The theory of detection tests

Setting and notation. Auctions (lettings) are indexed by $t = 1, \ldots, T$. The set of bidders in auction t is $\mathcal{N}_t$, with n_t members. Bidder i has cost c_{it} of performing the contract and submits the bid b_{it}. Public information Ω_t contains the characteristics of the job and each bidder's observed cost shifters x_{it}, a row vector. The probability that bidder i wins with bid b is $\mathcal{P}_{it}(b)$. In this section α_t denotes an auction effect and β a vector of coefficients, which differ from the demand parameters of the earlier chapters. We write bidder i's bid function as $s_i(\cdot)$, so that β always denotes coefficients.

Assumption 13.64 (Competitive procurement benchmark)**.**

(a) The set of bidders $\mathcal{N}_t$ is common knowledge.

(b) Conditional on Ω_t, costs are independent across bidders, with $c_{it} \sim F_i(\cdot \mid \Omega_t)$ continuous. The distributions may differ across bidders.

(c) Each bidder knows its own cost and the cost distributions of its rivals.

(d) Bidders are risk neutral. The lowest bid wins and is paid its bid.

(e) Bidders play a Bayesian Nash equilibrium in pure strategies $b_{it} = s_i(c_{it}; \Omega_t)$, and equilibrium bid distributions have no atoms.

Let G_{jt} be the distribution of rival j's bid conditional on Ω_t, with density g_{jt}. By parts (b) and (e), rivals' bids are independent and ties occur with probability zero. Bidder i therefore

solves

$$\max_b \, (b - c_{it})\, \mathcal{P}_{it}(b), \qquad \mathcal{P}_{it}(b) = \prod_{j \neq i} \big[1 - G_{jt}(b)\big]. \tag{13.107}$$

The first term is the margin if the bid wins, and the second is the probability of winning. The first-order condition is equation (1) of Porter and Zona (1993):

$$\mathcal{P}_{it}(b_{it}) + (b_{it} - c_{it})\, \mathcal{P}'_{it}(b_{it}) = 0. \tag{13.108}$$

Taking logs of the product in (13.107) gives $\ln \mathcal{P}_{it}(b) = \sum_{j \neq i} \ln[1 - G_{jt}(b)]$, so that

$$\frac{\mathcal{P}'_{it}(b)}{\mathcal{P}_{it}(b)} = -\sum_{j \neq i} \frac{g_{jt}(b)}{1 - G_{jt}(b)}.$$

Substituting into (13.108) and solving for the markup gives

$$b_{it} - c_{it} = -\frac{\mathcal{P}_{it}(b_{it})}{\mathcal{P}'_{it}(b_{it})} = \left[\sum_{j \neq i} \frac{g_{jt}(b_{it})}{1 - G_{jt}(b_{it})} \right]^{-1}. \tag{13.109}$$

The equilibrium markup is the inverse of the sum of the rivals' bid hazard rates at the bid. More rivals, or rivals whose bids are dense near b_{it}, lower the markup. Equation (13.109) is the procurement mirror image of the inversion of Guerre et al. (2000) in Chapter 15. The model behind it is the procurement auction of Chapter 14.

Proposition 13.65 (Restrictions implied by competitive bidding)**.** *Under Assumption 13.64 the following hold.*

(i) Monotonicity. *If $\mathcal{P}_{it}$ is strictly decreasing, each bid function $s_i(\cdot; \Omega_t)$ is nondecreasing in own cost.*

(ii) Conditional independence. *For $i \neq j$, the bids b_{it} and b_{jt} are independent conditional on Ω_t. The same holds for any decisions, such as participation, that depend only on own cost and Ω_t.*

(iii) Exchangeability. *Suppose that $F_i(\cdot \mid \Omega_t) = F(\cdot \mid x_{it}, W_t)$, where W_t collects the job characteristics, and that the equilibrium is symmetric, $s_i(c; \Omega_t) = s(c; x_{it}, X_{-i,t}, W_t)$ with s symmetric in the elements of the collection $X_{-i,t}$ of rivals' covariates. Then the distribution of b_{it} given Ω_t is unchanged by any permutation of the rivals' covariates.*

(iv) Rank order. *If all bidders in auction t use the same strictly increasing bid function, the ranking of the bids reproduces the ranking of the costs.*

Proof. (i) Take costs $c < c'$ with optimal bids b and b'. Optimality of b at c and of b' at c' gives

$$(b - c)\, \mathcal{P}(b) \geq (b' - c)\, \mathcal{P}(b'),$$
$$(b' - c')\, \mathcal{P}(b') \geq (b - c')\, \mathcal{P}(b).$$

Adding the two inequalities and cancelling the terms $b\mathcal{P}(b)$ and $b'\mathcal{P}(b')$ leaves

$$-c\, \mathcal{P}(b) - c'\, \mathcal{P}(b') \geq -c\, \mathcal{P}(b') - c'\, \mathcal{P}(b),$$

which rearranges to $(c' - c)\big[\mathcal{P}(b) - \mathcal{P}(b')\big] \geq 0$. Since $c' > c$, we get $\mathcal{P}(b) \geq \mathcal{P}(b')$, and a strictly decreasing $\mathcal{P}$ implies $b \leq b'$.

(ii) Conditional on Ω_t, the bid $b_{it} = s_i(c_{it}; \Omega_t)$ is a function of c_{it} alone. Functions of independent random variables are independent.

(iii) Bidder i's objective depends on its rivals only through $\mathcal{P}_{it}(b) = \prod_{j \neq i}[1 - G(b \mid x_{jt}, X_{-j,t}, W_t)]$. Under symmetry, the factor for rival j is determined by j's own covariate and the collection of everyone else's covariates. A permutation of the rivals' covariates therefore only permutes the factors of the product, and $\mathcal{P}_{it}$ is unchanged. So is the optimal bid of every cost type, and hence the distribution of b_{it}.

(iv) A strictly increasing common function preserves order. □

Each restriction suggests a test. Conditional independence implies that residuals from bid regressions, or from participation equations, are uncorrelated across pairs of firms. Exchangeability implies that a firm's bid responds in the same way to the covariates of each of its rivals. Bajari and Ye (2003) build tests of both restrictions for highway procurement auctions. Their tests ask whether bid residuals are correlated across firms and whether a firm's bid responds equally to the cost shifters of different rivals. The rank-order restriction underlies the tests of Porter and Zona (1993) developed below. All four restrictions are necessary conditions for competition. They hold in every equilibrium of the independent private costs model, so a violation is evidence against that model. Some collusive schemes satisfy them, as we show below.

Remark 13.66 (Asymmetric bidders). With asymmetric cost distributions, bidders use different bid functions, and a low-cost bidder can bid above a high-cost rival (Chapter 14). The rank restriction (iv) then fails even under competition. Rank-based tests must therefore condition on the observables that create the asymmetry, as the covariates x_{it} do in the applications below.

What collusion changes. Collusion in procurement takes several forms. In *bid rotation*, ring members take turns winning, and often only the designated member bids. In *territorial allocation*, each member is assigned the customers or districts near its plants, and the others stay away. In *complementary bidding*, also called cover or phantom bidding, the ring designates a winner and its bid, and other members submit higher bids designed to lose. Such bids create the appearance of competition. A ring may also suppress bids altogether or compensate losers through subcontracts. Each scheme violates a different restriction of Proposition 13.65. Table 13.39 summarizes the footprints.

Why simple indicators mislead. A common view treats a rotation of winners, or stable market shares, as irrefutable evidence of collusion (Porter and Zona, 1993, p. 1). Both can arise in competitive equilibria. Zona (1986) shows that bid rotation is a competitive outcome under decreasing returns, for example with capacity constraints. A firm that has just won carries a large backlog, faces a high cost of one more job, and bids high on the next one. Lang and Rosenthal (1991) study a game in which firms bid simultaneously on several contracts. Its noncooperative mixed-strategy equilibrium can produce negative correlation between a firm's bids, which looks like rotation. Comparisons of winning bids with the buyer's engineering estimates are also unreliable. The estimates may be built from past bids and so inherit any inflation (Porter and Zona, 1993, p. 2). Feinstein et al. (1985) model a cartel that submits cover bids close to the winning bid in order to raise the engineers' estimates for future lettings.

The deepest limit concerns inclusive rings. If a single test were widely used, a cartel that includes every bidder could choose its complementary bids so that the overall pattern passes the test (Porter and Zona, 1993, p. 3). The buyer runs an auction because it does not know costs, so any bid vector that is consistent with some plausible cost draw is unassailable. Detection

Table 13.39: Collusive schemes in procurement and the footprints they leave

Scheme	Participation	Bid levels and ranks	Tests with power
Bid rotation	Members rarely bid against each other. Submission residuals are negatively correlated.	Winning bids inflated when no outsider bids.	Correlation of participation residuals. Hard to separate from specialization in job types.
Territorial allocation	Members bid near their own plants and avoid other members' areas. Negative correlation of submission residuals.	Bids high inside the own territory, relatively low outside it.	Submission correlations. Bid gradients in distance compared with a control group.
Complementary bidding	Members bid together more often than observables predict. Positive correlation of submission residuals.	Cover bids high, clustered, and unrelated to costs. Bid residuals positively correlated.	Rank tests (Proposition 13.68). Correlation of bid residuals. Clustering of the lowest bids.
Inclusive ring scaling all bids	Unchanged.	All bids inflated by a common factor. Ranks follow costs.	None based on bid patterns. Requires costs, rates of return or an outside benchmark.

Notes: Our summary of the schemes discussed by Porter and Zona (1993, 1999) and of the restrictions in Proposition 13.65.

from bids alone therefore needs a group of bidders outside the ring whose behavior serves as a benchmark.

Bid clustering. Phantom bids are often placed just above the designated bid. A simple screen compares the gap between the two lowest bids in suspect and benchmark auctions. The screen must account for the number of bids, as the next example shows.

Example 13.67 (The gap between the two lowest bids)**.** Let costs be independent and uniform on $[0,1]$, with n symmetric bidders. The equilibrium bid function is $s(c) = c + \frac{1-c}{n}$. To verify it, invert to $c = \frac{nb-1}{n-1}$, so that a bid b wins with probability

$$\mathcal{P}(b) = \big[1 - c(b)\big]^{n-1} = \left[\frac{n(1-b)}{n-1}\right]^{n-1}, \qquad \frac{\mathcal{P}'(b)}{\mathcal{P}(b)} = -\frac{n-1}{1-b}.$$

By (13.109), the optimal markup is $b - c = \frac{1-b}{n-1}$. At $b = s(c)$ we have $1 - b = \frac{(n-1)(1-c)}{n}$, so $\frac{1-b}{n-1} = \frac{1-c}{n} = s(c) - c$, as required. The gap between the two lowest bids is

$$b_{(2)} - b_{(1)} = \left(1 - \frac{1}{n}\right)\big(c_{(2)} - c_{(1)}\big).$$

The expected spacing between consecutive order statistics of n uniform draws is $\frac{1}{n+1}$ (Appendix B). Hence

$$\mathbb{E}\big[b_{(2)} - b_{(1)}\big] = \frac{n-1}{n(n+1)},$$

which equals 0.167 for $n = 2$ and $n = 3$, 0.150 for $n = 4$ and 0.133 for $n = 5$ (our computation, confirmed by simulation in `pz_checks.py`). The expected gap does not rise as bidders are added, and it falls for $n \geq 3$. A comparison of mean gaps across groups of auctions with different numbers of bids confounds clustering with the number of bids.

Ranks and the exploded logit. The most informative tests in Porter and Zona (1993) use the order of the bids within an auction. They rest on a log-linear bid rule,

$$\ln b_{it} = \alpha_t + x_{it}\beta + \epsilon_{it}, \qquad \mathbb{E}[\epsilon_{it}] = 0, \quad \operatorname{Var}(\epsilon_{it}) = \sigma_t^2, \tag{13.110}$$

which is equation (2) of their paper. The auction effect α_t absorbs everything common to the bidders in auction t, such as the size of the job. The error ϵ_{it} is private cost information, with a variance that may differ across auctions. Let ζ denote a standard type-I extreme value (Gumbel) variable, with distribution function $\exp(-e^{-z})$, mean equal to Euler's constant γ_E and variance $\frac{\pi^2}{6}$ (Chapter 6, Appendix B). Suppose that

$$-\epsilon_{it} = \sigma_t \frac{\sqrt{6}}{\pi}(\zeta_{it} - \gamma_E), \qquad \zeta_{it} \text{ i.i.d.}, \tag{13.111}$$

so that ϵ_{it} has mean zero and variance σ_t^2. The lowest bid is the bid with the largest value of $-\ln b_{it}$. Dividing $-\ln b_{it}$ by the positive constant $\sigma_t \frac{\sqrt{6}}{\pi}$ does not change the order, and gives

$$\frac{\pi}{\sqrt{6}} \frac{-\ln b_{it}}{\sigma_t} = \alpha_t^* + Z_{it}\tilde{\beta} + \zeta_{it}, \qquad Z_{it} = -\frac{x_{it}}{\sigma_t}, \quad \tilde{\beta} = \frac{\pi}{\sqrt{6}}\beta, \tag{13.112}$$

with the auction constant $\alpha_t^* = -\frac{\pi}{\sqrt{6}}\frac{\alpha_t}{\sigma_t} - \gamma_E$. The ranking of bids is the ranking of independent Gumbel utilities with indices $\alpha_t^* + Z_{it}\tilde{\beta}$.

Proposition 13.68 (Rank-ordered (exploded) logit)**.** *Let $V_i = v_i + \zeta_i$ for $i = 1, \dots, n$, with ζ_i independent standard Gumbel variables. For any ordering $(r_1, \dots, r_n)$ of the indices,*

$$\mathbb{P}\big(V_{r_1} > V_{r_2} > \cdots > V_{r_n}\big) = \prod_{j=1}^{n-1} \frac{e^{v_{r_j}}}{\sum_{l=j}^{n} e^{v_{r_l}}}. \tag{13.113}$$

Under (13.110)–(13.112), the probability of the observed ranking of the n_t bids in auction t is therefore

$$\mathbb{P}\big(b_{r_1 t} < b_{r_2 t} < \cdots < b_{r_{n_t} t} \mid \Omega_t\big) = \prod_{j=1}^{n_t - 1} \frac{\exp(Z_{r_j t}\tilde{\beta})}{\sum_{l=j}^{n_t} \exp(Z_{r_l t}\tilde{\beta})}, \tag{13.114}$$

and the auction constant α_t^* cancels.

Proof. Define $E_i = e^{-V_i}$. For a standard Gumbel ζ and $y > 0$,

$$\mathbb{P}\big(e^{-\zeta} > y\big) = \mathbb{P}(\zeta < -\ln y) = \exp\big(-e^{\ln y}\big) = e^{-y},$$

so $e^{-\zeta}$ is exponential with rate one. Then $E_i = e^{-v_i} e^{-\zeta_i}$ satisfies $\mathbb{P}(E_i > y) = \mathbb{P}(e^{-\zeta_i} > e^{v_i} y) = e^{-\lambda_i y}$ with $\lambda_i = e^{v_i}$ (a local symbol in this proof). The E_i are independent exponential variables with rates λ_i, and the V_i are in decreasing order exactly when the E_i are in increasing order. We use two properties of independent exponentials with rates $\lambda_1, \dots, \lambda_m$ and $\Lambda = \sum_l \lambda_l$. First, the probability that E_k is the smallest is

$$\mathbb{P}\Big(E_k < \min_{l \neq k} E_l\Big) = \int_0^\infty \lambda_k e^{-\lambda_k y} \prod_{l \neq k} e^{-\lambda_l y}\, dy = \int_0^\infty \lambda_k e^{-\Lambda y}\, dy = \frac{\lambda_k}{\Lambda}.$$

Second, for $y_l \geq 0$,

$$\mathbb{P}\big(E_k \in dm,\ E_l - E_k > y_l \text{ for all } l \neq k\big) = \lambda_k e^{-\lambda_k m} \prod_{l \neq k} e^{-\lambda_l (m + y_l)}\, dm = \lambda_k e^{-\Lambda m}\, dm \prod_{l \neq k} e^{-\lambda_l y_l}.$$

The joint density factors, so conditional on E_k being the minimum, the excesses $E_l - E_k$ are independent exponentials with the original rates and are independent of the minimum (memorylessness). The probability of the ordering $E_{r_1} < E_{r_2} < \cdots < E_{r_n}$ is the probability that E_{r_1} is the smallest, which is $\frac{\lambda_{r_1}}{\sum_{l=1}^{n} \lambda_{r_l}}$, times the probability that the excesses of the other $n-1$ variables are ordered $r_2, \ldots, r_n$. By the second property the latter is the same problem with one variable fewer. Repeating the argument $n-1$ times gives (13.113) with $\lambda = e^{v}$. Applying (13.113) to (13.112), the common factor $e^{\alpha_t^*}$ appears in every numerator and every term of every denominator and cancels, which gives (13.114). □

The product in (13.114) treats the ranking as a sequence of choices. The lowest bid is "chosen" from all n_t bidders, the second lowest from the remaining $n_t - 1$, and so on. This *rank-ordered* or *exploded logit* is due to Beggs et al. (1981). Each factor is a conditional logit with a choice set that shrinks by one, so standard multinomial logit software estimates $\tilde{\beta}$. The last factor equals one and is omitted. Porter and Zona (1993) write the product up to n_t, which is equivalent.

Corollary 13.69 (Likelihood ratio test of equal coefficients across ranks)**.** *Write the log likelihood of the rankings as*

$$\ell(\tilde{\beta}) = \underbrace{\sum_{t} \Big[Z_{r_1 t}\tilde{\beta} - \ln \sum_{l=1}^{n_t} e^{Z_{r_l t}\tilde{\beta}} \Big]}_{\ell^{\text{low}}(\tilde{\beta})} + \underbrace{\sum_{t} \sum_{j=2}^{n_t - 1} \Big[Z_{r_j t}\tilde{\beta} - \ln \sum_{l=j}^{n_t} e^{Z_{r_l t}\tilde{\beta}} \Big]}_{\ell^{\text{high}}(\tilde{\beta})}. \tag{13.115}$$

Allow the coefficients to differ between the lowest rank and the higher ranks. Under the null hypothesis that the whole ranking follows (13.114)*,*

$$LR = 2\Big[\ell^{\text{low}}(\hat{\beta}^{\text{low}}) + \ell^{\text{high}}(\hat{\beta}^{\text{high}}) - \ell(\hat{\beta}) \Big] \xrightarrow{d} \chi^2_K, \tag{13.116}$$

where K is the number of coefficients, $\hat{\beta}^{\text{low}}$ and $\hat{\beta}^{\text{high}}$ maximize ℓ^{low} and ℓ^{high} separately, and $\hat{\beta}$ maximizes ℓ.

Proof. The unrestricted log likelihood $\ell^{\text{low}}(\tilde{\beta}^{\text{low}}) + \ell^{\text{high}}(\tilde{\beta}^{\text{high}})$ is additively separable in the two parameter vectors, so it is maximized by maximizing each part separately. The null hypothesis imposes the K restrictions $\tilde{\beta}^{\text{low}} = \tilde{\beta}^{\text{high}}$, and the standard likelihood ratio theorem applies (Appendix A). □

The test has power against complementary bidding for a simple reason. Suppose a ring designates its lowest-cost member, which bids to beat the outsiders, and places the other members' bids above it without regard to cost. The lowest ring bid then follows costs, so $\tilde{\beta}^{\text{low}} = \tilde{\beta}$. If the higher ring bids are ordered at random, the true probability of each higher-rank choice is $\frac{1}{n_t - j + 1}$, whatever the covariates. The model factor reproduces this probability only at $\tilde{\beta} = 0$. By the information inequality, the population maximizer of ℓ^{high} is then $\tilde{\beta}^{\text{high}} = 0$, and the statistic (13.116) grows with the number of auctions.

Figure 13.23 shows how much data the test needs. We simulate rankings from (13.112) with two standardized cost shifters, $\tilde{\beta} = (0.5, -0.5)$, and between two and four ranked bids per auction. The sample sizes mimic the cartel data of Porter and Zona (1993), with 50 auctions and about 35 higher-rank choices. Under competitive ranking the test has the correct size, rejecting in 5.7 percent of 2,000 samples at the 5 percent level. When the higher bids are ordered at random, it rejects in 47 percent of samples with 50 auctions, 76 percent with 100 and 98 percent with 200 (our computation, `pz_lr_sim.py`). A rank test on a few dozen auctions is therefore a low-power instrument, even against a stark alternative.

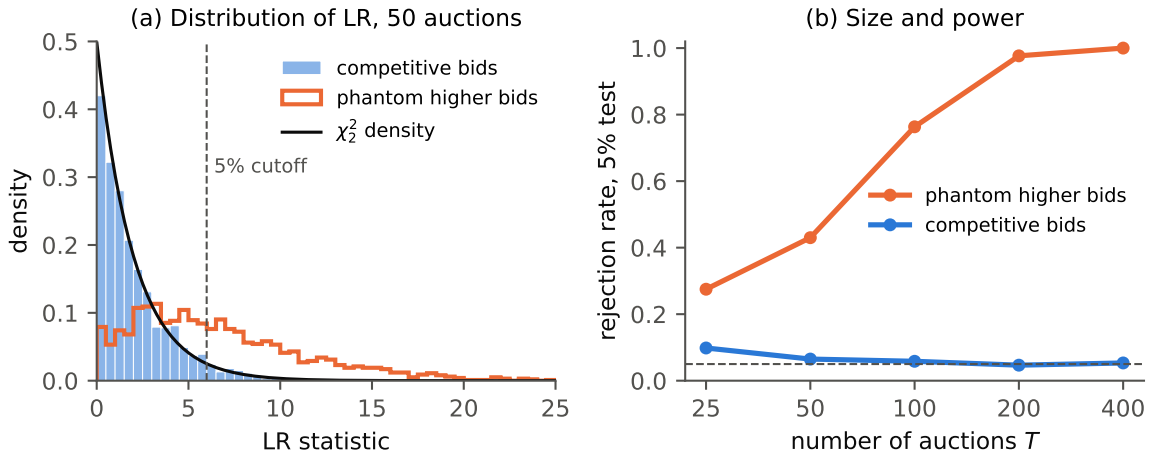

Figure 13.23: Size and power of the rank-based test of Corollary 13.69 in simulated data. Panel (a) shows the distribution of the likelihood ratio statistic over 2,000 samples of 50 auctions. The bars are for rankings that follow the exploded logit, the line for rankings in which the nonwinning bids are in random order, and the curve is the χ^2_2 density. Panel (b) shows the rejection rates of the 5 percent test against the number of auctions, with 600 samples per point. Our simulation, with sample sizes that mimic Porter and Zona (1993), Table 6.

13.9.3 Long Island highway paving: Porter and Zona (1993)

The question. Can econometric tests detect a bid-rigging ring from public bid data when the ring includes only some of the bidders? Porter and Zona (1993) study contracts let by the New York State Department of Transportation (DOT) on Long Island between April 1979 and March 1985. A group of firms bidding there was later named in bid-rigging suits. The paper proposes test procedures and stresses their limits. In the authors' words, the tests "will be poor substitutes for a wiretap or a disclosure by a dissident ring member" (Porter and Zona, 1993, p. 1). They are, however, better founded than the view that bid rotation or stable shares prove collusion.

Institutional setting. The DOT must award each highway contract to the lowest responsible bidder. It announces upcoming lettings in a "Notice of Highway Lettings," and interested firms request plans and specifications. A "Plan Buyers List" of the firms that bought plans for each job is distributed to subscribers, so each firm knows its potential rivals in advance. On the day of the letting, sealed bids are opened and every bid and bidder is announced. The DOT checks the low bid against its own cost estimate and then awards the contract. From April

1979 through March 1985 it awarded about $120 million of contracts in Nassau and Suffolk Counties, in 1969 dollars. There were 186 contracts, 161 of them below $1 million. Sixty-six firms bid on at least one of the small contracts, but only 22 bid on jobs above $1 million. Four firms submitted 45 percent of the bids on those large jobs.

The authors list features of the market that facilitate collusion (WP pp. 8–12). The product is homogeneous, because the contract defines the output, so a ring need only coordinate on price. Public announcement of bids and bidders reveals any undercutting, and the plan buyers lists make the set of potential bidders common knowledge. Demand was almost perfectly inelastic. With one exception, every contract was awarded to the low bidder whatever the DOT's cost estimate, so any inflation of winning bids became profit. The exception is telling. In February 1983 the DOT solicited bids to resurface 0.8 miles of road, received eight bids with a low bid of about $4 million, and declined to award. When the job was rebid in May 1983, the low bid was 20 percent higher and came from the same firm. A third letting in February 1984 drew three bids from firms that had bid both times before. The low bid was about 10 percent above the second letting and 30 percent above the first, and the ranking of bidders never changed. The contract had not been awarded by 1987.

Entry was difficult. Large jobs require batch concrete and asphalt plants, which incumbents owned, and newspaper accounts report that union leaders discouraged outside bidders. Joint bids were allowed, which gave firms reasons to communicate. Large jobs were let regularly, early each year, and usually one at a time. Such spacing limits what a defector can earn before others retaliate. Firms bought inputs in the same markets, used the same technology and employed members of the same unions, although backlogs and equipment differed.

The candidate cartel. In 1984 one of the five largest firms in the two counties was convicted in federal court of rigging bids on a Long Island highway project that predates the sample. Four other firms were named as unindicted co-conspirators, and all five were named in separate suits by New York State or Suffolk County. Each suit concerned a single job. The paper treats these five firms, called Firms 2, 3, 4, 10 and 14, as a candidate "cartel" that may have operated in any letting. The other bidders are called "competitive." The cartel firms submitted 54 percent of the bids on larger jobs and won 37 percent of all contracts. They also bid jointly at times (Table 1). Firms 4 and 2 did so in February 1980, with a winning bid of $5.3 million. Firms 3 and 14 did so in June 1980 ($7.3 million) and January 1982 ($4.0 million), and Firms 3, 4 and 8 in November 1984 ($8.0 million).

Table 13.40 shows that cartel firms regularly bid against each other on paving jobs. When Firm 2 bid, another cartel firm also bid 88 percent of the time, and every bid by Firm 14 was accompanied by another cartel bid. Insiders described the mechanism to a newspaper. Firms met around a conference table to review upcoming contracts and decide "who should get this one." Then "the contractors who were tagged to be the low bidders would work out their bid figures," and "the rest of the contractors would then come up with higher bids" (Porter and Zona, 1993, p. 17). Union representatives allegedly attended, communicated the low bids afterwards, and received a kickback of one percent of the low bid on jobs won. This is a complementary bidding scheme, and the tests below are designed to detect it.

Two conventional indicators. The first indicator is the stability of market shares. On paving jobs the cartel firms' annual shares varied substantially, and Firm 10 stopped bidding early in the sample (it bid only three times). No pattern of rotation is apparent. Newspaper accounts nonetheless report stable shares in state highway and sewer work for more than a decade, on many jobs outside the sample. Shares on paving alone would thus give an unwarranted impression of competition.

Table 13.40: Bidding by the candidate cartel on Long Island paving jobs

	Bids also submitted by					Pr(another cartel bid), %	
	Firm 2	Firm 3	Firm 4	Firm 10	Firm 14	Paving	Nonpaving
Firm 2	48	37	34	1	11	88	75
Firm 3	37	86	56	1	15	79	55
Firm 4	34	56	71	2	14	89	80
Firm 10	1	1	2	3	1	67	NA
Firm 14	11	15	14	1	20	100	NA

Notes: Left panel, Porter and Zona (1993), Table 2: number of paving jobs on which the row firm and the column firm both submitted individual bids. Diagonal entries are the row firm's total number of bids. Joint bids are excluded. Right panel, Table 3: percentage of the row firm's bids on which at least one other cartel firm also bid. NA: not available. NBER working-paper version.

The second indicator is the dispersion of bids within a job. The 116 paving jobs received 347 competitive bids on 103 jobs and 228 cartel bids on 109 jobs. On the 76 jobs with at least two cartel bids, the second-lowest cartel bid exceeded the lowest by 4.96 percent on average, measured as the mean difference in log bids. On the 75 jobs with at least two competitive bids, the corresponding figure is 6.25 percent. Competitive bids are more numerous per job, and Example 13.67 shows that more bids shrink the expected gap. The comparison therefore understates how much tighter the cartel bids are. The pattern resembles the clustering found by Feinstein et al. (1985) in North Carolina highway contracts.

Data. The analysis uses contracts that involve paving, where the facilitating features are strongest. Mowing, painting and traffic signal contracts are excluded. The 116 paving projects received 575 bids. Joint bids, under 2 percent of paving bids, are dropped. Estimating the auction-specific variance σ_t^2 requires at least two competitive bids, which leaves 75 projects with 319 competitive bids and 157 cartel bids.

The covariates measure cost differences across firms. $BACKLOG_{it}$ is the dollar value of DOT contracts that firm i has won but not completed, assuming completion at a constant pace over about three months. Capacity is the largest backlog the firm carried in the sample, $CAP_i = \max_t BACKLOG_{it}$, and enters with its square *CAPSQ*. *NOBACK* marks noncartel firms that never won, for which $CAP = 0$. Utilization is $UTIL_{it} = \frac{BACKLOG_{it}}{CAP_i}$ (zero when $CAP_i = 0$), and enters with its square *UTILSQ*. *ISLAND* marks firms headquartered on Long Island, which includes all cartel firms. No job-specific data are available, not even the engineers' estimates. The dependent variable is the log bid, in hundreds of thousands of 1969 dollars. The mean competitive bid was \$450,000 and the mean cartel bid \$713,000.

Model and estimating equations. The competitive model is Assumption 13.64, with cost distributions allowed to differ across firms and jobs. Equilibrium bids satisfy (13.108), and the bid rule (13.110) approximates the equilibrium bid function. It imposes two restrictions. Firms respond in the same way to the observed covariates, and all job-level heterogeneity is captured by the auction effect α_t. The authors emphasize between-firm rather than between-job variation because they have no job characteristics.

The bid levels are estimated by feasible generalized least squares in two steps. First, ordinary least squares on the competitive bids, with a dummy for each auction, gives residuals $\hat{\epsilon}_{it}$. The auction variance is estimated by the mean squared residual of the competitive bids in that

auction,

$$\hat{\sigma}_t^2 = \frac{1}{n_t^c} \sum_{i \in \mathcal{N}_t^c} \hat{\epsilon}_{it}^2, \tag{13.117}$$

where $\mathcal{N}_t^c$ is the set of n_t^c competitive bidders. Second, every observation is divided by $\hat{\sigma}_t$ and the auction-dummy regression is run again. The same weights are used for three samples: all bids, competitive bids, and cartel bids. If all bids are competitive, the three regressions estimate the same β. If cartel bids are not competitive, only the competitive regression is consistent. A Chow test compares the pooled regression with the two separate ones.

The rank analysis applies Proposition 13.68 with $Z_{it} = -\frac{x_{it}}{\hat{\sigma}_t}$. It is run separately on the ranking of competitive bids and on the ranking of cartel bids among themselves. Within each group, the coefficients are estimated from all ranks, from the lowest rank only and from the higher ranks only, and Corollary 13.69 gives the test.

Identification. Within an auction, bidders differ in backlog, capacity and location, and this variation identifies β. The auction effects absorb the size, type and location of the job, which are unobserved. The rank likelihood removes them altogether. The test for collusion rests on an asymmetry between cartel bids. A designated cartel winner must still beat the outsiders, so it trades a higher margin against a lower probability of winning, as a competitive bidder does. Complementary bids are designed to lose and need not respond to costs. Under phantom bidding, the determinants of the lowest cartel bid should therefore differ from those of the higher cartel bids. The same test applied to competitive bids is a placebo. Passing it makes it less likely that the model omits a variable that affects high and low bids differently. The test is agnostic about how the ring chooses its winner.

Results: bid levels. Table 13.41 reproduces the generalized least squares estimates. The competitive model fits well. The Wald statistic for the six covariates is 494.7, against a χ_6^2 distribution. Long Island firms bid about 3 percent less than other firms, although the coefficient is imprecise. Bids first fall and then rise with utilization. The effect of utilization u on the log bid is $-0.0973u + 0.1720u^2$. It equals -0.014 at $u = 0.3$ and 0.075 at full capacity, and it reaches its minimum at $u = 0.28$ (our computation). These values match the paper's statements that bids are about 1.5 percent lower at 30 percent utilization and 7.5 percent higher at full capacity. Bids also fall and then rise with capacity, with only one firm beyond the minimum.

The cartel estimates look very different. Utilization enters with the opposite curvature, and capacity enters with the opposite signs, significantly so. Many cartel coefficients do not have the expected sign. The Chow test statistic is $F(76, 319) = 9.38$, with a p-value below 10^{-40} (our computation), so bids from cartel firms differ statistically from competitive bids. The degrees of freedom reveal what the test compares. The denominator, 319, is the sum of the residual degrees of freedom of the two separate regressions, 238 + 81. The numerator, 76, equals the 4 cartel slopes plus 72 cartel auction constants (our reading of Table 4). The Chow test therefore compares the levels of cartel and competitive bids within auctions as well as their slopes.

Results: bid ranks. Table 13.42 reproduces the rank-based estimates. For competitive bids, the estimates are stable across ranks. Capacity matters with similar coefficients in the lowest rank and in the higher ranks (-1.641 and -2.100 for *CAP*, 6.517 and 7.020 for *CAPSQ*). The likelihood ratio statistic is

$$LR^{\text{comp}} = 2\left[-89.85 - 199.4 - (-291.4)\right] = 4.30,$$

against a χ_6^2 distribution, with $p = 0.64$ (our computation). The paper reports that the statistic

Notes: Reproduced from Porter and Zona (1993), Table 4 (NBER working-paper version). Absolute values of t-statistics in parentheses, as in the paper. Auction-specific constants included but not reported. All regressions use the auction variance weights estimated from competitive bids. Coefficients of *CAP* and *CAPSQ* are scaled up by 10^4 and 10^8. *NOBACK* and *ISLAND* are not identified for cartel firms. The Wald statistic tests the joint significance of the reported coefficients.

"is significant at about the 36 percent level," which is the value of the χ^2_6 distribution function. Competitive bids appear to be generated by the same process whether or not they are low.

For cartel bids the picture changes. The likelihood ratio statistic is

$$LR^{\text{cartel}} = 2\left[-44.58 - 24.92 - (-73.97)\right] = 8.94,$$

against a χ^2_4 distribution, because *NOBACK* and *ISLAND* are not identified. The p-value is 0.063 (our computation), which the paper describes as significance "at about the 94 percent level." The authors reject the null hypothesis of no phantom bidding and conclude that cartel bids are generated by a different process depending on whether they are low or not. The bookkeeping of the samples is informative. The 85 cartel choice sets come from 50 auctions with two or more cartel bids, so these auctions contain 135 cartel bids, and only 35 choices inform the higher-rank coefficients (our computation).

Two further features of the estimates deserve attention. The cartel rank estimates resemble the cartel bid-level estimates of Table 13.41 and differ from all the competitive estimates. The two methods are also mutually consistent for competitive bids. Under (13.112) the rank coefficients should equal $\frac{\pi}{\sqrt{6}} \approx 1.28$ times the bid-equation coefficients. Scaled by this factor, the competitive estimates of *CAP* and *CAPSQ* in Table 13.41 are −1.63 and 6.22 (our computation). Given their standard errors, they are close to the rank estimates of −1.89 and 6.87. The small utilization coefficients fail this check, but they are imprecise in the rank model.

Robustness. The paper reports few robustness checks beyond the competitive-rank test, which serves as a specification check. The agreement between bid-level and rank-based results for each group of firms is a second check. The authors argue that their classification is conservative. If some ring members were classified as competitive, the competitive benchmark would be contaminated, which works against finding a difference.

Table 13.42: Rank-ordered logit estimates for competitive and cartel bids, Long Island paving

	Competitive bids (Table 5)			Cartel bids (Table 6)

LR test	4.30 (χ^2_6), $p = 0.64$			8.94 (χ^2_4), $p = 0.063$		

Notes: Reproduced from Porter and Zona (1993), Tables 5 and 6 (NBER working-paper version). Absolute t-statistics in parentheses. Coefficients of *CAP* and *CAPSQ* scaled up by 10^4 and 10^8. A choice set is one factor of (13.114): an auction with n ranked bids contributes one low-rank and $n-2$ higher-rank choice sets. The p-values are our computation from the reported statistics.

Interpretation. Competitive bids are related to backlog and capacity at every rank, as cost-based bidding requires. The ranking of the higher cartel bids does not reflect the same cost measures, and it differs from the determinants of the lowest cartel bid. This is the footprint of complementary bids that are designed to lose. Together with the frequency of cartel firms bidding against one another and the tight clustering of their bids, the evidence fits the scheme that insiders described. The authors conclude that, since they have no reason to believe the difference is structural, they "may have found evidence of cartel activity" (Porter and Zona, 1993, p. 36).

Critiques and limitations. Several limitations follow from the design.

(1) Ring membership is not random. Cartel firms were larger, with a mean bid of $713,000 against $450,000, and all were based on Long Island. Their bids could differ for structural reasons. The passing competitive-rank test argues against general misspecification, but it cannot rule out effects specific to these firms.

(2) The rank test is weak. The rejection relies on 35 higher-rank choices and has a p-value of 0.063. The simulation in Figure 13.23 suggests a power of about one half at this sample size even when the higher bids ignore costs entirely.

(3) The weights and standardized regressors use $\hat{\sigma}_t$, estimated in some auctions from just two competitive bids. The reported standard errors do not account for this first step.

(4) The covariates are crude. Backlog assumes three-month completion, there are no job characteristics, and the model assumes independent private costs with a common response to the covariates.

(5) The designated winner need not be the lowest-cost member. The cartel low-rank

coefficients on capacity have signs opposite to the competitive ones, although they are imprecise. This is consistent with a winner chosen by turns or by equity criteria (our reading). The test remains valid in that case, because it only requires the higher bids to be uninformative about costs.

(6) A ring can adapt. If the procedure were announced, an effective cartel could scale all its bids by a common factor, so that its ranking matches cost rankings. A noninclusive ring would then look like a group of firms with different costs (Porter and Zona, 1993, p. 36). Marshall and Marx (2012, pp. 246–247) make the same point. They call the rank test a plus factor that is not substantive, because a ring can alter its losing bids at no cost to its mechanism (Section 13.9.1).

Contribution. The paper turned the detection of bid rigging into a problem of testing a competitive model against a specific footprint of collusion. Its central idea is that designated and complementary bids obey different economic logic, and that firms outside the ring provide a benchmark for the competitive model. The rank-ordered logit lets the test ignore unobserved job characteristics. Later work, including Porter and Zona (1999) and Bajari and Ye (2003), follows the same logic of a competitive model, a control group and scheme-specific restrictions. Chapter 15 returns to tests for collusion based on structural auction models.

13.9.4 Ohio school milk: Porter and Zona (1999)

The question. Did dairies around Cincinnati collude in school milk auctions in the 1980s, and by how much did collusion raise the prices paid by school districts? In *State of Ohio v. Louis Trauth Dairy, Inc., et al.*, the State charged thirteen dairies with collusion in school milk auctions from 1980 through 1990. The case settled before trial. Porter and Zona (1999) adapt their reports for the plaintiff. Unlike the Long Island data, the Ohio data describe the districts and the contract terms, so both the decision to bid and the level of the bid can be modeled.

Setting. Ohio has more than 600 school districts. Each district solicits bids between May and August for the supply of milk in half pints during the next school year. A district might announce, for example, that it expects to buy 50,000 half pints of whole white milk and 30,000 of whole chocolate milk, enough for about 450 students. Bidders submit a list of prices, and the district may require coolers, straws or napkins, or allow escalator clauses that index prices to raw milk. The low bidder usually wins.

Demand is insensitive to price. Using 609 districts in May 1990, the authors regress the log of half pints bought on log enrollment and the log of the standardized price (WP p. 6, footnote 4). The estimates are

$$\ln q = 2.69 + 1.029 \ln(\text{enrollment}) + 0.21 \ln(\text{price}), \qquad R^2 = 0.84.$$

The t-statistics on the slopes are 56.6 and 1.4, so price has no significant effect. A firm that controls supply to a district can therefore command a much higher price there.

Costs are similar across dairies apart from distance. Raw milk prices are regulated by location and type, and the raw milk in a half pint costs about seven cents. Packaging costs about two cents and delivery about one cent, so total incremental cost is about ten cents per half pint (WP pp. 6–9). A cooler adds about 0.2 cents. Suppliers are processors, which pasteurize and package milk, or distributors, which buy from processors. School milk is under 10 percent of processors' revenues, and no plant was built to serve schools alone. Transport costs and regulation make competition local.

Facilitating features and the testimony. The paper lists many features that facilitate collusion (WP pp. 10–13). Firms compete only on price, bids and bidders are announced, and districts let contracts at different times. Staggered lettings let a ring adjust its allocation during the season and retaliate almost at once. Demand is predictable, district boundaries make territories easy to define, and the set of potential bidders is small and stable. Dairies meet in many markets, which by Bernheim and Whinston (1990) relaxes the incentive constraints that limit collusion. Firms obtained rivals' price lists through grocery customers, dairies bought from one another, and trade associations met regularly. Price decks assigned districts to a few price levels, and one level could serve for complementary bids.

In 1993 representatives of two dairies in southwestern Ohio confessed to rigging bids during the sample period. The paper later identifies their testimony as that of Meyer and Coors (WP p. 28). They described a scheme of respecting incumbency. If a cartel member had served a district the previous year, the others submitted high complementary bids that would not undercut it, or did not bid. The specific arrangements were worked out through frequent communication during each bidding season. The witnesses also testified that the cartel broke down in two school years, 1983–84 and 1989–90. The authors note that territorial assignment would be the more practical scheme for firms that are far apart.

Data. The State of Ohio collected bid data for as many as 509 of the roughly 600 districts from 1980 through 1990, with about 60 bidders at some point in the sample. Table 13.43 summarizes the data. Of 68 processing plants with sales in Ohio during the period, 46 supplied school milk in 1987. A map of these plants (Figure 1 of the paper) shades areas by the concentration of plant ownership within 75 miles. The northeast is least concentrated, and Columbus and the southern tip of the state are most concentrated. The number of plants serving districts fell from 54 to 43 between 1980 and 1990, and the number of bidding dairies from 43 to 26.

Table 13.43: The Ohio school milk data, 1980–1990

Year	Districts	Enrollment	Plants	Dairies	Average price	Raw milk price
1980	366	1,257,925	54	43	0.12823	0.0718
1981	398	1,379,619	50	44	0.12950	0.0769
1982	415	1,371,164	46	40	0.12954	0.0760
1983	436	1,415,281	48	40	0.12883	0.0764
1984	448	1,430,644	53	38	0.13133	0.0741
1985	463	1,460,697	48	35	0.13215	0.0708
1986	481	1,457,437	47	36	0.13042	0.0700
1987	494	1,566,591	46	33	0.13099	0.0701
1988	509	1,520,635	44	30	0.13378	0.0666
1989	491	1,564,869	43	26	0.13886	0.0708
1990	412	1,296,587	43	26	0.15751	0.0797

Notes: Reproduced from Porter and Zona (1999), Table 1 (NBER working-paper version). Districts: school districts or cooperatives in the data. Enrollment: total enrollment in those districts. Plants: plants operated by submitting dairies. Dairies: dairies submitting bids. Prices in dollars per half pint. The raw milk price is the July Federal Milk Order No. 33 Class I price, converted at 186 half pints per hundredweight.

Distance shapes participation. A non-defendant firm bids on 19.5 percent of the districts within 10 miles of its plant (Table 2). The probability falls to 7.6 percent at 20 to 30 miles, 2.3 percent at 40 to 50 miles and 0.5 percent at 100 to 150 miles. The probability of winning is 13.6 percent within 10 miles. These figures come from 2,053 bids out of 73,965 bid opportunities, of which 1,260 won. About 85 percent of suppliers serve districts from plants less than 75 miles

away. Few firms bid in any auction (Table 3). Of 3,866 auctions, 45.0 percent drew one bidder, 33.6 percent two and 18.2 percent three, with a mean of 1.8. The firm with the plant closest to the district submitted 42.8 percent of the 6,965 bids and won 48.8 percent of the 3,511 contracts (Table 4).

The competitive model: bid submission. Non-defendant firms form the *control group*, whose behavior defines the competitive benchmark. A competitive dairy decides where to bid and how much to bid. Let d index districts and t years. The submission decision of firm i is a probit,

$$S^*_{idt} = w_{idt}\gamma + u_{idt}, \qquad S_{idt} = \mathbf{1}\{S^*_{idt} > 0\}, \qquad u_{idt} \sim N(0,1). \tag{13.118}$$

The covariates w_{idt} include distance from the firm's nearest plant to the district, and a processor dummy and its interactions. They include *Direction*, the share of the firm's bids placed in the quadrant where the district lies, which proxies for route structure. They also include *Size*, the firm's share of Ohio students served, dummies for the closest and second-closest plants, district enrollment, contract terms and year effects. Three specifications are estimated: pooled, with bidder fixed effects, and with bidder and district fixed effects. The last has over 400 coefficients and is estimated on two halves of the districts. Its distance coefficient is identified because plant closures change distances over time.

Table 13.44 reports selected estimates. Processors bid more often than distributors. Distance sharply lowers the probability of bidding, more so for processors. Firms bid more often in the direction of their existing routes, and the closest firm is more likely to bid. Figure 13.24a plots the predicted probability of bidding by distance for a hypothetical control-group processor. The probability starts near or above one half at zero distance and steps down where the firm loses its locational advantage. It is close to zero beyond 75 miles.

The competitive model: bid levels and selection. The bid variable is a summary price per half pint for two-percent chocolate milk. Each submitted price for another type of milk is converted with a pairwise regression, for example of chocolate on white milk prices, and the predictions are averaged. The bid equation is

$$b_{idt} = x_{idt}\beta + e_{idt}, \qquad b_{idt} \text{ observed only if } S_{idt} = 1, \tag{13.119}$$

with (e_{idt}, u_{idt}) bivariate normal, $\operatorname{Var}(e_{idt}) = \sigma_e^2$ and correlation ϱ. Bids are observed only for firms that chose to bid, so ordinary least squares on submitted bids is biased if $\varrho \neq 0$.

Lemma 13.70 (Selection correction)**.** *In the model* (13.118)–(13.119)*,*

$$\mathbb{E}\big[b_{idt} \mid x_{idt}, w_{idt}, S_{idt} = 1\big] = x_{idt}\beta + \varrho\,\sigma_e\,\lambda(w_{idt}\gamma), \qquad \lambda(z) = \frac{\phi(z)}{\Phi(z)}, \tag{13.120}$$

where ϕ and Φ are the standard normal density and distribution function, and λ is the inverse Mills ratio*.*

Proof. For a bivariate normal pair with $\operatorname{Var}(u) = 1$, the regression of e on u is linear, $\mathbb{E}[e \mid u] = \varrho\sigma_e u$. Since $S = 1$ exactly when $u > -w\gamma$, iterated expectations give $\mathbb{E}[e \mid u > -w\gamma] = \varrho\sigma_e\,\mathbb{E}[u \mid u > -w\gamma]$. Write $a = w\gamma$. Using $\phi'(u) = -u\phi(u)$,

$$\mathbb{E}[u \mid u > -a] = \frac{\int_{-a}^{\infty} u\,\phi(u)\,du}{1 - \Phi(-a)} = \frac{\big[-\phi(u)\big]_{-a}^{\infty}}{\Phi(a)} = \frac{\phi(-a)}{\Phi(a)} = \frac{\phi(a)}{\Phi(a)},$$

where the last two steps use the symmetry of the normal distribution. Adding $x\beta$ gives (13.120). □

The two-step estimator of Heckman (1979) estimates the probit, forms $\hat{\lambda}_{idt} = \lambda(w_{idt}\hat{\gamma})$, and regresses submitted bids on x_{idt} and $\hat{\lambda}_{idt}$. The coefficient on $\hat{\lambda}$ estimates $\varrho\sigma_e$ (Appendix A). Identification does not rest on the normal functional form alone, because several probit regressors are excluded from the bid equation. Comparing Tables 6 and 7 of the paper, *Direction* and its interactions, *Size* and its interactions, and the second-closest dummy shift participation but not the bid. Route structure and scale plausibly affect the cost of adding a district to a delivery schedule, and hence the decision to bid, more than the bid itself. This exclusion is nonetheless an assumption.

Notes: Selected rows of Porter and Zona (1999), Tables 6 and 7, columns (a)–(d) (NBER working-paper version). Signed t-statistics as in the paper. Both equations also include contract terms, delivery and cooperative variables, and the bid equation includes year effects for 1981–1990. The tables also report a specification with bidder and district fixed effects with similar coefficients of interest. The inverse Mills ratio in each bid equation uses the corresponding probit.

Panel B of Table 13.44 shows the bid results. The coefficient on the inverse Mills ratio is positive. Since λ falls as the probability of bidding rises, firms that are likely to submit a bid tend to bid low. Bids rise with distance. Table 8 of the paper reports the derivative of the predicted bid with respect to distance, including the effect that runs through the selection term. For a firm that is not the closest supplier, the base model gives 0.0096 dollars per half pint per hundred miles. The specifications with bidder effects and with bidder and district effects give 0.0154 and 0.0194. The direct distance coefficients in column (a) imply only 0.0036 dollars per

hundred miles for a processor (our computation). Most of the base-model gradient therefore appears to work through selection (our reading). As distance rises, the probability of bidding falls, λ rises and the predicted bid rises with it. Figure 13.24b plots the predicted bid against distance. A bid 100 miles away is over a penny higher than a bid next to the plant. Moderate increases in distance raise bids by about ten percent (WP pp. 20 and 24). With bidder effects, an escalating bid is about 0.2 cents lower than a fixed bid (0.001174 + 0.000890). The 1990 year effect of about three cents reflects the jump in the raw milk price that year (Table 13.43).

The authors conclude that the control group bids in a way consistent with competition in a spatial market where each firm has some local market power. Bids rise with distance, and firms rarely bid far from their plants.

Defendants versus the control group. The paper studies six southwestern Ohio defendants: Beatrice, Borden, Coors Brothers, H. Meyer, Louis Trauth and Meadow Gold. Beatrice and Meadow Gold are the same firm bidding under two names. Two tests ask whether each defendant follows the control-group model.

The first test concerns submission. For each defendant, the authors append its submission data to the control-group data and estimate the probit twice. Under the null hypothesis the defendant shares the control group's slopes but has its own intercept. Under the alternative it has its own slopes. The likelihood ratio statistic is $2(\ell^{\text{alt}} - \ell^{\text{null}})$. The second test concerns bid levels. For each defendant the residual $r_{idt} = b_{idt} - x_{idt}\hat{\beta}^{\text{control}}$ is regressed on x_{idt} and a constant. Under the null hypothesis of identical slopes, with a possibly different intercept, the slope coefficients of this regression are zero, and an F test checks this. The authors describe it as a Lagrange multiplier test chosen for convenience.

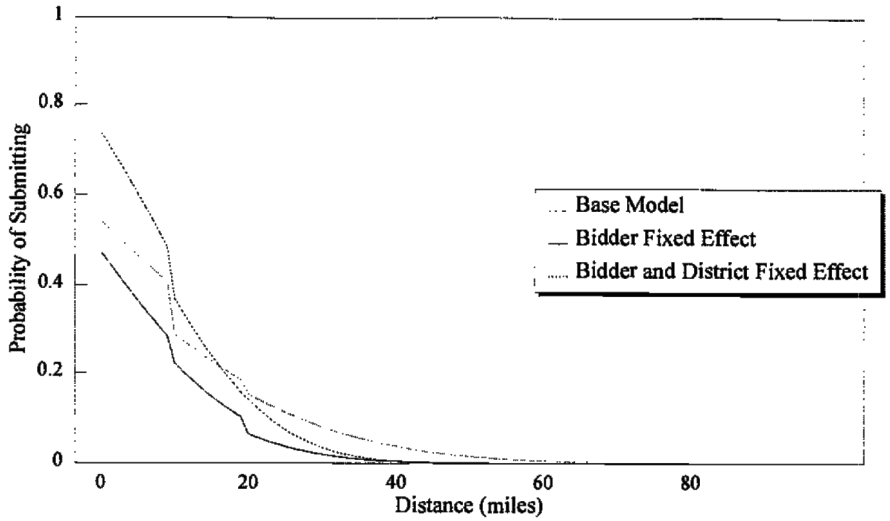
Table 13.45 reports both tests. Every defendant rejects the control-group submission model at the 1 percent level. For Borden, for example, the statistic is 445.9 with 20 degrees of freedom, against a 1 percent point of 37.6 (our computation). The bid-level test rejects for every defendant except bids under the Beatrice name. That test uses few observations, and the same firm's many bids under the Meadow Gold name reject. Results for the fixed-effects specifications lead to the same conclusions. The authors stress that behavioral differences are not necessarily anticompetitive. The question is how the defendants differ.

Table 13.45: Southwestern Ohio defendants compared with the control group

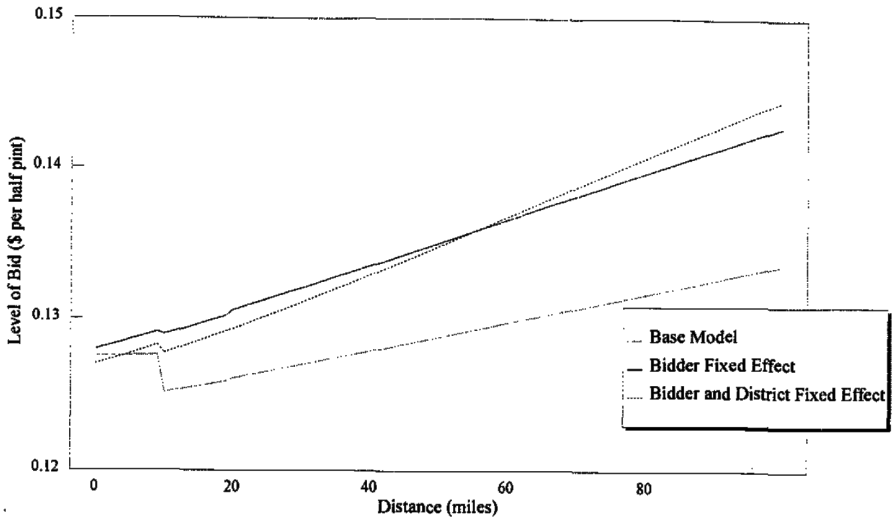
	Submission	Bid level		Deviation at 0–10 miles	
Defendant	LR (df)	F (df)	p-value	Submissions	Bid
Beatrice	157.9 (18)	1.09 (19, 78)	0.3774	−13.7% <	−4.9% <
Borden	445.9 (20)	10.13 (26, 386)	0.0000	−0.2%	1.9% >
Coors Brothers	187.8 (19)	5.02 (25, 102)	0.0000	24.2% >	9.3% >
H. Meyer	477.5 (20)	11.53 (26, 384)	0.0000	5.6% >	2.7% >
Louis Trauth	319.2 (20)	9.66 (25, 345)	0.0000	7.0% >	5.5% >
Meadow Gold	503.8 (20)	7.09 (25, 771)	0.0000	0.0%	0.1%

Notes: From Porter and Zona (1999), Tables 9–12 (NBER working-paper version), base models. LR: test of equal probit slopes, all significant at 1 percent. F: test that the slopes of the regression of bid residuals on the control-group regressors are zero. Submissions: actual minus predicted bids as a percentage of district-years within 10 miles of the firm's plant (Table 11). Bid: average deviation of actual from predicted bids, in percent of the predicted bid (Table 12). > (<): actual significantly above (below) predicted at 95 percent confidence.

Where the defendants differ. Since distance dominates the control-group model, the authors



(a) Predicted probability of submitting a bid



(b) Predicted level of submitted bids, dollars per half pint

Figure 13.24: The competitive benchmark in Ohio school milk: predictions for a hypothetical control-group processor by distance from its plant, under the three specifications. Variables unrelated to distance are at their means, the firm is the closest supplier within 10 miles and the second closest between 10 and 20 miles. The steps occur where the firm loses these positions. The bidder fixed-effects curves are solid. In panel (a) the base model is the dotted curve with the longest tail, and in panel (b) it is the lowest curve beyond 10 miles. The scans are darkened for legibility. Source: Porter and Zona (1999), Figures 2 and 3 (NBER working-paper version).

examine deviations by distance. Table 11 of the paper tabulates actual minus predicted submissions in bands of ten miles, as a percentage of the district-years in each band. Coors Brothers submitted 24.2 percent more bids than predicted within 10 miles of its plant and 42.9 percent more at 10 to 20 miles. Coors, Meyer and Trauth bid more often than predicted at distances up to about 30 miles, and Meyer and Trauth also at some greater distances. Beatrice, Meadow Gold and Borden bid less often than predicted within about 40 miles, where they would have a cost advantage. Borden and Meadow Gold bid more often than predicted at 70 to 100 miles.

Table 12 tabulates bid residuals, as a percentage of the predicted bid, by regressing each firm's residuals on distance-band indicators. Its first row is the deviation within 10 miles, and later rows are increments relative to that row. Coors bid 9.3 percent above the prediction within 10 miles, and about 10.0 percent above it at 10 to 20 miles. For Borden, Meyer, Trauth and Meadow Gold, the deviation falls significantly with distance. Borden's bids at 70 to 80 miles, for example, are 5.1 percent lower relative to its local deviation. Under competition, local bids should be lower than distant bids, because shipping costs are lower and the Cincinnati area has many potential suppliers. Bids that fall with distance relative to the control group are hard to explain without collusion (Porter and Zona, 1999, p. 28). They fit territorial allocation near the plants and more competitive bidding farther away.

Correlation tests. Under the null hypothesis of independent action based on public information, Proposition 13.65(ii) implies that the unexplained parts of two firms' decisions are uncorrelated. Under complementary bidding, when one ring member bids the others also bid, so submission residuals are positively correlated. Under territorial allocation, when one member bids the others stay out, so the correlation is negative. For bid levels, a complementary scheme implies that when one member bids high, the cover bids are high too.

The authors test independence of submission decisions with the Lagrange multiplier (LM) statistic of Kiefer (1982). Its logic is easy to derive. Consider two firms facing the same district-year, with probits $S_k = \mathbf{1}\{a_k + u_k > 0\}$, $a_k = w_k\gamma_k$, $k = 1, 2$, and let (u_1, u_2) be standard bivariate normal with correlation ρ_{12} (a local symbol). With $q_k = 2S_k - 1$, the probability of the observed pair is $\Phi_2(q_1a_1, q_2a_2; q_1q_2\rho_{12})$, where Φ_2 is the bivariate normal distribution function. The derivative of Φ_2 with respect to its correlation argument is the bivariate normal density ϕ_2, which at zero correlation equals $\phi(q_1a_1)\phi(q_2a_2)$. By the chain rule and the symmetry of ϕ, the score at $\rho_{12} = 0$ is

$$\left.\frac{\partial \ln \mathbb{P}(S_1, S_2)}{\partial \rho_{12}}\right|_{\rho_{12}=0} = \frac{q_1q_2\,\phi(a_1)\phi(a_2)}{\Phi(q_1a_1)\,\Phi(q_2a_2)} = g_1g_2, \qquad g_k = \frac{\phi(a_k)\big[S_k - \Phi(a_k)\big]}{\Phi(a_k)\big[1 - \Phi(a_k)\big]}. \tag{13.121}$$

Here g_k is the generalized residual of probit k. It equals $\frac{\phi(a_k)}{\Phi(a_k)}$ when $S_k = 1$ and $-\frac{\phi(a_k)}{1-\Phi(a_k)}$ when $S_k = 0$. The test asks whether the products $g_{1m}g_{2m}$ average to zero over district-years m, with the statistic

$$LM = \frac{\big(\sum_m g_{1m}g_{2m}\big)^2}{\sum_m g_{1m}^2 g_{2m}^2} \xrightarrow{d} \chi^2_1. \tag{13.122}$$

Because $\mathbb{E}[g_2] = 0$, the score for ρ_{12} is uncorrelated with the probit scores at $\rho_{12} = 0$, so estimated probit coefficients can be plugged in. Table 13.46 reports the Spearman rank correlations of standardized residuals $\frac{S-\hat{\Phi}}{\sqrt{\hat{\Phi}(1-\hat{\Phi})}}$ above the diagonal, with significance from the LM test. Below the diagonal it reports Spearman correlations of bid-level residuals for district-years in which both firms bid.

Table 13.46: Correlations of residuals across pairs of defendants

Notes: Above the diagonal, Porter and Zona (1999), Table 13: Spearman correlations of standardized submission residuals from the base probit, with significance from the LM test of Kiefer (1982). Below the diagonal, Table 14: Spearman correlations of bid-level residuals from the base model. Numbers of observations in brackets. ** significant at 1 percent, * at 10 percent. NBER working-paper version.

The correlations are large and positive for the pairs among Coors, Meyer and Trauth. Submission residuals correlate at 0.58 (Coors and Meyer), 0.54 (Meyer and Trauth) and 0.43 (Coors and Trauth). Their bid residuals correlate at 0.66, 0.67 and 0.54, on 126, 267 and 114 common district-years. When one of these firms bids, the others tend to bid too, and their bids move together, beyond what proximity, size and contract terms predict. Borden is positively correlated with Meyer and Trauth in both submissions and bids, and Meadow Gold's bids correlate with Trauth's (0.63). Some pairs involving Beatrice rest on as few as three to eleven observations and carry little information. The bid correlation test has little power against a pure territorial scheme, because ring members would then rarely bid in the same district in the same year (WP p. 27, footnote 30).

Interpretation. The pieces fit together. Coors, Meyer and Trauth submit more bids than predicted within about 30 miles of their plants, these bids are high, their submissions are positively correlated, and their bids move together. This is the footprint of complementary bidding near their plants. The authors conclude that the collective behavior of these three firms "is best characterized as collusive" (Porter and Zona, 1999, p. 28), which supports the testimony of Meyer and Coors. Beatrice, Meadow Gold and Borden refrain from bidding in their local areas, where they would have a comparative advantage, and their bidding is correlated with Trauth's. This pattern is consistent with a complementary bidding scheme that involves them as well.

Damages: a collusion index. To measure the overcharge, the authors regress the price of the winning bid on market structure and on an index of exposure to the alleged conspiracy. Market structure is measured by the number of *equivalent firms*, the inverse of a Herfindahl index. For district d, let s_{fd} be the fraction of school milk processing plants within 75 miles of the district that firm f owns, and define

$$HHI_d = \sum_f s_{fd}^2, \qquad N_d^e = \frac{1}{HHI_d}. \tag{13.123}$$

With ten owners of one plant each, $N_d^e = 10$. Under collusion, the conspirators C with plants

within 75 miles act as one owner with share $s_{Cd} = \sum_{f \in C} s_{fd}$. The Herfindahl index becomes

$$HHI_d^{\text{col}} = HHI_d - \sum_{f \in C} s_{fd}^2 + \Big(\sum_{f \in C} s_{fd} \Big)^2 = HHI_d + 2 \sum_{\substack{f,g \in C \\ f<g}} s_{fd}\, s_{gd}.$$

The *collusion index* (the paper's "Delta") is the resulting loss of equivalent firms,

$$\Delta_d^{\text{col}} = \frac{1}{HHI_d} - \frac{1}{HHI_d^{\text{col}}} \geq 0. \tag{13.124}$$

Example 13.71 (Computing the collusion index)**.** Suppose six plants lie within 75 miles of a district, each with a different owner, and three owners are conspirators. Competition gives $HHI_d = 6 \times \frac{1}{36} = \frac{1}{6}$ and $N_d^e = 6$. Under collusion the shares are $\frac{3}{6}$ for the conspirators and $\frac{1}{6}$ for each of the three others, so $HHI_d^{\text{col}} = \frac{1}{4} + \frac{3}{36} = \frac{1}{3}$ and the number of equivalent firms is 3. The collusion index is $\Delta_d^{\text{col}} = 6 - 3 = 3$ (our computation).

The price equation, estimated by ordinary least squares on about 400 districts including districts outside southwestern Ohio, is

$$\ln p_{dt} = \mu_t + z_{dt}\eta + \omega_1 N_{dt}^e + \omega_2 (N_{dt}^e)^2 + \sum_{\tau} \mathbf{1}\{t = \tau\} \Big[a_{1\tau} \Delta_{dt}^{\text{col}} + a_{2\tau} (\Delta_{dt}^{\text{col}})^2 + a_{3\tau} \Delta_{dt}^{\text{col}} N_{dt}^e \Big] + e_{dt}. \tag{13.125}$$

Here p_{dt} is the standardized price of the winning bid, and μ_t are year effects that absorb raw milk and packaging costs. The vector z_{dt} contains the distances to the closest and second-closest plants, log enrollment, the number of deliveries and the contract terms. The quadratic terms allow diminishing effects of competition, and the interaction lets the effect of collusion depend on the initial level of competition. The year interactions let the effectiveness of the conspiracy vary over time. The predicted effect of collusion is the prediction with the collusion terms minus the prediction with all of them set to zero:

$$\hat{m}_{dt} = \hat{a}_{1t} \Delta_{dt}^{\text{col}} + \hat{a}_{2t} (\Delta_{dt}^{\text{col}})^2 + \hat{a}_{3t} \Delta_{dt}^{\text{col}} N_{dt}^e. \tag{13.126}$$

The paper evaluates this log difference at the mean values of the variables.

The competitive part of the price equation behaves as expected (Table 16, with 3,431 observations and $R^2 = 0.6239$). One more equivalent firm lowers the price by about 1.5 percent (coefficient -0.0150, $t = -5.7$). The distance to the second-closest plant raises the price (0.0003, $t = 3.1$), as the closest firm's advantage grows. Larger districts pay less (log enrollment -0.0134, $t = -11.9$), and escalator clauses lower prices (-0.0096, $t = -4.2$). The distance to the closest plant has a small negative coefficient (-0.0004, $t = -3.6$), which the theory does not predict.

Table 13.47 and Figure 13.25 show the estimated effects by year. The paper notes that the effect is small in 1983–84 and after 1989 in both columns (WP p. 31). These are the two breakdowns described in the testimony. The incumbency measure, column (e), shows them most clearly. It falls to 1.1 percent in 1983–84 and 3.4 percent in 1989–90, and it is negative in 1990–91. In the years between the breakdowns it ranges from 11.5 to 49.0 percent, and it reaches 40.2 percent in 1981–82. The average effect, column (d), shows the first breakdown less clearly. It is 4.5 percent in 1983–84, above its values in 1980–81, 1987–88 and 1988–89. It is negative in 1989–90 and 1990–91. The authors summarize the average effect of collusion as an increase of "about six and one half percent," roughly the cost of shipping school milk about 50 miles. The paper does not state how this average weights the years. Erutku and Hildebrand

Table 13.47: Estimated effect of collusion on prices paid by southwestern Ohio school districts

School year	$\hat{a}_{1t}$ (Delta) (a)	$\hat{a}_{2t}$ (Delta^2) (b)	$\hat{a}_{3t}$ (interaction) (c)	Average effect (d)	Effect given incumbency (e)
1980–81	−0.0014	−0.0015	0.00163	3.0%	3.2%
1981–82	0.01304	0.01167	0.00103	11.3%	40.2%
1982–83	0.02731	0.00225	0.00098	8.6%	23.2%
1983–84	0.02995	−0.0097	0.00156	4.5%	1.1%
1984–85	0.02147	0.00106	0.00199	6.7%	19.7%
1985–86	0.02684	−0.0023	0.00122	5.4%	11.5%
1986–87	0.02425	0.00173	0.0013	6.5%	20.5%
1987–88	0.00368	0.02901	0.0006	3.3%	49.0%
1988–89	−0.0227	0.03636	0.00229	2.9%	29.4%
1989–90	−0.0494	0.0134	0.0041	−1.6%	3.4%
1990–91	−0.0201	−0.0126	0.00634	−0.3%	−8.3%

Notes: Reproduced from Porter and Zona (1999), Table 17 (NBER working-paper version). Columns (a)–(c) are the year-specific coefficients of (13.125). Column (d) is the expected markup over competitive prices for the average district in southwestern Ohio, computed at mean values as a difference in predicted log prices. Column (e) conditions on a defendant being the incumbent. School years as labeled in the paper.

(2010, p. 235) describe it as the average "when excluding 3 years in which the cartel was said to have broken down." The simple mean of column (d) is 4.6 percent over all eleven years and 5.8 percent over 1980–81 to 1988–89. Excluding 1983–84, 1989–90 and 1990–91 gives $\frac{47.7}{8} = 6.0$ percent (our computation), so the weighting remains unstated. Erutku and Hildebrand also report the authors' suggestion that the 6.5 percent price effect amounts to a rise of roughly 30 percent in the markup.

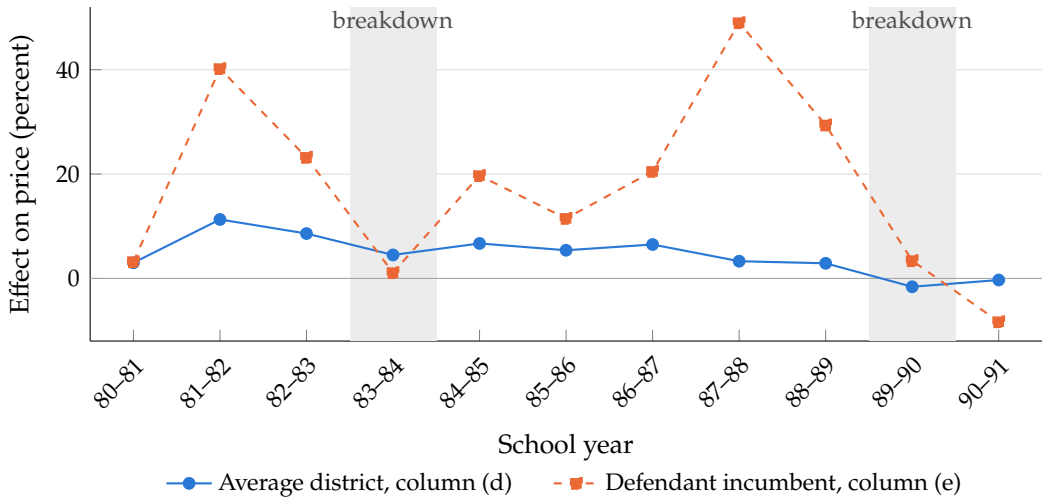

Figure 13.25: Estimated effect of collusion on the price of school milk in southwestern Ohio, by school year. Shaded years are the cartel breakdowns described in the testimony (1983–84 and 1989–90). Redrawn from Porter and Zona (1999), Table 17, columns (d) and (e).

Example 13.72 (From a log markup to damages)**.** The dependent variable of (13.125) is the log price, so column (d) of Table 13.47 is a log difference, $\hat{m} = \ln p - \ln p^{\text{bf}}$. The paper reports it as

a percentage change (WP p. 31). As in (13.131), the overcharge as a share of spending is

$$\frac{p - p^{\text{bf}}}{p} = 1 - e^{-\hat{m}}.$$

With $\hat{m} = 0.065$, the overcharge is $1 - e^{-0.065} = 6.3$ percent of spending. Reading 6.5 percent instead as a ratio markup $\frac{p}{p^{\text{bf}}} - 1$ would give $\frac{0.065}{1.065} = 6.1$ percent. A district that spent \$100,000 on milk would have overpaid about \$6,300 (a hypothetical district, our computation). Because school milk demand is nearly perfectly inelastic, this transfer is the whole of the district's loss.

The comparison with distance in the abstract can be checked against Table 13.44. Fifty miles at the base-model gradient of 0.0096 dollars per hundred miles adds 0.48 cents, or 3.6 percent of the mean price of 13.4 cents in Table 13.43. With bidder effects it adds 0.77 cents, or 5.7 percent (our computation). The authors' own illustration is a district next to the plants of two conspirators whose nearest competitors are at least 50 miles away. Prices there could be about half a penny, or five percent, above the competitive level (WP p. 31).

Critiques and limitations. The evidence is a set of imperfect tests, none decisive alone. The likelihood ratio tests of equal slopes reject for every defendant, and the authors note in footnote 15 that no single intercept represents all bidders. Such tests would probably reject for many individual non-defendants too, so the rejections carry little weight by themselves. The informative evidence is the pattern of deviations. Distance gradients are reversed and residuals are correlated, and both match the testimony. Positive correlations could also arise from an omitted factor that affects these firms alike (WP p. 27, footnote 28). The control group is assumed competitive. Collusion among non-defendants would bias the benchmark toward the defendants' behavior and work against the tests.

The damage regression is a reduced form. Its identifying variation is the cross-sectional exposure of districts to conspirators' plants, which is credible only if plant locations are unrelated to unobserved local cost and demand conditions. The 75-mile radius, the plant-count shares and the quadratic forms are approximations, and the competitive price for southwestern Ohio is predicted partly from districts elsewhere in the state. The year pattern, which matches the breakdowns in the testimony, is the strongest validation of the index.

Contribution. The paper extends the Long Island design to markets in which collusion takes the form of incumbency rights and territorial allocation. It models both the decision to bid and the level of the bid, with a selection correction. It then matches several scheme-specific tests to the alleged scheme and builds a reduced-form damages estimate whose time pattern can be compared with testimony. The combination of a competitive model estimated on a control group, tests of independence across suspected firms, and damages from exposure to the ring remains a template for procurement cases.

Later screens. Porter and Zona warn that a single test procedure able to detect all bid rigging is an impossible goal. Later work has therefore developed tests aimed at particular schemes and data (Asker and Nocke, 2021, p. 210). Bajari and Ye (2003) test conditional independence and exchangeability (Section 13.9.2). Athey et al. (2011) compare open and sealed timber auctions, as Chapter 15 explains. Kawai and Nakabayashi (2020) exploit the rounds of Japanese national procurement auctions, as reported by Asker and Nocke (2021, pp. 184–185). When no first-round bid meets the secret reserve price, the lowest first-round bid is announced and a second round follows. In the second round, the gap between the bids of the first-round runner-up and the first-round winner is almost never negative. The gap between the bids of

the first-round third and second bidders often is. The first-round winner thus almost always wins again, while lower ranks switch freely, which suggests that the winner was chosen before the auction. Applied across 2003–2006, the test flags about 970 firms as collusive. Conley and Decarolis (2016) detect groups of coordinating bidders in Italian procurement, and Ortner et al. (2020) develop screens that remain informative when cartels adapt to them. Section 12.1.5 uses the first two of these studies as evidence on the prevalence of collusion, and the book does not develop the three tests further.

13.10 Enforcement, Damages and What the Evidence Shows

The cartels of this chapter came to light in different ways, and the route matters for what they can teach. This section describes the enforcement institutions and the selection of cartels they induce (Section 13.10.1). It then develops the methods used to measure the effects of collusion (Section 13.10.2) and closes with what the evidence of the chapter shows (Section 13.10.3).

13.10.1 Enforcement institutions and the selection of observed cartels

Law and penalties. In the United States, Section 1 of the Sherman Act (1890) prohibits agreements in restraint of trade. Price fixing is illegal per se (Miller, 2010, p. 570). Section 1 is a criminal as well as a civil statute, so price fixing and bid rigging can be prosecuted as crimes (Kaplow, 2013, ch. 4, p. 74, footnote 13). Injured parties can sue for treble damages (Asker, 2010, p. 759). In the European Union, Article 101 of the Treaty on the Functioning of the European Union prohibits cartels. The European Commission imposes administrative fines, capped at 10 percent of a firm's turnover (Chen and Rey, 2013, p. 6). Page and footnote references to Chen and Rey (2013) are to its working-paper version. Table 12.2 lists the largest fines the Commission has imposed. On the conventional view, liability for price fixing requires proof of an agreement, usually through evidence of communication, and plus factors serve as circumstantial support (Kaplow, 2013, pp. 4, 21 and 109–110). Section 12.8.4 discusses Kaplow's critique of this requirement, and Section 13.9.1 the market-based evidence itself.

Leniency. Proving an agreement is the hard part of enforcement, and leniency programs address it. The United States adopted a corporate leniency program in 1978. Its 1993 revision guarantees amnesty to the first firm that reports, and only to the first, and keeps the first informant eligible after an investigation has started (Chen and Rey, 2013, p. 1). The European Commission adopted a program in 1996 and revised it in 2002 (Chen and Rey, 2013, footnote 1). It revised it again in its 2006 Notice on Immunity from Fines and Reduction of Fines in Cartel Cases. As Chen and Rey (2013, footnote 6) describe it, the EU program reduces fines by 75 to 100 percent before an investigation and by 50 to 75 percent once one is under way. Many recent prosecutions involve a whistleblower.

In the repeated-game language of Chapter 12, leniency changes both sides of a member's incentive constraint. Asker and Nocke (2021, pp. 209–210) summarize the opposing effects identified by Harrington (2008a). The *deviator amnesty effect* lets a member that undercuts its rivals also report the cartel and escape the fine. Cheating becomes more attractive, which tightens the no-cheating constraint. The *cartel amnesty effect* works the other way. Lenient treatment of the first confessor lowers the expected fines that members pay, which raises the value of colluding and eases the constraint. A third force, the *race-to-the-courthouse effect*, counteracts the second (p. 209, note 77). A more lenient program can move the members from a state in which no firm applies to one in which all race to report. Expected fines then rise

and the value of colluding falls. Leniency can also be exploited. If it is too generous, a cartel can collude and have members report in turn, paying reduced fines. Chen and Rey (2013) characterize the optimal design. Some leniency before an investigation is always desirable. Leniency during an investigation is desirable when investigations are unlikely to succeed without a report. Restricting leniency to the first informant is useful, and their analysis does not support denying leniency to repeat offenders. The theory is developed in Chapter 12.

Measuring the effect of a leniency program runs into the problem that cartels are unobserved (Asker and Nocke, 2021, p. 209). A rise in detected cartels after a program begins could reflect better detection or more cartels. Miller (2009) separates the two with a model of cartel formation, detection and dissolution. He estimates it by Poisson regression on the U.S. indictments and information reports for violations of Section 1 from 1985 to 2005 (Asker and Nocke, 2021, pp. 186–187). Remark 13.74 shows the logic of his identification in the notation of Proposition 13.73. The 1993 program raised cartel discoveries by about 60 percent, which indicates better detection. Read through the model, the later path of discoveries indicates greater deterrence.

How the cartels of this chapter came to light. Table 13.48 records the source of evidence for each case. The legal cartels left records because they had no reason to hide. The prosecuted cases surfaced through complaints, wiretaps, convictions and confessions. Asker's stamp ring collapsed after a dealer outside the ring alerted antitrust enforcement. Asker suggests that strong members kept the weak ones partly because an expelled member could report the ring and seek leniency (Section 13.8). A leniency program thus shapes the internal organization of a cartel as well as its stability. Section 13.9.1 classifies the kind of evidence that decided each case.

Table 13.48: How the cartels studied in this chapter came to light

Case	Source of evidence
Joint Executive Committee, 1880–1886	Open agreement before the Interstate Commerce Act, weekly cartel records and trade-press reports of price wars
Sugar Institute, 1927–1936	Trade association later ruled illegal by the Supreme Court, meeting notes kept by a member
Bromine pools, 1885–1914	Contracts, firm papers and trade press
Danish ready-mixed concrete, 1993–1996	Prices published by the competition authority itself
Overlap group, 1950s–1991	Department of Justice suit in 1991
Airline Tariff Publishing, 1990s	Department of Justice suit in 1992 and consent decrees
Quebec gasoline, 2002–2006	Competition Bureau wiretaps, raids and guilty pleas
Lysine, citric acid and other industrial cartels, 1990s	Prosecutions and European Commission decisions
Stamp-auction ring, until 1997	Complaint by a dealer outside the ring, faxed records kept by a member
Long Island paving, 1979–1985	Federal conviction in 1984 and state and county suits
Ohio school milk, 1980–1990	State suit, confessions by two dairies in 1993

Notes: Compiled from the case studies of this chapter (Sections 13.3 to 13.9).

Selection. We observe cartels that were legal or that were caught. Estimates of how long cartels last and how much they raise prices are therefore conditional on detection. Levenstein and Suslow (2006) survey cross-section studies in which average cartel duration ranges from 3.7 to 10 years (their Table 1). Their own sample covers 42 international cartels prosecuted by the United States or the European Commission in the 1990s. These cartels lasted 5 years on average,

with a standard deviation of 4.5 and a range of 0 to 20 years (Table 1). Their text on p. 51 gives 5.4 years and 4.7 for the same sample. The distribution of duration is bimodal. Many cartels break up within a year, many last five to ten years, and some last decades (p. 43). They warn that "in some cases, samples are literally selected by prosecutors" (p. 44). The surge in U.S. prosecutions of international cartels followed the 1993 revision of the amnesty program (p. 50, footnote 21). Case-study samples are selected differently, by researchers who choose industries with long or eventful cartel histories. Their mean duration is 14 years, with a median of 6 (pp. 52–53).

Prosecuted cartels are also a small part of all cartels. The U.S. Department of Justice filed 92 criminal cartel cases in 1982, with fines of $36.8 million (Asker and Nocke, 2021, p. 182). In 2017 it filed 21 cases, with fines of $2.79 billion. Fewer cases need not mean less collusion, because penalties, detection and the size of the economy all changed. Where collusion can be measured directly, it is common. Kawai and Nakabayashi (2020) flag about 970 collusive firms in Japanese national procurement, and scaling up their estimate implies that collusion affects about 0.85 percent of Japan's GDP. Conley and Decarolis (2016) find that coordination among bidders affected more than 30 percent of Italian regional procurements from 2005 to 2010. When Finnish cartels were legal and had to register, Hyytinen et al. (2018) count 900 of them between 1951 and 1990. Section 12.1.5 discusses this evidence further.

Selection begins before detection, at formation. Asker and Nocke (2021, p. 187) write the participation constraint of a potential member i as

$$V_i^{\text{comp}} \;\le\; V_i^{\text{coll}} - \eta_i. \tag{13.127}$$

Here V_i^{coll} is the firm's value inside the cartel, V_i^{comp} its value outside when the other firms join, and η_i a one-time cost of joining that captures the frictions of organizing. It is constraint (12.102) of Chapter 12. A cartel forms only where the gain from collusion covers these frictions for every member it needs. The cartels that exist are therefore already selected toward markets with large collusive gains, before detection selects them again. The direction of the second bias depends on how detection works, as a simple model shows.

Proposition 13.73 (Duration of detected cartels)**.** *In each period of operation, a cartel breaks down for internal reasons with probability $q \in (0,1)$, so its natural duration L is geometric with $\mathbb{E}[L] = \frac{1}{q}$. Independently, in each period of operation it is detected with probability $h \in (0,1)$. Let $r = (1-q)(1-h)$, a local symbol for the probability that a cartel neither breaks down nor is detected in a period.*

(a) If detection uncovers the cartel without ending it, so that a cartel is eventually discovered if it is detected in at least one period of its life, then

$$\mathbb{E}[L \mid \textit{discovered}] = \frac{1-r}{h}\left[\frac{1}{q} - \frac{q(1-h)}{(1-r)^2}\right] > \frac{1}{q}. \tag{13.128}$$

(b) If detection ends the cartel, the observed duration of detected cartels satisfies

$$\mathbb{E}[L \mid \textit{detected}] = \frac{1}{1-r} < \frac{1}{q}. \tag{13.129}$$

Proof. (a) A cartel of duration L escapes detection with probability $(1-h)^L$, so the probability of discovery is

$$\mathbb{P}(\text{discovered}) = \sum_{L=1}^{\infty} q(1-q)^{L-1}\left[1-(1-h)^L\right] = 1 - q(1-h)\sum_{L=1}^{\infty} r^{L-1} = 1 - \frac{q(1-h)}{1-r} = \frac{h}{1-r},$$

where the last step uses $1 - r - q(1-h) = 1 - (1-h)(1-q+q) = h$. Using $\sum_{L\geq 1} L r^{L-1} = \frac{1}{(1-r)^2}$,

$$\mathbb{E}\big[L\,\mathbf{1}\{\text{discovered}\}\big] = \frac{1}{q} - q(1-h)\sum_{L=1}^{\infty} L\,r^{L-1} = \frac{1}{q} - \frac{q(1-h)}{(1-r)^2}.$$

Dividing by $\mathbb{P}(\text{discovered})$ gives the equality in (13.128). For the inequality, the probability of discovery $1-(1-h)^L$ is increasing in L. Two increasing functions of the same random variable are positively correlated, so $\mathbb{E}[L\,(1-(1-h)^L)] > \mathbb{E}[L]\,\mathbb{E}[1-(1-h)^L]$, which is the inequality after division.

(b) A cartel survives each period with probability r, so it is detected in period ℓ with probability $r^{\ell-1}h$. Conditional on detection, the duration is geometric with parameter $1-r$ and mean $\frac{1}{1-r}$. Since $1 - r = q + h(1-q) > q$, this mean is below $\frac{1}{q}$. □

With $q = 0.2$, so that the natural mean duration is 5 years, and a detection probability of $h = 0.05$ per year, cartels discovered after the fact last 8.17 years on average. Cartels ended by detection last 4.17 years. With $h = 0.2$ the figures are 6.78 and 2.78 years (our computation, `pz_checks.py`). Prosecuted samples mix both mechanisms, so their bias can go either way. The same logic applies to overcharges. Cartels with large overcharges may draw complaints from customers and be overrepresented, while sophisticated cartels may evade detection and be underrepresented. Legal cartels avoid detection-driven selection but face another one, since we study those whose records survived.

Remark 13.74 (Reading cartel discoveries). The model of Proposition 13.73 also explains how Miller (2009) reads enforcement statistics. Consider a population of industries of mass one. In each period a competitive industry forms a cartel with probability ϕ (a local symbol). A cartel is detected with probability h and otherwise breaks down with probability q, so it survives the period with probability $r = (1-q)(1-h)$. An industry whose cartel ends returns to competition. In a steady state, the flow into collusion equals the flow out of it:

$$\phi\,(1-\bar{\pi}) = (1-r)\,\bar{\pi}, \qquad \text{so} \qquad \bar{\pi} = \frac{\phi}{\phi + 1 - r},$$

where $\bar{\pi}$ is the share of industries that collude. Discoveries per period are $h\bar{\pi}$. Substituting $1 - r = q + h(1-q)$ and differentiating,

$$h\bar{\pi} = \frac{h\phi}{\phi + q + h(1-q)}, \qquad \frac{\partial\,(h\bar{\pi})}{\partial h} = \frac{\phi\,(\phi+q)}{\big[\phi + q + h(1-q)\big]^2} > 0.$$

Two predictions follow, which are those of Miller's model as summarized by Asker and Nocke (2021, p. 186). When a policy raises h, the share $\bar{\pi}$ cannot change at once, so discoveries jump in proportion to the rise in h. An immediate rise in discoveries therefore reveals better detection. In the new steady state, a higher h with unchanged ϕ and q would keep discoveries above their old level. A long-run level of discoveries below the old one therefore requires a fall in the formation rate ϕ, which is deterrence. The discrete-time version and its timing are our simplification of Miller's model.

13.10.2 Measuring the effects of collusion

Overcharges and damages. Let p_t be the price paid in period t, Q_t the quantity bought and p_t^{bf} the *but-for price*, the price that would have prevailed without the cartel. The *overcharge* is

$p_t - p_t^{\text{bf}}$ per unit, and overcharge damages are

$$D = \sum_t \left(p_t - p_t^{\text{bf}}\right) Q_t. \tag{13.130}$$

Most methods estimate the log overcharge $\tau_t = \ln p_t - \ln p_t^{\text{bf}}$. Since $p_t^{\text{bf}} = p_t e^{-\tau_t}$, damages in terms of observed spending are

$$D = \sum_t \left(1 - e^{-\tau_t}\right) p_t Q_t. \tag{13.131}$$

Buyers also lose the surplus on units they no longer buy. The change in consumer surplus is

$$\Delta CS = -\int_{p^{\text{bf}}}^{p} Q(s)\, ds \approx -\left(p - p^{\text{bf}}\right) \frac{Q + Q^{\text{bf}}}{2} = -\left(p - p^{\text{bf}}\right) Q - \frac{1}{2}\left(p - p^{\text{bf}}\right)\left(Q^{\text{bf}} - Q\right),$$

where the approximation is exact for linear demand. The first term is the overcharge, a transfer to the cartel. The second is the deadweight loss. In procurement with inelastic demand, as on Long Island and in Ohio, $Q^{\text{bf}} = Q$ and the overcharge is the whole loss.

Direct purchasers who resell pass part of an overcharge on. If a cartel raises a downstream firm's unit cost by Δw and downstream pass-through is ρ (Chapter 2), the downstream price rises by about $\rho\,\Delta w$. To first order, direct purchasers then bear $(1 - \rho)\Delta w$ per unit and their customers bear $\rho\,\Delta w$, apart from volume effects.

Umbrella damages and the loss of welfare. Overcharge damages measure only part of the harm. Asker and Nocke (2021, pp. 210–212) separate the measures of a cartel's impact in a static market with a competitive fringe (Figure 13.26). In their figure the members' aggregate marginal cost MC_1 slopes upward and meets demand at the competitive price. For simplicity we draw MC_1 constant, so the competitive price equals MC_1. Fringe firms have higher costs and are inactive under competition. When the cartel restricts output, the price rises and fringe firms produce until their marginal cost reaches the cartel price. The overcharge is the price increase, AG in the figure. Antitrust damages are the overcharge times the cartel's sales, the rectangle $GAHF$, and courts treble this measure. *Umbrella damages* are the overcharge times the fringe's sales, the rectangle $HCEF$. Buyers pay them to firms outside the cartel that raise prices under its umbrella. Buyers also lose the triangle CDE on units they no longer buy. The three areas together make up the loss of consumer surplus $GACD$. Antitrust damages thus exclude both umbrella damages and the consumers' share of the deadweight loss (pp. 211–212).

Total surplus calls for different areas. The overcharge on the cartel's sales is a transfer. *Productive inefficiency* is the extra resource cost $BCEF$ of output produced by high-cost fringe firms instead of the cartel's members. With constant MC_1, as in our drawing, part of the umbrella overcharge is dissipated in this way. With an upward-sloping MC_1, as in their figure, the points F and E lie below the competitive price. The area $BCEF$ is then no longer contained in the umbrella rectangle. The total welfare loss $BFDC$ is the sum of productive inefficiency and the deadweight loss CDE. With the illustrative curves of the figure, damages are 10, umbrella damages 6 and the deadweight loss 8, so consumers lose 24. Productive inefficiency is 4.5, fringe firms keep 1.5 of the umbrella overcharge, and the total welfare loss is 12.5 (our computation). Umbrella damages are 37.5 percent of all overcharge damages in this example. Caoui (2020) estimates that umbrella damages exceeded 35 percent of total damages in the Texas school milk cartel of 1980–1992 (Asker and Nocke, 2021, p. 212, note 82).

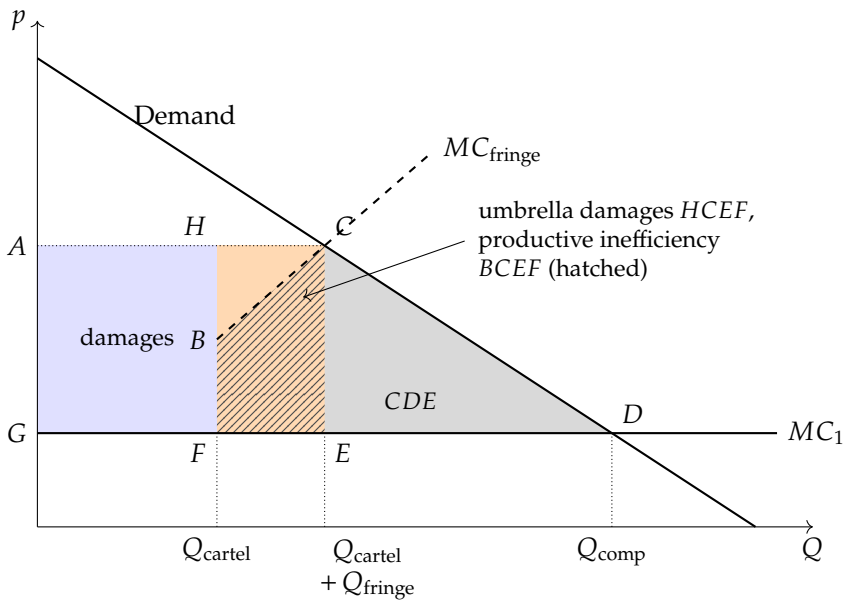

Figure 13.26: Measures of a cartel's impact with a competitive fringe. In our drawing the cartel's members have constant marginal cost MC_1, which is also the competitive price G. The cartel sells Q_{cartel} at the price A, and fringe firms with marginal cost MC_{fringe} add Q_{fringe}. The overcharge is AG. Antitrust damages are the rectangle $GAHF$, umbrella damages the rectangle $HCEF$ and the deadweight loss the triangle CDE. Productive inefficiency is the hatched area $BCEF$, and the total welfare loss is $BFDC$. We redraw the decomposition in Asker and Nocke (2021), Figure 5, which has an upward-sloping MC_1. We take MC_1 constant and use illustrative linear curves (demand $p = 10 - Q$, $MC_1 = 2$, cartel price 6). The point H is our addition.

Attributing harm when other distortions are present. Markets with cartels often have other distortions, such as taxes or market power outside the cartel. Which part of the total distortion should be attributed to collusion? The next example, from Asker and Nocke (2021, pp. 212–213), shows that the answer depends on the thought experiment.

Example 13.75 (A cartel and a tax)**.** Firms sell a homogeneous good at constant marginal cost c and face inverse demand $p = a - bq$, with $a > c$. A unit tax $t < a - c$ is levied on sellers. Without a cartel the firms compete in prices, and with a cartel they act as a monopolist (Example 2.1 of Asker and Nocke). Bertrand competition without the tax gives $p^c = c$. With the tax, competition drives the price to cost including the tax, $p^t = c + t$. A monopolist without the tax maximizes $(p - c)\frac{a-p}{b}$. Its first-order condition is $a - p - (p - c) = 0$, so $p^k = \frac{a+c}{2}$. With the tax it maximizes $(p - c - t)\frac{a-p}{b}$, and the same steps give $p^{t+k} = \frac{a+c+t}{2}$. The total distortion is

$$p^{t+k} - p^c = \frac{a - c + t}{2}.$$

Two decompositions add up to it. If the tax comes first, the tax adds $p^t - p^c = t$ and the cartel adds

$$p^{t+k} - p^t = \frac{a + c + t}{2} - (c + t) = \frac{a - c - t}{2}.$$

If the cartel comes first, the cartel adds $p^k - p^c = \frac{a-c}{2}$ and the tax adds $p^{t+k} - p^k = \frac{t}{2}$. With $a = 10$, $c = 2$ and $t = 2$, the four prices are 2, 4, 6 and 7. The cartel's effect is 3 in the first decomposition and 4 in the second (our numbers).

The first decomposition measures the *marginal* impact of the cartel, holding the other distortion fixed. The second measures its *inframarginal* impact, its effect in a world without other distortions (p. 213). In an antitrust case, the but-for world holds everything else constant, so the marginal measure is almost always the right one for damages. Comparisons with a control market, and structural models that recover costs or values from first-order conditions, naturally measure marginal impacts, because they take other distortions as given (pp. 213–214). The choice matters for the academic question of how much of a market's distortion collusion explains. For OPEC's productive inefficiency the two measures are close (Asker et al., 2019). For total welfare they differ greatly (Asker et al., 2021), because the deadweight loss is sensitive to the counterfactual quantities (Asker and Nocke, 2021, p. 214).

The central problem of measurement is the but-for price, which is never observed. Four families of methods estimate it. Table 13.50 summarizes them.

Before, during and after. The simplest method compares prices during the cartel with prices before or after it, controlling for cost and demand shifters x_t:

$$\ln p_t = x_t\beta + \tau D_t + e_t, \tag{13.132}$$

where D_t marks cartel periods. Ordinary least squares estimates τ consistently if $\mathbb{E}[e_t \mid x_t, D_t] = 0$. The comparison of published Danish concrete prices with consumer prices (Section 13.5.2) is of this type, with an estimated effect of about $\ln 1.19 - \ln 1.019 = 0.155$. So are Levenstein's comparisons of cooperative and noncooperative bromine prices (Section 13.4.3) and the Sugar Institute margins before and after 1927 (Section 13.4.1). Porter's regime comparison for the JEC is a version in which D_t is latent and estimated (Section 13.3).

Three threats are common. Cartels may form when prices are falling, which makes the before period a poor benchmark (Levenstein and Suslow, 2006, p. 45). Prices after a cartel may

stay high, because coordination persists or because firms under investigation want to limit their liability. Levenstein and Suslow (2006, pp. 80–81) report a survey of twenty-five price-fixing cases between 1973 and 1984 in which prices four years after indictment were about 7 percent higher. Finally, the dates of the cartel may be wrong.

The choice of controls x_t raises a further problem (Marshall and Marx, 2012, pp. 215–220). A cartel can influence variables that look exogenous. It may set inventories, capacity utilization and advertising strategically, and input prices may reflect its bargaining power with suppliers. Exchange rates can serve as cover if the cartel times its increases to coincide with currency movements. Such variables should not enter a regression estimated over both periods, because their coefficients would mix competitive and collusive responses. Marshall and Marx prefer to estimate a predictive model on the benchmark period alone. They choose its variables by how well it predicts blocks of benchmark data withheld from estimation, and then use it to predict but-for prices in the cartel period. The coefficients of such a model are weights for prediction, without a structural interpretation (p. 220). A path of actual prices well outside the model's predictions is their first super-plus factor (Section 13.9.1).

Remark 13.76 (Misdated cartel periods). Suppose the analyst uses an indicator $\tilde{D}_t$ in place of the true D_t, with no other regressors, and the error in dating is unrelated to e_t. Then $\mathbb{E}[\ln p_t \mid \tilde{D}_t] = \text{const} + \tau \mathbb{P}(D_t = 1 \mid \tilde{D}_t)$, so the regression slope converges to

$$\operatorname{plim} \hat{\tau} = \tau \big[\mathbb{P}(D_t = 1 \mid \tilde{D}_t = 1) - \mathbb{P}(D_t = 1 \mid \tilde{D}_t = 0) \big],$$

which is smaller than τ in absolute value whenever dating errors occur. In the JEC, trade-press reports of price wars often lead the estimated regime series at the start of a war (Section 13.3). Such disagreements attenuate regime effects estimated with the wrong series.

Yardsticks and difference in differences. A *yardstick* is a comparable market that the cartel did not affect. With markets m and periods t,

$$\ln p_{mt} = a_m + \lambda_t + \tau \, (C_m \times A_t) + x_{mt}\beta + e_{mt}, \tag{13.133}$$

where C_m marks cartelized markets, A_t marks cartel periods, a_m are market effects and λ_t are period effects (λ_t is a local symbol). Without covariates and with two markets and two periods,

$$\begin{aligned} \tau = &\big\{ \mathbb{E}[\ln p_{mt} \mid C = 1, A = 1] - \mathbb{E}[\ln p_{mt} \mid C = 1, A = 0] \big\} \\ &- \big\{ \mathbb{E}[\ln p_{mt} \mid C = 0, A = 1] - \mathbb{E}[\ln p_{mt} \mid C = 0, A = 0] \big\}, \end{aligned}$$

because the first difference removes a_m and the second removes λ_t. The identifying assumption is parallel trends. Without the cartel, prices in the two markets would have moved alike, conditional on x_{mt} (Appendix A, Chapter 11).

The chapter offers three applications. Erutku and Hildebrand (2010) estimate that Sherbrooke gasoline prices fell 1.75 cents per liter (standard error 0.80) relative to Montreal after the cartel investigation became public. Relative to Quebec City they rose 0.26 (0.82) (Table 13.29). The estimate depends on the choice of control. Miller (2010) finds that fares in markets affected by the Airline Tariff Publishing case fell \$13.57 relative to control markets during the investigation. They rose \$12.71 after the settlement, leaving no significant net change (Table 13.18). Carlton et al. (1995) use a cross-sectional yardstick, comparing Overlap schools with other private colleges conditional on observables. The Ivy-plus-MIT coefficient of −\$322 (standard error 679) has a 95 percent interval of [−\$1,653, \$1,008] (Table 13.19, our computation), so the data cannot rule out sizable effects.

The main threats are contamination and differential shocks. Firms outside a cartel often raise their prices under its umbrella. If the yardstick market is affected in this way, $\hat{\tau}$ is biased toward zero. With a single treated market, inference relies on the time-series behavior of one pair of markets.

Collusion-index regressions. The regression (13.125) of Porter and Zona (1999) replaces a binary treatment with a continuous measure of exposure to the ring. The identifying variation is cross-sectional. Districts with more conspirators' plants nearby should pay more, holding market structure and costs fixed. The assumption is that exposure is unrelated to unobserved local price determinants. The year-by-year coefficients provide a check against the dates of known breakdowns.

Structural counterfactuals. The most demanding method estimates the primitives of a model of collusive behavior and simulates the competitive outcome. Asker (2010) recovers the stamp dealers' value distributions from knockout bids and simulates competitive target auctions (Section 13.8). True damages to sellers are \$36.99 or \$26.50 per ring win under his two bounding assumptions, against naive damages of \$74.21 (Table 13.35). The ratios are 0.50 and 0.36 (our computation). Naive damages overstate harm because knockout bids exceed values. Clark and Houde (2013) simulate incentive constraints and the value of delays as transfers (Section 13.6.4). Porter's reduced form for the JEC predicts a price 66 percent higher in cooperative weeks (Table 13.5). Structural estimates depend on the assumed but-for conduct, for example Bertrand or Cournot, which the data may not pin down (Chapter 3, Proposition 13.9).

What collusion costs. Estimates of the effects of collusion vary widely. Connor and Bolotova (2006) compile overcharges for 395 cartel episodes from sources that reach back to 1770. The median overcharge is 19 percent and the mean 29 percent, with a range from −10 to 322 percent (Asker and Nocke, 2021, pp. 214–215). Table 13.49 adds the six surveys collected by Erutku and Hildebrand (2010, Table 7). Their means range from 7.7 to 49 percent and their medians from 7.8 to 44.5 percent. Against these numbers, the Sherbrooke overcharge of 2.7 percent is small and the Ohio school milk estimate of about 6.5 percent is modest. Prices fell by at least 20 percent when the German cement cartel of 1991–2002 collapsed (Asker and Nocke, 2021, p. 198). Measured against the post-collapse price, the overcharge was thus at least $\frac{0.2}{0.8} = 25$ percent (our computation). This lower bound lies between the median and the mean of the Connor and Bolotova sample. Asker and Nocke describe it as a roughly 20 percent overcharge, unremarkable compared with other cartels (p. 198, note 53).

Table 13.49: Surveys of cartel overcharges

Survey	Cartels	Mean overcharge (%)	Median overcharge (%)
Cohen and Scheffman (1989)	5–7	7.7–10.8	7.8–14.0
Werden (2003)	13	21	18
Posner (2001)	12	49	38
Levenstein and Suslow (2002)	22	43	44.5
Griffin (1989)	38	46	44
OECD (2003)	12	15.75	12.75
Connor and Bolotova (2006)	395	29	19

Notes: The first six rows reproduce Erutku and Hildebrand (2010), Table 7, who take them from a compilation by Connor. The surveys are named as in that table. The last row is from Asker and Nocke (2021, p. 215).

Price effects alone say little about welfare. Barkley (2020) studies a cartel of the four largest generic insulin manufacturers in Mexico from 2003 to 2007, as reported by Asker and Nocke (2021, p. 215). Bid rigging kept prices stable until a large public health-care provider changed its procurement design, which destabilized the cartel. Competitive bidding more than doubled the supply of insulin to the provider's patients. The number of patients with access to insulin rose 42 percent, diabetes-related complications fell 25 percent and diabetes-related deaths fell 3.4 percent. At the other end of the scale is OPEC. Asker et al. (2019) estimate total distortions in the allocation of world oil extraction of $744 billion in net present value. Of this, 14 to 22 percent is attributable to OPEC's market power (Asker and Nocke, 2021, p. 214). Between 1970 and 2014, OPEC generated $148 to $233 billion of productive inefficiency and total welfare losses between $700 billion and $5.7 trillion, in 2014 dollars (Asker et al., 2019, 2021). The two OPEC figures for productive inefficiency are not directly comparable. The 14 to 22 percent share of the $744 billion net present value is $104 to $164 billion (our computation). The $148 to $233 billion range is an inframarginal measure in 2014 dollars. Its width reflects different assumptions about OPEC's effect on the internal efficiency of its members' production (Asker and Nocke, 2021, p. 215, note 92). The range for total welfare reflects the gap between the marginal and inframarginal approaches (note 92). The largest estimate is about 0.15 percent of world GDP over the period (Asker and Nocke, 2021, pp. 215–216). Collusion of this scale can affect the aggregate economy.

Table 13.50: Methods for measuring the effects of collusion

Method	Estimating equation	Identifying assumption	Main threats	Examples
Before, during and after	(13.132)	Cartel periods unrelated to unobserved cost and demand shocks	Cartels form when prices fall, sticky post-cartel prices, misdated periods	Concrete, bromine, Sugar Institute, JEC
Yardstick, difference in differences	(13.133)	Parallel trends in a market the cartel did not affect	Umbrella pricing in the control, differential shocks, one treated unit	Quebec gasoline, ATPCO, Overlap
Collusion index	(13.125)	Exposure to the ring unrelated to local unobservables	Endogenous plant locations, functional form	Ohio school milk
Structural counterfactual	Model of collusive conduct and its primitives	Correct model, equilibrium and but-for conduct	Misspecification, conduct not identified	Stamp ring, Quebec delays, JEC

Notes: Our summary. Equation numbers refer to this chapter.

13.10.3 What the evidence shows

Tables 13.51 and 13.52 collect the cases of this chapter. For each case they report the setting, the type of evidence, the data and method, the key quantitative finding and what it says about the theories of Chapter 12.

Lessons. Six lessons emerge.

(1) *When collusion works, it raises prices substantially, and its effects vary widely.* Cooperative JEC rates were 66 percent above war rates. Bromine pool prices were 65 to 75 percent above

Table 13.51: What the evidence shows: legal cartels, information and gasoline

Case	Evidence	Data and method	Key finding	Theory
Porter (1983a): JEC railroad cartel, 1880–1886	Legal cartel	Weekly rates and tonnage, switching simultaneous equations, EM	Price 66% higher and quantity 33% lower in cooperative weeks, conduct $\theta = 0.336$ (Tables 3–4)	Price wars on the equilibrium path (Green and Porter, 1984), prices below static monopoly
Ellison (1994): JEC re-examined	Legal cartel	Markov switching with logit transitions, serially correlated demand	Unanticipated demand innovations predict wars, coefficient −4.15 (2.64) (Table 3), weekly probability 0.975 that collusion continues, implied by Table 2	Triggers of Green and Porter (1984) fit better than booms (Rotemberg and Saloner, 1986), some secret cuts
Genesove and Mullin (2001): Sugar Institute, 1927–1936	Legal trade association, narrative	Meeting notes, direct marginal cost and Lerner index	Lerner index from 0.031 (1925–27) to 0.080 (1928–30) (Table 1)	Monitoring rules (Stigler, 1964), limited retaliation against cheating
Levenstein (1997): bromine, 1885–1914	Legal pools, narrative	Trade press and firm papers, Markov tests of war regimes	Shields pool price 40.88 vs 24.75 cents. After 1902, 29.3 vs 16.8 cents in cooperation and war	Short wars from imperfect information, long wars from bargaining
Albæk et al. (1997): Danish concrete, 1993–1995	Government-assisted transparency	Published transaction prices, before-after against price indices	Prices of reported grades up 19% from January to October 1994, consumer prices up 1.9%	Transparency facilitates collusion (Proposition 13.19)
Miller (2010): Airline Tariff Publishing, 1991–1995	Prosecuted facilitating practice	Ticket sample; difference in differences, affected vs control routes	Relative fares −$13.57 during the investigation, +$12.71 after settlement, no net change (Table 2)	Signaling, remedies that leave monitoring intact
Carlton et al. (1995): Overlap group, 1984–1990	Prosecuted nonprofits	Cross-section of colleges; regression with Overlap indicators	Ivy-plus-MIT effect −$322 (679), insignificant (Table 6)	Agreement on aid rules need not raise mean prices, low power
Borenstein and Shepard (1996): 59 U.S. cities, 1986–1991	Tacit, no case	Monthly margins, 2SLS on expected demand and cost	Margin elasticities 0.37 to expected demand and −0.37 to expected cost (Table 2)	Collusive margins follow expected future demand
Noel (2007): Toronto, 2001	Competitive benchmark	Twelve-hourly station prices, Markov switching	Asymmetric cycles: relenting jumps of 5.6 cents per liter, cycle of 13.8 half-days (Tables II–III)	Competitive Edgeworth cycles
Clark and Houde (2013): Quebec, 2002–2006	Prosecuted, wiretaps	Court documents, logit demand, simulated incentive constraints	Timed delays raise low-cost firms' volumes 4–6% (Table 7)	Transfers within a cartel (Harrington and Skrzypacz, 2011)
Erutku and Hildebrand (2010): Sherbrooke, 2005–2007	Prosecuted, end of cartel	Weekly prices, difference in differences	−1.75 (0.80) cents per liter vs Montreal, 0.26 (0.82) vs Quebec City (Table 6)	Overcharge estimates depend on the control market

Notes: Our summary of Sections 13.3 to 13.6. Table numbers refer to the cited papers.

Table 13.52: What the evidence shows: prosecuted cartels and statistical detection

Case	Evidence	Data and method	Key finding	Theory
Bernheim and Madsen (2017): lysine, nucleotides, citric acid, EC decisions 2000–2005	Prosecuted	Case records	9 of 22 Commission decisions describe discordant cartels, 6 fully concordant (footnote 2), deviations often unpunished	Tolerated business stealing in imperfect cartels
Asker (2010): New York stamp auctions, 1996–1997	Prosecuted bidding ring	Knockout records, structural private-values model	Seller damages \$36.99 or \$26.50 per ring win vs naive \$74.21 (Table 7)	Knockout design induces overbidding, weak members subsidized
Porter and Zona (1993): Long Island paving, 1979–1985	Detection, with convictions	Public bids, GLS and rank-ordered logit	Cartel ranks LR 8.94, $p = 0.06$, competitive ranks LR 4.3, $p = 0.64$ (Tables 5–6)	Complementary bidding
Porter and Zona (1999): Ohio school milk, 1980–1990	Detection, with confessions	Bids, probit with selection correction, residual correlations, collusion index	Average overcharge about 6.5%, small in the breakdown years, especially conditional on incumbency (Table 17)	Complementary bidding and territorial allocation, multimarket contact

Notes: Our summary of Sections 13.7 to 13.9. Table numbers refer to the cited papers.

prices in noncooperative periods. The Sugar Institute more than doubled the Lerner index, published concrete prices rose 15 to 20 percent within a year, and Ohio school milk cost about 6.5 percent more. Across 395 episodes compiled by Connor and Bolotova (2006), the median overcharge is 19 percent and the mean 29 percent, with a range from −10 to 322 percent. Some cartels achieve much less. The Sherbrooke overcharge was 2.7 percent, and the Overlap estimate cannot be distinguished from zero. Welfare losses can exceed what overcharges suggest. The collapse of a Mexican insulin cartel cut diabetes-related deaths by 3.4 percent, and OPEC's welfare cost may reach trillions of dollars (Section 13.10.2).

(2) *Price wars are real, but they have more than one cause.* The JEC wars fit the monitoring logic of Green and Porter (1984), and Ellison's evidence favors triggers over booms. Levenstein's long bromine wars were bargaining over the division of rents after entry or the expiry of contracts.

(3) *Statistical detection works when part of the market stays outside the ring.* The tests of Porter and Zona (1993, 1999) use the firms outside the ring to define competitive behavior. An inclusive ring can disguise itself. A rejection of the competitive model for one group of firms is evidence that falls short of proof.

(4) *Internal organization matters.* Successful cartels relied on rules that close channels for secret price cuts, on communication, on transfers through delays or inter-firm sales, and on knockout auctions. Cheating was common and often tolerated, as Bernheim and Madsen (2017) predict.

(5) *Price patterns alone rarely identify collusion.* Parallel prices are no evidence, and a price increase becomes informative only together with quantities, costs and the allocation of output (Proposition 13.59). Asymmetric cycles appear in competitive Toronto and in the Quebec cartel. Margins that track expected demand are evidence of tacit collusion only through a specific dynamic restriction. Plus factors that are weak alone can be strong together (Remark 13.62).

(6) *Credible inference needs a competitive benchmark and a theory of the specific scheme.* The most convincing studies combine a model of competitive behavior, a restriction that a particular collusive scheme violates, and outside information, such as testimony or wiretaps, that confirms the mechanism.

Connections. Several threads continue elsewhere in the book. Chapter 15 develops the test of Athey et al. (2011) for collusion among mills in open timber auctions. Competitive and collusive behavior predict the same entry and allocation there, and differ only in prices in sales with two or more mills. Northern open-auction prices lie between the competitive and the fully collusive predictions. Chapter 11 discusses coordinated effects of mergers, which arise when a merger makes tacit collusion easier, as in the analysis of the MillerCoors joint venture. Chapter 6 presents the test of Bresnahan (1987) of collusion against competition in the 1955 automobile price war, which nests the two conduct hypotheses in one model of demand and supply.

13.11 Bibliographic notes

The econometrics of collusion began with the Joint Executive Committee. Porter (1983a) introduced the switching simultaneous-equations model, building on the switching regressions of Kiefer (1980) and the EM algorithm of Dempster et al. (1977). Lee and Porter (1984) added imperfect sample separation, Porter (1985) studied the incidence and duration of the wars, and Hajivassiliou (1989) related the regimes to grain production. Cosslett and Lee (1985) and Hamilton (1989) developed the Markov switching models that Ellison (1994) used to test what started the wars. Berry and Briggs (1988) proposed the test of the order of the regime process. Davies (1987) and Hansen (1992) treat likelihood-ratio tests when a parameter is not identified under the null hypothesis. The history of the cartel is told by MacAvoy (1965) and Ulen (1979).

Narrative evidence from the records of cartels has grown into a literature of its own, and Genesove and Mullin (2001) and Levenstein (1997) are its models. Levenstein and Suslow (2006) survey what determines cartel success. Asker and Nocke (2021) survey the current evidence on collusion, from its prevalence and organization to its detection and its effects on welfare. Marshall and Marx (2012) give a book-length treatment of cartels and bidding rings that draws on many prosecuted cases. Their chapters on the structures of cartels and rings, on the effect of auction design on rings, and on the plus factors of each are used in this chapter. Harrington and Skrzypacz (2011) document the quota-and-transfer schemes of industrial cartels, and Marshall et al. (2013) document how often cartels were troubled by discord. Bernheim and Madsen (2017) explain why a cartel may tolerate cheating.

On information, Stigler (1964) remains the starting point. Albæk et al. (1997) give the cleanest evidence that transparency can raise prices, and Fuller et al. (1990) and Schmitz and Fuller (1995) report related evidence from rail contracts. Borenstein (2004) and Miller (2010) study the Airline Tariff Publishing case, and Carlton et al. (1995) analyze the Overlap case. Kaplow (2013) examines how the law should define a prohibited agreement and questions the weight it places on evidence of communication. His chapters on detection classify market-based evidence, structural conditions, internal records and communications.

Borenstein and Shepard (1996) brought dynamic models of collusion to retail gasoline. The theory of Edgeworth cycles is due to Maskin and Tirole (1988), with the asymmetric extension of Eckert (2003), and Noel (2007) provided the first detailed test. Wang (2009) exploits a regulation of the timing of price changes. Clark and Houde (2013, 2014) and Erutku and

Hildebrand (2010) study the Quebec cartel, using the cost estimates of Houde (2012). Byrne and de Roos (2019) show how stations in Perth learned to coordinate tacitly through price leadership. Abrantes-Metz et al. (2006) propose a screen for collusion based on the variance of prices.

The theory of bidding rings starts with Graham and Marshall (1987), Graham et al. (1990), Mailath and Zemsky (1991) and McAfee and McMillan (1992). Lopomo et al. (2005) show the limits of efficient collusion at English auctions. Asker (2010) is the most detailed empirical study of the internal mechanism of a ring, and Pesendorfer (2000) studies collusion in school milk auctions from outcome data. The deconvolution methods behind Asker's estimates are due to Kotlarski (1966), Li and Vuong (1998) and Krasnokutskaya (2011).

Porter and Zona (1993, 1999) set the template for statistical detection in procurement, and Feinstein et al. (1985) study the clustering of bids. Bajari and Ye (2003) develop tests of conditional independence and exchangeability. Kawai and Nakabayashi (2020), Conley and Decarolis (2016) and Ortner et al. (2020) develop newer screens for procurement. Harrington (2008b) surveys methods for detecting cartels. Harrington (2008a) identifies the opposing effects of leniency on cartel stability, and Chen and Rey (2013) analyze the design of leniency programs, whose theory is in Chapter 12. Miller (2009) measures the effects of the 1993 U.S. program on detection and deterrence. Tests based on the comparison of auction formats, such as that of Athey et al. (2011), are treated in Chapter 15.

On the costs of collusion, Connor and Bolotova (2006) compile overcharges across several hundred cartel episodes. Asker et al. (2019) measure the productive inefficiency caused by OPEC. Barkley (2020) and Caoui (2020) show that the welfare effects of cartels can reach far beyond the overcharge on their own sales.

13.12 Exercises

1. *Conduct and margins in the JEC.*

   (a) Show that the conduct index (13.9) and the collusive Lerner index (13.10) satisfy $\theta = \varepsilon L^c$, with $\varepsilon = -\alpha_1$.

   (b) Treat $\hat{\alpha}_1$ and $\hat{\beta}_3$ as uncorrelated. Use the delta method (Appendix A) to compute the standard error of $\hat{\theta}$ for Porter's maximum likelihood estimates (Table 13.4) and for Ellison's standard model (Table 13.8). You should find about 0.04 and about 0.61.

   (c) Compute the standard error of the Lerner index $1 - e^{-\hat{\beta}_3}$ in both cases. Explain why the margin is much better determined than conduct in Ellison's estimates.

   (d) For model 3 of Table 13.11, compute θ and the value of β_3 that static joint profit maximization would imply (Corollary 13.5). Did the JEC price below the static monopoly level in that model?

2. *Cournot reversion and market shares.* In the model of Assumption 13.2, suppose that price wars are Cournot reversions, so $\theta_{it} = s_{it}$ in wars.

   (a) Show that shares in a war satisfy $p_t \left(1 + \frac{s_{it}}{\alpha_1}\right) = \psi a_i (s_{it} Q_t)^{\psi - 1}$. With two firms, show that

   $$\frac{\alpha_1 + s_{1t}}{\alpha_1 + s_{2t}} = \frac{a_1}{a_2} \left(\frac{s_{1t}}{s_{2t}}\right)^{\psi - 1},$$

   so that war shares do not depend on p_t or Q_t.

(b) Let $\psi = 2$, $a_1 = 1$ and $a_2 = 2$. Show that firm 1's share is $\frac{2}{3}$ under common conduct. Compute its share in a Cournot war when $\alpha_1 = -1.8$ and when $\alpha_1 = -20$. You should find about 0.62 and about 0.66.

(c) Show that, with two firms, the low-cost firm's share is smaller in a Cournot war than under common conduct, and that the difference vanishes as $\alpha_1 \to -\infty$.

(d) Explain how movements of market shares between regimes can help separate conduct regimes from cost regimes (Proposition 13.9). What does the evidence on shares in Section 13.3.2 suggest about the form of reversion in the JEC?

3. *The EM algorithm for a switching regression.* Let $y_t = x_t\beta + \beta_3 I_t + u_t$ for $t = 1, \dots, T$, with $u_t \sim N(0, \sigma^2)$ i.i.d., and with I_t i.i.d. Bernoulli(λ) and independent of (x_t, u_t).

(a) Write the E-step. Use (13.19) to show that the M-step for (β, β_3) solves the normal equations of a least-squares regression of y_t on (x_t, w_t), except that $\sum_t w_t^2$ is replaced by $\sum_t w_t$. Show that the update of the variance is $\hat{\sigma}^2 = \frac{1}{T}\sum_t \left[(y_t - x_t\beta - \beta_3 w_t)^2 + \beta_3^2 w_t(1 - w_t)\right]$.

(b) Explain why replacing I_t by w_t in ordinary least squares, without the correction in (a), does not deliver the maximum likelihood estimator.

(c) Simulate $T = 328$ observations with $x_t = 1$, $\lambda = 0.62$ and $\frac{\beta_3}{\sigma} \in \{1, 2, 3, 5\}$. Run EM from several starting values, classify periods with Proposition 13.11, and report the share of misclassified periods. Compare your results with panel (b) of Figure 13.2, which uses the simultaneous model. Explain why the error at a ratio of 1 is close to that of calling every period collusive.

4. *Transparency with lags and informed buyers.*

(a) In the model of Proposition 13.19, suppose that a secret price cut is detected for sure, but only $k \geq 1$ periods after it begins. The deviator undercuts in every period until then. Show that collusion at p^m with Nash reversion is sustainable if and only if $\delta^k \geq 1 - \frac{1}{N}$. Compute the threshold for $N = 2$ and $k = 1, 2, 4$.

(b) Show that the threshold of Remark 13.22 can be written $\underline{\delta} = \left(1 + \frac{\mu}{N\omega - 1}\right)^{-1}$. A policy raises the detection probability from μ' to μ'' and the share of the market that a secret cut captures from ω' to ω'', with $\omega' > \frac{1}{N}$. Show that the policy makes collusion harder if and only if $\frac{N\omega'' - 1}{N\omega' - 1} > \frac{\mu''}{\mu'}$.

(c) The Danish Competition Council published prices with a lag of about three months (Section 13.5.2). Use (a) and (b) to discuss how the lag affected the two channels through which publication works.

5. *Asymmetric retailers and transfers.* Use the two-firm model of Proposition 13.30 with $\bar{p} = 1$ and $c = 0.6$.

(a) Show that collusion with equal shares is impossible for every $\delta < 1$. Find the share s_L^* that minimizes the threshold discount factor $\underline{\delta}(s_L)$.

(b) The cartel cannot allocate shares directly. At equal prices each firm serves half the market. The low-cost firm can be allowed to serve an extra fraction τ of the market each period, for example by delaying price increases. Find the smallest τ that sustains collusion when $\delta = 0.9$. You should find 0.14.

(c) Clark and Houde (2013) estimate that delays raised the volumes of the low-cost firms by about 4 to 6 percent (Table 13.26). Explain why transfers of this size can matter for stability in their setting, although they are small next to the answer to (b). Relate your answer to the differences between the two models, such as product differentiation, the number of firms and finite punishments (Table 13.27).

6. *Knockouts.*

(a) Knockout bids are 9,000 (A), 8,000 (G), 7,500 (B) and 5,100 (J). Compute the sidepayments under the rule of Definition 13.44 and under the older equal-split rule when the target price is 6,750 and when it is 7,800. Explain why the two rules coincide in the second case.

(b) A member with value $v \in [0,1]$ faces one rival. Suppose that the rival's knockout bid and the highest outside value are independent and uniform on $[0,1]$. Use (13.95) to show that the optimal bid is $b(v) = \frac{4v+1}{5}$, and check the answer against (13.96). For which values does the member overbid?

(c) Remove the sidepayments, so that the payoff is $G(b)A(b)$ as in Remark 13.51. Find the optimal bid under the assumptions of (b), and compare the amount of overbidding with your answer to (b).

(d) In (13.101), suppose that $\ln \kappa_k \sim N(\mu, s^2)$ and $\ln \beta(v_{jk}) \sim N(m_j, a_j^2)$ for $j = 1, 2$, with $m_1 = 0$ and all three components independent. Use Theorem 13.56 to recover the characteristic function of $\ln \kappa_k$, and show that $\mathrm{Cov}(\ln \hat{b}_{1k}, \ln \hat{b}_{2k}) = s^2$. What does the theorem identify that this covariance does not?

7. *Imperfect collusion in a numerical example.* In the model of Section 13.7.2, let $D(p) = 1 - p$, $c_H = 0$, $c_A = 0.2$ and $\phi = 0.04$.

(a) Compute p_H^*, $\underline{p}_A$, Π^C and Π^M. In the stage game, compute the away firm's quoting probability λ_A and the home firm's atom at p_H^*. You should find $\underline{p}_A \approx 0.254$ and $\lambda_A \approx 0.243$.

(b) Verify the condition of Theorem 13.39 and compute δ^0 and δ^M.

(c) For $\delta = 0.3$, solve (13.91) for the price floor and compute $\bar{\Pi}$ and the away firm's entry probability. You should find a floor of about 0.419.

(d) Show that a clean split of the markets at this floor violates (13.92). Explain in words why the cartel tolerates raids above the floor.

8. *Detecting and measuring the effects of collusion.*

(a) Take the reported standard error of the Overlap regression of Table 13.19 as given. Compute the smallest effect of Ivy-plus-MIT membership that a two-sided 5 percent test would detect with probability 0.8. Express it as a share of the average net price of \$12,366.

(b) A cartel operated in months 31 to 90 of a sample of 120 months. An analyst dates it to months 43 to 90 and runs the regression of Remark 13.76. By what factor is the estimated overcharge attenuated?

(c) Use Proposition 13.73 with $q = 0.25$ and $h = 0.1$ to compute the mean duration of cartels discovered after the fact and of cartels ended by detection. Compare both with

the natural mean duration. Which mechanism better describes cartels that end because a member applies for leniency?

(d) Explain why naive damages overstate the seller's loss in Asker's ring, and why bidders outside the ring may also have a claim (Section 13.8.5).

(e) In Example 13.75, let $a = 10$ and $c = 2$. For which taxes $t \in (0, 8)$ is the marginal effect of the cartel less than half of its inframarginal effect? Which of the two effects would a court use to compute damages, and why? You should find $t > 4$.

(f) A screen flags a market when prices leave the 95 percent band of a benchmark model, so that $\mathbb{P}[F \mid \text{not } C] = 0.05$. Suppose $\mathbb{P}[F \mid C] = 0.6$ and the prior probability of collusion is 0.02. Use Remark 13.62 to compute the posterior probability of collusion after one flag, and after two flags from screens that are independent conditional on C and on not C. You should find about 0.20 and about 0.75. Explain why two screens built on the same price series would not be conditionally independent.

(g) Use (13.106) to find the smallest elevation m at which a firm that can triple its output breaks even in the short run on a 20 percent price cut. Relate your answer to the claim that a leniency program for the first price cutter works better than a mandatory price freeze (Example 13.60).

Part IV

Auctions

Chapter 14

Auction Theory for Single-Object Auctions

In most markets the rules of competition are implicit. Auctions are a prominent exception. The seller states how bids will be turned into an allocation and into payments, and the bidders compete under those rules. Offshore oil leases, timber, construction contracts, art and online advertising are all sold or bought this way. For empirical industrial organization the written rules are a gift. In Chapter 3 the way firms compete was an unknown parameter, and in Chapters 4 and 8 marginal costs were recovered only after a demand system had been estimated. In an auction the game form is known, and the remaining assumptions concern the bidders' information and equilibrium play. This chapter develops the theory that turns those assumptions into predictions about bids.

The chapter builds the theory of single-object auctions from the ground up. It proves the results that the book relies on, or sketches the proof where the full argument is long. It starts with the standard formats, the ways in which bidders' information can be related, and the second-price and ascending auctions, where bidding one's value is a dominant strategy. It then solves the first-price auction with symmetric independent private values in two ways, proves the revenue equivalence theorem and derives the optimal auction. A deep dive into Milgrom and Weber (1982) follows. Their model of affiliated values explains the winner's curse, the linkage principle, the revenue ranking of the formats and the seller's incentive to disclose information. The last part relaxes symmetry, fixed participation and noncooperative bidding, and it treats procurement auctions as the mirror image of sales. Along the way we report the empirical magnitudes that the survey of Hortaçsu and Perrigne (2021) and the book on bidding rings by Marshall and Marx (2012) attach to the theory. Worked examples with uniform values run through the chapter. Every number in them is derived in the text or computed numerically by a method that the text describes.

The chapter is the theoretical half of a pair. Its first-order conditions, which express each value as a bid plus a markdown, are the equations that Chapter 15 inverts to recover value distributions from bid data. The markdown is the buyer's version of the Lerner rule of Chapter 2, and the inversion mirrors the recovery of marginal costs in Chapter 4. The analysis of bidding rings connects to the cartel theory of Chapter 12 and to the stamp-auction ring of Chapter 13. A merger of bidders is a special case of the merger analysis of Chapter 11. Appendix B collects the mathematical tools used here, including the envelope theorem, order statistics and affiliation. Section 14.1.3 gives a detailed plan of the chapter and its notation.

14.1 Why Study Auctions

An *auction* is a market institution in which explicit rules map the bids of the participants into an allocation of the object for sale and a set of payments. Auctions organize a large volume of trade. Art and antiques, government procurement contracts, offshore oil and gas leases, timber, electricity, Treasury bills and goods on internet platforms such as eBay are all sold or bought by auction. Internet advertising is priced by auction as well. Writing in the early 1980s, Milgrom and Weber (1982, p. 1089) observed that the U.S. Treasury sold billions of dollars of bills and notes every week by sealed bid. The Department of the Interior sold mineral rights on federal property at auction. The sums at stake can be large. On September 30, 1980, U.S. oil companies paid $2.8 billion for drilling rights on 147 tracts in the Gulf of Mexico. The three most expensive tracts sold for $165 million, $162 million and $121 million (Milgrom and Weber, 1982, p. 1089, footnote 3).

Auctions are also old. Milgrom and Weber (1982, p. 1089), drawing on Cassady (1967), recall that the Greek historian Herodotus described the sale of women as wives in Babylonia around the fifth century B.C. The auction of plundered booty was common during the closing years of the Roman Empire. In China, the personal belongings of deceased Buddhist monks were sold at auction as early as the seventh century A.D.

Sellers choose auctions for two practical reasons. The first is *transparency*. A public agency that procures a road or sells a timber tract under announced rules, with the award determined by the bids, leaves little room for favoritism. The second is *price discovery*. The seller need not know what the object is worth, because competition among bidders who know more than the seller pushes the price toward their valuations.

14.1.1 Why auctions are attractive to empirical economists

The empirical analysis of auction data has grown fast over the past thirty years. Hortaçsu and Perrigne (2021, Section 1, pp. 83–84) give three reasons. The first is the volume of trade. A large share of the goods and services in modern economies is sold or allocated by auction, from procurement contracts and government securities to spectrum rights and wholesale electricity. With the internet, auctions have also become the central mechanism for placing advertisements on users' screens. The second reason is that behavior under well-defined rules is captured well by models of private information and strategic behavior. Auction theory is among the most successful applications of microeconomic theory. Six Nobel laureates in economics since 2001 have published on auctions, including Paul Milgrom and Robert Wilson in 2020 (Hortaçsu and Perrigne, 2021, p. 83).

The third reason is the data. Auction data are plentiful and often public, because transparency laws require the public agencies that run many auctions to release them. They are also of high quality. The analyst usually knows the auction mechanism in detail, and the records do not suffer from the non-response or incomplete response of surveys (Hortaçsu and Perrigne, 2021, pp. 83–84). This matters in industrial organization, where firms rarely reveal the sensitive information that a researcher needs. Theory and data also complement each other. Auction theory does not always settle policy questions. For example, it does not tell a central bank whether to sell Treasury bills by a discriminatory or a uniform price auction. Empirical work fills such gaps with counterfactuals that predict how revenue or procurement costs would change under other rules (Hortaçsu and Perrigne, 2021, p. 83).

Two features of auction data make them valuable for structural work. The first is that the data are rich. Auction records typically contain every bid or at least the winning bid, the

identities of the bidders and of the winner, the number of bidders and characteristics of the object. Many similar objects are often sold under the same rules, which yields large samples of comparable games.

The second feature is that the rules of the game are known to the researcher. Athey and Haile (2007, Section 1) note that the primitives of any strategic model are the set of players, the information structure, the rules of play and the players' objectives. In auction markets these elements can often be described with an unusually high degree of confidence. Contrast this with the industries studied in Chapter 3. There the econometrician does not observe whether firms set prices, set quantities or collude, so conduct becomes a parameter to be estimated. In an auction the seller writes down the game form. The remaining assumptions concern the bidders' information and equilibrium play.

The structural approach to auctions exploits this feature. A model specifies the joint distribution of the bidders' values and information, which we call the *primitives*. Equilibrium play maps the primitives into a distribution of bids. Because the rules are known, this mapping can often be inverted, so that the observed bids reveal the distribution of private information that generated them. Chapter 15 develops this logic in detail, with formal definitions of identification and testability taken from Athey and Haile (2007, Section 1). Much of what can be learned this way requires no parametric assumptions on distribution functions. Identification often rests only on restrictions implied by economic theory. The same authors also stress the limits. Models with common values, risk aversion or unobserved auction heterogeneity are identified only under strong a priori restrictions, and the difficulty is greatest for ascending auctions (Athey and Haile, 2007, Section 1).

Structural empirical work on auctions has addressed a wide range of economic questions. Athey and Haile (2007, Section 1) list the following, among others.

- How are rents divided in auctions of public resources?
- Are the reserve prices set in government auctions adequate?
- How do mergers of bidders affect procurement costs?
- Would different auction rules raise more revenue?
- Is the bundling of procurement contracts efficient?
- How valuable are seller reputations?
- How do the costs of acquiring information affect participation and profits?
- Does bidders' private information create adverse selection?
- Do bidders behave as if they were risk averse?

Auction data also allow us to study the entry of bidders, collusion among bidders and the choice of auction rules. These questions recur throughout this chapter and Chapter 15.

14.1.2 A first look at auction data: offshore oil leases

Hendricks and Porter (1988) provide a vivid illustration of how information shapes auction outcomes. The U.S. federal government leased tracts on the Outer Continental Shelf (OCS) off the coasts of Louisiana and Texas. The leases they study were sold by first-price sealed-bid auctions. The winning bid, called the *bonus*, was paid at the time of the sale. The government also received a royalty equal to one-sixth of the revenues from any oil or gas extracted (Hendricks and Porter, 1988, p. 871). If no exploratory work was done within five years, ownership of the

lease reverted to the government. Until the lease expired or production began, the firm paid a nominal annual rental of $3 per acre on wildcat tracts and $10 per acre on drainage tracts. The government also acted as a bidder in two ways. It announced a reserve price of $25 per acre on most drainage leases, and it kept the right to reject the high bid if it judged the bid too low. In the sample of Hendricks and Porter (1988, p. 871), the high bid was rejected on 7 percent of the wildcat tracts and on 15 percent of the drainage tracts. Their 144 drainage tracts exclude 25 tracts on which the high bid was rejected, for which they have no data. Hortaçsu and Perrigne (2021, Section 4.1, p. 124) describe the same institutions as typical of these sales.

Two kinds of tracts were sold. A *wildcat* tract lies in an area that has not been drilled, and firms may acquire only seismic information about it. A *drainage* tract is adjacent to a tract on which a deposit has been discovered. Firms that own the neighboring tracts learn about the drainage tract from their own drilling. Other firms rely on private seismic surveys and on observable production from adjacent tracts (Hendricks and Porter, 1988, pp. 865–866). Table 14.1 reproduces Table 1 of Hendricks and Porter (1988), which summarizes the wildcat and drainage tracts sold between 1954 and 1969. Tract value is the estimated ex post present value of revenues minus drilling costs. Net profit is tract value minus the discounted royalty and bonus payments of the winning firm.

Table 14.1: Wildcat and drainage tracts on the Outer Continental Shelf, 1954–1969

	Wildcat	Drainage
Number of tracts	1056	144
Number of tracts drilled	748	124
Number of productive tracts	385	86
Average winning bid	2.67	5.76
	(0.18)	(1.07)
Average net profits	1.22	4.63
	(0.50)	(1.59)
Average tract value	5.27	13.51
	(0.64)	(2.84)
Average number of bidders	3.46	2.73

Notes: Reproduced from Hendricks and Porter (1988, Table 1), who take the figures from Hendricks et al. (1987). Dollar figures are in millions of 1972 dollars. Numbers in parentheses are standard deviations of the sample means.

Several facts stand out (Hendricks and Porter, 1988, p. 866). Drainage tracts were drilled and found productive far more often than wildcat tracts. From the table, 86 percent of drainage tracts were drilled against 71 percent of wildcat tracts, and 60 percent were productive against 36 percent. The average value of a drainage tract was more than twice that of a wildcat tract. Yet drainage tracts attracted fewer bidders, 2.73 against 3.46 on average. Average net profit was roughly four times higher on drainage tracts. The government captured 77 percent of the value of wildcat tracts but only 66 percent of the value of drainage tracts.

Why would firms compete less for tracts that were more valuable and less risky? The answer lies in the distribution of information. In a wildcat sale, information is roughly symmetric, because the precision of seismic surveys is unlikely to vary much across firms. In a drainage sale, the neighbor firms are better informed. A non-neighbor firm tends to win precisely when the neighbors' information says the tract is poor. This is a severe form of the *winner's curse*, which Section 14.3.4 studies. Hendricks and Porter (1988, p. 866) report that the neighbor firms'

average share of the value of drainage tracts was about 44 percent, while non-neighbor firms earned approximately zero profits. The example carries three lessons for this chapter. Values can have a large common component, information can be distributed asymmetrically, and data on bids and outcomes allow us to test the theory. Section 14.8.5 derives the equilibrium of a first-price auction with one informed bidder, and Chapter 15 examines the evidence.

14.1.3 Plan of the chapter and notation

The chapter develops the theory in the order in which empirical work uses it. Section 14.2 defines the standard auction formats and shows which of them are strategically equivalent. Section 14.3 sets out the general model of values and information. It defines affiliation, explains the winner's curse and collects the facts about order statistics that we use repeatedly. Section 14.4 solves the second-price and ascending auctions with private values. Section 14.5 solves the first-price auction with symmetric independent private values, Section 14.6 proves revenue equivalence, and Section 14.7 characterizes reserve prices and optimal auctions. Sections 14.8 and 14.9 study affiliated values following Milgrom and Weber (1982). Sections 14.10 to 14.12 treat asymmetric bidders, entry and collusion. Section 14.13 turns to procurement, and Section 14.14 summarizes what the theory hands to empirical work.

Table 14.2 lists the notation of the chapter. Upper-case letters denote random variables and lower-case letters their realizations. Bold letters denote vectors. Values and equilibrium bids have continuous distributions, so ties occur with probability zero and the tie-breaking rule does not matter. The exceptions are the one-informed-bidder model of Section 14.8.5 and the weak cartel of Section 14.12. There bids have atoms, and ties at the reserve price are broken at random.

14.2 Auction Formats and Strategic Equivalence

Auctions differ in many details. Three questions classify the formats used in practice. How many objects are sold? How do the allocation and the payments depend on the bids? How is the bidding organized? This section answers them, defines the formats we study and shows that some formats that look different are the same game.

14.2.1 A classification

The first question is the number of objects. In a *single-unit* auction one indivisible object is sold or procured, such as an oil lease, a painting, a road construction contract or a timber tract. In a *multi-unit* auction many units are sold at once, as in auctions of Treasury bills, electricity and spectrum licenses. Multi-unit auctions use either *discriminatory* (pay-as-bid) pricing, in which each winning bid pays its own price, or *uniform* pricing, in which all winning units pay one market-clearing price. This book treats single-unit auctions, apart from a short treatment of divisible-good auctions in Section 15.11.

The second question is the rule that determines the winner and the payments. In a *first-price* auction the highest bidder wins and pays its own bid. First-price rules govern most public procurement and some timber sales. In a *second-price* auction the highest bidder wins and pays the second-highest bid. Second-price payment rules, or rules that produce the same outcome, are used in internet advertising, on eBay and in art sales.

The third question is how bids are submitted. In a *sealed-bid* auction each bidder submits one bid without observing the others. Procurement auctions, Treasury bill auctions, internet

Table 14.2: Notation for the auction chapters

Symbol	Meaning
n, $\mathcal{N} = \{1, \ldots, n\}$	number and set of participating bidders
N	number of potential bidders (entry models only)
V_i, v_i	bidder i's value for the object (random variable, realization)
S_i, s_i, $\boldsymbol{S}$, $\boldsymbol{S}_{-i}$	bidder i's signal (type), the vector of all signals and the signals of i's rivals
$\boldsymbol{A} = (A_1, \ldots, A_m)$	other variables that affect values (object attributes)
S_0	the seller's information
$u(\boldsymbol{A}, S_i, \boldsymbol{S}_{-i})$	value function in the general model, $V_i = u(\boldsymbol{A}, S_i, \boldsymbol{S}_{-i})$
V	pure common value
$Y_1 \geq Y_2 \geq \cdots \geq Y_{n-1}$	rivals' signals (or values) in decreasing order, $Y_1 = \max_{j \neq i} S_j$
$v(s, y)$	$\mathbb{E}[V_1 \mid S_1 = s, Y_1 = y]$, expected value given own and highest rival signal
$V_{(k:n)}$, $F_{(k:n)}$	k-th lowest of n draws and its CDF
$\Lambda_n(x)$	$nx^{n-1}(1-x) + x^n$, the map from F to the CDF of $V_{(n-1:n)}$
F, f, F_i, f_i	value distribution and density, and their bidder-specific versions
$\underline{v}$, $\bar{v}$	lower and upper bounds of the support of values
r	reserve price
B_i, b_i, $\beta(\cdot)$, $\beta_i(\cdot)$	bid and equilibrium bid function
G, g	CDF and density of one rival's equilibrium bid
$M_i = \max_{j \neq i} B_j$	highest rival bid
P, R	transaction price and expected revenue $R = \mathbb{E}[P]$
$\phi_i = \beta_i^{-1}$	inverse bid function of bidder i
$G_{M\|B}$, $g_{M\|B}$	distribution and density of the highest rival bid given one's own bid
$L(\alpha \mid s)$	integrating factor of the first-price equilibrium with affiliated signals
$q_i(\boldsymbol{v})$, $\tau_i(\boldsymbol{v})$	allocation and payment rules of a direct mechanism
$Q_i(v)$, $m_i(v)$, $\pi_i(v)$	interim probability of winning, expected payment and expected surplus
$\psi_i(v)$	virtual valuation $v - \frac{1-F_i(v)}{f_i(v)}$
v_0	seller's own value for the object (not a reserve price)
$\eta(b)$	elasticity of the probability of winning with respect to the bid
$\mathcal{U}$	bidder's utility of money, with $\mathcal{U}(0) = 0$
K, p	entry cost and entry probability (entry models only)
$\pi(k)$, $\Pi(p)$	expected profit of an entrant facing $k-1$ rivals, ex ante profit from entry
ω	half-width of the uniform noise in the mineral rights example
c_i, F_c	costs and their distribution in procurement auctions

advertising and some timber sales use sealed bids. In an *open ascending* auction the price rises until only one bidder remains. Art sales, eBay and some timber sales are open ascending auctions. In an *open descending* auction the price falls until a bidder accepts it. Flowers for export are sold this way in the Netherlands (Milgrom and Weber, 1982, footnote 5), and so are some corporate debt securities and initial public offerings.

Combining the answers gives the four standard single-object formats. We define them formally for n bidders and a reserve price $r \geq 0$.

Definition 14.1 (Standard single-object auctions)**.** A *reserve price* r is the minimum bid the seller accepts. Bids below r are rejected, which is the same as not participating.

(i) In the *first-price sealed-bid auction* (FPA) bidders submit bids simultaneously. The highest bid wins if it is at least r, and the winner pays its bid.

(ii) In the *second-price sealed-bid auction* (SPA, or *Vickrey auction*) bidders submit bids simultaneously. The highest bid wins if it is at least r, and the winner pays the larger of r and the highest rival bid.

(iii) In the *English auction* the price rises continuously and bidders drop out until one bidder remains, who wins at the price at which the last rival dropped out. Definition 14.2 makes the rules precise.

(iv) In the *Dutch auction* the auctioneer starts at a price above any bidder's value and lowers it continuously. The first bidder to stop the clock wins and pays the current price, provided it is at least r.

With private values and risk neutrality, bidder i's payoffs in the two sealed-bid formats are

$$u_i^{\mathrm{FP}} = (v_i - b_i)\,\mathbf{1}\Big\{b_i > \max_{j \neq i} b_j,\ b_i \geq r\Big\}, \tag{14.1}$$

$$u_i^{\mathrm{SP}} = \Big(v_i - \max\Big\{r, \max_{j \neq i} b_j\Big\}\Big)\,\mathbf{1}\Big\{b_i > \max_{j \neq i} b_j,\ b_i \geq r\Big\}. \tag{14.2}$$

Two further formats are useful as theoretical devices. In an *all-pay auction* every bidder pays its bid and the highest bid wins. In a *third-price auction* with $n \geq 3$ bidders the highest bid wins and pays the third-highest bid. Section 14.6 uses both to illustrate revenue equivalence.

An *entry fee* is a payment required to submit a bid. Reserve prices and entry fees both screen out bidders with low values, and Section 14.7 studies the resulting trade-off. In a *procurement* (or low-bid) auction a buyer purchases a contract and the bidders are sellers. Each seller has a cost c_i, the lowest bid wins, and the reserve price is the highest price the buyer accepts. Every result in this chapter has a mirror image for procurement, with costs in place of values and the inequalities reversed. Section 14.13 spells this out. Table 14.3 summarizes the formats.

The institutions vary with the good for sale, and Hortaçsu and Perrigne (2021) organize their survey of empirical work around this fact. Governments sell timber harvesting contracts by both first-price sealed bids and ascending auctions, often with binding reserve prices. In U.S. Forest Service *scale auctions*, a bidder submits a price per unit of each species on the tract. The agency ranks bids by their inner product with its own estimates of species volumes. The winner then pays on the volumes harvested. Bidders usually survey the tract themselves before bidding, a step called a *cruise* (Hortaçsu and Perrigne, 2021, Section 2, p. 86). Most procurement auctions are first-price sealed-bid. Contractors bid unit prices on a list of line items with estimated quantities, and public procurement alone accounts for an estimated 10 percent of U.S. GDP (Hortaçsu and Perrigne, 2021, Section 3, p. 101). Oil and gas leases are usually sold by first-price sealed bid (Hortaçsu and Perrigne, 2021, Section 4, p. 124).

Table 14.3: Standard single-object auction formats

Format	Winner	Winner pays	Information revealed during the auction	Typical uses
First-price sealed-bid	highest bid	own bid	none	public procurement, offshore oil and gas leases, some timber sales
Second-price sealed-bid (Vickrey)	highest bid	highest rival bid	none	rare in pure form (internet advertising and eBay proxy bidding use related rules)
English (ascending, button model)	last active bidder	price at which the last rival quits	exit prices and number of active bidders	art and antiques, timber, internet auctions
Dutch (descending)	first bidder to stop the clock	price on the clock	none before the auction ends	flowers in the Netherlands, some debt securities and IPOs
Procurement (low-bid)	lowest bid	own bid, or the lowest rival bid in second-price versions	as in the corresponding sale format	construction and highway contracts, government purchases

Notes: With a reserve price r, bids below r are rejected and a winner pays at least r (at most r in procurement). Uses follow Milgrom and Weber (1982, pp. 1089–1091), Athey and Haile (2007, Section 1 and footnote 2), Hendricks and Porter (1988, p. 871) and Hortaçsu and Perrigne (2021, pp. 86, 101 and 124).

14.2.2 Varieties of the English auction

The English auction comes in several variants, and they are different games (Milgrom and Weber, 1982, pp. 1103–1104). In some, the bidders call out their own bids and the auction ends when nobody is willing to raise the standing bid. In others, the auctioneer calls the bids and a willing bidder indicates assent by a slight gesture, often in a way that preserves the bidder's anonymity. In a variant used in Japan and described by Cassady (1967), the price is posted on an electronic display and rises continuously. A bidder who wishes to remain active holds down a button. Releasing the button is an irreversible withdrawal.

Definition 14.2 (Button auction)**.** Following Milgrom and Weber (1982, p. 1104) and Athey and Haile (2007, Section 2.2.2), the *button auction* (or *clock auction*) has the following rules.

(i) All bidders are active at the starting price, which is zero or the reserve price r.

(ii) The price p rises continuously.

(iii) A bidder may drop out at any price, and a bidder who has dropped out cannot become active again.

(iv) The price at which each bidder drops out and the number of active bidders are observed by all.

(v) When one bidder remains, the auction ends. That bidder obtains the object and pays the price at which the last rival dropped out.

From now on, the term English auction refers to the button auction. A strategy specifies the price at which to quit as a function of the bidder's signal and of the exits observed so far. If k rivals have quit at prices $p_1 \le \cdots \le p_k$, bidder i's strategy is a function $\beta_{ik}(s_i \mid p_1, \ldots, p_k) \ge p_k$. It gives the price at which i quits if no further exit occurs first (Milgrom and Weber, 1982, p. 1104). The auction ends at the second-highest exit price. Figure 14.1 illustrates a button auction with four bidders who quit at their values.

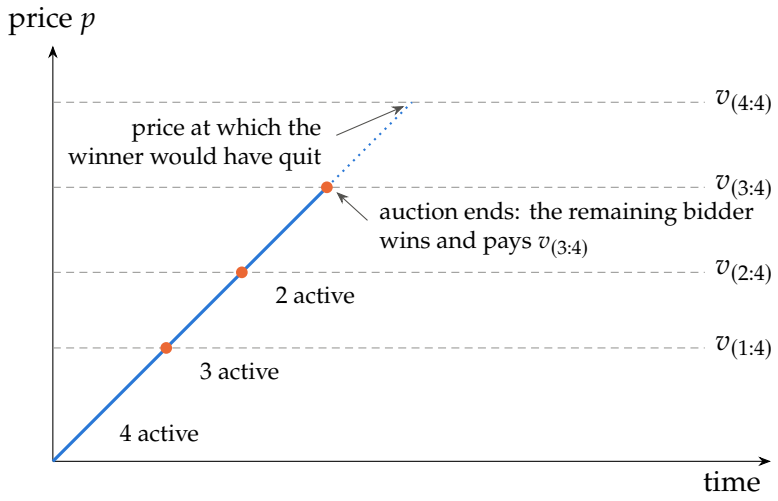

Figure 14.1: A button auction with four bidders. The price rises continuously. Each bidder quits when the price reaches its value (dots), and the number of active bidders is public. The auction ends at the second-highest value $v_{(3:4)}$, and the bidder with the highest value $v_{(4:4)}$ wins.

Real open-outcry auctions depart from this idealization. Bidders call their own prices and may raise the standing bid by large jumps. A bidder may stay silent until late in the auction

and need not reveal the price at which it would quit. Athey and Haile (2007, Section 2.2.2) warn that the button model may then be too great an abstraction. Haile and Tamer (2003) replace it with two weak behavioral restrictions. Bidders never bid more than they are willing to pay, and they never let a rival win at a price they would have been willing to beat. Chapter 15 shows that these restrictions yield bounds on the distribution of values.

14.2.3 Strategic equivalence

Some formats that look different are the same game. The following definition makes this precise.

Definition 14.3 (Strategic equivalence)**.** Two auction formats are *strategically equivalent* if, for every bidder, there is a one-to-one correspondence between the strategies available in the two formats with the following property. Every profile of corresponding strategies produces the same allocation and the same payments, for every realization of the bidders' information.

Strategic equivalence is a property of the rules alone. Payoffs depend on the rules only through the allocation and the payments. Strategically equivalent formats therefore give every bidder the same expected payoff under every strategy profile, so they have the same equilibria. This conclusion holds whatever the bidders' values, information and attitudes toward risk. The equilibrium concept throughout is *Bayesian Nash equilibrium*, a profile of strategies in which each bidder's strategy maximizes its expected payoff given its own information and the strategies of the others. Definition 14.29 states it formally.

Proposition 14.4 (Dutch and first-price auctions)**.** *For any number of bidders, any distribution of values and signals and any preferences over outcomes, the Dutch auction and the first-price sealed-bid auction with the same reserve price are strategically equivalent. Their sets of Bayesian Nash equilibria coincide, and corresponding equilibria produce the same allocation and payments.*

Proof. Consider the Dutch auction. The game ends at the first moment at which some bidder stops the clock. Before that moment, the only event a bidder can observe is that nobody has stopped the clock yet. This event is implied by the fact that the game is still being played. It therefore carries no information beyond the current price, which every bidder can foresee. The decision of a bidder is essentially static (Milgrom and Weber, 1982, p. 1091). A strategy reduces to a function $b_i(s_i)$ that gives the price at which bidder i will stop the clock if nobody has stopped it earlier, where $b_i(s_i) < r$ means never stopping. Given a profile $(b_1, \dots, b_n)$, the winner is the bidder with the highest stopping price, provided it is at least r, and the winner pays that price.

In the first-price auction a strategy is a function $b_i(s_i)$ that gives the sealed bid. The winner is the highest bidder, provided the bid is at least r, and the winner pays its bid. Map each Dutch strategy to the first-price strategy given by the same function $b_i(\cdot)$. This map is one-to-one. Under it, every profile yields the same winner and the same payment for every realization of the signals. The two formats are therefore strategically equivalent, and the equality of their equilibria follows. □

Remark 14.5. The argument uses no assumption about values (Milgrom and Weber, 1982, footnote 11). A bidder need not know its value, and values may be private or common. What the argument requires is that bidders learn nothing while the clock falls. This holds because no bidder acts before the game ends.

Proposition 14.6 (English and second-price auctions with two bidders)**.** *With two bidders, the English (button) auction and the second-price sealed-bid auction with the same reserve price are strategically equivalent, for any joint distribution of values and signals.*

Proof. In the button auction with two bidders, each bidder observes only that its rival is still active as long as both are active. The first exit ends the auction. A strategy is therefore a single number for each signal, the price $d_i(s_i)$ up to which bidder i stays in if the rival is still active (Milgrom and Weber, 1982, p. 1104). A choice $d_i(s_i) < r$ means not participating. The bidder with the higher number wins and pays the price at which the rival quits. That price is the rival's number, or r if the rival does not participate. In the second-price auction the bidder with the higher bid wins and pays the larger of r and the rival's bid. Map each English strategy $d_i(\cdot)$ to the sealed bid $b_i(\cdot) = d_i(\cdot)$. The map is one-to-one, and corresponding profiles give identical outcomes for every realization of the signals. □

Remark 14.7. With three or more bidders the equivalence fails. The prices at which the first bidders quit are public, and a remaining bidder can condition its own quitting price on them through the functions β_{ik}. The strategy sets of the English auction are therefore strictly richer than those of the second-price auction. With interdependent values, early exits also convey information about the value of the object (Milgrom and Weber, 1982, p. 1104). Under private values the two formats remain equivalent in a weaker sense. Each has a dominant strategy equilibrium, and the two equilibria produce the same outcome (Section 14.4). Under affiliated interdependent values the English auction raises at least as much expected revenue as the second-price auction (Proposition 14.64).

14.3 Values, Signals, and Information Structures

What a bidder knows, and how that knowledge relates to the value of the object, drives auction theory. It determines equilibrium bids, the ranking of formats by revenue and what bid data can reveal. This section sets up a general model and classifies its special cases. It then develops three tools used throughout the chapter, namely affiliation, the winner's curse and order statistics.

14.3.1 The general model

There are $n \geq 2$ bidders, indexed by $i \in \mathcal{N} = \{1, \ldots, n\}$, who compete for a single indivisible object. Bidder i's *value* V_i is the money value of the object to bidder i. It may depend on variables nobody knows at the time of the auction, such as the amount of oil in a tract or the price at which a painting can be resold. Bidder i's private information is summarized by a scalar *signal* S_i, also called its *type*, with support $[\underline{s}_i, \bar{s}_i]$. We write $\boldsymbol{S} = (S_1, \ldots, S_n)$ for the vector of signals, $\boldsymbol{S}_{-i}$ for the signals of i's rivals and B_i for i's bid. These conventions follow Athey and Haile (2007, Section 2.1).

We maintain two assumptions on preferences unless we say otherwise. There are *no externalities*, so a losing bidder's payoff does not depend on who wins. Bidders are *risk neutral*. A bidder who wins and pays P receives $V_i - P$, and a bidder who loses and pays nothing receives zero. Bidder i's expected payoff from winning, gross of the payment and conditional on all signals, is

$$\mathbb{E}\big[V_i \mid S_i = s_i, \boldsymbol{S}_{-i} = \boldsymbol{s}_{-i}\big]. \tag{14.3}$$

Information is *incomplete*. Bidder i observes the realization s_i of its own signal but not the rivals' signals. Under *complete information* each bidder would also observe $\boldsymbol{s}_{-i}$. The set of bidders and the joint distribution $F_{S,V}$ of signals and values are common knowledge (Athey and Haile, 2007, Section 2.1). Signals are *informative*, in the sense that the expectation (14.3) strictly increases in s_i for every $\boldsymbol{s}_{-i}$.

Models of auctions differ along two dimensions. The first is statistical. Signals are *independent* if their joint distribution is the product of the marginal distributions, $F_S = \prod_{i=1}^{n} F_i$, and *dependent* otherwise. The second dimension concerns whether rivals' information matters for a bidder's own value.

Definition 14.8 (Private and common values)**.** Bidders have *private values* if, for all i and all $\boldsymbol{s}$,

$$\mathbb{E}\big[V_i \mid \boldsymbol{S} = \boldsymbol{s}\big] = \mathbb{E}\big[V_i \mid S_i = s_i\big]. \tag{14.4}$$

Bidders have *common values* if, for all i and j, $\mathbb{E}[V_i \mid \boldsymbol{S} = \boldsymbol{s}]$ strictly increases in s_j (Athey and Haile, 2007, Definition 2.1).

Under private values, a bidder has no private information about its rivals' values. A bidder would like to know its rivals' signals for strategic reasons, to predict their bids. Learning them would not change its estimate of its own value. Under common values, learning a rival's signal would change that estimate. This is the source of the winner's curse (Athey and Haile, 2007, Section 2.1). The two definitions are not exhaustive. A model in which V_i depends on some rivals' signals but not on others, or only for some realizations, is neither. Athey and Haile (2007, footnote 6) adopt the strict definition of common values for simplicity. Some authors use the term *interdependent values* for the whole framework that allows both private and common values (Athey and Haile, 2007, footnote 8).

Signals play a purely informational role. Any strictly increasing transformation of S_i contains the same information as S_i itself, so the marginal distribution of S_i is not a primitive of the model. Without loss of generality we may therefore impose the normalization

$$S_i = \mathbb{E}\big[V_i \mid S_i\big]. \tag{14.5}$$

Athey and Haile (2007, footnote 5) stress that this degree of freedom belongs to the theoretical model and has nothing to do with econometric identification. Under private values, (14.4) and (14.5) give $\mathbb{E}[V_i \mid \boldsymbol{S}] = S_i$. A risk-neutral bidder then behaves exactly as if it knew its value to be S_i. In private-values models we therefore set $V_i = S_i$ and speak of bidder i's value v_i.

Remark 14.9 (A common factor does not create common values). Suppose that

$$S_i = V_i = V_0 + \epsilon_i, \qquad i = 1, \ldots, n, \tag{14.6}$$

where V_0 is a shock common to all bidders and ϵ_i is idiosyncratic. This is a private-values model, because each bidder knows its own value with certainty (Athey and Haile, 2007, Section 7). The common factor V_0 makes values and signals correlated across bidders. It even makes one bidder's signal correlated with another bidder's value. Still, once bidder i has seen s_i, no rival has information relevant to i's value. The same is true if $V_i = S_i + \eta_i$ with η_i independent of every S_j, $j \neq i$ (Athey and Haile, 2007, footnote 78). The distinction between private and common values concerns what rivals know about one's own value. Correlation of values is a separate matter.

Milgrom and Weber (1982) proposed a general symmetric model that nests the private and common value models. Let $\boldsymbol{A} = (A_1, \ldots, A_m)$ be a vector of additional real-valued variables that influence the value of the object to the bidders. Some components of $\boldsymbol{A}$ may be observed by the seller, such as appraisals of a painting. Others may be observed by nobody at the time of the sale, such as the tastes of connoisseurs who will determine its resale value (Milgrom and Weber, 1982, p. 1097). Bidder i's value is $V_i = u_i(\boldsymbol{A}, \boldsymbol{S})$, and $f(\boldsymbol{a}, \boldsymbol{s})$ denotes the joint density of $(\boldsymbol{A}, \boldsymbol{S})$. Milgrom and Weber write S for our $\boldsymbol{A}$ and X for our $\boldsymbol{S}$.

Assumption 14.10 (General symmetric model)**.** The following hold (Milgrom and Weber, 1982, Assumptions 1–5, pp. 1097–1098).

(i) There is a function u on $\mathbb{R}^{m+n}$ such that $u_i(\boldsymbol{A}, \boldsymbol{S}) = u(\boldsymbol{A}, S_i, \{S_j\}_{j \neq i})$ for all i. All bidders' values depend on $\boldsymbol{A}$ in the same manner, and each bidder's value is a symmetric function of the rivals' signals.

(ii) The function u is nonnegative, continuous and nondecreasing in all its arguments.

(iii) For each i, $\mathbb{E}[V_i] < \infty$.

(iv) The density f is symmetric in its last n arguments, the signals.

(v) The variables $A_1, \ldots, A_m, S_1, \ldots, S_n$ are affiliated (Definition 14.11 below).

The private-values model is the special case $m = 0$ and $V_i = S_i$. The pure common value model is the special case $m = 1$ and $V_i = A_1$ for every i (Milgrom and Weber, 1982, p. 1098). Bidders are risk neutral, so a bidder who wins and pays b receives $V_i - b$. Section 14.9.5 discusses risk aversion in this model.

Two features of Assumption 14.10 deserve comment. First, summarizing a bidder's information by one real number is a substantive assumption. The signal must be a sufficient statistic for the bidder's information about its own value, and it must also summarize what the bidder knows about the rivals' signals (Milgrom and Weber, 1982, footnote 14). Second, the existence of a joint density simplifies the statements. All results except the explicit formulas for equilibrium strategies survive without it, with randomized strategies in place of pure ones (Milgrom and Weber, 1982, footnote 15).

Milgrom and Weber (1982, Section 2.3) motivate the general model with the sale of a painting. The independent private values model requires that each bidder know its value and that values be statistically independent. The first requirement rules out resale at an unknown price, the prestige of owning a painting that others admire and doubts about authenticity. The second rules out a bidder inferring from its own admiration of the painting that others are likely to value it highly too. The general model allows all of these.

14.3.2 A taxonomy of information structures

Restrictions on the joint distribution of signals and values generate the special cases used in the literature. Following Athey and Haile (2007, Section 2.1), we list the main ones.

- *Independent private values* (IPV) are private values with $V_1, \ldots, V_n$ independent.
- *Symmetric independent private values* (SIPV) are private values with $V_1, \ldots, V_n$ independent and identically distributed with CDF F, so that $F_{\boldsymbol{V}}(v_1, \ldots, v_n) = \prod_{i=1}^{n} F(v_i)$.
- *Affiliated private values* (APV) are private values with $(V_1, \ldots, V_n)$ affiliated.

- Values are *common* (CV) when $\mathbb{E}[V_i \mid \boldsymbol{S}]$ strictly increases in every signal, as in Definition 14.8.
- *Pure common values* are common values with $V_i = V$ for all i, so that the object is worth the same to every bidder.
- The *mineral rights* model has pure common values and signals that are independent and identically distributed conditional on V (Wilson, 1977).
- The *general symmetric model* of Assumption 14.10 nests the symmetric versions of all of the above whose signals are affiliated.

A model is *symmetric* if the joint distribution of signals and values is exchangeable in the bidder indices, and *asymmetric* otherwise. Terminology varies across papers. Early work sometimes used "common values" for what we call pure common values. It sometimes used "affiliated values" for what we call common values, even though private values can be affiliated (Athey and Haile, 2007, footnote 8).

Dependence of signals is neither necessary nor sufficient for common values (Athey and Haile, 2007, Section 2.1). Affiliated private values combine dependent signals with private values. Conversely, let S_1 and S_2 be independent and uniform on $[0, 1]$, and suppose both bidders value the object at $V = \frac{S_1+S_2}{2}$. Signals are independent, yet each bidder's value rises with the rival's signal, so values are common. Example 14.44 solves this example. Figure 14.2 maps the models, and Table 14.4 gives definitions and examples.

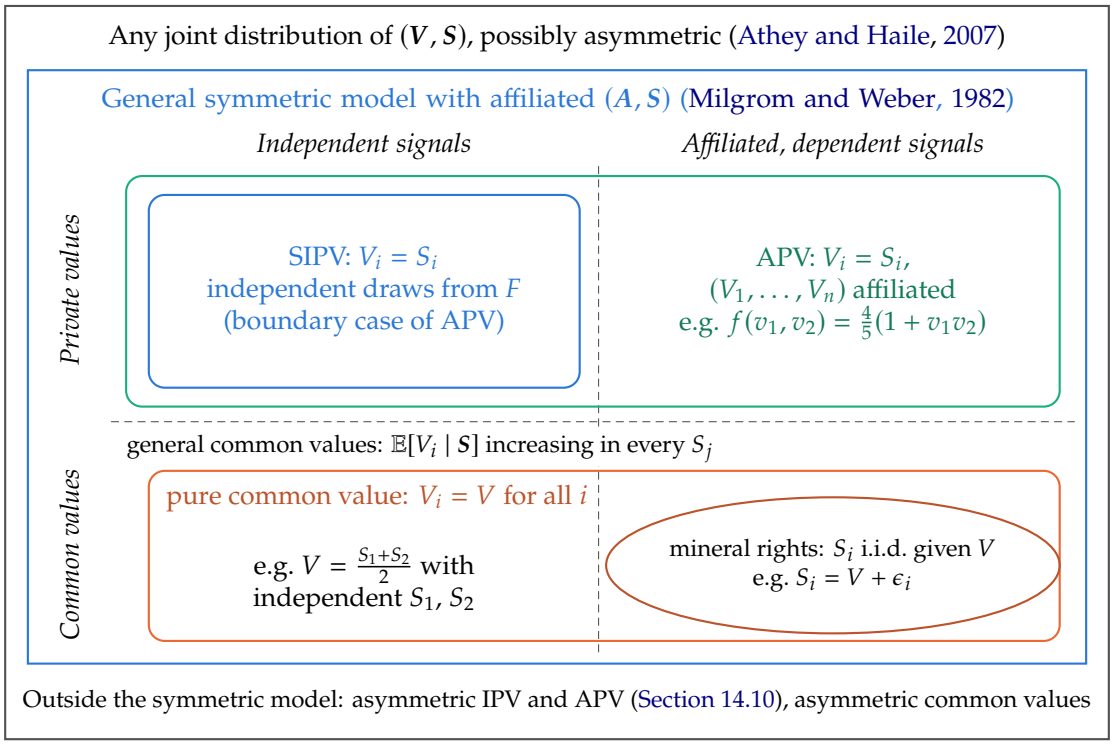

Figure 14.2: A map of information structures. Columns separate independent from affiliated signals, and rows separate private from common values. Independence is the boundary case of affiliation, so SIPV lies inside APV. Pure common values can have independent or dependent signals. The mineral rights model has dependent signals. All symmetric models with affiliated signals and values are special cases of the general model of Milgrom and Weber (1982).

Table 14.4: Information structures: definitions and canonical examples

Model	Definition	Example
SIPV	$V_i = S_i$, values i.i.d. with CDF F	nondurable consumer goods bought for own use (Milgrom and Weber, 1982, p. 1093)
IPV (asymmetric)	$V_i = S_i$, values independent with CDFs F_i	timber tracts sold to mills and loggers with different costs (Athey et al., 2011)
APV	$V_i = S_i$, $(V_1, \ldots, V_n)$ affiliated	a painting bought for own enjoyment by bidders with correlated tastes (Milgrom and Weber, 1982, p. 1099)
Common values	$\mathbb{E}[V_i \mid \boldsymbol{S}]$ strictly increasing in every S_j	timber: private cost differences plus private estimates of timber quality, volume and future market conditions (Athey et al., 2011, Section II.F)
Pure common value	$V_i = V$ for all i	oil, gas and mineral rights (Milgrom and Weber, 1982, Section 2.2)
Mineral rights	pure common value, S_i i.i.d. given V	offshore oil tract with independent seismic estimates (Milgrom and Weber, 1982, p. 1094)
General symmetric model	$V_i = u(\boldsymbol{A}, S_i, \boldsymbol{S}_{-i})$, u symmetric, $(\boldsymbol{A}, \boldsymbol{S})$ affiliated	a painting with resale value, prestige and uncertain authenticity (Milgrom and Weber, 1982, Section 2.3)

Which structure fits a market is an empirical judgment. Milgrom and Weber (1982, p. 1093) argue that the private values assumption is most nearly satisfied in auctions of nondurable consumer goods, whose consumption is a personal matter. Mineral rights are the canonical common-value case. The value of an oil tract depends on the unknown amount of recoverable oil, its quality, the ease of recovery and future prices. To a first approximation these are the same for all bidders, while their estimates differ (Milgrom and Weber, 1982, pp. 1093–1094). Athey and Haile (2007, Section 7) add that common values arise whenever the good is not consumed immediately and bidders have different information about future market conditions. They also arise when bidders run their own surveys, or process the same public data with different methods. Many markets mix both elements. In timber auctions, differences in bidders' costs and contractual arrangements create private value differences. Bidders also form private estimates of the quality and quantity of timber and may disagree about future market conditions. This adds a potential common value component (Athey et al., 2011, Section II.F). Resale opportunities can create common values even when final consumption values are private (Haile, 2001). In Haile's model of timber auctions, a bidder's value includes the option to resell the contract or to buy timber afterward in an active secondary market. The losing bidders are potential buyers at resale, so rivals' information matters for each bidder's value. Resale makes the prices at which bidders drop out rise with the number of bidders. Under common values the winner's curse makes them fall (Hortaçsu and Perrigne, 2021, Section 2.6.4, p. 100).

14.3.3 Affiliation

Most results on interdependent values require that signals and values be positively related in a strong sense, called affiliation. For vectors $z, z' \in \mathbb{R}^k$, write $z \vee z'$ for their component-wise maximum and $z \wedge z'$ for their component-wise minimum.

Definition 14.11 (Affiliation)**.** Random variables $\boldsymbol{Z} = (Z_1, \ldots, Z_k)$ with joint density f are *affiliated* if, for all $z, z' \in \mathbb{R}^k$,

$$f(z \vee z')\, f(z \wedge z') \;\geq\; f(z)\, f(z'). \tag{14.7}$$

Inequality (14.7) is also known as the FKG inequality and as the MTP_2 property (multivariate total positivity of order two). Roughly, it says that large values of some of the variables make the other variables more likely to be large than small (Milgrom and Weber, 1982, p. 1098). To see this, take $k = 2$, $z = (x', y)$ and $z' = (x, y')$ with $x' > x$ and $y' > y$. Then $z \vee z' = (x', y')$ and $z \wedge z' = (x, y)$, and (14.7) reads

$$f(x', y')\, f(x, y) \;\geq\; f(x', y)\, f(x, y'). \tag{14.8}$$

Pairs of points in which both coordinates move together are at least as likely as pairs in which they move in opposite directions. When z and z' are ordered, say $z \leq z'$, we have $z \vee z' = z'$ and $z \wedge z' = z$, so (14.7) holds with equality. Only unordered pairs impose restrictions. Taking logarithms shows that affiliation means that $\ln f$ is *supermodular*,

$$\ln f(z \vee z') + \ln f(z \wedge z') \;\geq\; \ln f(z) + \ln f(z').$$

Section B.9.6 restates the definition for reference, together with a version that does not require densities. The next result makes the condition easy to check.

Proposition 14.12 (Characterization of affiliation)**.** *Let $f : \mathbb{R}^k \to \mathbb{R}$ be a density.*

(i) If f is strictly positive and twice continuously differentiable, then f is affiliated if and only if $\frac{\partial^2 \ln f}{\partial z_i\, \partial z_j} \geq 0$ for all $i \neq j$.

(ii) If $f(z) = g(z)h(z)$, where g and h are nonnegative functions that satisfy (14.7), then f is affiliated.

Proof. Part (ii) follows by multiplying the inequalities for g and h, which is legitimate because both sides are nonnegative:

$$\begin{aligned} f(z \vee z')f(z \wedge z') &= \big[g(z \vee z')g(z \wedge z')\big]\big[h(z \vee z')h(z \wedge z')\big] \\ &\geq g(z)g(z')\, h(z)h(z') \\ &= f(z)f(z'). \end{aligned}$$

For part (i), consider first the bivariate case $k = 2$ with $z = (x, y)$. Suppose that $\frac{\partial^2 \ln f}{\partial x\, \partial y} \geq 0$ everywhere. Ordered pairs satisfy (14.7) with equality. For an unordered pair, relabel so that $z = (x', y)$ and $z' = (x, y')$ with $x' > x$ and $y' > y$. Taking logarithms in (14.8), we must show that

$$\Delta \equiv \ln f(x', y') - \ln f(x, y') - \ln f(x', y) + \ln f(x, y) \;\geq\; 0.$$

Apply the fundamental theorem of calculus first in the first argument,

$$\Delta = \int_x^{x'} \left[\frac{\partial \ln f(a, y')}{\partial a} - \frac{\partial \ln f(a, y)}{\partial a} \right] da,$$

and then in the second argument,

$$\Delta = \int_{x}^{x'} \int_{y}^{y'} \frac{\partial^2 \ln f(a,c)}{\partial a\, \partial c}\, dc\, da \;\geq\; 0.$$

Conversely, suppose f is affiliated. Then $\Delta \geq 0$ for all $x' > x$ and $y' > y$. Divide Δ by $(x'-x)(y'-y)$ and let $x' \to x$ and $y' \to y$. By the double-integral representation and the continuity of the cross partial, the limit is $\frac{\partial^2 \ln f(x,y)}{\partial x\, \partial y}$, which is therefore nonnegative.

For $k > 2$, the "only if" direction follows from the same argument applied to any pair of coordinates (z_i, z_j) with the other coordinates held fixed. The "if" direction uses a result of Topkis (1978, p. 310): a twice continuously differentiable function on a product of intervals is supermodular if and only if all its cross partials are nonnegative. Applied to $\ln f$, this gives part (i) (Milgrom and Weber, 1982, p. 1098). □

For two variables, affiliation is equivalent to a familiar property of conditional densities, and it implies a chain of stochastic orderings.

Proposition 14.13 (Affiliation, likelihood ratios and stochastic dominance)**.** *Let (X, Z) have a strictly positive joint density $f(x,z)$ on $[\underline{x}, \bar{x}] \times [\underline{z}, \bar{z}]$, with marginal density f_Z, conditional density $f(x \mid z)$ and conditional CDF $F(x \mid z)$.*

(i) (X, Z) are affiliated if and only if $f(x \mid z)$ has the monotone likelihood ratio property *(MLRP): for all $z' > z$, the ratio $\frac{f(x|z')}{f(x|z)}$ is nondecreasing in x.*

(ii) If (X, Z) are affiliated, then the ratio $\frac{F(x|z)}{f(x|z)}$ is nonincreasing in z and the hazard rate $\frac{f(x|z)}{1-F(x|z)}$ is nonincreasing in z, for every x.

(iii) If (X, Z) are affiliated, then $F(x \mid z') \leq F(x \mid z)$ for all x and all $z' > z$. Equivalently, $\mathbb{P}(X \geq x \mid Z = z)$ is nondecreasing in z.

Proof. (i) For two variables the only restrictions in (14.7) come from unordered pairs, so affiliation is the inequality $f(x',z')f(x,z) \geq f(x,z')f(x',z)$ for all $x' > x$ and $z' > z$. Divide both sides by $f_Z(z)f_Z(z') > 0$:

$$f(x' \mid z')\, f(x \mid z) \;\geq\; f(x \mid z')\, f(x' \mid z).$$

Divide by $f(x' \mid z) f(x \mid z) > 0$:

$$\frac{f(x' \mid z')}{f(x' \mid z)} \;\geq\; \frac{f(x \mid z')}{f(x \mid z)}.$$

This is the MLRP. Each step can be reversed, which gives the converse (Milgrom and Weber, 1982, footnote 16).

(ii) Fix $z' > z$ and x. For every $t \leq x$, the MLRP gives $\frac{f(t|z')}{f(t|z)} \leq \frac{f(x|z')}{f(x|z)}$, that is,

$$f(t \mid z')\, f(x \mid z) \;\leq\; f(x \mid z')\, f(t \mid z).$$

Integrate both sides over $t \in [\underline{x}, x]$:

$$F(x \mid z')\, f(x \mid z) \;\leq\; f(x \mid z')\, F(x \mid z).$$

Rearranging gives $\frac{F(x|z')}{f(x|z')} \le \frac{F(x|z)}{f(x|z)}$. For the hazard rate, use $t \ge x$ instead. The MLRP gives $f(t \mid z')f(x \mid z) \ge f(x \mid z')f(t \mid z)$. Integrating over $t \in [x, \bar{x}]$ gives $\big[1 - F(x \mid z')\big]f(x \mid z) \ge f(x \mid z')\big[1 - F(x \mid z)\big]$, which rearranges to $\frac{f(x|z')}{1-F(x|z')} \le \frac{f(x|z)}{1-F(x|z)}$.

(iii) By part (ii), for every t,

$$\frac{d}{dt}\ln F(t \mid z') = \frac{f(t \mid z')}{F(t \mid z')} \;\ge\; \frac{f(t \mid z)}{F(t \mid z)} = \frac{d}{dt}\ln F(t \mid z).$$

Integrate from x to $\bar{x}$ and use $F(\bar{x} \mid z') = F(\bar{x} \mid z) = 1$:

$$-\ln F(x \mid z') \;\ge\; -\ln F(x \mid z).$$

Hence $F(x \mid z') \le F(x \mid z)$, and $\mathbb{P}(X \ge x \mid Z = z) = 1 - F(x \mid z)$ is nondecreasing in z. □

The proposition gives the chain

$$\begin{aligned}\text{affiliation} &\iff \text{MLRP}\\ &\implies \text{reverse hazard rate dominance and hazard rate dominance}\\ &\implies \text{first-order stochastic dominance.}\end{aligned}$$

None of the converse implications holds in general. Part (iii) is the sense in which a high value of Z is good news about X. The step from part (ii) to part (iii) reappears in Section 14.10, where reverse hazard rate dominance (Definition 14.73) compares strong and weak bidders. A version of part (ii) for the highest rival signal is a lemma of Milgrom and Weber (1982) (Lemma 14.50).

Example 14.14 (Affiliated and non-affiliated densities)**.**

(a) *Independence.* If $f(\boldsymbol{z}) = \prod_i f_i(z_i)$, then (14.7) holds with equality, because the two sides contain the same factors $f_i(z_i)$ and $f_i(z_i')$. Independent variables are always affiliated (Milgrom and Weber, 1982, p. 1099), and the IPV model is the boundary case of the APV model.

(b) *Mineral rights.* Let V have density h, and let the signals be i.i.d. given V with conditional density $g(s \mid v)$. The joint density is $f(v, \boldsymbol{s}) = h(v)\prod_{i=1}^{n} g(s_i \mid v)$. Suppose g has the MLRP, so that $g(s \mid v)$ satisfies the affiliation inequality in (s, v). As a function of the whole vector $(v, \boldsymbol{s})$, each factor $g(s_i \mid v)$ depends on two coordinates in which it satisfies (14.7). Because $\vee$ and $\wedge$ act coordinate by coordinate, it satisfies (14.7) on the whole vector. The factor $h(v)$ depends on one coordinate and satisfies it trivially. By Proposition 14.12(ii), f is affiliated (Milgrom and Weber, 1982, p. 1099).

(c) *Normal signals.* Let $S_i = V + \epsilon_i$ with $\epsilon_i \sim N(0, \sigma^2)$ independent of V. Then $\ln g(s \mid v) = \text{const} - \frac{(s-v)^2}{2\sigma^2}$, so $\frac{\partial^2 \ln g}{\partial s\,\partial v} = \frac{1}{\sigma^2} > 0$. The MLRP holds, and by part (b) $(V, \boldsymbol{S})$ are affiliated for any prior density of V. More generally, let $\boldsymbol{Z} \sim N(\boldsymbol{\mu}, \Sigma)$. Then $\ln f(\boldsymbol{z}) = \text{const} - \frac{1}{2}(\boldsymbol{z} - \boldsymbol{\mu})^{\top}\Sigma^{-1}(\boldsymbol{z} - \boldsymbol{\mu})$, and

$$\frac{\partial^2 \ln f}{\partial z_i\,\partial z_j} = -\big(\Sigma^{-1}\big)_{ij}.$$

A normal vector is affiliated if and only if every off-diagonal element of the precision matrix Σ^{-1} is nonpositive. For $k = 2$ with standard deviations σ_x, σ_y and correlation ρ, the cross partial equals $\frac{\rho}{(1-\rho^2)\sigma_x\sigma_y}$. The pair is affiliated if and only if $\rho \ge 0$, so a negatively correlated normal pair is not affiliated. For $k \ge 3$, nonnegative correlations are not enough, because the condition concerns partial correlations.

(d) *A polynomial density.* Let (S_1, S_2) have density

$$f(s_1, s_2) = \frac{4}{5}(1 + s_1 s_2) \qquad \text{on } [0,1]^2. \tag{14.9}$$

It integrates to one, since $\int_0^1 \int_0^1 (1 + s_1 s_2)\, ds_1\, ds_2 = 1 + \frac{1}{4} = \frac{5}{4}$. The cross partial of the log density is

$$\frac{\partial^2}{\partial s_1 \partial s_2} \ln(1 + s_1 s_2) = \frac{\partial}{\partial s_2}\left[\frac{s_2}{1 + s_1 s_2}\right] = \frac{(1 + s_1 s_2) - s_2 s_1}{(1 + s_1 s_2)^2} = \frac{1}{(1 + s_1 s_2)^2} > 0,$$

so the density is affiliated. The marginal density of S_1 is $\frac{4}{5}\left(1 + \frac{s_1}{2}\right)$, the conditional density is $f(s_2 \mid s_1) = \frac{2(1+s_1 s_2)}{2+s_1}$, and the conditional CDF is

$$F(s_2 \mid s_1) = \frac{s_2(2 + s_1 s_2)}{2 + s_1}, \qquad \frac{\partial F(s_2 \mid s_1)}{\partial s_1} = \frac{2 s_2 (s_2 - 1)}{(2 + s_1)^2} \le 0.$$

As Proposition 14.13(iii) requires, a higher s_1 shifts the distribution of S_2 up. For example, $F(\frac{1}{2} \mid s_1)$ equals $\frac{1}{2}$, $\frac{9}{20}$ and $\frac{5}{12}$ at $s_1 = 0$, $\frac{1}{2}$ and 1. With $V_i = S_i$ this is an APV model, which Sections 14.8 and 14.9 use as a running example. Figure 14.3 plots the density and the conditional CDFs.

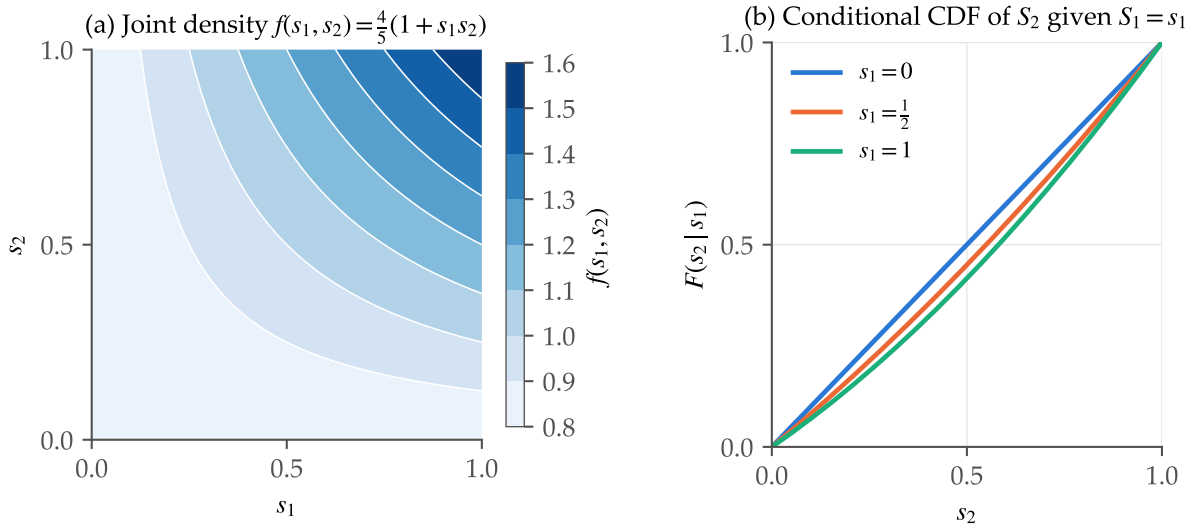

Figure 14.3: The affiliated density $f(s_1, s_2) = \frac{4}{5}(1 + s_1 s_2)$ of Example 14.14(d). Panel (a): the density is highest where both signals are high. Panel (b): the conditional CDF of S_2 shifts down as s_1 rises, so a high signal for one bidder makes high signals of the other more likely.

Affiliation also has a probabilistic meaning that explains why it is the right condition for auction theory. Call a set $A \subseteq \mathbb{R}^k$ *increasing* if its indicator function is nondecreasing. Random variables $\boldsymbol{Z}$ are *associated* if $\mathbb{P}(\boldsymbol{Z} \in A \cap B) \ge \mathbb{P}(\boldsymbol{Z} \in A)\mathbb{P}(\boldsymbol{Z} \in B)$ for all increasing sets A and B. A set $\mathcal{S} \subseteq \mathbb{R}^k$ is a *sublattice* if $\boldsymbol{z} \vee \boldsymbol{z}'$ and $\boldsymbol{z} \wedge \boldsymbol{z}'$ belong to $\mathcal{S}$ whenever $\boldsymbol{z}$ and $\boldsymbol{z}'$ do. Rectangles and order intervals $\{\boldsymbol{z} : \boldsymbol{a} \le \boldsymbol{z} \le \boldsymbol{b}\}$ are sublattices. The general definition in the appendix of Milgrom and Weber (1982) calls $\boldsymbol{Z}$ affiliated if it is associated conditional on every sublattice. For variables with a density this coincides with Definition 14.11 (Milgrom and Weber, 1982, Theorem 24).

Proposition 14.15 (Association and the covariance inequality)**.**

(a) The following statements are equivalent (Milgrom and Weber, 1982, Theorem 22).

(i) $\mathbf{Z}$ is associated.

(ii) For every pair of nondecreasing functions g and h, $\mathbb{E}[g(\mathbf{Z})h(\mathbf{Z})] \geq \mathbb{E}[g(\mathbf{Z})]\,\mathbb{E}[h(\mathbf{Z})]$.

(iii) For every nondecreasing function g and increasing set A, $\mathbb{E}[g(\mathbf{Z}) \mid A] \geq \mathbb{E}[g(\mathbf{Z})] \geq \mathbb{E}[g(\mathbf{Z}) \mid \bar{A}]$, where $\bar{A}$ is the complement of A.

(b) $\mathbf{Z}$ is affiliated if and only if (ii) and (iii) hold conditional on every sublattice $\mathcal{S}$ (Milgrom and Weber, 1982, Theorem 23). That is, $\mathbb{E}[gh \mid \mathcal{S}] \geq \mathbb{E}[g \mid \mathcal{S}]\,\mathbb{E}[h \mid \mathcal{S}]$ and $\mathbb{E}[g \mid A \cap \mathcal{S}] \geq \mathbb{E}[g \mid \mathcal{S}] \geq \mathbb{E}[g \mid \bar{A} \cap \mathcal{S}]$.

Proof sketch for part (a). To show that (i) implies (ii), take g and h nonnegative and bounded. For a positive integer K, define the step function

$$g_K(\boldsymbol{z}) = \frac{1}{K} \sum_{l \geq 1} \mathbf{1}\Big\{g(\boldsymbol{z}) > \frac{l}{K}\Big\},$$

which satisfies $g(\boldsymbol{z}) - \frac{1}{K} \leq g_K(\boldsymbol{z}) \leq g(\boldsymbol{z})$. Each set $A_l = \{\boldsymbol{z} : g(\boldsymbol{z}) > \frac{l}{K}\}$ is increasing. Define h_K and increasing sets $B_{l'}$ in the same way. Association gives

$$\mathbb{E}[g_K h_K] = \frac{1}{K^2} \sum_{l} \sum_{l'} \mathbb{P}(A_l \cap B_{l'}) \;\geq\; \frac{1}{K^2} \sum_{l} \sum_{l'} \mathbb{P}(A_l)\mathbb{P}(B_{l'}) = \mathbb{E}[g_K]\,\mathbb{E}[h_K].$$

Letting $K \to \infty$ proves (ii) for nonnegative bounded functions, and the extension to general g and h is routine. To show that (ii) implies (iii), take $h = \mathbf{1}_A$. Then $\mathbb{E}[g\mathbf{1}_A] \geq \mathbb{E}[g]\mathbb{P}(A)$, which is $\mathbb{E}[g \mid A] \geq \mathbb{E}[g]$. The second inequality follows because $\mathbb{E}[g] = \mathbb{P}(A)\mathbb{E}[g \mid A] + \mathbb{P}(\bar{A})\mathbb{E}[g \mid \bar{A}]$ is a weighted average. To show that (iii) implies (i), take $g = \mathbf{1}_B$. Then $\mathbb{P}(B \mid A) \geq \mathbb{P}(B)$, which is association (Milgrom and Weber, 1982, p. 1119). □

Part (a)(ii) says that nondecreasing functions of affiliated variables are positively correlated. Part (b) says this remains true conditional on order-interval events, such as the event that the highest rival signal lies below one's own. This is the form in which affiliation enters equilibrium analysis. The properties of affiliation used most often are collected next. Write $Y_1 \geq Y_2 \geq \cdots \geq Y_{n-1}$ for the signals of bidder 1's rivals arranged in decreasing order, so that $Y_1 = \max_{j \neq 1} S_j$.

Proposition 14.16 (Properties of affiliated variables)**.** *Let $\mathbf{Z} = (Z_1, \ldots, Z_k)$ be affiliated.*

(i) If $g_1, \ldots, g_k$ are all nondecreasing or all nonincreasing, then $g_1(Z_1), \ldots, g_k(Z_k)$ are affiliated (Milgrom and Weber, 1982, Theorem 3).

(ii) Every subvector of $\mathbf{Z}$ is affiliated. In particular $Z_1, \ldots, Z_{k-1}$ are affiliated (Milgrom and Weber, 1982, Theorem 4).

(iii) For every nondecreasing function H, the function

$$h(a_1, b_1; \ldots; a_k, b_k) = \mathbb{E}\big[H(\mathbf{Z}) \mid a_1 \leq Z_1 \leq b_1, \ldots, a_k \leq Z_k \leq b_k\big]$$

is nondecreasing in all its arguments. In particular, $\mathbb{E}[H(\mathbf{Z}) \mid Z_1 = z_1, \ldots, Z_l = z_l]$ is nondecreasing in $(z_1, \ldots, z_l)$ for each $l = 1, \ldots, k$ (Milgrom and Weber, 1982, Theorem 5).

(iv) Under Assumption 14.10, the variables $A_1, \dots, A_m, S_1, Y_1, \dots, Y_{n-1}$ are affiliated (Milgrom and Weber, 1982, Theorem 2).

Proof. Parts (i) and (ii) follow from Proposition 14.15(b)(ii), and part (iii) follows from Proposition 14.15(b)(iii) (Milgrom and Weber, 1982, p. 1119). Section 14.8.3 gives the arguments. For part (iv), note first that the symmetry of f in the signals implies that the joint density of $(\boldsymbol{A}, S_1, Y_1, \dots, Y_{n-1})$ is

$$(n-1)!\, f(\boldsymbol{a}, s_1, y_1, \dots, y_{n-1})\, \mathbf{1}\{y_1 \geq y_2 \geq \cdots \geq y_{n-1}\} \tag{14.10}$$

(Milgrom and Weber, 1982, eq. (4)). The factor $(n-1)!$ counts the orderings of the rivals' signals that produce the same ordered vector, each of which has the same density by symmetry. The density f is affiliated by Assumption 14.10(v). The indicator of any sublattice satisfies (14.7). If both points lie in the sublattice, both sides equal one, and otherwise the right side is zero. The set $\{y_1 \geq \cdots \geq y_{n-1}\}$ is a sublattice, because the component-wise maximum and minimum of two nonincreasing sequences are nonincreasing. By Proposition 14.12(ii) the product (14.10) is affiliated. □

Parts (iii) and (iv) together imply that $\mathbb{E}[V_1 \mid S_1 = s, Y_1 = y_1, \dots, Y_{n-1} = y_{n-1}]$ is nondecreasing in all its arguments (Milgrom and Weber, 1982, p. 1100). In particular, the expected value of the object to bidder 1 conditional on its own signal and on the highest rival signal, $v(s, y) = \mathbb{E}[V_1 \mid S_1 = s, Y_1 = y]$, is nondecreasing in both arguments. Proposition 14.51 shows that $v(s, s)$ is the equilibrium bid in the second-price auction with affiliated values. Appendix B collects these results with the other mathematical tools of the book.

14.3.4 The winner's curse

Suppose bidders form conditionally independent estimates of a common value V, and each estimate is unbiased. Other things being equal, the bidder with the largest estimate makes the highest bid. The winner therefore tends to be the bidder who overestimated the value the most. On average, the winner finds that it had overestimated V (Milgrom and Weber, 1982, p. 1094). This phenomenon is the *winner's curse*. Petroleum engineers Capen et al. (1971) claimed that it was responsible for the low profits that oil companies earned on offshore tracts in the 1960s (Milgrom and Weber, 1982, p. 1094).

In equilibrium the winner's curse concerns information, and rational bidders do not lose money because of it. Winning reveals to the winner that its signal was more optimistic than its rivals' signals. This revelation is "bad news" about the value of the object (Milgrom, 1981a). Rational bidders anticipate it and condition their bids on the event of winning. The presence of a winner's curse therefore does not imply that winners regret winning (Athey and Haile, 2007, footnote 7). Losses arise for naive bidders who ignore the information contained in winning.

The following result makes the bad news precise in the general symmetric model. Recall that $v(s, y) = \mathbb{E}[V_1 \mid S_1 = s, Y_1 = y]$. In a symmetric equilibrium with a strictly increasing bid function, bidder 1 wins exactly when $Y_1 < S_1$.

Proposition 14.17 (The bad news in winning)**.** *Suppose Assumption 14.10 holds. For every signal s with $\mathbb{P}(Y_1 < s \mid S_1 = s) > 0$,*

$$\mathbb{E}\big[V_1 \mid S_1 = s,\ Y_1 < s\big] \ \leq\ \min\Big\{v(s, s),\ \mathbb{E}\big[V_1 \mid S_1 = s\big]\Big\}. \tag{14.11}$$

Both inequalities are strict if $v(s, y)$ is strictly increasing in y and $\mathbb{P}(Y_1 < s \mid S_1 = s) < 1$. Under private values, $v(s, y) = s$ and both hold with equality.

Proof. By the law of iterated expectations,

$$\mathbb{E}\big[V_1 \mid S_1 = s,\ Y_1 < s\big] = \mathbb{E}\big[v(s, Y_1) \mid S_1 = s,\ Y_1 < s\big].$$

By Proposition 14.16(iii) and (iv), $\varphi(y) \equiv v(s, y)$ is nondecreasing in y. All expectations below are conditional on $S_1 = s$. For $y < s$ we have $\varphi(y) \le \varphi(s)$, so

$$\mathbb{E}[\varphi(Y_1) \mid Y_1 < s] \ \le\ \varphi(s) = v(s, s),$$

which is the first inequality. For $y \ge s$ we have $\varphi(y) \ge \varphi(s)$, so $\mathbb{E}[\varphi(Y_1) \mid Y_1 \ge s] \ge \varphi(s) \ge \mathbb{E}[\varphi(Y_1) \mid Y_1 < s]$. The unconditional mean is a weighted average of the two conditional means,

$$\begin{aligned}\mathbb{E}[V_1 \mid S_1 = s] = \mathbb{E}[\varphi(Y_1)] &= \mathbb{P}(Y_1 < s)\,\mathbb{E}[\varphi(Y_1) \mid Y_1 < s] + \mathbb{P}(Y_1 \ge s)\,\mathbb{E}[\varphi(Y_1) \mid Y_1 \ge s] \\ &\ge \mathbb{P}(Y_1 < s)\,\mathbb{E}[\varphi(Y_1) \mid Y_1 < s] + \mathbb{P}(Y_1 \ge s)\,\mathbb{E}[\varphi(Y_1) \mid Y_1 < s] \\ &= \mathbb{E}[\varphi(Y_1) \mid Y_1 < s],\end{aligned}$$

which is the second inequality. If φ is strictly increasing, the inequalities between conditional means are strict whenever both events have positive probability. Under private values, $\mathbb{E}[V_1 \mid S_1 = s, Y_1 = y] = s$ for all y. □

The proof uses affiliation only to guarantee that $v(s, y)$ is nondecreasing in y. Interdependence of values is what creates the curse. In the example $V = \frac{S_1+S_2}{2}$ with independent signals, $v(s, y) = \frac{s+y}{2}$ rises strictly with y, and the curse is present without any dependence between signals.

The proposition explains why naive bidding fails. Suppose that in a first-price auction every bidder naively bids its unconditional estimate $\mathbb{E}[V_1 \mid S_1 = s]$, which increases with s. Bidder 1 then wins exactly when $Y_1 < s$. Its expected profit conditional on winning is

$$\mathbb{E}\big[V_1 \mid S_1 = s,\ Y_1 < s\big] - \mathbb{E}\big[V_1 \mid S_1 = s\big] \ \le\ 0,$$

which is strictly negative under common values. Naive bidders lose money on average whenever they win. Equilibrium bids correct for the bad news, as Section 14.8 shows.

Example 14.18 (The size of the curse with uniform errors)**.** Consider a mineral rights model with $S_i = V + \epsilon_i$, where the errors ϵ_i are i.i.d. uniform on $[-\omega, \omega]$ and independent of V, and $\omega > 0$ is the half-width of the noise. Each signal is an unbiased estimate, $\mathbb{E}[S_i - V] = 0$. The highest signal is $S_{(n:n)} = V + \epsilon_{(n:n)}$. Write $\epsilon_i = -\omega + 2\omega U_i$ with U_i i.i.d. uniform on $[0, 1]$, so that $\epsilon_{(n:n)} = -\omega + 2\omega U_{(n:n)}$. The maximum of n uniforms has CDF x^n on $[0, 1]$, so

$$\mathbb{E}\big[U_{(n:n)}\big] = \int_0^1 \big(1 - x^n\big)\,dx = 1 - \frac{1}{n+1} = \frac{n}{n+1}.$$

Therefore

$$\mathbb{E}\big[S_{(n:n)} - V\big] = -\omega + 2\omega\,\frac{n}{n+1} = \omega\,\frac{2n - (n+1)}{n+1} = \omega\,\frac{n-1}{n+1}. \tag{14.12}$$

The bias is zero for $n = 1$, equals $\frac{\omega}{3}$ for $n = 2$ and rises toward ω as n grows. The same steps with $\mathbb{E}[U_{(n-1:n)}] = \frac{n-1}{n+1}$, derived in (14.19) below, give $\mathbb{E}[S_{(n-1:n)} - V] = \omega\frac{n-3}{n+1}$. Figure 14.4 plots both.

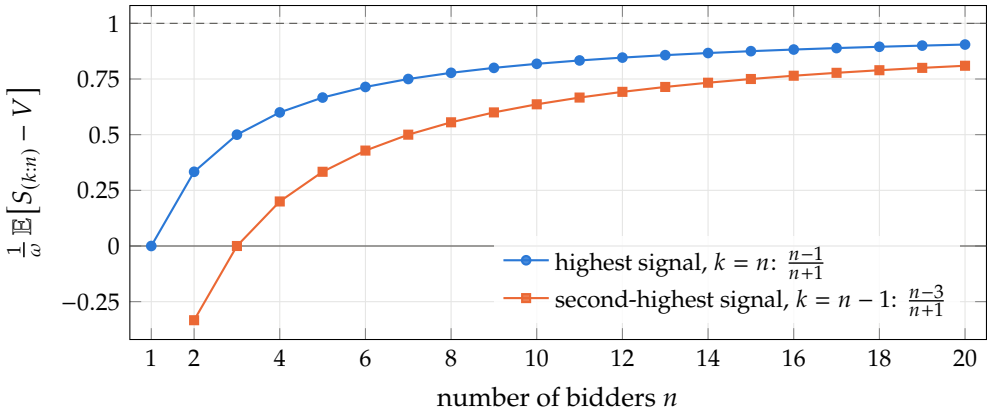

Figure 14.4: The winner's curse in the mineral rights model with uniform errors on $[-\omega, \omega]$ (Example 14.18). Each signal is unbiased, yet the highest of n signals overstates the common value by $\omega\frac{n-1}{n+1}$ on average. The bias grows with the number of bidders and approaches ω (dashed line).

More competition makes the bad news in winning worse. With private values, more bidders make each bidder bid more aggressively (Section 14.5). With common values, a rational bidder must also correct for a larger bias in the event of winning. In Example 14.18, suppose that the prior on V is *diffuse*, that is, flat over every value that the signals allow. The second-price equilibrium bid is then $s - \omega\frac{n-2}{n}$, a correction that grows with n (Example 14.52). The net effect of more bidders on bids is therefore ambiguous under common values. For the same reason, bids that fall as the number of bidders rises are a misleading test for the winner's curse (Laffont, 1997). Section 14.8.4 describes a sharper test based on the pivotal value. Hendricks and Porter (1988) test whether bidders in the drainage sales of Table 14.1 bid in a way that accounts for the curse (Chapter 15).

Remark 14.19 (Information aggregation). The winner's curse has a positive counterpart. It is tempting to think that the price in a mineral rights auction conveys no more information than the winner's own estimate. This reasoning is incorrect, since the winning estimate is the maximum of all estimates and so bounds every loser's estimate (Milgrom and Weber, 1982, p. 1094). Let $g(s \mid v)$ be the density of a bidder's estimate when $V = v$. Many one-parameter families have the MLRP, so that for $v_1 < v_2$ the ratio $\frac{g(s|v_1)}{g(s|v_2)}$ declines as s increases. If this ratio approaches zero, the first-price price with many bidders is a consistent estimator of V, even if no bidder can estimate V closely on its own (Wilson, 1977; Milgrom, 1979). Prices can thus aggregate dispersed private information.

Remark 14.20 (Privacy versus accuracy of information). Milgrom and Weber (1982, p. 1094) stress that a bidder's expected profit in a mineral rights auction depends more on the privacy of its information than on its accuracy. In a first-price auction, a bidder whose information is also available to some other bidder earns zero expected profit in equilibrium (Engelbrecht-Wiggans et al., 1983). This logic fits the near-zero profits of the non-neighbor firms in the drainage sales, whose information was public and therefore also known to the neighbor firms. Proposition 14.54 proves a related result for second-price auctions.

14.3.5 Order statistics

Payments and winning probabilities in auctions are governed by order statistics of bids or values. The winner of a second-price auction pays the second-highest bid. In a first-price

auction a bidder's probability of winning is the probability that the highest rival bid is lower than its own. This subsection collects the facts used throughout this chapter and Chapter 15. Section B.6 restates them for reference and adds joint distributions and identification results.

Let $V_1, \dots, V_n$ be i.i.d. with continuous CDF F and density f. Denote by $V_{(k:n)}$ the k-th lowest of the n draws, so that $V_{(n:n)}$ is the maximum and $V_{(n-1:n)}$ is the second highest. Denote by $F_{(k:n)}$ its CDF. This indexing from lowest to highest follows Athey and Haile (2007, Section 2.1).

Proposition 14.21 (Distribution of an order statistic)**.** *For $k = 1, \dots, n$,*

$$F_{(k:n)}(z) = \frac{n!}{(n-k)!\,(k-1)!} \int_0^{F(z)} t^{k-1}(1-t)^{n-k}\,dt, \tag{14.13}$$

and the density of $V_{(k:n)}$ is

$$f_{(k:n)}(z) = \frac{n!}{(n-k)!\,(k-1)!}\, F(z)^{k-1}\big(1-F(z)\big)^{n-k} f(z). \tag{14.14}$$

Proof. The event $V_{(k:n)} \le z$ occurs if and only if at least k of the n draws are at most z. The number of draws at most z is binomial with parameters n and $F(z)$. Hence

$$F_{(k:n)}(z) = \sum_{j=k}^{n} \binom{n}{j} F(z)^j \big(1-F(z)\big)^{n-j}. \tag{14.15}$$

It remains to show that, for $x \in [0,1]$,

$$\sum_{j=k}^{n} \binom{n}{j} x^j (1-x)^{n-j} = \frac{n!}{(n-k)!\,(k-1)!} \int_0^x t^{k-1}(1-t)^{n-k}\,dt.$$

Both sides vanish at $x = 0$, so it suffices that their derivatives agree. Using $j\binom{n}{j} = n\binom{n-1}{j-1}$ and $(n-j)\binom{n}{j} = n\binom{n-1}{j}$, the derivative of a typical term on the left is

$$\frac{d}{dx}\binom{n}{j} x^j (1-x)^{n-j} = n\binom{n-1}{j-1} x^{j-1}(1-x)^{n-j} - n\binom{n-1}{j} x^j (1-x)^{n-j-1}.$$

Summing over $j = k, \dots, n$, the sum telescopes. The second term for j cancels the first term for $j+1$, and the second term for $j = n$ is zero because $\binom{n-1}{n} = 0$. What remains is the first term for $j = k$,

$$n\binom{n-1}{k-1} x^{k-1}(1-x)^{n-k} = \frac{n!}{(n-k)!\,(k-1)!}\, x^{k-1}(1-x)^{n-k},$$

which is the derivative of the right side. Formula (14.14) follows by differentiating (14.13) with respect to z and applying the chain rule. □

Formula (14.13) appears as equation (5) in Athey and Haile (2002). The density (14.14) has a direct interpretation. One draw falls at z, $k-1$ draws fall below and $n-k$ fall above, and the multinomial coefficient $\frac{n!}{(k-1)!\,1!\,(n-k)!}$ counts the ways of assigning the draws to these three groups.

From bidder i's point of view, the most important order statistic is the highest of its rivals' values, $Y_1 = \max_{j \neq i} V_j$. Under independence, $Y_1 \le y$ if and only if every rival's value is at most y, so

$$F_{Y_1}(y) = F(y)^{n-1}, \qquad f_{Y_1}(y) = (n-1)F(y)^{n-2} f(y). \tag{14.16}$$

This is the case $k = n-1$ of (14.13) applied to the sample of $n-1$ rivals, since $Y_1 = V_{(n-1:n-1)}$ in that sample. If all bidders use the same strictly increasing bid function, a bidder with value v wins with probability $F(v)^{n-1}$.

The transaction price in second-price and ascending auctions is the second-highest value. Its CDF is

$$F_{(n-1:n)}(v) = nF(v)^{n-1}\big(1-F(v)\big) + F(v)^n = \Lambda_n\big(F(v)\big), \qquad \Lambda_n(x) \equiv nx^{n-1}(1-x) + x^n. \quad (14.17)$$

We derive it in two ways. By counting, $V_{(n-1:n)} \le v$ if and only if at least $n-1$ of the n draws are at most v. Either all n draws are at most v, with probability $F(v)^n$, or exactly $n-1$ are, with probability $nF(v)^{n-1}(1-F(v))$. The factor n counts the choices of the single draw above v. Alternatively, set $k = n-1$ in (14.13):

$$\begin{aligned} F_{(n-1:n)}(v) &= \frac{n!}{1!\,(n-2)!}\int_0^{F(v)} t^{n-2}(1-t)\,dt \\ &= n(n-1)\left[\frac{F(v)^{n-1}}{n-1} - \frac{F(v)^n}{n}\right] \\ &= nF(v)^{n-1} - (n-1)F(v)^n \\ &= nF(v)^{n-1}\big(1-F(v)\big) + F(v)^n. \end{aligned}$$

The map Λ_n is a strictly increasing bijection of $[0,1]$. Indeed $\Lambda_n(0) = 0$, $\Lambda_n(1) = 1$, and writing $\Lambda_n(x) = nx^{n-1} - (n-1)x^n$,

$$\Lambda_n'(x) = n(n-1)x^{n-2} - n(n-1)x^{n-1} = n(n-1)x^{n-2}(1-x) > 0 \qquad \text{for } x \in (0,1).$$

Consequently,

$$F(v) = \Lambda_n^{-1}\big(F_{(n-1:n)}(v)\big), \quad (14.18)$$

so the distribution of the second-highest value determines F. The same argument applies to any order statistic, because the right side of (14.13) is strictly increasing in $F(z)$. Athey and Haile (2002, Theorem 1) use this fact to show that F is identified from transaction prices alone, a result developed in Chapter 15.

When F is uniform on $[0,1]$, the density of $V_{(k:n)}$ is $\frac{n!}{(n-k)!\,(k-1)!}x^{k-1}(1-x)^{n-k}$, a beta density with parameters k and $n-k+1$. Using $\int_0^1 x^a(1-x)^b\,dx = \frac{a!\,b!}{(a+b+1)!}$ for nonnegative integers a and b, its mean is

$$\mathbb{E}\big[V_{(k:n)}\big] = \frac{n!}{(n-k)!\,(k-1)!}\int_0^1 x^k(1-x)^{n-k}\,dx = \frac{n!}{(n-k)!\,(k-1)!}\cdot\frac{k!\,(n-k)!}{(n+1)!} = \frac{k}{n+1}. \quad (14.19)$$

The n draws split $[0,1]$ into $n+1$ segments of equal expected length. In particular $\mathbb{E}[V_{(n:n)}] = \frac{n}{n+1}$ and $\mathbb{E}[V_{(n-1:n)}] = \frac{n-1}{n+1}$. Figure 14.5 plots the densities of the two highest of four uniform values, together with the density of the highest of three rival values.

Finally, two facts about expectations are used repeatedly. For a nonnegative random variable X, $\mathbb{E}[X] = \int_0^\infty \mathbb{P}(X > x)\,dx$. For values supported on $[0,\bar v]$, this gives

$$\mathbb{E}\big[V_{(n-1:n)}\big] = \int_0^{\bar v}\Big[1 - \Lambda_n\big(F(v)\big)\Big]dv. \quad (14.20)$$

When signals are dependent, the order statistics of the rivals' signals have the joint density (14.10). In the descending notation of Milgrom and Weber (1982), Y_k is the k-th highest of the $n-1$ rivals' signals, which is $S_{(n-k:n-1)}$ in the ascending notation applied to the rivals' sample.

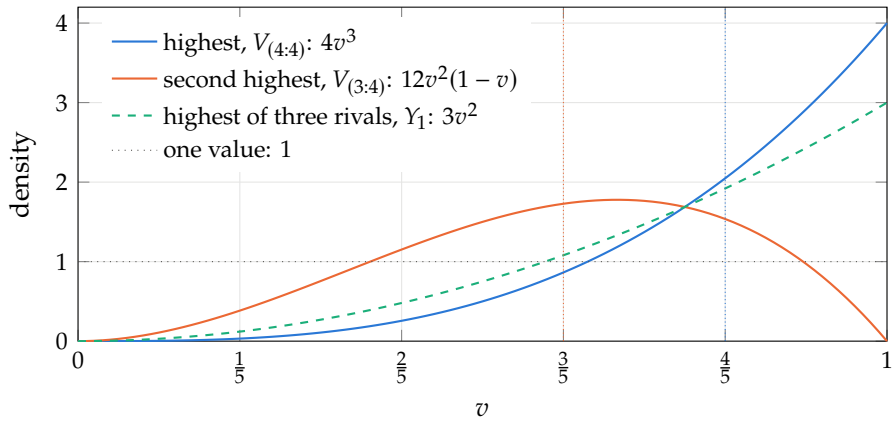

Figure 14.5: Densities of order statistics of $n = 4$ values drawn from the uniform distribution on $[0, 1]$. The vertical lines mark the means $\mathbb{E}[V_{(4:4)}] = \frac{4}{5}$ and $\mathbb{E}[V_{(3:4)}] = \frac{3}{5}$ from (14.19). The dashed curve is the density of the highest of a bidder's three rivals, $f_{Y_1}(v) = 3v^2$, from (14.16).

14.4 Second-Price and Ascending Auctions with Private Values

We now solve the simplest auctions in the simplest information structure. Throughout this section values are private, so each bidder knows its own value v_i. The first two results allow any joint distribution of values. The third specializes to the SIPV model to compute revenue and surplus.

14.4.1 Truthful bidding in the second-price auction

Consider a second-price sealed-bid auction with reserve price $r \geq 0$. Fix bidder i with value v_i and any bids of its rivals. Let

$$\tilde{m} = \max\Big\{r,\ \max_{j \neq i} b_j\Big\}$$

be the *price to beat*, the lowest price at which bidder i can win. By (14.2), bidder i's payoff from a bid $b \geq r$ is

$$u_i(b; \tilde{m}) = (v_i - \tilde{m})\,\mathbf{1}\{b > \tilde{m}\}, \tag{14.21}$$

and its payoff from a bid below r is zero. The payment does not depend on bidder i's own bid, which only determines whether i wins. A strategy is *weakly dominant* if it does at least as well as any other strategy against every profile of rivals' bids. It must also do strictly better than each alternative against some profile. Bids below r are all rejected, so we treat them as one action, not bidding.

Proposition 14.22 (Vickrey 1961)**.** *With private values, bidding one's value, $b_i = v_i$, is a weakly dominant strategy in the second-price sealed-bid auction with any reserve price. The result requires no assumption on the number of bidders, on the joint distribution of values or on the bidder's knowledge of that distribution.*

Proof. Fix $\tilde{m}$. Every bid leads to one of two outcomes. Bidder i either wins and receives $v_i - \tilde{m}$, or loses and receives zero. The bid $b = v_i$ wins exactly when $v_i > \tilde{m}$, so it yields

$$u_i(v_i; \tilde{m}) = \max\{v_i - \tilde{m},\ 0\},$$

the larger of the two possible payoffs. No bid does better against any $\tilde{m}$. If $v_i < r$, the bid v_i is rejected and earns zero, which is optimal because any winning bid pays at least $r > v_i$.

Every other bid does strictly worse against some $\tilde{m}$ (for $v_i < r$, every bid below r is the same action as bidding v_i). A bid $b > v_i$ wins when $v_i < \tilde{m} < b$ and then earns $v_i - \tilde{m} < 0$, where bidding v_i would have earned zero. A bid $b < v_i$ loses when $b < \tilde{m} < v_i$ and earns zero, where bidding v_i would have earned $v_i - \tilde{m} > 0$. Hence $b_i = v_i$ is weakly dominant (Vickrey, 1961). □

Figure 14.6 draws the three cases. Bidding one's value is optimal against every possible price to beat, so a bidder needs no forecast of rivals' behavior. This is why the result needs neither symmetry, nor independence, nor common knowledge of the distribution of values.

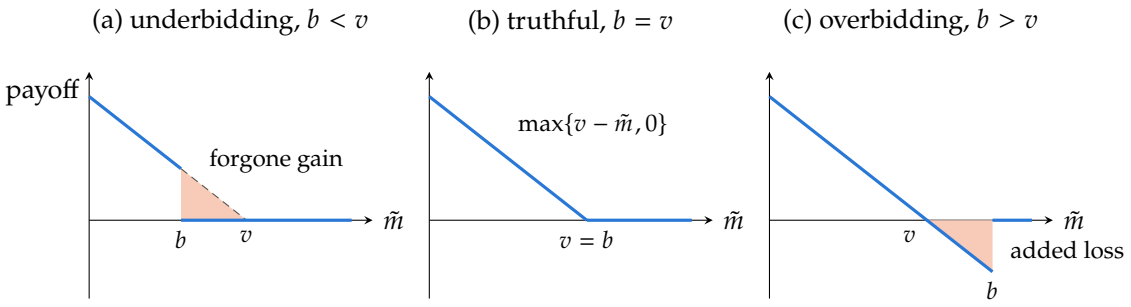

Figure 14.6: Payoff in a second-price auction as a function of the price to beat $\tilde{m}$, for a bidder with value v. Truthful bidding (b) attains $\max\{v - \tilde{m}, 0\}$ for every $\tilde{m}$. Underbidding (a) loses the auction when $b < \tilde{m} < v$ and forgoes the shaded gains. Overbidding (c) wins when $v < \tilde{m} < b$ and adds the shaded losses.

Remark 14.23 (What the result does and does not need). The proof compares only the sign of $v_i - \tilde{m}$. It therefore holds for any increasing utility of money $\mathcal{U}$ with $\mathcal{U}(0) = 0$, so a risk-averse bidder also bids its value (Section 14.5 uses this). The proof does require private values. With interdependent values a bidder does not know its value when it bids, and the payoff $v_i - \tilde{m}$ is replaced by an expectation that depends on what winning at price $\tilde{m}$ reveals. Proposition 14.51 shows that the equilibrium bid then becomes $v(s, s)$.

Remark 14.24 (Other equilibria). Truthful bidding is the only weakly undominated strategy, up to the equivalence of all bids below r. The second-price auction has other Bayesian Nash equilibria in weakly dominated strategies. Let values lie in $[\underline{v}, \bar{v}]$ and set $r = \underline{v}$. Suppose bidder 1 bids $\bar{v}$ whatever its value and every other bidder bids $\underline{v}$. Bidder 1 always wins and pays $\underline{v} \leq v_1$, and no other bid gives it more. Any other bidder could win only by bidding above $\bar{v}$, and would then pay $\bar{v} \geq v_j$. Hence no bidder gains by deviating. This equilibrium misallocates the object whenever a rival values it more than bidder 1, and it yields revenue $\underline{v}$. Following Athey and Haile (2007, Section 2.2), we restrict attention to equilibria in weakly undominated strategies.

Remark 14.25 (Second-price auctions in practice). Pure second-price sealed-bid auctions are uncommon in practice (Athey and Haile, 2007, footnote 2). The proxy bidding system of eBay has the flavor of a second-price auction. A bidder submits a maximum, and the system bids on its behalf up to that maximum, so the winner pays roughly the second-highest maximum. Bidders can usually observe and respond to the bids of at least some rivals, however, as in an ascending auction.

14.4.2 The English auction with private values

The same logic solves the button auction of Definition 14.2. The dynamic structure adds nothing under private values, because a bidder has nothing to learn from rivals' exits about its own value.

Proposition 14.26 (English auction with private values)**.** *With private values, consider the English (button) auction with any reserve price. For each bidder, the strategy of remaining active until the price reaches v_i, whatever the history of exits, is weakly dominant. When all bidders follow it, the bidder with the highest value wins whenever that value is at least r. The winner pays*

$$P = \max\{V_{(n-1:n)},\ r\} \qquad \text{if } V_{(n:n)} \geq r, \tag{14.22}$$

where $V_{(n:n)}$ and $V_{(n-1:n)}$ are the highest and second-highest values. If $V_{(n:n)} < r$, the object is not sold. The second-price sealed-bid auction with truthful bids produces the same allocation and price.

Proof. Fix bidder i, the strategies of its rivals and the realization of the rivals' values. Rivals observe the price and the set of active bidders. As long as bidder i is active, its plans for the future do not affect what the rivals observe. Hence the path of rival exits up to the moment bidder i quits is the same for every strategy of bidder i. Let $\tilde{m}$ be the price at which the last rival would quit along this path. Set $\tilde{m} = r$ if no rival is active at the reserve price, and $\tilde{m} = +\infty$ if some rival never quits. Any strategy of bidder i results in some quitting price d along this path, which may depend on the rival exits it observes. Bidder i wins if $d > \tilde{m}$ and then pays $\tilde{m}$, so its payoff is

$$(v_i - \tilde{m})\,\mathbf{1}\{d > \tilde{m}\}.$$

This has the form (14.21). By the argument in the proof of Proposition 14.22, quitting at $d = v_i$ yields $\max\{v_i - \tilde{m}, 0\}$, the largest payoff available against any $\tilde{m}$. This holds for every profile of rival strategies and every realization of rival values, so the strategy is weakly dominant.

When every bidder follows this strategy, bidders quit in increasing order of their values. The auction ends when the bidder with the second-highest value quits at price $V_{(n-1:n)}$, or at r if that value is below r. The bidder with the highest value wins, provided its value is at least r. The second-price auction with truthful bids gives the same winner and the same price. □

Under private values the English and second-price auctions are therefore equivalent in a weaker sense than strategic equivalence (Milgrom and Weber, 1982, p. 1091). Each has a unique dominant strategy equilibrium, and the two equilibria produce the same outcome. The equilibrium strategy is the one recorded in equation (2.6) of Athey and Haile (2007), under which each bidder bids up to its value. The argument requires that each bidder know its value. It fails when the value depends on what others know, as with minerals of unknown quantity or a painting to be resold at an unknown price.

An allocation is *efficient* if the object goes to the bidder who values it most. Both auctions allocate efficiently whenever some bidder values the object above r. Without a reserve price the outcome is always efficient, or Pareto optimal in the terms of Milgrom and Weber (1982, p. 1091). This conclusion does not depend on symmetry or independence. In symmetric models the Dutch and first-price auctions also allocate efficiently. With asymmetric bidders they need not (Section 14.10). Bidders also need no knowledge of rivals' value distributions or of the number of rivals. Athey and Haile (2007, Section 2.1) note that the common knowledge assumptions are inconsequential for ascending auctions with private values.

14.4.3 Revenue and surplus with symmetric independent private values

We now compute expected revenue and bidders' expected surplus in the SIPV model. Values are i.i.d. with CDF F and density f on $[\underline{v}, \bar{v}]$, with $\underline{v} \geq 0$, and the reserve price satisfies $r \in [\underline{v}, \bar{v}]$. By Proposition 14.26 the formulas apply to both the second-price and the English auction.

Proposition 14.27 (Revenue and surplus in the second-price and English auctions)**.** *Consider the SIPV model with reserve price r.*

(i) Expected revenue is

$$R(r) = r\big[1 - F(r)^n\big] + \int_r^{\bar{v}} \Big[1 - \Lambda_n\big(F(v)\big)\Big] dv. \tag{14.23}$$

Without a binding reserve price, $r = \underline{v}$, this equals $\mathbb{E}[V_{(n-1:n)}] = \underline{v} + \int_{\underline{v}}^{\bar{v}} \big[1 - \Lambda_n(F(v))\big] dv$.

(ii) A bidder with value $v \geq r$ wins with probability $Q(v) = F(v)^{n-1}$, makes the expected payment

$$m(v) = rF(r)^{n-1} + \int_r^v y\, dF(y)^{n-1} = vF(v)^{n-1} - \int_r^v F(y)^{n-1}\, dy, \tag{14.24}$$

and earns the expected surplus

$$\pi(v) = vQ(v) - m(v) = \int_r^v F(y)^{n-1}\, dy. \tag{14.25}$$

Bidders with values below r earn zero.

(iii) If values are uniform on $[0, 1]$, then

$$R(r) = \frac{n-1}{n+1} + r^n - \frac{2n}{n+1} r^{n+1}, \qquad \pi(v) = \frac{v^n - r^n}{n}. \tag{14.26}$$

Without a reserve price, revenue is $\frac{n-1}{n+1}$, each bidder's ex ante expected surplus is $\frac{1}{n(n+1)}$, and total surplus is $\frac{n}{n+1}$.

Proof. (i) The price is $P = \max\{V_{(n-1:n)}, r\}$ if $V_{(n:n)} \geq r$ and zero otherwise. Since $P \geq 0$, $\mathbb{E}[P] = \int_0^\infty \mathbb{P}(P > p)\, dp$. For $p < r$, $P > p$ if and only if the object is sold, that is, $V_{(n:n)} \geq r$. This has probability $1 - F(r)^n$. For $p \geq r$, $P > p$ if and only if $V_{(n-1:n)} > p$, since $V_{(n-1:n)} > p \geq r$ already implies $V_{(n:n)} > r$. By (14.17) this has probability $1 - \Lambda_n(F(p))$, which is zero for $p \geq \bar{v}$. Hence

$$R(r) = \int_0^r \big[1 - F(r)^n\big] dp + \int_r^{\bar{v}} \Big[1 - \Lambda_n\big(F(p)\big)\Big] dp,$$

which is (14.23). With $r = \underline{v}$ we have $F(r) = 0$, and the first term equals $\underline{v}$.

(ii) A bidder with value $v \geq r$ wins if and only if $Y_1 < v$. By (14.16), $Q(v) = F(v)^{n-1}$. When it wins, it pays $\max\{Y_1, r\}$. Hence

$$m(v) = \mathbb{E}\big[\max\{Y_1, r\}\, \mathbf{1}\{Y_1 < v\}\big] = rF(r)^{n-1} + \int_r^v y\, dF(y)^{n-1}.$$

Integration by parts gives

$$\int_r^v y\, dF(y)^{n-1} = vF(v)^{n-1} - rF(r)^{n-1} - \int_r^v F(y)^{n-1}\, dy.$$

Substituting, $m(v) = vF(v)^{n-1} - \int_r^v F(y)^{n-1}dy$, and therefore $\pi(v) = vF(v)^{n-1} - m(v) = \int_r^v F(y)^{n-1}dy$.

(iii) With $F(v) = v$ on $[0,1]$ we have $\Lambda_n(v) = nv^{n-1} - (n-1)v^n$. Then

$$\int_r^1 \big[1 - \Lambda_n(v)\big]dv = (1-r) - (1-r^n) + \frac{n-1}{n+1}\big(1 - r^{n+1}\big).$$

Adding $r(1-r^n)$ gives

$$\begin{aligned} R(r) &= r - r^{n+1} + r^n - r + \frac{n-1}{n+1} - \frac{n-1}{n+1}\,r^{n+1} \\ &= \frac{n-1}{n+1} + r^n - \frac{2n}{n+1}\,r^{n+1}. \end{aligned}$$

With $r = 0$, revenue is $\frac{n-1}{n+1}$, which matches $\mathbb{E}[V_{(n-1:n)}]$ in (14.19). The surplus is $\pi(v) = \int_r^v y^{n-1}dy = \frac{v^n - r^n}{n}$. With $r = 0$, the ex ante surplus is $\mathbb{E}[\pi(V)] = \frac{1}{n}\int_0^1 v^n\,dv = \frac{1}{n(n+1)}$. Total surplus is $\mathbb{E}[V_{(n:n)}] = \frac{n}{n+1}$, because the allocation is efficient. As a check, revenue plus the surplus of all n bidders is $\frac{n-1}{n+1} + \frac{n}{n(n+1)} = \frac{n}{n+1}$. □

Formula (14.25) is the first appearance of a general principle. The interim surplus of a bidder depends only on the probabilities of winning of lower types,

$$\pi(v) = \pi(r) + \int_r^v Q(y)\,dy.$$

Section 14.6 shows that this relation holds in every auction and is the source of revenue equivalence.

The reserve price trades off two effects. Differentiating (14.26),

$$R'(r) = nr^{n-1} - 2nr^n = nr^{n-1}(1-2r).$$

Revenue rises with r up to $r = \frac{1}{2}$ and falls afterward, for every n. A higher reserve raises the price when exactly one bidder values the object above r. It loses the sale when nobody does. For uniform values, Section 14.7 shows that $r = \frac{1}{2}$ maximizes expected revenue among all selling mechanisms, a result due to Myerson (1981) and Riley and Samuelson (1981). Table 14.5 evaluates the formulas of Proposition 14.27 for several numbers of bidders.

Table 14.5: Second-price and English auctions with uniform values on $[0,1]$

	Expected revenue		Total surplus		Surplus per bidder		Probability
n	$r=0$	$r=\frac{1}{2}$	$r=0$	$r=\frac{1}{2}$	$r=0$	$r=\frac{1}{2}$	of no sale, $r=\frac{1}{2}$
2	0.3333	0.4167	0.6667	0.5833	0.1667	0.0833	0.2500
3	0.5000	0.5313	0.7500	0.7031	0.0833	0.0573	0.1250
5	0.6667	0.6719	0.8333	0.8203	0.0333	0.0297	0.0313
10	0.8182	0.8183	0.9091	0.9086	0.0091	0.0090	0.0010

Notes: Computed from Proposition 14.27. Revenue is $\frac{n-1}{n+1} + r^n - \frac{2n}{n+1}r^{n+1}$, total surplus is $\frac{n}{n+1}(1-r^{n+1})$, surplus per bidder is $\frac{1}{n}\left[\frac{1-r^{n+1}}{n+1} - r^n(1-r)\right]$ and the probability of no sale is r^n. With $n = 2$ the exact values are $\frac{1}{3}$ and $\frac{5}{12}$ for revenue, $\frac{2}{3}$ and $\frac{7}{12}$ for total surplus and $\frac{1}{6}$ and $\frac{1}{12}$ for surplus per bidder.

Three patterns stand out in Table 14.5. Revenue rises and bidder surplus falls as the number of bidders grows, because the second-highest value moves toward the highest. With two bidders, the reserve price raises revenue from $\frac{1}{3}$ to $\frac{5}{12}$, a gain of 25 percent. Total surplus falls from $\frac{2}{3}$ to $\frac{7}{12}$, because the object goes unsold with probability $\frac{1}{4}$. As n grows, the gain from the reserve price vanishes, since it becomes unlikely that fewer than two bidders value the object above r.

14.4.4 What second-price and English auctions reveal

The dominant strategy results have strong empirical implications, which Chapter 15 develops. In a second-price auction with private values, bids equal values. If all bids from SIPV auctions are observed, they are i.i.d. draws from F, and their empirical distribution estimates F directly. In an English auction the winner's value is never revealed, because the auction stops when the bidder with the second-highest value quits. The transaction price is the most reliably observed outcome. By (14.22) it equals $V_{(n-1:n)}$ when the reserve price does not bind. Because Λ_n is strictly increasing, the distribution of transaction prices in auctions with n bidders determines F through (14.18) (Athey and Haile, 2002, Theorem 1).

Both arguments rest on private values and on the button model. With interdependent values, bids no longer equal values (Section 14.8). In real open-outcry auctions, recorded bids need not equal the prices at which bidders would quit (Section 14.2.2). With asymmetric independent private values, truthful bidding remains dominant and the allocation remains efficient. Revenue is then the expected second-highest of values drawn from different distributions (Section 14.10).

14.5 First-Price Auctions with Symmetric Independent Private Values

In a first-price sealed-bid auction each bidder submits one sealed bid, the highest bid wins, and the winner pays its own bid. Unlike in the second-price auction of Section 14.4, no bidder has a dominant strategy in this format. The best bid depends on how aggressively the rivals bid, so the analysis requires an equilibrium of a game of incomplete information. This section solves that game in the benchmark model of symmetric independent private values (SIPV). We derive the equilibrium bid function in two ways and study its shape in closed-form examples. We then rewrite the equilibrium condition in terms of the distribution of bids, which is the starting point of the empirical methods in Chapter 15. The section ends with reserve prices, multiple equilibria, and risk-averse bidders.

14.5.1 The first-price auction as a Bayesian game

We maintain the following assumption throughout Section 14.5, except where we relax risk neutrality in Section 14.5.7.

Assumption 14.28 (Symmetric independent private values)**.** (i) There are $n \geq 2$ risk-neutral bidders and one indivisible object. (ii) Bidder i privately observes its value V_i. (iii) The values $V_1, \ldots, V_n$ are independent draws from a distribution F with support $[\underline{v}, \bar{v}]$, where $0 \leq \underline{v} < \bar{v} \leq \infty$. The distribution has a finite mean and a continuous density f that is strictly positive on $(\underline{v}, \bar{v})$. (iv) A losing bidder receives zero, whoever wins. (v) The number of bidders n and the distribution F are common knowledge.

The first-price auction (FPA) under Assumption 14.28 is a Bayesian game. The players are the n bidders. A player's type is its value v_i, and types are drawn from the product distribution $\prod_{i=1}^{n} F(v_i)$. An action is a bid $b_i \in \mathbb{R}$. The seller may announce a *reserve price* $r \geq \underline{v}$, which is the lowest bid it accepts. A bidder who does not wish to buy at a price of r or more submits no bid, and we treat this as a bid below r. When bidder i's bid is accepted, its payoff is

$$u_i(b_i, \boldsymbol{b}_{-i}; v_i) = (v_i - b_i)\,\mathbf{1}\Big(b_i > \max_{j \neq i} b_j\Big). \tag{14.27}$$

The payoff depends on the rivals only through their bids. This is the content of private values together with the absence of externalities. Ties are broken at random. They occur with probability zero in every equilibrium we study, because equilibrium bids have continuous distributions.

A *strategy* for bidder i is a bid function β_i that maps each value into a bid. We write $B_j = \beta_j(V_j)$ for bidder j's random bid.

Definition 14.29 (Bayesian Nash equilibrium)**.** A strategy profile $(\beta_1, \ldots, \beta_n)$ is a *Bayesian Nash equilibrium* (BNE) if, for every bidder i and every value v_i, the bid $\beta_i(v_i)$ maximizes

$$\mathbb{E}\Big[(v_i - b)\,\mathbf{1}\Big(b > \max_{j \neq i} \beta_j(V_j)\Big)\Big]$$

over b. The expectation is over the rivals' values. The equilibrium is *symmetric* if $\beta_i = \beta$ for every i.

Each bidder best-responds to the strategies of the others. It knows its own value, treats the rivals' values as random, and shares with them the knowledge of F and of the payoff function.

Consider a bidder who values the object at \$10. If it bids \$10, its payoff is zero whether it wins or loses. If it bids \$9, it earns \$1 each time the bid wins. Any bid with a positive chance of winning beats bidding one's value, so equilibrium bids lie below values. We call the gap $v_i - b_i$ the *shading* of the bid. How much to shade is a trade-off. A lower bid raises the profit conditional on winning but lowers the probability of winning. Let

$$H(b) = \mathbb{P}\Big(\max_{j \neq i} B_j < b\Big)$$

denote the probability that a bid b wins. Bidder i then maximizes

$$U(b; v_i) = (v_i - b)\,H(b). \tag{14.28}$$

This is the problem of a monopsonist that buys one unit. The value plays the role of the buyer's marginal value, the bid is the price, and H is the residual supply curve. We make the analogy precise in Section 14.5.5.

Independence implies that H is the same function for every value v_i. Bidder i's value tells it nothing about the rivals' values, hence nothing about their bids. The next lemma exploits this fact.

Lemma 14.30 (Monotone bidding)**.** *Fix the rivals' strategies and let H be the induced win probability. Let $v' > v$, let b be an optimal bid for value v, and let b' be an optimal bid for value v'. If $H(b) > 0$, then $b' \geq b$. Hence in every equilibrium each bidder's strategy is nondecreasing on the set of values that win with positive probability.*

Proof. Optimality of b for v and of b' for v' gives two inequalities:

$$(v-b)H(b) \geq (v-b')H(b'),$$
$$(v'-b')H(b') \geq (v'-b)H(b).$$

We add them. The terms $-bH(b)$ and $-b'H(b')$ appear on both sides and cancel, which leaves

$$vH(b) + v'H(b') \geq vH(b') + v'H(b).$$

Collecting terms gives

$$(v'-v)\big[H(b') - H(b)\big] \geq 0.$$

Since $v' > v$, we obtain $H(b') \geq H(b)$. Suppose now that $b' < b$. Because H is nondecreasing, $H(b') \leq H(b)$, so $H(b') = H(b) > 0$. Then the bid b' gives value v the payoff $(v-b')H(b)$, which exceeds $(v-b)H(b)$. This contradicts the optimality of b for v, so $b' \geq b$. □

The proof uses one property of the objective. The difference $U(b;v') - U(b;v) = (v'-v)H(b)$ is nondecreasing in b, so the objective has *increasing differences* in (b, v). A higher value makes higher bids relatively more attractive. With affiliated values, H would depend on v_i, and monotonicity requires the stronger tools of Section 14.8.7.

14.5.2 Equilibrium by the first-order condition

Let $Y_1 = \max_{j \neq i} V_j$ denote the highest value among bidder i's rivals. Under Assumption 14.28 its distribution function and density are

$$F_{Y_1}(y) = F(y)^{n-1}, \qquad f_{Y_1}(y) = (n-1)F(y)^{n-2} f(y).$$

The following result is the central equilibrium characterization for first-price auctions.

Proposition 14.31 (Riley and Samuelson, 1981)**.** *Let Assumption 14.28 hold, and let the seller accept only bids of at least $r \in [\underline{v}, \bar{v})$. There is exactly one symmetric equilibrium in strategies that are continuous on $[r, \bar{v})$ and strictly increasing and differentiable on $(r, \bar{v})$. In it, a bidder with value $v < r$ does not bid, and a bidder with value $v \geq r$ bids*

$$\beta(v) = v - \frac{\int_r^v F(t)^{n-1}\,dt}{F(v)^{n-1}}, \tag{14.29}$$

with $\beta(r) = r$. Equivalently,

$$\beta(v) = \mathbb{E}\left[\max\{Y_1, r\} \mid Y_1 < v\right]. \tag{14.30}$$

When $r = \underline{v}$, the fraction in (14.29) has the form $\frac{0}{0}$ at $v = \underline{v}$. The bound $\int_{\underline{v}}^{v} F(t)^{n-1}dt \leq (v-\underline{v})F(v)^{n-1}$ shows that the fraction is at most $v - \underline{v}$, so it vanishes as v falls to $\underline{v}$ and $\beta(\underline{v}) = \underline{v}$. When no reserve price is announced, the rules still bound bids from below, for example by zero. Milgrom and Weber (1982, footnote 25) interpret such a floor as an implicit reserve price. Section 14.5.6 shows what happens without any floor.

Proof. We first derive the bid function from the necessary conditions. We then verify that it is an equilibrium.

Step 1. We establish participation and the boundary condition. Suppose all bidders use a strategy β with the stated properties. A bidder with $v < r$ who wins pays at least $r > v$, so

it prefers not to bid. A bidder must earn a nonnegative expected payoff, since it can always abstain. For $v > r$ this payoff is $(v - \beta(v))F(v)^{n-1}$, which requires $\beta(v) \le v$. Letting v fall to r and using continuity gives $\beta(r) \le r$. Bids below r are rejected, so $\beta(r) \ge r$. Hence

$$\beta(r) = r.$$

Step 2. We write the bidder's objective. Consider a bidder with value $v \ge r$ who bids b in the range $[r, \beta(\bar{v})]$. It wins when every rival bids less than b. A rival with value below r does not bid. A rival with value $V_j \ge r$ bids less than b exactly when $V_j < \beta^{-1}(b)$, because β is strictly increasing. The rivals' values are independent, so the expected payoff is

$$\Pi(b; v) = (v - b)\, F\big(\beta^{-1}(b)\big)^{n-1}. \tag{14.31}$$

Step 3. We derive the first-order condition. By the inverse function rule, $\frac{d}{db}\beta^{-1}(b) = \frac{1}{\beta'(\beta^{-1}(b))}$. Differentiating (14.31) gives

$$\frac{\partial \Pi(b; v)}{\partial b} = -F\big(\beta^{-1}(b)\big)^{n-1} + (v - b)(n-1)F\big(\beta^{-1}(b)\big)^{n-2} f\big(\beta^{-1}(b)\big) \frac{1}{\beta'\big(\beta^{-1}(b)\big)}.$$

For $v \in (r, \bar{v})$ the equilibrium bid $\beta(v)$ lies in the interior of the range, so the derivative vanishes at $b = \beta(v)$. Substituting $\beta^{-1}(\beta(v)) = v$ yields

$$0 = -F(v)^{n-1} + \big(v - \beta(v)\big)(n-1)F(v)^{n-2} f(v) \frac{1}{\beta'(v)}.$$

Step 4. We rewrite the condition as a differential equation. Multiplying by $\beta'(v)$ gives the equilibrium differential equation

$$\beta'(v)F(v)^{n-1} = \big(v - \beta(v)\big)(n-1)F(v)^{n-2} f(v). \tag{14.32}$$

We move the term in $\beta(v)$ to the left:

$$\beta'(v)F(v)^{n-1} + \beta(v)(n-1)F(v)^{n-2} f(v) = v(n-1)F(v)^{n-2} f(v).$$

The left side is the derivative of the product $\beta(v)F(v)^{n-1}$, and the right side is v times the derivative of $F(v)^{n-1}$:

$$\frac{d}{dv}\Big[\beta(v)F(v)^{n-1}\Big] = v\, \frac{d}{dv}\Big[F(v)^{n-1}\Big].$$

Step 5. We solve the differential equation. We integrate both sides from r to v:

$$\beta(v)F(v)^{n-1} - \beta(r)F(r)^{n-1} = \int_r^v t\, d\big[F(t)^{n-1}\big].$$

Integration by parts evaluates the right side:

$$\int_r^v t\, d\big[F(t)^{n-1}\big] = vF(v)^{n-1} - rF(r)^{n-1} - \int_r^v F(t)^{n-1}\, dt.$$

We substitute and use $\beta(r) = r$ from Step 1. The terms $rF(r)^{n-1}$ cancel, which leaves

$$\beta(v)F(v)^{n-1} = vF(v)^{n-1} - \int_r^v F(t)^{n-1}\, dt.$$

Dividing by $F(v)^{n-1} > 0$ gives (14.29). Every candidate satisfies this equation, so there is at most one symmetric equilibrium of the stated form.

Step 6. We check that the candidate is strictly increasing. Rearranging (14.32) gives

$$\beta'(v) = (n-1)\frac{f(v)}{F(v)}\big(v - \beta(v)\big).$$

By (14.29), $v - \beta(v) = \frac{\int_r^v F(t)^{n-1}dt}{F(v)^{n-1}} > 0$ for $v > r$. Hence $\beta'(v) > 0$ on $(r, \bar{v})$, and the candidate is strictly increasing, as assumed.

Step 7. We verify that the candidate is an equilibrium. Suppose all rivals use (14.29). Let $\bar{b} = \sup_v \beta(v)$. A bid above $\bar{b}$ wins for sure, like a bid of $\bar{b}$, but costs more, so it is dominated. A bid below r is rejected and earns zero. Every bid in $[r, \bar{b})$ equals $\beta(z)$ for exactly one $z \in [r, \bar{v})$. A bidder with value v who bids $\beta(z)$ wins with probability $F(z)^{n-1}$, so its payoff from mimicking type z is

$$\Pi(z; v) = \big(v - \beta(z)\big)F(z)^{n-1}.$$

Its derivative with respect to z is

$$\frac{\partial \Pi(z;v)}{\partial z} = -\beta'(z)F(z)^{n-1} + \big(v - \beta(z)\big)(n-1)F(z)^{n-2}f(z).$$

The differential equation (14.32) at z replaces $\beta'(z)F(z)^{n-1}$ by $\big(z - \beta(z)\big)(n-1)F(z)^{n-2}f(z)$. Therefore

$$\frac{\partial \Pi(z;v)}{\partial z} = (n-1)F(z)^{n-2}f(z)\Big[\big(v - \beta(z)\big) - \big(z - \beta(z)\big)\Big] = (n-1)F(z)^{n-2}f(z)\,(v - z).$$

For $v \geq r$ the derivative is positive for $z < v$ and negative for $z > v$. Mimicking one's own type is optimal, and it earns $\int_r^v F(t)^{n-1}dt \geq 0$, which is at least the payoff from abstaining. For $v < r$ the derivative is negative for all $z \geq r$. The best accepted bid is then r, which earns $(v - r)F(r)^{n-1} \leq 0$, so abstaining is optimal.

Step 8. We derive the conditional expectation form. The random variable $\max\{Y_1, r\}$ equals r when $Y_1 < r$. Hence

$$\mathbb{E}\big[\max\{Y_1, r\}\mathbf{1}(Y_1 < v)\big] = rF(r)^{n-1} + \int_r^v y\, d\big[F(y)^{n-1}\big].$$

By the integration by parts of Step 5, the right side equals $vF(v)^{n-1} - \int_r^v F(t)^{n-1}dt$. Dividing by $\mathbb{P}(Y_1 < v) = F(v)^{n-1}$ gives (14.30). □

The conditional expectation form (14.30) has a sharp interpretation. In a second-price auction with reserve price r, a winner with value v pays $\max\{Y_1, r\}$. Conditional on winning, that is on $Y_1 < v$, its expected payment is the right side of (14.30). In the first-price auction it bids exactly this amount. Each bidder acts as if its value were the highest and bids its best estimate of the price that the second-highest value (or the reserve) would set. Type by type, expected payments in the two formats coincide, and Section 14.6 explains why.

Two features of the equilibrium deserve comment. First, the bid of the marginal participant equals the reserve price. When $r > \underline{v}$, so that $F(r) > 0$, the bid function is also flat there. Letting v fall to r in the formula of Step 6 gives $\beta'(r) = (n-1)\frac{f(r)}{F(r)}\big(r - \beta(r)\big) = 0$. Without a binding reserve the slope at $\underline{v}$ need not vanish. With uniform values on $[0, 1]$ it equals $\frac{n-1}{n}$

(Example 14.32). Second, uniqueness extends beyond the class of symmetric differentiable strategies. Consider an independent private values model with a common compact support and a continuously differentiable density that is positive on its interior. Its FPA has a unique equilibrium, which is in pure, strictly increasing and differentiable strategies (Athey and Haile, 2007, Theorem 2.1(ii)). Lebrun (1999) and Maskin and Riley (2003) establish the uniqueness results behind this statement. With symmetric bidders, the unique equilibrium is therefore the one in Proposition 14.31. Theorem 14.61 collects the existence and uniqueness results. The multiplicity example of Section 14.5.6 shows that such uniqueness results rely on a floor on bids.

The original paper. Riley and Samuelson (1981) ask which auction a seller with independent private value buyers should use to maximize expected revenue. They model a broad class of auctions in which the highest bidder wins. Within it, they derive the first-price equilibrium (14.29) with a reserve price and prove that all auctions in the class yield the same expected revenue. They also characterize the revenue-maximizing reserve price, which we derive in Section 14.7. Milgrom and Weber (1982, pp. 1092–1093) place the paper with Harris and Raviv (1981) and Myerson (1981) in the self-selection approach, which explained revenue equivalence and was then applied to optimal auction design. Vickrey (1961) had already solved the first-price auction for uniformly distributed values.

14.5.3 Equilibrium by the envelope theorem

A second derivation uses the bidder's equilibrium payoff instead of its first-order condition. It requires less smoothness, and it is the template for the revenue equivalence theorem.

Let $\pi(v)$ denote the equilibrium expected payoff of a bidder with value $v \geq r$. Since a bid $\beta(z)$ wins with probability $F(z)^{n-1}$, and since mimicking the own type is optimal,

$$\pi(v) = \max_{z} \big(v - \beta(z)\big)F(z)^{n-1}.$$

For each fixed z the objective is an affine function of v with slope $F(z)^{n-1}$. The *envelope theorem* states that the derivative of the maximized value equals the partial derivative of the objective with respect to the parameter, evaluated at the optimal choice. The optimal choice is $z = v$, so

$$\pi'(v) = \frac{\partial}{\partial v}\Big[\big(v - \beta(z)\big)F(z)^{n-1}\Big]_{z=v} = F(v)^{n-1}.$$

The step is rigorous here because π is the upper envelope of a family of affine functions of v. Such an envelope is convex, hence absolutely continuous, and its derivative equals the slope of the maximizing line wherever the derivative exists (Milgrom and Segal, 2002). Appendix B states the envelope theorem in general form.

The marginal participant earns nothing, because $\pi(r) = \big(r - \beta(r)\big)F(r)^{n-1} = 0$. Integrating π' from r gives

$$\pi(v) = \int_{r}^{v} F(t)^{n-1}\,dt. \tag{14.33}$$

The payoff is also the probability of winning times the surplus when winning:

$$\pi(v) = \big(v - \beta(v)\big)F(v)^{n-1}.$$

Equating the two expressions and solving for $\beta(v)$ gives (14.29) again.

The argument used only two features of the first-price auction. The first is that a bidder with value v wins with probability $F(v)^{n-1}$, so the object goes to the highest value among the participants. The second is that the marginal participant earns zero. The pricing rule entered only when we translated $\pi(v)$ into a bid. Any format with these two features gives every type the same payoff (14.33), hence the same expected payment $vF(v)^{n-1} - \pi(v)$. Section 14.6 develops this observation into the revenue equivalence theorem.

14.5.4 Examples

We now compute the equilibrium for four families of distributions. Each computation applies (14.29) directly.

Example 14.32 (Uniform values)**.** Let $F(v) = v$ on $[0, 1]$ and $r = 0$. Then $F(t)^{n-1} = t^{n-1}$ and

$$\int_0^v t^{n-1}\,dt = \frac{v^n}{n}.$$

Substituting into (14.29) gives

$$\beta(v) = v - \frac{\frac{v^n}{n}}{v^{n-1}} = v - \frac{v}{n} = \frac{n-1}{n}\,v.$$

With two bidders, each bids half its value. The highest value $V_{(n:n)}$ has distribution function v^n, density nv^{n-1} and mean $\frac{n}{n+1}$. The winner pays its bid, so expected revenue is

$$\mathbb{E}\big[\beta(V_{(n:n)})\big] = \frac{n-1}{n}\cdot\frac{n}{n+1} = \frac{n-1}{n+1}.$$

This equals the expected second-highest value $\mathbb{E}[V_{(n-1:n)}] = \frac{n-1}{n+1}$, the revenue of the second-price auction (Proposition 14.27). By (14.33), a bidder with value v earns $\pi(v) = \frac{v^n}{n}$, so each bidder's ex ante payoff is $\int_0^1 \frac{v^n}{n}dv = \frac{1}{n(n+1)}$. As a check, expected total surplus equals revenue plus the payoffs of all n bidders:

$$\frac{n-1}{n+1} + n\cdot\frac{1}{n(n+1)} = \frac{n}{n+1} = \mathbb{E}\big[V_{(n:n)}\big].$$

Example 14.33 (Uniform values with a reserve price)**.** Keep $F(v) = v$ on $[0, 1]$ and let $r \in (0, 1)$. Then

$$\int_r^v t^{n-1}\,dt = \frac{v^n - r^n}{n},$$

and (14.29) gives, for $v \geq r$,

$$\beta(v) = v - \frac{v^n - r^n}{nv^{n-1}} = \frac{n-1}{n}\,v + \frac{r^n}{n\,v^{n-1}}.$$

The reserve raises the bid of every participant by $\frac{r^n}{nv^{n-1}}$. For $n = 2$ and $r = \frac{1}{2}$,

$$\beta(v) = \frac{v}{2} + \frac{1}{8v}, \qquad v \in \left[\frac{1}{2}, 1\right],$$

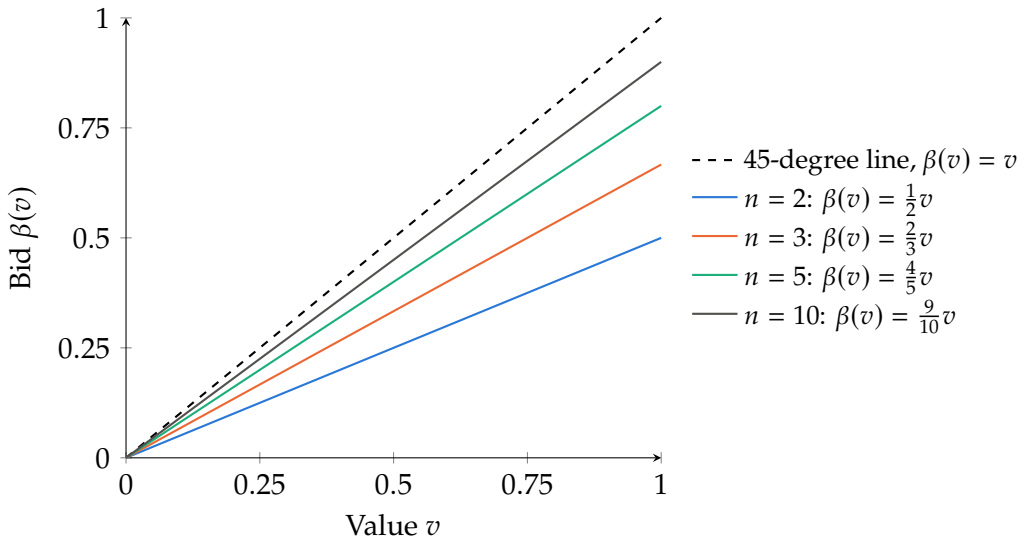

Figure 14.7: Equilibrium bids in the first-price auction with values uniform on $[0,1]$ and no reserve price, $\beta(v) = \frac{n-1}{n}v$. Shading falls as the number of bidders grows.

so that $\beta(\frac{1}{2}) = \frac{1}{2}$ and $\beta(1) = \frac{5}{8}$. The object is sold when the highest value $V_{(2:2)}$, with density $2v$, is at least $\frac{1}{2}$. Expected revenue is

$$\int_{\frac{1}{2}}^{1} \left(\frac{v}{2} + \frac{1}{8v}\right) 2v \, dv = \int_{\frac{1}{2}}^{1} \left(v^2 + \frac{1}{4}\right) dv = \left[\frac{v^3}{3} + \frac{v}{4}\right]_{\frac{1}{2}}^{1} = \frac{7}{12} - \frac{1}{6} = \frac{5}{12}.$$

The reserve price raises expected revenue from $\frac{1}{3}$ to $\frac{5}{12}$. Section 14.7 shows that $r = \frac{1}{2}$ is the revenue-maximizing reserve for these values.

Example 14.34 (Power distribution)**.** Let $F(v) = v^{\gamma}$ on $[0,1]$ with $\gamma > 0$, and $r = 0$. Then $F(t)^{n-1} = t^{\gamma(n-1)}$ and

$$\int_0^v t^{\gamma(n-1)} \, dt = \frac{v^{\gamma(n-1)+1}}{\gamma(n-1)+1}.$$

Substituting into (14.29) gives

$$\beta(v) = v - \frac{v^{\gamma(n-1)+1}}{\big(\gamma(n-1)+1\big)v^{\gamma(n-1)}} = v - \frac{v}{\gamma(n-1)+1} = \frac{\gamma(n-1)}{\gamma(n-1)+1}\, v.$$

The parameters enter only through the product $\gamma(n-1)$. The reason is that bidding depends on F and n only through the distribution of the highest rival value, $F_{Y_1}(y) = y^{\gamma(n-1)}$. A bidder facing $n-1$ rivals with exponent γ bids like a bidder facing one rival with exponent $\gamma(n-1)$. A larger γ shifts probability toward high values, which stiffens competition and reduces shading.

Example 14.35 (Exponential values, two bidders)**.** Let $F(v) = 1 - e^{-\lambda v}$ on $[0,\infty)$ with $\lambda > 0$, $n = 2$ and $r = 0$. Then

$$\int_0^v \big(1 - e^{-\lambda t}\big) dt = v - \frac{1 - e^{-\lambda v}}{\lambda}.$$

Substituting into (14.29) gives

$$\beta(v) = v - \frac{v - \frac{1-e^{-\lambda v}}{\lambda}}{1 - e^{-\lambda v}} = v - \frac{v}{1 - e^{-\lambda v}} + \frac{1}{\lambda} = \frac{1}{\lambda} - \frac{v\, e^{-\lambda v}}{1 - e^{-\lambda v}}.$$

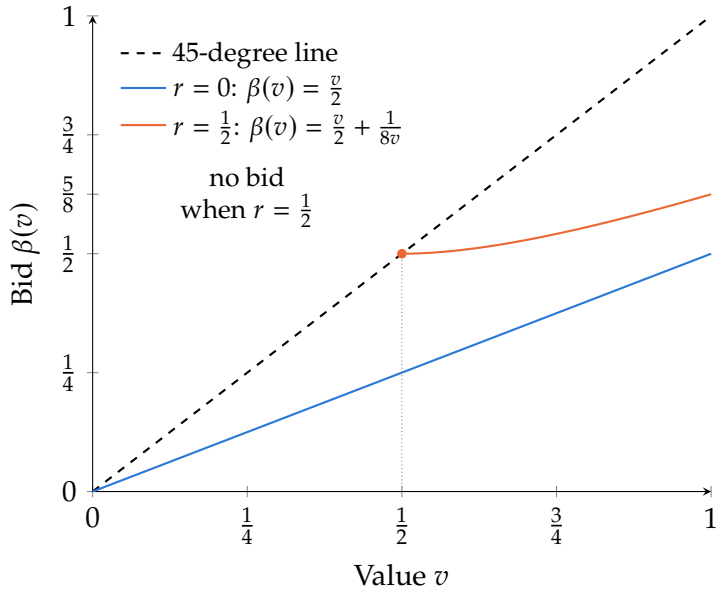

Figure 14.8: Equilibrium bids with two bidders and values uniform on $[0, 1]$, without a reserve price and with $r = \frac{1}{2}$. Values below the reserve do not bid. Participants bid more than without a reserve, and the bid function is flat at $v = r$.

The last term equals $\frac{v}{e^{\lambda v}-1}$. It tends to $\frac{1}{\lambda}$ as $v \to 0$ and to 0 as $v \to \infty$. Hence $\beta(0) = 0$ and $\beta(v)$ rises toward $\frac{1}{\lambda} = \mathbb{E}[V]$. Values are unbounded, yet no bid exceeds the mean value. Form (14.30) explains why: with two bidders, $\beta(v) = \mathbb{E}[V_j \mid V_j < v]$, which is below $\mathbb{E}[V_j]$. Expected revenue equals $\frac{1}{2\lambda}$, the mean of the lower of two independent exponential values.

The examples suggest that bids rise with the number of bidders. The next result confirms this for every distribution.

Proposition 14.36 (More bidders, less shading)**.** *Let Assumption 14.28 hold and fix r. For every $v > r$, the shading $v - \beta(v)$ strictly decreases in n and converges to zero as $n \to \infty$. Equilibrium bids therefore rise with n and converge to values.*

Proof. By (14.29), the shading of type v is

$$v - \beta(v) = \int_r^v \left(\frac{F(t)}{F(v)}\right)^{n-1} dt.$$

The density is positive on $(\underline{v}, \bar{v})$, so F is strictly increasing there and $0 \le \frac{F(t)}{F(v)} < 1$ for $t < v$. The integrand therefore decreases in n at every $t < v$, strictly wherever $F(t) > 0$. This set of t has positive length in $[r, v]$, so the integral strictly decreases in n. As $n \to \infty$ the integrand converges to zero at every $t < v$. It is bounded by one on the bounded interval $[r, v]$, so the dominated convergence theorem gives convergence of the integral to zero. □

Conditional on winning, a bidder's estimate of the second-highest value rises with the number of rivals. More bidders thus discipline markdowns in the way that more Cournot competitors discipline markups (Chapter 2).

Table 14.6 collects the uniform-value equilibria of six auction formats. The all-pay and third-price bids are derived in Section 14.6. Every format yields expected revenue $\frac{n-1}{n+1}$, and

every type makes the same expected payment in every format. This regularity motivates Section 14.6.

Table 14.6: Equilibrium bids, expected payments and expected revenue in six formats, with n symmetric bidders, values uniform on $[0,1]$, and no reserve price.

Format	Bid of type v	Expected payment of type v	Expected revenue
First-price sealed bid	$\frac{n-1}{n}v$	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$
Dutch (descending clock)	stop at $\frac{n-1}{n}v$	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$
Second-price sealed bid	v	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$
English (button)	exit at v	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$
All-pay	$\frac{n-1}{n}v^n$	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$
Third-price ($n \geq 3$)	$\frac{n-1}{n-2}v$	$\frac{n-1}{n}v^n$	$\frac{n-1}{n+1}$

Notes: The expected payment of type v is taken before the outcome is known, so it includes the event of losing. In the first-price and Dutch auctions it equals the bid times the win probability v^{n-1}. In the second-price and English auctions it equals $\mathbb{E}[Y_1\mathbf{1}(Y_1 < v)] = \int_0^v y\,(n-1)y^{n-2}dy$. In the all-pay auction it equals the bid. Expected revenue is $n\int_0^1 \frac{n-1}{n}v^n\,dv$.

14.5.5 The first-order condition in terms of the bid distribution

The equilibrium can be characterized without reference to F or β. Let G denote the distribution function of a single rival's equilibrium bid and g its density, and suppose the reserve price does not bind ($r = \underline{v}$). In the symmetric equilibrium, $G(b) = \mathbb{P}\big(\beta(V_j) \leq b\big) = F\big(\beta^{-1}(b)\big)$ on the bid support $[\underline{b}, \bar{b}] = [\beta(\underline{v}), \beta(\bar{v})]$. A bidder with value v_i takes G as given and solves

$$\max_b\ (v_i - b)\,G(b)^{n-1}.$$

The first-order condition is

$$-G(b)^{n-1} + (v_i - b)(n-1)G(b)^{n-2}g(b) = 0.$$

Dividing by $(n-1)G(b)^{n-2}g(b)$ and solving for v_i gives

$$v_i = b + \frac{G(b)}{(n-1)\,g(b)}. \tag{14.34}$$

Equation (14.34) is the differential equation (14.32) written in terms of the bid distribution. To see this, differentiate $G(b) = F(\beta^{-1}(b))$ to get $g(b) = \frac{f(\beta^{-1}(b))}{\beta'(\beta^{-1}(b))}$. At $b = \beta(v)$,

$$\frac{G(b)}{(n-1)g(b)} = \frac{F(v)\,\beta'(v)}{(n-1)f(v)} = v - \beta(v),$$

where the last equality is (14.32). For uniform values, $\beta(v) = \frac{n-1}{n}v$, so bids lie in $[0, \frac{n-1}{n}]$ with $G(b) = \frac{nb}{n-1}$ and $g(b) = \frac{n}{n-1}$. Then $\frac{G(b)}{(n-1)g(b)} = \frac{b}{n-1}$, and (14.34) gives $v = \frac{nb}{n-1}$, which inverts the bid function.

The right side of (14.34) involves only the bid, the bid distribution, and the number of bidders. All three are observable when bids are recorded. Each bid can therefore be mapped

into the value that rationalizes it, without solving a differential equation and without knowing F. Guerre et al. (2000) build their identification result and their two-step nonparametric estimator on this observation (Chapter 15). In equilibrium the map $b \mapsto b + \frac{G(b)}{(n-1)g(b)}$ equals β^{-1}, so it must be strictly increasing. This is a testable restriction on bid data.

The condition also has an economic reading. Rewrite (14.34) as a markdown relative to the bid:

$$\frac{v_i - b}{b} = \frac{1}{\eta(b)}, \qquad \eta(b) = (n-1)\frac{b\, g(b)}{G(b)} = \frac{d \ln G(b)^{n-1}}{d \ln b}. \tag{14.35}$$

Here $\eta(b)$ is the elasticity of the win probability $G(b)^{n-1}$ with respect to the bid. Athey and Haile (2007, footnote 13) compare this markdown to that of an *oligopsonist*, a buyer that sets its price from the equilibrium elasticity of its residual supply curve. In the auction, the distribution of the highest rival bid plays the role of the residual supply curve. A buyer that values one unit at v and faces residual supply $S(w)$ maximizes $(v-w)S(w)$, which gives $\frac{v-w}{w} = \frac{1}{\varepsilon_S}$ with ε_S the supply elasticity. With a single rival the bidder is a monopsonist facing that rival's bid distribution, which is our own reading of the analogy. The markdown rule is the buyer's mirror image of the Lerner rule $\frac{p-c}{p} = \frac{1}{\varepsilon}$ (Chapter 2). Recovering a value from a bid mirrors recovering marginal cost from a pricing first-order condition (Chapter 4). For uniform values $\eta(b) = n-1$ at every bid, so the relative markdown is $\frac{1}{n-1}$. Section 14.13 develops the same analogy for procurement auctions, where the bid is a price and the win probability a quantity.

Integrating (14.34) over the bid distribution yields a simple relation between mean values and mean bids (Athey and Haile, 2007, Section 2.2.1).

Proposition 14.37 (Mean values and mean bids)**.** *In the symmetric equilibrium of the first-price auction under Assumption 14.28 with a nonbinding reserve price, let B denote an equilibrium bid, with support $[\underline{b}, \bar{b}]$. Then*

$$\mathbb{E}[V] = \frac{n-2}{n-1}\,\mathbb{E}[B] + \frac{1}{n-1}\,\bar{b}, \qquad \mathbb{E}[V - B] = \frac{1}{n-1}\big(\bar{b} - \mathbb{E}[B]\big). \tag{14.36}$$

Proof. In equilibrium $V = B + \frac{G(B)}{(n-1)g(B)}$, where B has density g. Taking expectations,

$$\mathbb{E}[V] = \mathbb{E}[B] + \frac{1}{n-1}\int_{\underline{b}}^{\bar{b}} \frac{G(b)}{g(b)}\, g(b)\, db = \mathbb{E}[B] + \frac{1}{n-1}\int_{\underline{b}}^{\bar{b}} G(b)\, db.$$

Integration by parts with $G(\underline{b}) = 0$ and $G(\bar{b}) = 1$ gives

$$\int_{\underline{b}}^{\bar{b}} G(b)\, db = \Big[b\, G(b)\Big]_{\underline{b}}^{\bar{b}} - \int_{\underline{b}}^{\bar{b}} b\, g(b)\, db = \bar{b} - \mathbb{E}[B].$$

Substituting,

$$\mathbb{E}[V] = \mathbb{E}[B] + \frac{\bar{b} - \mathbb{E}[B]}{n-1} = \frac{n-2}{n-1}\mathbb{E}[B] + \frac{1}{n-1}\bar{b}.$$

The second equation in (14.36) follows by subtracting $\mathbb{E}[B]$. □

With two bidders the relation reduces to $\mathbb{E}[V] = \bar{b}$: the highest bid in the support equals the mean value. Form (14.30) gives the same result directly, since $\beta(\bar{v}) = \mathbb{E}[Y_1 \mid Y_1 < \bar{v}] = \mathbb{E}[V]$ when $n = 2$. For uniform values with n bidders, $\mathbb{E}[B] = \frac{n-1}{2n}$ and $\bar{b} = \frac{n-1}{n}$, and (14.36) returns $\frac{n-2}{2n} + \frac{1}{n} = \frac{1}{2} = \mathbb{E}[V]$. Athey and Haile (2007, Section 2.2.1) observe that such moment relations had not been exploited in econometric work.

14.5.6 Reserve prices, the Dutch auction, and multiplicity

The Dutch auction is strategically equivalent to the first-price auction (Proposition 14.4). Its equilibrium is therefore the same: a bidder with value $v \geq r$ stops the descending clock at the price $\beta(v)$ given by (14.29).

A reserve price has two effects in the first-price auction. It excludes all values below r, and it raises the bids of all participants. Write β_r for the equilibrium bid with reserve r and $\beta_{\underline{v}}$ for the bid without a binding reserve. By (14.29), for $v > r$,

$$\beta_r(v) - \beta_{\underline{v}}(v) = \frac{\int_{\underline{v}}^{v} F(t)^{n-1}dt - \int_{r}^{v} F(t)^{n-1}dt}{F(v)^{n-1}} = \frac{\int_{\underline{v}}^{r} F(t)^{n-1}\,dt}{F(v)^{n-1}} > 0.$$

The reserve acts like an extra competitor who bids r. With uniform values the increase is $\frac{r^n}{nv^{n-1}}$, as in Example 14.33. The effect fades as v rises, because a high-value bidder rarely faces a situation in which the reserve is the binding competitor. The net effect on revenue weighs the higher bids against the lost sales, and Section 14.7 resolves it.

The boundary condition $\beta(r) = r$ in Proposition 14.31 came from the floor on bids. Milgrom and Weber (1982, footnote 25) show that the floor matters. Suppose any real number is a valid bid, including a negative one, which would oblige the seller to pay the winner. Step 1 of the proof then fails. Integrating the differential equation without a boundary condition gives

$$\beta(v)F(v)^{n-1} = \int_{\underline{v}}^{v} t\, d\big[F(t)^{n-1}\big] - k$$

for an arbitrary constant k. Hence the family of candidates is

$$\beta_k(v) = \beta(v) - \frac{k}{F(v)^{n-1}}, \tag{14.37}$$

where β is the bid (14.29) with $r = \underline{v}$. With uniform values on $[0,1]$ this family is

$$\beta_k(v) = \frac{n-1}{n}\,v - \frac{k}{v^{n-1}}, \qquad k \geq 0.$$

Milgrom and Weber (1982, footnote 25) print the slope of this family as $\frac{n}{n+1}$. That is a misprint. The footnote carries it into the ranges of the strategies, which it prints as $\big(0, \frac{n}{n+1}\big)$ for $k = 0$ and $\big(-\infty, \frac{n}{n+1} - k\big)$ for $k > 0$. The slope $\frac{n}{n+1}$ violates the first-order condition, since the two sides of (14.32) then differ by $\frac{v^{n-1}}{n+1}$, or by $\frac{1}{n+1}$ after dividing by v^{n-1}. The slope $\frac{n-1}{n}$ satisfies it and reproduces exactly the ex ante payoff $\frac{1}{n(n+1)} + k$ that the footnote reports, as we now verify.

Fix $k \geq 0$ and suppose all rivals use β_k. Its derivative is $\beta_k'(v) = \frac{n-1}{n} + \frac{(n-1)k}{v^n} > 0$, so β_k is strictly increasing. For $k > 0$ its range is $\big(-\infty, \frac{n-1}{n} - k\big)$, and for $k = 0$ it is $\big(0, \frac{n-1}{n}\big)$. A bid $\beta_k(z)$ wins with probability z^{n-1}, so a bidder with value v who mimics type z earns

$$\Pi_k(z; v) = \big(v - \beta_k(z)\big)z^{n-1} = v\,z^{n-1} - \frac{n-1}{n}z^n + k.$$

Differentiating with respect to z,

$$\frac{\partial \Pi_k(z;v)}{\partial z} = (n-1)z^{n-2}v - (n-1)z^{n-1} = (n-1)z^{n-2}(v - z).$$

The payoff peaks at $z = v$. A bid above the range wins for sure at a higher cost than the top of the range, and a bid below the range (possible only when $k = 0$) never wins. Hence β_k is a symmetric equilibrium for every $k \geq 0$. Type v earns $\Pi_k(v; v) = \frac{v^n}{n} + k$, and the ex ante payoff is

$$\int_0^1 \Big(\frac{v^n}{n} + k\Big) dv = \frac{1}{n(n+1)} + k.$$

The allocation is efficient in every member of the family, so total surplus is the same. Each bidder gains k, and the seller's expected revenue falls to $\frac{n-1}{n+1} - nk$. In the equilibria with $k > 0$, low types submit large negative bids, and even a bidder with value zero expects to receive k. Milgrom and Weber (1982, footnote 25) suggest that this possibility may explain why almost all observed auctions have at least an implicit reserve price. The lesson is that the floor on bids, set by a reserve price or by a nonnegativity rule, selects the equilibrium. In empirical work the floor is part of the rules and should be recorded with the bids.

14.5.7 Risk-averse bidders

We now replace risk neutrality in Assumption 14.28(i). Each bidder has a utility of money $\mathcal{U}$ that is strictly increasing and concave, with $\mathcal{U}(0) = 0$, and twice differentiable on $(0, \infty)$. A bidder with value v who wins at price b receives $\mathcal{U}(v - b)$, and a losing bidder receives $\mathcal{U}(0) = 0$. We look for a symmetric equilibrium with strictly increasing bid function β_u and bid distribution G.

A bidder with value v solves

$$\max_b \; \mathcal{U}(v - b)\, G(b)^{n-1}.$$

The first-order condition is

$$-\mathcal{U}'(v - b)\, G(b)^{n-1} + \mathcal{U}(v - b)(n - 1)G(b)^{n-2} g(b) = 0,$$

which simplifies, after division by $G(b)^{n-2}$, to

$$\mathcal{U}'(v - b)\, G(b) = (n - 1)\, \mathcal{U}(v - b)\, g(b).$$

Following Athey and Haile (2007, eq. (6.24)), define the ratio

$$\ell(s) = \frac{\mathcal{U}(s)}{\mathcal{U}'(s)}. \tag{14.38}$$

They denote this ratio by λ. We write ℓ to keep λ for the exponential rate of Example 14.35. The first-order condition becomes $\ell(v - b) = \frac{G(b)}{(n-1)g(b)}$, so

$$v = b + \ell^{-1}\Big(\frac{G(b)}{(n - 1)\, g(b)}\Big), \tag{14.39}$$

which is their eq. (6.25). The ratio has three properties. First, $\ell(0) = \lim_{s \downarrow 0} \ell(s) = 0$. Second, $\ell'(s) = 1 - \frac{\mathcal{U}(s)\mathcal{U}''(s)}{\mathcal{U}'(s)^2} \geq 1$, so ℓ is strictly increasing and invertible. Third, concavity and $\mathcal{U}(0) = 0$ give $0 = \mathcal{U}(0) \leq \mathcal{U}(s) + \mathcal{U}'(s)(0 - s)$, that is,

$$\ell(s) \geq s \quad \text{for } s \geq 0,$$

with strict inequality for $s > 0$ when $\mathcal{U}$ is strictly concave. Under risk neutrality $\ell(s) = s$, and (14.39) reduces to (14.34).

In terms of the bid function, $G(b) = F(\beta_u^{-1}(b))$, so at $b = \beta_u(v)$ we have $\frac{G(b)}{(n-1)g(b)} = \frac{F(v)\beta_u'(v)}{(n-1)f(v)}$. Substituting into $\ell(v-b) = \frac{G(b)}{(n-1)g(b)}$ and solving for $\beta_u'(v)$,

$$\beta_u'(v) = \frac{\mathcal{U}\big(v-\beta_u(v)\big)}{\mathcal{U}'\big(v-\beta_u(v)\big)}\,\frac{f_{Y_1}(v)}{F_{Y_1}(v)} \;\geq\; \big(v-\beta_u(v)\big)\frac{f_{Y_1}(v)}{F_{Y_1}(v)}, \tag{14.40}$$

where $\frac{f_{Y_1}}{F_{Y_1}} = (n-1)\frac{f}{F}$ and the inequality uses $\ell(s) \geq s$. This is eq. (11) of Milgrom and Weber (1982). The boundary condition is again $\beta_u(\underline{v}) = \underline{v}$, by the argument of Step 1 of Proposition 14.31.

Example 14.38 (Constant relative risk aversion)**.** Let $\mathcal{U}(x) = x^a$ with $0 < a \leq 1$, a case of constant relative risk aversion (CRRA), so that the coefficient of relative risk aversion is $1-a$. Then $\ell(s) = \frac{s^a}{a s^{a-1}} = \frac{s}{a}$. Let values be uniform on $[0,1]$, so $\frac{f_{Y_1}(v)}{F_{Y_1}(v)} = \frac{n-1}{v}$. Equation (14.40) becomes

$$\beta_u'(v) = \frac{(n-1)\big(v-\beta_u(v)\big)}{a\,v},$$

a linear differential equation:

$$\beta_u'(v) + \frac{n-1}{a\,v}\,\beta_u(v) = \frac{n-1}{a}.$$

We try $\beta_u(v) = cv$. Substituting gives $c + \frac{(n-1)c}{a} = \frac{n-1}{a}$, so $c(a+n-1) = n-1$. The homogeneous equation adds solutions $Cv^{-\frac{n-1}{a}}$, which are unbounded near zero, and the boundary condition $\beta_u(0) = 0$ forces $C = 0$. Hence

$$\beta_u(v) = \frac{n-1}{n-1+a}\,v.$$

With $a = 1$ we recover $\frac{n-1}{n}v$. As a falls, bids rise, and they approach values as $a \to 0$. Expected revenue is $\frac{n-1}{n-1+a} \cdot \frac{n}{n+1}$. Its ratio to the second-price revenue $\frac{n-1}{n+1}$ is $\frac{n}{n-1+a}$, which exceeds one whenever $a < 1$. For example, with $n = 2$ and $a = \frac{1}{2}$, bids are $\frac{2}{3}v$ and expected revenue is $\frac{4}{9}$, against $\frac{1}{3}$ in the second-price auction.

The example ranks the formats. To prove the ranking in general we need a simple comparison lemma, which Section 14.9 also uses.

Lemma 14.39 (Crossing lemma, Milgrom and Weber, 1982, Lemma 2)**.** *Let h_1 and h_2 be continuous on $[\underline{x}, \bar{x}]$ and differentiable on $(\underline{x}, \bar{x}]$. Suppose (i) $h_1(\underline{x}) \geq h_2(\underline{x})$, and (ii) $h_1(x) < h_2(x)$ implies $h_1'(x) \geq h_2'(x)$. Then $h_1(x) \geq h_2(x)$ for all $x \in [\underline{x}, \bar{x}]$.*

Proof. Let $d = h_1 - h_2$ and suppose, to the contrary, that $d(x) < 0$ for some $x > \underline{x}$. The set $\{t \in [\underline{x}, x] : d(t) \geq 0\}$ is closed and contains $\underline{x}$. Let x_0 be its largest element. Then $d(x_0) \geq 0$, $x_0 < x$, and $d < 0$ on $(x_0, x]$. By the mean value theorem there is $\hat{x} \in (x_0, x)$ with

$$d'(\hat{x}) = \frac{d(x) - d(x_0)}{x - x_0} < 0.$$

At $\hat{x}$ we have $h_1(\hat{x}) < h_2(\hat{x})$ and $h_1'(\hat{x}) < h_2'(\hat{x})$, which contradicts (ii). □

Proposition 14.40 (Risk aversion favors the first-price auction, Holt, 1980; Maskin and Riley, 1984)**.** *Let Assumption 14.28 hold with risk neutrality replaced by a common utility $\mathcal{U}$ that is strictly increasing and concave, with $\mathcal{U}(0) = 0$, and twice differentiable on $(0, \infty)$. Let there be no binding reserve price. Then the first-price auction yields at least as much expected revenue as the second-price auction. The ranking is strict when $\mathcal{U}$ is strictly concave.*

Proof. Step 1. We start with the second-price auction. Bidding one's value remains a weakly dominant strategy. The proof of Proposition 14.22 compares the surplus $v - m$ from winning at the highest rival bid m with zero, and an increasing $\mathcal{U}$ preserves its sign. Expected revenue is therefore $\mathbb{E}[V_{(n-1:n)}]$, as with risk neutrality. Let β_N be the risk-neutral first-price bid. By (14.30) with $r = \underline{v}$, $\beta_N(v) = \mathbb{E}[Y_1 \mid Y_1 < v]$. Conditional on $V_{(n:n)} = v$, the second-highest value is distributed as Y_1 given $Y_1 < v$. The law of iterated expectations therefore gives $\mathbb{E}[V_{(n-1:n)}] = \mathbb{E}[\beta_N(V_{(n:n)})]$.

Step 2. We show that risk-averse bidders bid more. The risk-neutral bid satisfies $\beta_N'(v) = \big(v - \beta_N(v)\big)\frac{f_{Y_1}(v)}{F_{Y_1}(v)}$. We apply Lemma 14.39 with $h_1 = \beta_u$ and $h_2 = \beta_N$. Condition (i) holds because $\beta_u(\underline{v}) = \beta_N(\underline{v}) = \underline{v}$. For condition (ii), suppose $\beta_u(v) < \beta_N(v)$. Then (14.40) gives

$$\beta_u'(v) \geq \big(v - \beta_u(v)\big)\frac{f_{Y_1}(v)}{F_{Y_1}(v)} > \big(v - \beta_N(v)\big)\frac{f_{Y_1}(v)}{F_{Y_1}(v)} = \beta_N'(v).$$

The lemma yields $\beta_u(v) \geq \beta_N(v)$ for all v.

Step 3. We compare revenues. Both bid functions are strictly increasing, so the bidder with the highest value wins in both cases. Expected first-price revenue with risk aversion is $\mathbb{E}[\beta_u(V_{(n:n)})] \geq \mathbb{E}[\beta_N(V_{(n:n)})]$, which is the second-price revenue by Step 1.

Step 4. We prove strictness. If $\mathcal{U}$ is strictly concave, then $\ell(s) > s$ for $s > 0$. Let $d = \beta_u - \beta_N \geq 0$ and suppose $d(v) = 0$ at some $v > \underline{v}$. Then $v - \beta_u(v) = v - \beta_N(v) > 0$, and (14.40) holds with strict inequality, so $d'(v) > 0$. Hence $d < 0$ just to the left of v, a contradiction. Thus $\beta_u > \beta_N$ on $(\underline{v}, \bar{v}]$, and the revenue ranking is strict. □

The intuition is that shading is a gamble. A lower bid raises the gain from winning but lowers the chance of winning. A risk-averse bidder dislikes this gamble and buys insurance against losing by bidding more. In the second-price auction the bid does not affect the price paid upon winning, so there is no gamble to manage. Milgrom and Weber (1982, p. 1114) combine this result with their ranking for affiliated values. With both affiliation and risk aversion, the first-price and second-price auctions cannot be ranked in general (Section 14.9.5).

Risk aversion also complicates the inversion of bids. Equation (14.39) requires the function ℓ, which a single bid distribution cannot pin down (Athey and Haile, 2007, Section 6.4). In the CRRA case, $\ell^{-1}(x) = ax$, so values satisfy $V = B + a\frac{G(B)}{(n-1)g(B)}$. Bids rationalized by exponent a are equally well rationalized by any $\tilde{a} \in (0, a)$ with values

$$\tilde{V} = B + \frac{\tilde{a}}{a}(V - B),$$

which lie between the bids and the original values. More risk-averse bidders with lower values produce the same bids. Chapter 15 returns to this identification problem.

Empirical work suggests that the effect is not small. Campo et al. (2011) break the indeterminacy with a parametric utility function and a parametric quantile restriction. In sealed-bid timber auctions of the U.S. Forest Service, they estimate a CRRA measure of 0.278 (Hortaçsu and Perrigne, 2021, Section 2.4, p. 95). Under CRRA, risk aversion acts like an

increase in competition and lowers the bidders' information rents. Exercise 3(b) of Section 14.16 makes this precise. Bidders already bid aggressively, so the seller needs a smaller reserve price. The simulated optimal reserve price is about 19 percent below the one computed under risk neutrality (Hortaçsu and Perrigne, 2021, p. 95).

The original papers. Holt (1980) studies procurement auctions with risk-averse bidders and shows that the first-price format yields a lower expected cost to the buyer than the oral or second-price formats. Maskin and Riley (1984) characterize the revenue-maximizing auction when buyers are risk averse. They show that the first-price auction dominates the second-price auction and that the optimal mechanism differs from all the standard formats. Milgrom and Weber (1982, p. 1093) list the risk-aversion ranking as the seventh conclusion of the independent private values model. They credit it to Harris and Raviv (1981), Holt (1980), a 1980 discussion paper by Maskin and Riley, and a 1979 working paper by Matthews. On p. 1114 they give the proof by Lemma 14.39 that we follow.

14.6 Revenue Equivalence

Every format in Table 14.6 yields the same expected revenue. Each type even makes the same expected payment in every format. This section explains the regularity. We first present the geometric argument of Milgrom and Weber (1982), then the mechanism-design formulation of Myerson (1981). We use the theorem to solve for equilibria of new formats, extend it to interdependent values with independent signals, and list the assumptions whose failure breaks it.

14.6.1 The self-selection view

With independent private values, the four standard formats yield the same expected revenue. Milgrom and Weber (1982, p. 1092) credit this finding to Ortega-Reichert (1968) and Vickrey (1962). They add that it remained a puzzle until the self-selection approach of Harris and Raviv (1981), Myerson (1981) and Riley and Samuelson (1981). We follow their exposition. In this subsection only, p denotes a probability of winning, as in their paper.

Fix the rules of an auction and the strategies of bidder i's rivals. Every action available to bidder i, whether a bid, a stopping price or a plan of exits, leads to some probability of winning p and some expected payment. Let $e(p)$ denote the lowest expected payment among the actions that win with probability p. Because values are independent, the menu of pairs $(p, e(p))$ depends only on the rules and on the rivals' strategies. It does not depend on bidder i's own value.

A bidder with value v who chooses the pair (p, e) obtains expected utility $vp - e$. Its indifference curves in the (p, e) plane are straight lines $e = vp -$ constant with slope v. A lower intercept means a higher utility. It therefore chooses the point of the menu that touches the lowest line of slope v. Let $p^*(v)$ denote the chosen probability. Figure 14.9 illustrates the choice.

Two facts follow from the geometry. First, p^* is nondecreasing. Optimality of $p^*(v)$ for v and of $p^*(v')$ for v' gives two revealed-preference inequalities. Adding them, as in the proof of Lemma 14.30, yields $(v' - v)\big[p^*(v') - p^*(v)\big] \geq 0$. Second, where p^* is differentiable, the line of slope v is tangent to the menu, so $e'(p^*(v)) = v$. The chain rule then gives

$$\frac{d}{dv}\, e\big(p^*(v)\big) = e'\big(p^*(v)\big)\frac{dp^*(v)}{dv} = v\,\frac{dp^*(v)}{dv}.$$

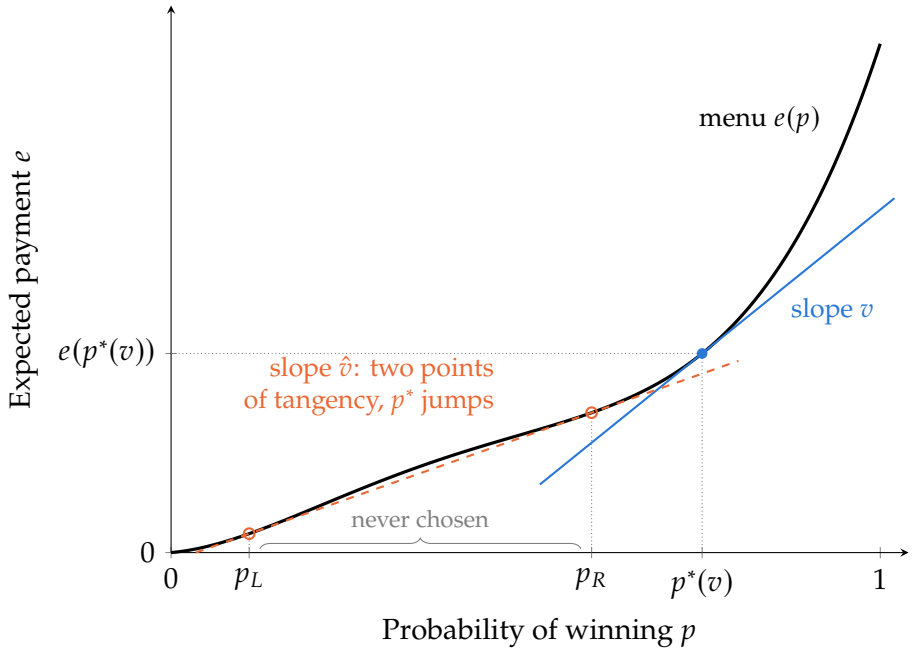

Figure 14.9: The bidder's choice among pairs of win probability and expected payment. Indifference lines have slope equal to the value. A bidder with value v chooses the point where the lowest line of slope v touches the menu. At the value $\hat{v}$ the line touches the menu twice, and the chosen win probability jumps from p_L to p_R. Redrawn after Milgrom and Weber (1982), Figure 1, with an illustrative menu.

Where the line touches the menu at two points, a small increase in v makes p^* jump by Δp^*. Both points lie on the same line of slope v, so the payment jumps by $\Delta e = v\,\Delta p^*$. Combining the smooth parts and the jumps, and integrating from the lowest value $\underline{v}$,

$$e\big(p^*(v)\big) = e\big(p^*(\underline{v})\big) + \int_{\underline{v}}^{v} t\,dp^*(t). \tag{14.41}$$

Equation (14.41) is the core of revenue equivalence. Each type's expected payment depends on the rules only through two objects: the function p^* and the payment of the lowest type. The seller's expected revenue is the sum of the bidders' expected payments, so the same is true of revenue. Every auction that always awards the object to the highest value has $p^*(v) = F(v)^{n-1}$. If, in addition, the lowest type pays nothing, all such auctions produce the same expected revenue. The menu need not be smooth or even continuous (Milgrom and Weber, 1982, footnote 12). It always contains a point $(0, e(0))$ with $e(0) \le 0$, because a bidder can abstain. The payment $e(0)$ is negative only if the seller subsidizes losing bidders.

For uniform values and two bidders, the first-price menu is easy to compute. A bid $b \in [0, \frac{1}{2}]$ wins against a rival who bids half its value with probability $p = 2b$. The expected payment is $e = bp = \frac{p^2}{2}$. Tangency requires $e'(p) = p = v$, so $p^*(v) = v = F(v)$, and the expected payment is $\frac{v^2}{2} = \int_0^v t\,dt$, as (14.41) predicts.

14.6.2 Mechanisms and incentive compatibility

The general formulation allows asymmetric bidders and arbitrary selling procedures. We use it here and in Section 14.7.

Assumption 14.41 (Independent private values)**.** There are n risk-neutral bidders. Bidder i's value V_i is drawn from a distribution F_i with a finite mean, support $[\underline{v}_i, \bar{v}_i]$ with $\underline{v}_i$ finite and $\bar{v}_i \leq \infty$, and a density f_i that is strictly positive on the support. Values are independent across bidders. The seller's own value for the object is v_0, and it is risk neutral.

The seller's value v_0 is what the object is worth to the seller if it is not sold. It is not a reserve price.

A *direct mechanism* asks each bidder to report a value. It consists of an allocation rule and a payment rule. The allocation rule $q_i(\boldsymbol{v}) \in [0,1]$ is the probability that bidder i receives the object when the reports are $\boldsymbol{v} = (v_1, \ldots, v_n)$, with $\sum_i q_i(\boldsymbol{v}) \leq 1$. The payment rule $\tau_i(\boldsymbol{v})$ is the amount bidder i pays. Bidder i cares about the *interim* allocation and payment, which average over the rivals' values:

$$Q_i(v_i) = \mathbb{E}\big[q_i(v_i, \boldsymbol{V}_{-i})\big], \qquad m_i(v_i) = \mathbb{E}\big[\tau_i(v_i, \boldsymbol{V}_{-i})\big].$$

A bidder with value v_i who reports z while the others report truthfully obtains $v_i Q_i(z) - m_i(z)$. Its truthful payoff is

$$\pi_i(v_i) = v_i Q_i(v_i) - m_i(v_i).$$

The mechanism is *incentive compatible* (IC) if truth-telling is optimal,

$$\pi_i(v_i) \geq v_i Q_i(z) - m_i(z) \quad \text{for all } i,\ v_i,\ z, \tag{14.42}$$

and *individually rational* (IR) if participation is voluntary,

$$\pi_i(v_i) \geq 0 \quad \text{for all } i,\ v_i. \tag{14.43}$$

The *revelation principle* (Myerson, 1981) makes direct mechanisms a general tool. Take any auction and any Bayesian Nash equilibrium $(\beta_1, \ldots, \beta_n)$ of it. Define $q_i(\boldsymbol{v})$ and $\tau_i(\boldsymbol{v})$ as the allocation and payments that result when the bidders play $\beta_1(v_1), \ldots, \beta_n(v_n)$. This direct mechanism is incentive compatible. A type v_i who gained by reporting z would have gained in the original auction by playing $\beta_i(z)$, contradicting equilibrium. The direct mechanism produces the same allocation and payments as the auction for every profile of values. Hence any statement about IC direct mechanisms applies to the equilibrium outcomes of all auctions.

Lemma 14.42 (Characterization of incentive compatibility)**.** *Under Assumption 14.41, a direct mechanism is incentive compatible if and only if, for every bidder i, (a) Q_i is nondecreasing, and (b) for every v_i,*

$$\pi_i(v_i) = \pi_i(\underline{v}_i) + \int_{\underline{v}_i}^{v_i} Q_i(t)\, dt. \tag{14.44}$$

Proof. We drop the subscript i.

Necessity. Let v and v' be two values. The IC constraint of type v against report v' reads $\pi(v) \geq vQ(v') - m(v')$. Since $m(v') = v'Q(v') - \pi(v')$, this is

$$\pi(v) \geq \pi(v') + (v - v')\, Q(v').$$

Exchanging the roles of v and v' gives

$$\pi(v') \geq \pi(v) + (v' - v)\, Q(v).$$

Together the two inequalities give

$$(v' - v)\,Q(v) \le \pi(v') - \pi(v) \le (v' - v)\,Q(v').$$

For $v' > v$, dividing by $v' - v$ shows $Q(v) \le Q(v')$, which is (a). Because $0 \le Q \le 1$, the same chain gives $|\pi(v') - \pi(v)| \le |v' - v|$. So π is Lipschitz, hence absolutely continuous and differentiable almost everywhere. Letting $v' \to v$ in the chain shows that $\pi'(v) = Q(v)$ wherever Q is continuous, which is almost everywhere because Q is monotone. An absolutely continuous function is the integral of its derivative, which gives (b).

Sufficiency. Suppose (a) and (b) hold. For any v and z, using $m(z) = zQ(z) - \pi(z)$ and (b),

$$\pi(v) - \big[vQ(z) - m(z)\big] = \pi(v) - \pi(z) - (v - z)Q(z) = \int_z^v \big[Q(t) - Q(z)\big]\,dt.$$

If $z < v$, the integrand is nonnegative on $[z, v]$ by (a). If $z > v$, the integral equals $\int_v^z \big[Q(z) - Q(t)\big]\,dt$, which is also nonnegative by (a). Hence truth-telling is optimal. □

Condition (b) is the envelope formula of Section 14.5.3 in general form. Since $m_i(v_i) = v_i Q_i(v_i) - \pi_i(v_i)$, it yields the *payment identity*

$$m_i(v_i) = v_i Q_i(v_i) - \pi_i(\underline{v}_i) - \int_{\underline{v}_i}^{v_i} Q_i(t)\,dt. \tag{14.45}$$

In an incentive compatible mechanism, the interim allocation and the payoff of the lowest type determine every interim payment.

14.6.3 The revenue equivalence theorem

Proposition 14.43 (Revenue equivalence, Myerson, 1981; Riley and Samuelson, 1981)**.** *Let Assumption 14.41 hold. Consider two auctions, each with a Bayesian Nash equilibrium. Suppose the two equilibria induce the same interim allocation Q_i for every bidder, and give the lowest type of each bidder the same expected payoff $\pi_i(\underline{v}_i)$. Then every type of every bidder makes the same expected payment in the two auctions, and the seller's expected revenue is the same. In particular, let bidders be symmetric ($F_i = F$). Then any auction whose equilibrium awards the object to the highest value and charges the lowest type nothing yields expected revenue $\mathbb{E}[V_{(n-1:n)}]$.*

Proof. By the revelation principle, each auction with its equilibrium is an incentive compatible direct mechanism. By the payment identity (14.45), each interim payment $m_i(v_i)$ depends only on Q_i and $\pi_i(\underline{v}_i)$, which the two auctions share. Expected revenue is $\sum_i \mathbb{E}[m_i(V_i)]$, so it is also the same.

For the symmetric case, the highest value wins, so $Q(v) = F(v)^{n-1} = F_{Y_1}(v)$. The lowest type never wins and pays nothing, so $\pi(\underline{v}) = 0$. The payment identity and integration by parts give

$$m(v) = vF(v)^{n-1} - \int_{\underline{v}}^{v} F(t)^{n-1}\,dt = \int_{\underline{v}}^{v} y\,dF_{Y_1}(y) = \mathbb{E}\big[Y_1 \mathbf{1}(Y_1 < v)\big].$$

This is the expected payment of type v in the second-price auction. Summing over bidders,

$$\sum_{i=1}^{n} \mathbb{E}\big[m(V_i)\big] = \sum_{i=1}^{n} \mathbb{E}\Big[\max_{j \ne i} V_j\ \mathbf{1}\Big(V_i > \max_{j \ne i} V_j\Big)\Big] = \mathbb{E}\big[V_{(n-1:n)}\big].$$

The last equality holds because exactly one bidder has the highest value, and for that bidder the highest rival value is the second-highest value overall. □

Milgrom and Weber (1982, Theorem 0) state the symmetric case as follows. Assume the independent private values model and a noncooperative equilibrium of some auction mechanism. Suppose that in equilibrium the bidder with the highest value is certain to receive the object, and that a bidder with the lowest possible value has an expected payment of zero. Then the seller's expected revenue equals the expected value of the object to the second-highest evaluator. The symmetric equilibria of the English, Dutch, first-price and second-price auctions satisfy these conditions, so all four yield the same expected price. Proposition 14.43 generalizes Theorem 0 in two directions: bidders may be asymmetric, and the allocation need not be efficient.

Milgrom and Weber (1982, p. 1093) give the theorem an appealing economic reading. Whatever competitive mechanism sets the price, the sale on average takes place at the lowest price at which supply equals demand. The supply is one unit. At a price p, demand is the number of bidders with values above p. Demand equals one exactly when p lies between $V_{(n-1:n)}$ and $V_{(n:n)}$, and the lowest such price is $V_{(n-1:n)}$. Revenue equivalence thus says that auctions deliver, on average, the competitive price.

14.6.4 Using revenue equivalence to solve for equilibria

Revenue equivalence gives a shortcut to equilibrium bids. Suppose a format has a symmetric equilibrium with a strictly increasing bid function, so that the highest value wins, and the lowest type pays nothing. Then Proposition 14.43 fixes the expected payment of every type at $m(v) = \mathbb{E}[Y_1 \mathbf{1}(Y_1 < v)]$. Writing $m(v)$ in terms of the format's bid function gives an equation for that function. The shortcut produces a candidate. Its optimality must still be verified, which we do in each case.

First-price auction. The winner pays its bid, so $m(v) = \beta(v)F(v)^{n-1}$. Revenue equivalence gives

$$\beta(v) = \frac{\mathbb{E}[Y_1 \mathbf{1}(Y_1 < v)]}{F_{Y_1}(v)} = \mathbb{E}\left[Y_1 \,|\, Y_1 < v\right],$$

which is (14.30) without a reserve price. With a reserve price r, the allocation is $Q(v) = F(v)^{n-1}\mathbf{1}(v \geq r)$ and the type r earns zero. The payment identity then gives $m(v) = vF(v)^{n-1} - \int_r^v F(t)^{n-1}dt = \mathbb{E}[\max\{Y_1, r\}\mathbf{1}(Y_1 < v)]$ for $v \geq r$, which again delivers (14.30). Proposition 14.31 verified optimality.

All-pay auction. Every bidder pays its bid, win or lose. All-pay auctions model lobbying, research races and other contests in which effort is sunk. Here $m(v) = \beta(v)$, so

$$\beta^{AP}(v) = \mathbb{E}\big[Y_1 \mathbf{1}(Y_1 < v)\big] = \int_{\underline{v}}^{v} y \, dF_{Y_1}(y).$$

For uniform values, $\beta^{AP}(v) = \int_0^v y(n-1)y^{n-2}dy = \frac{n-1}{n}v^n$. To verify optimality, note that a bidder with value v who bids $\beta^{AP}(z)$ earns $vz^{n-1} - \frac{n-1}{n}z^n$. Its derivative with respect to z is $(n-1)z^{n-2}(v-z)$, which changes sign from positive to negative at $z = v$.

Third-price auction. With $n \geq 3$ bidders, the highest bidder wins and pays the third-highest bid. Let Y_2 denote the second-highest rival value. With a strictly increasing β, the expected payment is $m(v) = \mathbb{E}[\beta(Y_2)\mathbf{1}(Y_1 < v)]$. Revenue equivalence requires, for every v,

$$\int_{\underline{v}}^{v} \mathbb{E}\big[\beta(Y_2) \mid Y_1 = y\big] f_{Y_1}(y)\, dy = \int_{\underline{v}}^{v} y \, f_{Y_1}(y)\, dy.$$

Differentiating with respect to v and dividing by $f_{Y_1}(v)$ gives

$$\mathbb{E}\big[\beta(Y_2) \mid Y_1 = v\big] = v. \tag{14.46}$$

Given $Y_1 = v$, the other $n-2$ rival values are independent with distribution function $\frac{F(y)}{F(v)}$ on $[\underline{v}, v]$. The variable Y_2 is their maximum, with distribution function $\big(\frac{F(y)}{F(v)}\big)^{n-2}$. Condition (14.46) becomes

$$\int_{\underline{v}}^{v} \beta(y)\,(n-2)F(y)^{n-3}f(y)\,dy = v\,F(v)^{n-2}.$$

Differentiating with respect to v,

$$\beta(v)(n-2)F(v)^{n-3}f(v) = F(v)^{n-2} + v(n-2)F(v)^{n-3}f(v).$$

Dividing by $(n-2)F(v)^{n-3}f(v)$ gives

$$\beta^{III}(v) = v + \frac{F(v)}{(n-2)\,f(v)}. \tag{14.47}$$

The bid function is increasing whenever $\frac{F}{f}$ is nondecreasing, which holds for log-concave F. For uniform values, $\beta^{III}(v) = \frac{n-1}{n-2}v$, so bids exceed values. A bidder's own bid sets the price only when it ranks third, and then it loses anyway. Raising the bid above the value matters only when it overtakes the highest rival bid. The bidder then pays the second-highest rival bid, which may well lie below its value, so overbidding has a positive expected return. To verify optimality, a bidder with value v who bids $\beta^{III}(z)$ earns

$$\mathbb{E}\big[(v-\beta^{III}(Y_2))\mathbf{1}(Y_1 < z)\big] = \int_{\underline{v}}^{z} \big(v - \mathbb{E}[\beta^{III}(Y_2) \mid Y_1 = y]\big) f_{Y_1}(y)\,dy = \int_{\underline{v}}^{z} (v-y) f_{Y_1}(y)\,dy,$$

using (14.46). Its derivative with respect to z is $(v-z)f_{Y_1}(z)$, so $z = v$ is optimal.

14.6.5 Interdependent values with independent signals

Revenue equivalence survives interdependent values as long as signals are independent. We show this in an example that Section 14.9.2 reuses as the benchmark that affiliation breaks.

Example 14.44 (A common value with independent signals)**.** Two bidders observe signals S_1, S_2 that are independent and uniform on $[0,1]$. The object has the common value $V = \frac{S_1+S_2}{2}$ for both.

Second-price auction. We claim that bidding $\beta(s) = s$ is a symmetric equilibrium. Suppose bidder 2 bids S_2. Bidder 1 with signal s who bids $b \le 1$ wins when $S_2 < b$ and then pays S_2. Its expected payoff and its derivative are

$$\int_0^b \Big(\frac{s+s_2}{2} - s_2\Big) ds_2 = \int_0^b \frac{s-s_2}{2}\,ds_2, \qquad \frac{d}{db}\int_0^b \frac{s-s_2}{2}\,ds_2 = \frac{s-b}{2}.$$

The derivative is positive for $b < s$ and negative for $b > s$, so $b = s$ is optimal. Expected revenue is $\mathbb{E}[\min\{S_1, S_2\}] = \frac{1}{3}$.

First-price auction. We look for an equilibrium $\beta(s) = cs$. Suppose bidder 2 bids cS_2. Bidder 1 with signal s who bids b wins when $S_2 < \frac{b}{c}$. Its expected payoff is

$$\Pi(b) = \int_0^{\frac{b}{c}} \Big(\frac{s + s_2}{2} - b\Big) ds_2 = \frac{b}{c}\Big(\frac{s}{2} - b\Big) + \frac{b^2}{4c^2}.$$

The first-order condition is

$$\Pi'(b) = \frac{s}{2c} - \frac{2b}{c} + \frac{b}{2c^2} = 0.$$

At $b = cs$ it reads $\frac{s}{2c} - 2s + \frac{s}{2c} = 0$, so $c = \frac{1}{2}$. The second derivative is $-\frac{2}{c} + \frac{1}{2c^2} = -2 < 0$ at $c = \frac{1}{2}$, so the bid $\beta(s) = \frac{s}{2}$ is a best response. Expected revenue is $\frac{1}{2}\mathbb{E}[\max\{S_1, S_2\}] = \frac{1}{2} \cdot \frac{2}{3} = \frac{1}{3}$.

The two formats yield the same revenue. The envelope argument explains why. The value depends on the own signal with slope $\frac{1}{2}$, and a bidder with signal s wins with probability s in both formats. Hence $\pi'(s) = \frac{1}{2}s$, and with $\pi(0) = 0$ we get $\pi(s) = \frac{s^2}{4}$ in both formats. Direct computation confirms this: in the second-price auction $\int_0^s \frac{s - s_2}{2} ds_2 = \frac{s^2}{4}$, and in the first-price auction $\int_0^s \big(\frac{s+s_2}{2} - \frac{s}{2}\big) ds_2 = \frac{s^2}{4}$.

The example generalizes. With independent signals, a bidder's signal does not change the distribution of rival signals. The derivative of its equilibrium payoff with respect to its signal therefore depends only on who wins, as in Lemma 14.42. Two formats with the same allocation and the same payoff of the lowest type then have the same expected payments. Myerson (1981) allows for such interdependence through what he calls revision effects.

14.6.6 When revenue equivalence fails

Each hypothesis of Proposition 14.43 can fail in practice, and each failure leads to a result later in the chapter.

- Risk aversion makes payoffs nonlinear in money, so the envelope formula changes. The first-price auction then raises more revenue than the second-price auction (Proposition 14.40).
- Affiliated signals let a bidder's signal shift the distribution of rival signals, so the payment identity no longer holds. The English auction then yields at least as much revenue as the second-price auction, which yields at least as much as the first-price auction (Proposition 14.64).
- Asymmetric bidders break the efficiency of the first-price auction, so the interim allocations of the formats differ (Section 14.10).
- Endogenous entry with asymmetric bidders lets formats attract different sets of participants (Section 14.11).
- Collusive bidders do not play the noncooperative equilibrium, and formats differ in how easily a ring sustains its agreement (Section 14.12).
- Budget constraints make payoffs nonlinear in money, and the standard formats are then no longer equivalent (Che and Gale, 1998).

14.7 Reserve Prices and Optimal Auctions

Revenue equivalence says that the format does not matter once the allocation and the payoff of the lowest type are fixed. A seller can still raise revenue by changing the allocation. It can exclude low values with a reserve price, or it can favor some bidders over others. This section asks which allocation rule maximizes the seller's expected payoff. Myerson (1981) answered the question for independent private values in general, and Riley and Samuelson (1981) answered it for symmetric bidders and standard auctions. We maintain Assumption 14.41.

14.7.1 Expected revenue in terms of virtual values

Define bidder i's *virtual valuation*

$$\psi_i(v) = v - \frac{1 - F_i(v)}{f_i(v)}. \tag{14.48}$$

The next derivation expresses expected revenue in terms of virtual valuations.

Start from the payment identity (14.45) and take expectations over V_i:

$$\mathbb{E}\big[m_i(V_i)\big] = \int_{\underline{v}_i}^{\bar{v}_i} v Q_i(v) f_i(v)\, dv - \pi_i(\underline{v}_i) - \int_{\underline{v}_i}^{\bar{v}_i} \Big[\int_{\underline{v}_i}^{v} Q_i(t)\, dt\Big] f_i(v)\, dv.$$

The double integral runs over the triangle $\underline{v}_i \le t \le v \le \bar{v}_i$. Exchanging the order of integration (Fubini's theorem) gives

$$\int_{\underline{v}_i}^{\bar{v}_i} \Big[\int_{\underline{v}_i}^{v} Q_i(t)\, dt\Big] f_i(v)\, dv = \int_{\underline{v}_i}^{\bar{v}_i} Q_i(t)\Big[\int_{t}^{\bar{v}_i} f_i(v)\, dv\Big] dt = \int_{\underline{v}_i}^{\bar{v}_i} Q_i(t)\big(1 - F_i(t)\big)\, dt.$$

We substitute, rename the integration variable, and factor out $f_i(v)$:

$$\mathbb{E}\big[m_i(V_i)\big] = \int_{\underline{v}_i}^{\bar{v}_i} \Big[v - \frac{1 - F_i(v)}{f_i(v)}\Big] Q_i(v) f_i(v)\, dv - \pi_i(\underline{v}_i) = \mathbb{E}\big[\psi_i(V_i) Q_i(V_i)\big] - \pi_i(\underline{v}_i).$$

Since $Q_i(v_i) = \mathbb{E}[q_i(v_i, \boldsymbol{V}_{-i})]$ and values are independent, the law of iterated expectations gives $\mathbb{E}[\psi_i(V_i) Q_i(V_i)] = \mathbb{E}[\psi_i(V_i) q_i(\boldsymbol{V})]$. Summing over bidders,

$$\mathbb{E}\Big[\sum_{i=1}^{n} m_i(V_i)\Big] = \mathbb{E}\Big[\sum_{i=1}^{n} \psi_i(V_i)\, q_i(\boldsymbol{V})\Big] - \sum_{i=1}^{n} \pi_i(\underline{v}_i). \tag{14.49}$$

The seller also keeps the object, worth v_0, when it is not sold. Its expected payoff is therefore

$$\mathbb{E}\Big[\sum_{i=1}^{n} m_i(V_i)\Big] + v_0\, \mathbb{E}\Big[1 - \sum_{i=1}^{n} q_i(\boldsymbol{V})\Big] = v_0 + \mathbb{E}\Big[\sum_{i=1}^{n} \big(\psi_i(V_i) - v_0\big) q_i(\boldsymbol{V})\Big] - \sum_{i=1}^{n} \pi_i(\underline{v}_i). \tag{14.50}$$

The virtual valuation is a marginal revenue (Bulow and Roberts, 1989). Consider a seller who posts a price p to a single buyer with value distribution F. It sells with probability $x = 1 - F(p)$, which plays the role of a quantity. The inverse demand is $p(x) = F^{-1}(1 - x)$, with $p'(x) = -\frac{1}{f(p)}$. Revenue is $R(x) = x\, p(x)$, and marginal revenue is

$$R'(x) = p + x\, p'(x) = p - \frac{1 - F(p)}{f(p)} = \psi(p).$$

Selling to a buyer with value v adds v to surplus but forces the seller to leave rent to all higher types. The term $\frac{1-F(v)}{f(v)}$ measures that *information rent*, just as the inframarginal loss $x\,p'(x)$ enters a monopolist's marginal revenue (Chapter 2). Equation (14.50) says that the seller should allocate the object to the bidder with the highest marginal revenue, provided it exceeds its marginal cost v_0.

14.7.2 The optimal auction

Definition 14.45 (Regularity)**.** The distribution F_i is *regular* if its virtual valuation ψ_i is strictly increasing. It satisfies the *monotone hazard rate* condition if $\frac{f_i(v)}{1-F_i(v)}$ is nondecreasing.

The monotone hazard rate condition implies regularity, because then $\frac{1-F_i}{f_i}$ is nonincreasing and ψ_i is the sum of the strictly increasing function v and a nondecreasing function. Uniform, exponential and normal distributions satisfy it. For the uniform distribution on $[0,\bar v]$, $\psi(v) = v - (\bar v - v) = 2v - \bar v$. For the exponential distribution with rate λ, $\psi(v) = v - \frac{1}{\lambda}$.

Proposition 14.46 (Optimal auction, Myerson, 1981)**.** *Let Assumption 14.41 hold with every F_i regular. The following mechanism maximizes the seller's expected payoff among all incentive compatible and individually rational mechanisms.*

(i) The object goes to the bidder with the highest virtual valuation $\psi_i(v_i)$ if that virtual valuation exceeds v_0. Otherwise the seller keeps it.

(ii) The lowest type of every bidder earns zero, $\pi_i(\underline v_i) = 0$. One payment rule with this property charges the winner the lowest value it could have reported and still won: $\tau_i(\boldsymbol v) = q_i(\boldsymbol v)\inf\{z : \psi_i(z) \ge v_0 \text{ and } \psi_i(z) \ge \max_{j\neq i}\psi_j(v_j)\}$.

The seller's maximal expected payoff is $\mathbb{E}\big[\max\{v_0, \psi_1(V_1), \dots, \psi_n(V_n)\}\big]$.

Proof. By (14.50), the seller's expected payoff from any IC mechanism is

$$v_0 + \mathbb{E}\Big[\sum_i \big(\psi_i(V_i) - v_0\big)q_i(\boldsymbol V)\Big] - \sum_i \pi_i(\underline v_i).$$

IR requires $\pi_i(\underline v_i) \ge 0$, so the last term is at least zero. We maximize the middle term pointwise. Fix a profile $\boldsymbol v$ and maximize $\sum_i(\psi_i(v_i) - v_0)q_i$ subject to $q_i \ge 0$ and $\sum_i q_i \le 1$. The maximum places all probability on a bidder with the largest $\psi_i(v_i) - v_0$ when it is positive, and none otherwise. This is rule (i), and setting $\pi_i(\underline v_i) = 0$ minimizes the subtracted term.

It remains to check that the solution satisfies the constraints. Under regularity, $q_i(v_i, \boldsymbol v_{-i})$ from rule (i) is nondecreasing in v_i for every $\boldsymbol v_{-i}$, so Q_i is nondecreasing. By Lemma 14.42, payments defined by the payment identity with $\pi_i(\underline v_i) = 0$ make the mechanism IC. IR holds for every type, because $\pi_i(v_i) = \int_{\underline v_i}^{v_i} Q_i(t)dt \ge 0$. The payment rule in (ii) is one such rule. Under it, a bidder wins exactly when its report exceeds a threshold that does not depend on its report, and it pays the threshold. Truth-telling is then a dominant strategy, as in the second-price auction, and the lowest type pays nothing. Finally, with $\pi_i(\underline v_i) = 0$ and rule (i), the term inside the expectation in (14.50), plus v_0, equals $\max\{v_0, \max_i \psi_i(v_i)\}$ at every profile. Taking expectations gives the stated value. □

Regularity matters only for the monotonicity of Q_i. When ψ_i is not monotone, the pointwise rule can violate condition (a) of Lemma 14.42. Myerson (1981) then replaces ψ_i by an *ironed* virtual valuation that is flat on the intervals where monotonicity fails. We do not develop ironing here.

14.7.3 Symmetric bidders: the optimal reserve price

With symmetric bidders, the optimal mechanism is a standard auction with a reserve price.

Corollary 14.47 (Optimal reserve price, Riley and Samuelson, 1981; Myerson, 1981)**.** *Let Assumption 14.41 hold with $F_i = F$ regular for every i, and suppose $\psi(\underline{v}) < v_0 < \bar{v}$. Let r^* solve*

$$r^* - \frac{1 - F(r^*)}{f(r^*)} = v_0. \tag{14.51}$$

Then the following hold.

(i) The first-price, second-price, English and Dutch auctions with reserve price r^* are all optimal mechanisms.

(ii) The optimal reserve price exceeds the seller's value, $r^* > v_0$.

(iii) The optimal reserve price does not depend on the number of bidders.

Proof. With a common and strictly increasing ψ, the bidder with the highest virtual valuation is the bidder with the highest value. Rule (i) of Proposition 14.46 therefore awards the object to the highest value if $\psi(v) > v_0$, that is, if $v > r^*$. Each standard auction with reserve price r^* has a symmetric equilibrium with strictly increasing bids (Propositions 14.22 and 14.31). In it, the highest value wins whenever it is at least r^*, and the lowest type earns zero. By Proposition 14.43, its expected revenue equals that of the optimal mechanism, which proves (i). For (ii), $\frac{1-F(r^*)}{f(r^*)} > 0$ for $r^* < \bar{v}$, so (14.51) gives $r^* > v_0$. For (iii), neither F nor v_0 depends on n. □

A direct calculation in the second-price auction shows the trade-off behind (14.51). Raise the reserve from r to $r + dr$. The price rises by dr in the event that exactly one bidder has a value above r, which has probability $nF(r)^{n-1}\big(1 - F(r)\big)$. The sale is lost, and the seller receives v_0 instead of r, in the event that the highest value lies in $[r, r + dr]$, which has probability $nF(r)^{n-1} f(r)\, dr$. The marginal effect on the seller's payoff is

$$nF(r)^{n-1}\Big[\big(1 - F(r)\big) - (r - v_0) f(r)\Big] = nF(r)^{n-1} f(r)\big[v_0 - \psi(r)\big].$$

The seller gains from raising r while $\psi(r) < v_0$ and loses once $\psi(r) > v_0$. The number of bidders enters only through the positive factor $nF(r)^{n-1}$, which explains why r^* does not depend on n. The reserve price is a monopoly price. It is set as if the seller faced a single buyer, because it binds only when a single buyer is left.

Hortaçsu and Perrigne (2021, Section 2.1, p. 87) state the same condition, $r^* = v_0 + \frac{1-F(r^*)}{f(r^*)}$, and stress that it does not depend on the number of potential bidders. Setting r^* requires knowledge of F, which is what the empirical methods of Chapter 15 estimate. The estimated gains can be large. In ascending auctions of British Columbia timber, Paarsch (1997) finds average optimal reserve prices 3.4 to 4.2 times the observed ones. The range corresponds to seller values from zero to the appraised value of the timber (Hortaçsu and Perrigne, 2021, p. 88). Haile and Tamer (2003) bound the optimal reserve price in U.S. Forest Service ascending auctions. Depending on the seller's value, the implied gain in the seller's profit ranges from little to 34 percent (Hortaçsu and Perrigne, 2021, p. 88).

For values uniform on $[0, 1]$, $\psi(v) = 2v - 1$ and (14.51) gives $r^* = \frac{1+v_0}{2}$, so $r^* = \frac{1}{2}$ when $v_0 = 0$. For exponential values with rate λ, $\psi(v) = v - \frac{1}{\lambda}$ and $r^* = v_0 + \frac{1}{\lambda}$, which equals $\frac{1}{\lambda}$ when $v_0 = 0$.

Figure 14.10 shows the uniform case. Milgrom and Weber (1982, p. 1093) summarize the implication. For many common distributions, including the normal, exponential and uniform, the four standard formats with suitably chosen reserve prices or entry fees are optimal auctions.

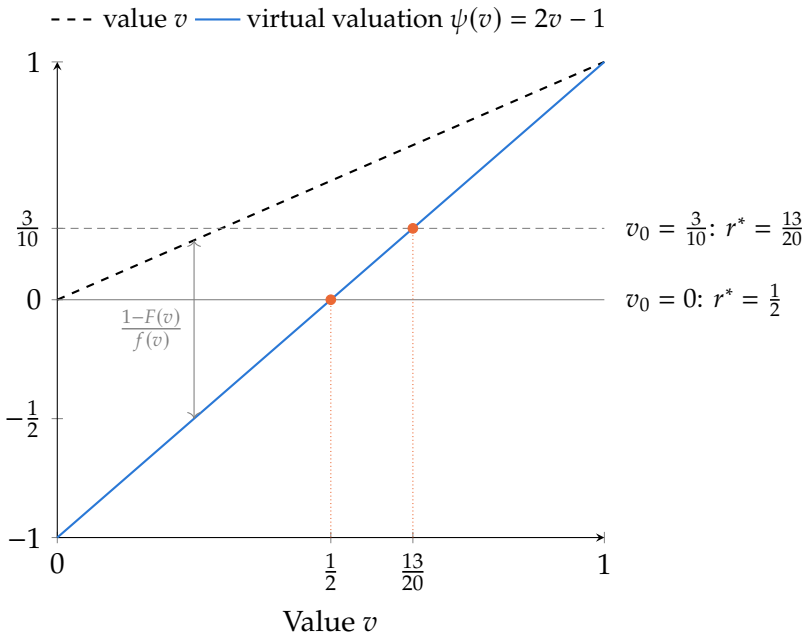

Figure 14.10: Virtual valuation for values uniform on $[0, 1]$. The gap between the value and the virtual valuation is the information rent $\frac{1-F(v)}{f(v)} = 1 - v$. The optimal reserve price is the value at which the virtual valuation equals the seller's value v_0, so it exceeds v_0.

14.7.4 The cost of a reserve price: a worked example

Let values be uniform on $[0, 1]$, $v_0 = 0$ and $n = 2$. Without a reserve price, revenue is $\mathbb{E}[V_{(1:2)}] = \frac{1}{3}$. With the optimal reserve $r^* = \frac{1}{2}$, Proposition 14.46 gives expected revenue

$$\mathbb{E}\big[\max\{0, \psi(V_{(2:2)})\}\big] = \int_{\frac{1}{2}}^{1} (2v-1)\, 2v\, dv = 2\int_{\frac{1}{2}}^{1} (2v^2 - v)\, dv = 2\Big[\frac{2v^3}{3} - \frac{v^2}{2}\Big]_{\frac{1}{2}}^{1} = 2\Big(\frac{1}{6} + \frac{1}{24}\Big) = \frac{5}{12}.$$

A direct computation in the second-price auction confirms the number. Both values exceed $\frac{1}{2}$ with probability $\frac{1}{4}$, and the price is then the lower value, with conditional mean $\frac{2}{3}$. Exactly one value exceeds $\frac{1}{2}$ with probability $\frac{1}{2}$, and the price is then $\frac{1}{2}$. Expected revenue is $\frac{1}{4} \cdot \frac{2}{3} + \frac{1}{2} \cdot \frac{1}{2} = \frac{5}{12}$, the same as the first-price revenue in Example 14.33.

The gain to the seller comes at a cost. With probability $\frac{1}{4}$ both values fall below $\frac{1}{2}$ and the object is not sold, although the seller values it at zero. The expected surplus lost in this event is $\int_0^{\frac{1}{2}} v\, 2v\, dv = \frac{1}{12}$. Total surplus falls from $\frac{2}{3}$ to $\frac{7}{12}$, and the bidders' combined surplus falls from $\frac{1}{3}$ to $\frac{1}{6}$. The reserve price thus transfers $\frac{1}{12}$ from bidders to the seller and destroys another $\frac{1}{12}$. This exclusion of buyers who value the object more than the seller is the auction analogue of the deadweight loss of monopoly pricing.

The gain from the reserve shrinks quickly with the number of bidders. For n uniform

bidders,

$$\int_{\frac{1}{2}}^{1} (2v-1)\, n v^{n-1}\, dv = \left[\frac{2n\, v^{n+1}}{n+1} - v^n\right]_{\frac{1}{2}}^{1} = \frac{n-1}{n+1} + \frac{1}{(n+1)2^n}.$$

The second term is the gain over the no-reserve revenue $\frac{n-1}{n+1}$. The reserve binds only when at most one value exceeds it, and that event becomes rare as n grows. Table 14.7 reports the numbers.

Table 14.7: The value of the optimal reserve price and of one more bidder, with values uniform on $[0,1]$ and $v_0 = 0$.

	Expected revenue, n bidders				Absolute auction,
n	No reserve	Reserve $r^* = \frac{1}{2}$	$\mathbb{P}$(no sale)	Surplus lost	$n+1$ bidders
1	0	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{8}$	$\frac{1}{3}$
2	$\frac{1}{3}$	$\frac{5}{12}$	$\frac{1}{4}$	$\frac{1}{12}$	$\frac{1}{2}$
3	$\frac{1}{2}$	$\frac{17}{32}$	$\frac{1}{8}$	$\frac{3}{64}$	$\frac{3}{5}$
4	$\frac{3}{5}$	$\frac{49}{80}$	$\frac{1}{16}$	$\frac{1}{40}$	$\frac{2}{3}$
5	$\frac{2}{3}$	$\frac{43}{64}$	$\frac{1}{32}$	$\frac{5}{384}$	$\frac{5}{7}$

Notes: Without a reserve price, revenue is $\frac{n-1}{n+1}$. With $r^* = \frac{1}{2}$, revenue is $\frac{n-1}{n+1} + \frac{1}{(n+1)2^n}$, the revenue of the optimal mechanism. The probability of no sale is 2^{-n}. Surplus lost is the expected value of the highest bidder when the object is not sold, $\frac{n}{n+1}2^{-(n+1)}$. The last column is the revenue of an English auction without reserve price and with $n+1$ bidders, $\frac{n}{n+2}$. With $n = 1$ the optimal mechanism is a posted price of $\frac{1}{2}$. All entries are exact.

14.7.5 Competition versus mechanism design

The last column of Table 14.7 anticipates a striking result. In every row, an auction without a reserve price and with one more bidder beats the optimal mechanism.

Proposition 14.48 (Bulow and Klemperer, 1996)**.** *Let Assumption 14.41 hold with symmetric bidders, a common regular distribution F on $[\underline{v}, \bar{v}]$, and $\underline{v} \geq v_0$. Then an English auction without a reserve price and with $n+1$ bidders yields at least as much expected revenue as the optimal mechanism with n bidders.*

Proof. Let R_n^* denote the seller's expected payoff in the optimal mechanism with n bidders. Construct a mechanism for $n+1$ bidders as follows. Run the optimal n-bidder mechanism among bidders $1, \ldots, n$. If it sells the object, stop. If it does not, give the object to bidder $n+1$ at the price $\underline{v}$. This mechanism is incentive compatible, since bidder $n+1$'s report affects nothing. It is individually rational, and every lowest type earns zero. It always sells the object.

By (14.49), the constructed mechanism yields

$$\mathbb{E}\Big[\sum_{i=1}^{n} \psi(V_i) q_i(\boldsymbol{V})\Big] + \mathbb{E}\big[\psi(V_{n+1})\big]\mathbb{P}(\text{no sale among } 1, \ldots, n),$$

where we used the independence of V_{n+1} from the other values. Integration by parts gives $\mathbb{E}[\psi(V)] = \mathbb{E}[V] - \int_{\underline{v}}^{\bar{v}} (1 - F(v))dv = \mathbb{E}[V] - (\mathbb{E}[V] - \underline{v}) = \underline{v}$. The optimal n-bidder mechanism yields the same first term plus $v_0\mathbb{P}$(no sale). Because $\underline{v} \geq v_0$, the constructed mechanism earns at least R_n^*.

Now consider all incentive compatible mechanisms for $n+1$ bidders that always sell and leave the lowest types with zero. By (14.49), revenue is $\mathbb{E}[\sum_i \psi(V_i)q_i(\boldsymbol{V})]$ with $\sum_i q_i = 1$. It is maximized pointwise by awarding the object to the highest virtual valuation, which under regularity is the highest value. The English auction without reserve price does exactly this, and its lowest types earn zero. Hence its revenue is at least that of the constructed mechanism, which is at least R_n^*. □

For uniform values, the optimal mechanism with two bidders earns $\frac{5}{12}$, while an English auction with three bidders earns $\frac{3-1}{3+1} = \frac{1}{2}$. Even a single buyer facing an optimal posted price yields only $\frac{1}{4}$, below the $\frac{1}{3}$ of a two-bidder auction. Bulow and Klemperer (1996) frame the result as auctions versus negotiations. A seller who can recruit one more serious bidder should do so rather than negotiate optimally with the bidders it has. Competition is worth more than bargaining power and knowledge of the value distribution. The result needs symmetric bidders, regular distributions and costless participation. Section 14.11 studies what changes when entry is costly.

The ranking also holds in data where its assumptions do not hold exactly. Roberts and Sweeting (2016) estimate a model of U.S. Forest Service timber auctions with asymmetric bidders and selective entry, in which entrants bid in a second-price auction. In their estimates, an additional bidder is worth more to the seller than an optimal reserve price (Hortaçsu and Perrigne, 2021, Section 2.2, p. 92).

14.7.6 Asymmetric bidders: favoring the weak

With asymmetric bidders, the optimal mechanism discriminates. Consider two bidders and $v_0 = 0$. The weak bidder's value is uniform on $[0,1]$ and the strong bidder's value is uniform on $[0,2]$. The virtual valuations are

$$\psi_w(v) = v - \frac{1-v}{1} = 2v - 1, \qquad \psi_s(v) = v - \frac{1-\frac{v}{2}}{\frac{1}{2}} = 2v - 2.$$

At equal values the weak bidder has the higher virtual valuation. By Proposition 14.46, the weak bidder wins when $2v_w - 1 > \max\{2v_s - 2, 0\}$, that is, when $v_w > \frac{1}{2}$ and $v_w > v_s - \frac{1}{2}$. The strong bidder wins when $v_s > 1$ and $v_s > v_w + \frac{1}{2}$. The mechanism sets bidder-specific reserve prices, $\frac{1}{2}$ for the weak bidder and 1 for the strong bidder, and gives the weak bidder a head start of $\frac{1}{2}$ in the competition.

Figure 14.11 shows the regions. Values are uniform on the rectangle $[0,1] \times [0,2]$, so each probability is half the corresponding area. The object is not sold with probability $\frac{1}{4}$. The weak bidder wins with probability $\frac{5}{16}$ and the strong bidder with probability $\frac{7}{16}$. With probability $\frac{1}{8}$ the weak bidder wins although the strong bidder values the object more. The seller's expected revenue is $\mathbb{E}[\max\{0, \psi_w(V_w), \psi_s(V_s)\}] = \frac{31}{48} \approx 0.646$. A second-price auction without reserve price earns $\mathbb{E}[\min\{V_w, V_s\}] = \frac{5}{12} \approx 0.417$. Section 14.10 computes the first-price revenue in the same example. Expected total surplus is $\frac{11}{12}$ under the optimal mechanism, against $\frac{13}{12}$ under the efficient allocation. Each fraction follows from integrating over the regions in Figure 14.11.

The logic resembles third-degree price discrimination, in which a monopolist charges less to the group with more elastic demand. In the auction the weak bidder plays the role of the elastic group. Here the head start for the weak bidder forces the strong bidder to pay more when it wins. The first-price auction also tilts outcomes toward weak bidders, although for different reasons (Section 14.10). This is one reason why it may raise more revenue than the

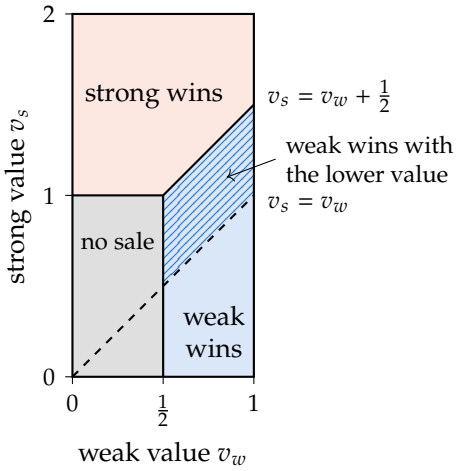

Figure 14.11: The optimal allocation with a weak bidder, $V_w \sim U[0,1]$, and a strong bidder, $V_s \sim U[0,2]$, when $v_0 = 0$. The hatched region is where the weak bidder wins although the strong bidder has the higher value.

second-price auction with asymmetric bidders. Bid preferences for small or domestic firms in public procurement have the same structure (McAfee and McMillan, 1989), as Section 14.13 discusses.

14.7.7 Entry fees

With symmetric independent private values, an entry fee can replace the reserve price. Suppose the seller runs a second-price auction without reserve price, values are bounded below by $\underline{v} = 0$, and each participant pays a fee e. A bidder with value v^* at the participation threshold wins only when no rival participates, which has probability $F(v^*)^{n-1}$, and then pays nothing. Its gross expected payoff is $v^*F(v^*)^{n-1}$, so the threshold solves $v^*F(v^*)^{n-1} = e$. Setting $e^* = r^*F(r^*)^{n-1}$ makes the threshold equal to r^*. The allocation is then the optimal one, and the threshold type earns zero. By Proposition 14.43, the entry fee e^* yields the optimal revenue. With uniform values and $n = 2$, $e^* = \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{4}$. Each bidder enters with probability $\frac{1}{2}$, so fees bring in $2 \cdot \frac{1}{2} \cdot \frac{1}{4} = \frac{1}{4}$, and the price paid when both enter adds $\frac{1}{4} \cdot \frac{2}{3} = \frac{1}{6}$. The total is $\frac{5}{12}$, as with the optimal reserve price.

With affiliated values the equivalence breaks down. Milgrom and Weber (1982) compare reserve prices and entry fees that screen out the same types, and Section 14.9.4 presents their result. With costly entry before bidders learn their values, reserve prices and fees also affect how many bidders participate (Section 14.11). The optimal reserve depends on F, which the seller does not observe directly. Chapter 15 shows how F can be recovered from bids.

The original papers. Myerson (1981) poses the general design problem. A seller faces bidders with independent private information and may use any selling procedure. He proves the revelation principle for this setting, derives the payment identity and revenue equivalence, and shows that the optimal mechanism allocates by virtual valuations, with ironing when they are not monotone. Riley and Samuelson (1981) reach the optimal reserve price (14.51) within the class of standard auctions and show that it is independent of the number of bidders. Hortaçsu and Perrigne (2021, p. 87) attribute the formula to both papers. Milgrom and Weber (1982, p. 1093) credit the optimal auction to the self-selection approach of Harris and Raviv (1981),

Myerson (1981) and Riley and Samuelson (1981). Bulow and Roberts (1989) interpret virtual valuations as marginal revenues and recast optimal auction design as monopoly pricing. Bulow and Klemperer (1996) prove Proposition 14.48 and draw the lesson that attracting bidders matters more than fine-tuning the mechanism.

14.8 Affiliated Values I: Equilibrium Bidding

The private-values theory of Sections 14.4 to 14.7 rests on two assumptions. Each bidder knows the value of the object to itself, and values are statistically independent. Many of the auctions that motivate the theory violate both. An oil company bidding for a drilling lease does not know how much oil lies under the tract, and its geologists' estimate is correlated with the estimates of its rivals. This section and the next study the model of Milgrom and Weber (1982), which drops both assumptions at once and still delivers sharp predictions. Their model became the standard framework for auctions with interdependent values, and we treat the paper as a deep dive.

This section sets out the questions, the model and the properties of affiliation, and then derives the symmetric equilibria of the second-price, English and first-price auctions. It also covers bidders with inferior information, including the one-informed-bidder model that Hendricks and Porter (1988) take to offshore oil data. Section 14.9 uses these equilibria to rank the formats by expected revenue, studies the seller's disclosure of information, reserve prices, entry fees and risk aversion, and assesses the paper. We keep the book's conventions from Section 14.3. Bidder i's signal is S_i (Milgrom and Weber write X_i), other value-relevant variables are $\boldsymbol{A} = (A_1, \ldots, A_m)$ (their S), and the seller's information is S_0 (their X_0).

14.8.1 The question and the setting

Milgrom and Weber (1982, pp. 1089–1090) open with two sets of questions. The first concerns design. Why do the English, Dutch, first-price and second-price auctions coexist, and which one should a seller use in a given circumstance? The second concerns the link with competitive theory. Do auction prices resemble competitive prices, and do they approach them when there are many bidders? When bidders hold different information about the intrinsic qualities of the object, do prices aggregate that information, as they do in rational expectations models of markets? Answering either set requires a model in which one bidder's information matters for the value that others place on the object.

The benchmark at the time was the independent private values model, which Milgrom and Weber (1982, pp. 1090–1093) summarize in seven conclusions. All of them appear earlier in this chapter.

(1) The Dutch and first-price auctions are strategically equivalent (Proposition 14.4).

(2) With private values, the second-price and English auctions are equivalent in a weaker sense. Each has a dominant strategy, bidding (or staying in up to) one's value, and the two lead to the same outcome (Section 14.4).

(3) The English and second-price auctions allocate the object to the bidder who values it most, so their outcomes are Pareto optimal. In symmetric models the Dutch and first-price auctions do so as well (Section 14.5).

(4) All four formats yield the same expected revenue (Proposition 14.43).

(5) The self-selection approach explains this. Any mechanism that gives the object to the highest valuation and leaves the lowest type a zero payment yields the expected second-highest valuation (Section 14.6).

(6) For many common distributions, including the normal, exponential and uniform, the standard formats with a suitable reserve price or entry fee are optimal mechanisms (Section 14.7).

(7) When bidders are risk averse, the seller strictly prefers the Dutch or first-price auction to the English or second-price auction (Proposition 14.40).

For the design question this benchmark gives little guidance. Its main prediction is that the four common formats raise the same expected price (Milgrom and Weber, 1982, p. 1095).

Mineral rights are the leading example of a different environment (Milgrom and Weber, 1982, Section 2.2). To a first approximation the rights are worth the same to every bidder, and bidders differ only in their estimates of this common value. Section 14.3.4 described the resulting winner's curse and the two results of the mineral rights literature that foreshadow the general theory. Prices can aggregate dispersed information (Remark 14.19), and a bidder's profit depends more on the privacy of its information than on its accuracy (Remark 14.20). We prove a version of the second result in Section 14.8.5.

The sale of a painting (Section 14.3.1) shows why a general model is needed. Resale, prestige and doubts about authenticity break private values, and related information breaks independence. The common value model allows for statistical dependence but leaves no room for differences in tastes. Milgrom and Weber build a model that contains both the private values and common value models and the intermediate cases between them. Despite its generality, the model yields testable predictions (Milgrom and Weber, 1982, pp. 1095–1097).

(i) The Dutch and first-price auctions remain strategically equivalent.

(ii) When bidders are uncertain about their own values, the English auction generates higher expected prices than the second-price auction. Bidders learn from the prices at which rivals drop out, which weakens the winner's curse and makes them bid more aggressively.

(iii) When value estimates are positively dependent, the second-price auction generates higher expected prices than the first-price auction. The formats are ranked English, then second price, then Dutch and first price. Milgrom and Weber suggest that this ranking may explain an observation by Cassady. In his words, "an estimated 75 per cent, or even more, of all auctions in the world are conducted on an ascending-bid basis" (Cassady, 1967, p. 66, quoted in Milgrom and Weber 1982, p. 1095).

(iv) A seller with private information can commit to concealing it, reporting it fully, censoring it, summarizing it or adding noise to it. In the first-price, second-price and English auctions, reporting it fully maximizes the expected price.

(v) Holding fixed the set of bidders who participate, it pays to raise entry fees and lower reserve prices.

(vi) With risk-averse bidders, the first-price and second-price auctions cannot be ranked in general. With constant absolute risk aversion, the English auction still beats the second-price auction and full disclosure remains optimal in both.

The rest of this section and the next derive each prediction.

14.8.2 The model

We work with the general symmetric model of Section 14.3.1 and maintain Assumption 14.10 throughout this section and the next. There are $n \geq 2$ bidders and one indivisible object. Bidder i observes a real-valued signal S_i with realization s_i, which we also call its *value estimate*. The vector $\boldsymbol{A} = (A_1, \ldots, A_m)$ collects the other variables that affect the value of the object, such as an expert appraisal or the tastes of future buyers. The value to bidder i is $V_i = u(\boldsymbol{A}, S_i, \boldsymbol{S}_{-i})$, which may depend on variables that bidder i does not observe. Private values are the case $m = 0$ and $V_i = S_i$, and the pure common value model is the case $m = 1$ and $V_i = A_1$. Bidders are risk neutral until Section 14.9.5. A bidder who wins and pays b receives $V_i - b$, and losers receive zero.

By symmetry we can study bidder 1. Let $Y_1 \geq Y_2 \geq \cdots \geq Y_{n-1}$ denote the order statistics of the rivals' signals $S_2, \ldots, S_n$, largest first. Because u is symmetric in the rivals' signals, bidder 1's value depends on them only through their order statistics:

$$V_1 = u(\boldsymbol{A}, S_1, Y_1, \ldots, Y_{n-1}). \tag{14.52}$$

The joint density of $(\boldsymbol{A}, S_1, Y_1, \ldots, Y_{n-1})$ is (14.10), which is $(n-1)!$ times the density f restricted to ordered vectors of rival signals.

The function that drives all equilibria is the expected value of the object to bidder 1 when its signal is s and the highest rival signal is y:

$$v(s, y) = \mathbb{E}\left[V_1 \mid S_1 = s,\ Y_1 = y\right]. \tag{14.53}$$

We write $F_{Y_1}(\cdot \mid s)$ and $f_{Y_1}(\cdot \mid s)$ for the conditional distribution function and density of Y_1 given $S_1 = s$, and $[\underline{s}, \bar{s}]$ for the support of each signal. Milgrom and Weber add a *nondegeneracy* assumption, namely that $\mathbb{E}[V_1 \mid S_1 = s, Y_1 = y_1, \ldots, Y_{n-1} = y_{n-1}]$ is strictly increasing in s. It shortens proofs, and all results hold without it (Milgrom and Weber, 1982, p. 1100). A strategy for bidder i is a function $\beta_i : [\underline{s}, \bar{s}] \to \mathbb{R}_+$ from signals to bids. We study symmetric equilibria in which every bidder uses the same strictly increasing β.

14.8.3 Properties of affiliation

Affiliation was defined in Definition 14.11, and Proposition 14.12 gave its characterization for smooth densities (Milgrom and Weber's Theorem 1). Proposition 14.16 listed the four further properties that the equilibrium analysis uses (their Theorems 2 to 5), and Section 14.3.3 proved part (iv), which concerns order statistics. We now prove the other three parts, or sketch the proofs, in the generality that we need.

Proof of Proposition 14.16, parts (i) to (iii). Part (i). We prove the case of strictly increasing, differentiable g_j, which covers our applications. Let $\boldsymbol{W} = (g_1(Z_1), \ldots, g_k(Z_k))$ and $\boldsymbol{g}^{-1}(\boldsymbol{w}) = (g_1^{-1}(w_1), \ldots, g_k^{-1}(w_k))$. The change-of-variables formula gives the density of $\boldsymbol{W}$:

$$f_{\boldsymbol{W}}(\boldsymbol{w}) = f\left(\boldsymbol{g}^{-1}(\boldsymbol{w})\right) J(\boldsymbol{w}), \qquad J(\boldsymbol{w}) = \prod_{j=1}^{k} \frac{d g_j^{-1}(w_j)}{d w_j}.$$

Each g_j^{-1} is increasing and acts on one coordinate, so $\boldsymbol{g}^{-1}(\boldsymbol{w} \vee \boldsymbol{w}') = \boldsymbol{g}^{-1}(\boldsymbol{w}) \vee \boldsymbol{g}^{-1}(\boldsymbol{w}')$, and similarly for $\wedge$. The affiliation of f then gives $f(\boldsymbol{g}^{-1}(\boldsymbol{w} \vee \boldsymbol{w}'))\, f(\boldsymbol{g}^{-1}(\boldsymbol{w} \wedge \boldsymbol{w}')) \geq f(\boldsymbol{g}^{-1}(\boldsymbol{w}))\, f(\boldsymbol{g}^{-1}(\boldsymbol{w}'))$.

For the Jacobian, the pair $\{\max\{w_j, w_j'\}, \min\{w_j, w_j'\}\}$ equals the pair $\{w_j, w_j'\}$ in every coordinate, so $J(\boldsymbol{w} \vee \boldsymbol{w}')J(\boldsymbol{w} \wedge \boldsymbol{w}') = J(\boldsymbol{w})J(\boldsymbol{w}')$. Multiplying the two relations proves the claim. If all g_j are decreasing, then $\boldsymbol{g}^{-1}(\boldsymbol{w} \vee \boldsymbol{w}') = \boldsymbol{g}^{-1}(\boldsymbol{w}) \wedge \boldsymbol{g}^{-1}(\boldsymbol{w}')$, and the argument goes through because (14.7) is symmetric in the roles of $\vee$ and $\wedge$. Weakly monotone transformations can create atoms, and they require the general definition of affiliation in Milgrom and Weber's Appendix.

Parts (ii) and (iii). Milgrom and Weber derive both from the characterization of affiliation as conditional association in Proposition 14.15(b). For densities, Karlin and Rinott (1980) prove directly that integrating out a variable preserves (14.7), which is part (ii). Part (iii) follows from the conditional association inequality applied to $g = H$ and to indicators of increasing sets (see also Whitt, 1982). We prove (iii) in the bivariate case that we use most often. Let (Z_1, Z_2) have an affiliated density, let H be nondecreasing, and consider $\mathbb{E}[H(Z_2) \mid Z_1 = z,\, Z_2 \le x]$. Conditional on $Z_1 = z$ and $Z_2 \le x$, Z_2 has density $\frac{f(y|z)}{F(x|z)}$ on $y \le x$. For $z' > z$ the ratio of the densities under z' and z is $\frac{f(y|z')F(x|z)}{f(y|z)F(x|z')}$, which is nondecreasing in y by the monotone likelihood ratio property (Proposition 14.13). A likelihood ratio ordering implies first-order stochastic dominance, so the conditional mean of the nondecreasing function H rises with z. For $x' > x$, the ratio of the densities truncated at x' and at x equals the constant $\frac{F(x|z)}{F(x'|z)}$ on $y \le x$ and is infinite on $(x, x']$. It is nondecreasing in y, so the mean rises with x as well. □

Two consequences are used repeatedly.

Corollary 14.49. *Under Assumption 14.10, (S_1, Y_1) are affiliated, and $v(s, y)$ is nondecreasing in both arguments. Under nondegeneracy, v is strictly increasing in s.*

Proof. Affiliation of (S_1, Y_1) follows from parts (iv) and (ii) of Proposition 14.16. Let

$$\bar{v}(s, y_1, \ldots, y_{n-1}) = \mathbb{E}\left[V_1 \mid S_1 = s,\, Y_1 = y_1, \ldots, Y_{n-1} = y_{n-1}\right].$$

By (14.52), $\bar{v}$ is the conditional mean of the nondecreasing function u of the affiliated vector of Proposition 14.16(iv), so it is nondecreasing by part (iii). The law of iterated expectations gives

$$v(s, y) = \mathbb{E}\left[\bar{v}(S_1, Y_1, \ldots, Y_{n-1}) \mid S_1 = s,\, Y_1 = y\right],$$

which is nondecreasing by part (iii) again. If $\bar{v}$ is strictly increasing in s and $s' > s$, then

$$\begin{aligned} v(s', y) &= \mathbb{E}[\bar{v}(s', y, Y_2, \ldots, Y_{n-1}) \mid S_1 = s', Y_1 = y] \\ &> \mathbb{E}[\bar{v}(s, y, Y_2, \ldots, Y_{n-1}) \mid S_1 = s', Y_1 = y] \\ &\ge \mathbb{E}[\bar{v}(s, y, Y_2, \ldots, Y_{n-1}) \mid S_1 = s, Y_1 = y] = v(s, y). \end{aligned}$$

□

Lemma 14.50 (Milgrom and Weber, 1982, Lemma 1)**.** *Under Assumption 14.10, $\frac{F_{Y_1}(y|z)}{f_{Y_1}(y|z)}$ is nonincreasing in z.*

Proof. Let $g(z, y)$ be the joint density of (S_1, Y_1), which is affiliated by Corollary 14.49. Take $\alpha \le y$ and $z' \le z$, and apply (14.7) to the points (z, α) and (z', y). Their componentwise maximum is (z, y) and their minimum is (z', α), so

$$g(z, y)\, g(z', \alpha) \ge g(z, \alpha)\, g(z', y).$$

Dividing both sides by the marginal densities of S_1 at z and z' turns joint densities into conditional densities:

$$f_{Y_1}(y \mid z)\, f_{Y_1}(\alpha \mid z') \ge f_{Y_1}(\alpha \mid z)\, f_{Y_1}(y \mid z').$$

Rearranging gives $\frac{f_{Y_1}(\alpha|z)}{f_{Y_1}(y|z)} \le \frac{f_{Y_1}(\alpha|z')}{f_{Y_1}(y|z')}$ for every $\alpha \le y$. Integrating over $\alpha \in [\underline{s}, y]$ yields $\frac{F_{Y_1}(y|z)}{f_{Y_1}(y|z)} \le \frac{F_{Y_1}(y|z')}{f_{Y_1}(y|z')}$. □

14.8.4 The second-price auction

Suppose bidders $2, \dots, n$ use strategies β_j, and let $M_1 = \max_{j \neq 1} \beta_j(S_j)$ be the highest rival bid. Bidder 1 wins the second-price auction if its bid exceeds M_1, and then it pays M_1. With signal s it chooses b to solve

$$\max_b \ \mathbb{E}\left[(V_1 - M_1)\,\mathbf{1}\{M_1 < b\} \mid S_1 = s\right].$$

Proposition 14.51 (Milgrom and Weber, 1982, Theorem 6)**.** *Under Assumption 14.10, the strategy $\beta^{SP}(s) = v(s, s)$ used by every bidder is a symmetric equilibrium of the second-price auction.*

Proof. Let bidders $2, \dots, n$ use β^{SP}. Since β^{SP} is increasing, the highest rival bid is $M_1 = \beta^{SP}(Y_1) = v(Y_1, Y_1)$. Bidder 1's expected payoff from a bid b in the range of β^{SP} is

$$\begin{aligned}
&\mathbb{E}\left[(V_1 - \beta^{SP}(Y_1))\mathbf{1}\{\beta^{SP}(Y_1) < b\} \mid S_1 = s\right] \\
&\quad = \mathbb{E}\left[\mathbb{E}\left[(V_1 - \beta^{SP}(Y_1))\mathbf{1}\{\beta^{SP}(Y_1) < b\} \mid S_1, Y_1\right] \mid S_1 = s\right] \\
&\quad = \mathbb{E}\left[(v(S_1, Y_1) - v(Y_1, Y_1))\,\mathbf{1}\{\beta^{SP}(Y_1) < b\} \mid S_1 = s\right] \\
&\quad = \int_{\underline{s}}^{(\beta^{SP})^{-1}(b)} [v(s, \alpha) - v(\alpha, \alpha)]\, f_{Y_1}(\alpha \mid s)\, d\alpha.
\end{aligned}$$

The first line applies the law of iterated expectations. The second uses the definition (14.53) and the fact that $\beta^{SP}(Y_1)$ is known once Y_1 is. Because v is increasing in its first argument (Corollary 14.49), the integrand is positive for $\alpha < s$ and negative for $\alpha > s$. The integral is therefore maximized by choosing the upper limit equal to s, that is, $b = \beta^{SP}(s)$. A bid above $\beta^{SP}(\bar{s})$ wins against every rival and gives the integral up to $\bar{s}$. A bid below $\beta^{SP}(\underline{s})$ never wins. Neither does better. □

The equilibrium bid is the expected value of the object conditional on the bidder's own signal and on the event that the strongest rival has the same signal. A bidder's bid matters only when it ties the highest rival bid, because otherwise a small change does not affect the outcome or the price. In a symmetric increasing equilibrium, a tie means $Y_1 = s$. Athey and Haile (2007, eq. (2.3)) call $v(s, s)$ the expectation conditional on the bid being *pivotal*. The bid embeds the correction for the winner's curse. With private values $v(s, s) = s$, and the equilibrium reduces to the dominant strategy of Proposition 14.22. With common values the equilibrium is not in dominant strategies. The best bid depends on what winning reveals, and that depends on rivals' strategies. When bidder 1 wins, it pays $v(Y_1, Y_1)$, where Y_1 is the second-highest signal among all bidders. Milgrom and Weber (1982, footnote 17, p. 1100) note that their analysis of the second-price auction is very similar to that of Milgrom (1981b), in a somewhat different setup. Their Theorems 6 and 7, our Propositions 14.51 and 14.54, were first proved there.

Example 14.52 (Mineral rights with uniform noise)**.** Return to the mineral rights model of Example 14.18. The value is common, $V_i = V$, and the signals are $S_i = V + \epsilon_i$, where the noise terms ϵ_i are i.i.d. uniform on $[-\omega, \omega]$ and independent of V. Let V be uniform on an interval much wider than ω, and consider signals far from its ends. This is the *diffuse prior* idealization: given the signals, the prior is flat over every value that the signals allow. The

noise density $\frac{1}{2\omega}\mathbf{1}\{|x-v|\le\omega\}$ satisfies (14.7), because the band $\{(x,v):|x-v|\le\omega\}$ contains the componentwise maximum and minimum of any two of its points. So the example fits Assumption 14.10. Nondegeneracy fails, since the posterior mean of V depends only on the highest and lowest signals, but the results do not need it.

We compute $v(s,s)$. Given V, the event $\{S_1=s, Y_1=s\}$ has likelihood $f(s\mid V)\cdot(n-1)F(s\mid V)^{n-2}f(s\mid V)$, where $f(s\mid V)=\frac{1}{2\omega}$ and $F(s\mid V)=\frac{s-V+\omega}{2\omega}$ for $V\in[s-\omega,s+\omega]$. With a flat prior, the posterior density of V is proportional to $(s+\omega-V)^{n-2}$ on $[s-\omega,s+\omega]$. Substitute $t=s+\omega-V\in[0,2\omega]$. The density of t is $\frac{(n-1)t^{n-2}}{(2\omega)^{n-1}}$, with mean

$$\mathbb{E}[t]=\int_0^{2\omega} t\,\frac{(n-1)t^{n-2}}{(2\omega)^{n-1}}\,dt=\frac{n-1}{n}\,2\omega.$$

Hence

$$\beta^{SP}(s)=v(s,s)=s+\omega-\frac{2\omega(n-1)}{n}=s-\omega\,\frac{n-2}{n}. \tag{14.54}$$

The estimate is unbiased, $\mathbb{E}[V\mid S_1=s]=s$, yet the bidder shades by $\omega\frac{n-2}{n}$. The shading grows with n and approaches ω. With more rivals, tying the highest of them is worse news about V. With private values the number of bidders does not affect the second-price bid at all. With $n=2$ the bid equals s, because tying the only rival means two signals both equal to s.

The pivotal value is the object that empirical tests for common values target. Write $V(x,x,N)$ for $\mathbb{E}[V_i\mid S_i=x,\ \max_{j\neq i}S_j=x]$ with N bidders, which is $v(x,x)$ of (14.53). In a first-price auction, Laffont and Vuong (1996) show that the inverse equilibrium strategy recovers it from bids. In the notation of Hortaçsu and Perrigne (2021, Section 2.3, p. 93),

$$V(x,x,N)=B+\frac{G_{B_{\max}|B}(B\mid B)}{g_{B_{\max}|B}(B\mid B)},$$

where B is the bidder's bid and $B_{\max}$ the highest rival bid. This is (14.68) below, read with common values. With private values the left side is the bidder's own value. Haile et al. (2003) show that, with exogenous participation, $V(x,x,N)$ falls strictly in N under common values and does not vary with N under private values. Example 14.52 displays the first case. By (14.54), the pivotal value $s-\omega\frac{n-2}{n}$ falls in n at every signal, while with private values it equals s for every n. The test compares the estimated distributions of pivotal values across auctions with different numbers of bidders (Chapter 15). The bids themselves are a poor guide. A decline of bids in the number of bidders is a misleading test for the winner's curse (Laffont, 1997). Pinkse and Tan (2005) show that affiliated private values can make bids rise or fall with competition (Hortaçsu and Perrigne, 2021, footnote 10, p. 93).

Example 14.53 (Affiliated private values)**.** Let $n=2$, $V_i=S_i$, and let the signals have the joint density $f(s_1,s_2)=\frac{4}{5}(1+s_1s_2)$ on $[0,1]^2$, introduced in Example 14.14(d). The cross-partial of $\ln f$ is $\frac{1}{(1+s_1s_2)^2}>0$, so the values are affiliated. The correlation between them is small, $\frac{2}{37}\approx0.054$. With private values $v(s,y)=s$, so the second-price bid is $\beta^{SP}(s)=s$. For later use, the marginal density of S_1 is $\frac{2}{5}(2+s)$, and the conditional density and distribution function of $Y_1=S_2$ given $S_1=s$ are

$$f_{Y_1}(y\mid s)=\frac{2(1+sy)}{2+s},\qquad F_{Y_1}(y\mid s)=\frac{y(2+sy)}{2+s}. \tag{14.55}$$

14.8.5 Bidders with inferior information

How much is information worth when someone else has it too? Milgrom and Weber (1982, p. 1101) answer this in the *generalized mineral rights model*, in which $V_1 = \cdots = V_n = V$. It differs from the mineral rights model because the estimates need not be independent conditional on V. Suppose an $(n+1)$st bidder enters with an estimate S_{n+1} of V. We say that S_{n+1} is a *garbling* of (S_1, Y_1) if the joint density of $(V, S_1, \ldots, S_n, S_{n+1})$ factors as $g(V, S_1, \ldots, S_n)\, h(S_{n+1} \mid S_1, Y_1)$. This holds, for example, if bidder $n+1$ bases its estimate only on information that bidder 1 also has.

Proposition 14.54 (Milgrom and Weber, 1982, Theorem 7)**.** *In the generalized mineral rights model, let S_{n+1} be a garbling of (S_1, Y_1), and let bidders $1, \ldots, n$ use the n-bidder equilibrium strategy β^{SP} of Proposition 14.51. Then bidder $n+1$ has no strategy that earns a positive expected payoff. Consequently, the profile in which bidders $1, \ldots, n$ use β^{SP} and bidder $n+1$ bids zero is an equilibrium of the $(n+1)$-bidder second-price auction.*

Proof. Let $Z = \max\{S_1, Y_1\}$ be the highest signal among bidders $1, \ldots, n$. If bidder $n+1$ bids b, it wins when $\beta^{SP}(Z) < b$ and then pays $\beta^{SP}(Z) = v(Z, Z)$. Its expected payoff conditional on its estimate and on winning is

$$\begin{aligned}\mathbb{E}\left[V - \beta^{SP}(Z) \mid S_{n+1},\, \beta^{SP}(Z) < b\right] &= \mathbb{E}\left[\mathbb{E}\left[V - \beta^{SP}(Z) \mid S_1, Y_1, S_{n+1}\right] \mid S_{n+1},\, \beta^{SP}(Z) < b\right] \\ &= \mathbb{E}\left[v(S_1, Y_1) - v(Z, Z) \mid S_{n+1},\, \beta^{SP}(Z) < b\right].\end{aligned}$$

The second line uses $\mathbb{E}[V \mid S_1, Y_1, S_{n+1}] = \mathbb{E}[V \mid S_1, Y_1] = v(S_1, Y_1)$, which is what the garbling condition delivers. Since $Z \geq S_1$, $Z \geq Y_1$ and v is nondecreasing in both arguments, $v(S_1, Y_1) \leq v(Z, Z)$. The conditional expected payoff is therefore nonpositive for every bid. Bidding zero earns zero, so it is a best response. Against a bid of zero, the payoffs of bidders $1, \ldots, n$ are the same as in the n-bidder auction, so β^{SP} remains a best response for them. □

Information that a rival also holds earns no rent. Bidder $n+1$'s estimate adds nothing to what bidder 1 knows, and whenever it wins it pays at least the expected value of the object given everything the others know. We now turn to a model in which one bidder has private information and the rest share only public information. It was introduced by Wilson (1967) and characterized by Engelbrecht-Wiggans et al. (1983). Hendricks and Porter (1988) restate it and test it on federal auctions of offshore drainage leases, tracts adjacent to tracts where oil has been found. Oil and gas leases are the classic common value auction, and they are usually sold by first-price sealed bid (Hortaçsu and Perrigne, 2021, Section 4, p. 124). We present their version with symmetric valuations and leave the evidence to Chapter 15.

The model. A tract has common value V. One *informed* bidder, the owner of the neighboring tract in the application, observes a private signal X and a public signal Z. A set of $n \geq 1$ *uninformed* bidders observe only Z. We fix z and suppress it. The informed bidder's information is summarized by $H = \mathbb{E}[V \mid X, Z]$, which has an atomless distribution F_H with density f_H, support $[\underline{h}, \bar{h}]$ (possibly unbounded above), and finite mean μ_H. The value is common and the uninformed observe only Z. By the law of iterated expectations, an uninformed bidder's expected value of the tract conditional on any event about X equals the conditional mean of H on that event. The seller sets a reserve price r with $\underline{h} \leq r < \mu_H$, and a bid of zero means no bid. The informed bidder uses a bid function $\sigma(h)$, strictly increasing and differentiable where it exceeds r, with inverse ϕ on that range. Uninformed bidder i randomizes according to a distribution function G_i on the nonnegative reals. The highest uninformed bid then has distribution function $G(b) = \prod_{i=1}^{n} G_i(b)$.

When G has no atom at $b \geq r$, the informed bidder with estimate h who bids b earns

$$(h - b)\, G(b), \tag{14.56}$$

which is equation (1) of Hendricks and Porter (1988) at $b = \sigma(h)$. Uninformed bidder i who bids $b > r$ wins when the informed bid is lower, that is, when $H < \phi(b)$. Its expected payoff is

$$\mathbb{E}\left[(H - b)\mathbf{1}\{H < \phi(b)\}\right] \prod_{j \neq i} G_j(b) = F_H(\phi(b))\left(\mathbb{E}[H \mid H < \phi(b)] - b\right) \prod_{j \neq i} G_j(b), \tag{14.57}$$

which is their equation (2). Hendricks and Porter (1988) also allow the uninformed bidders' value to be lower by a constant $c \geq 0$, reflecting cost differences or the neighbor's ability to internalize drainage externalities. We set $c = 0$ throughout.

Finding the equilibrium. Three conditions pin down the equilibrium. First, uninformed bidders mix, so they must be indifferent among all bids in the support of their mixture. In equilibrium their expected profit is zero (Hendricks and Porter, 1988, p. 869). At a bid $b > r$ in that support, (14.57) is zero only if $b = \mathbb{E}[H \mid H < \phi(b)]$. Writing $h' = \phi(b)$, this says that the informed bidder's bid function is

$$\sigma(h') = \mathbb{E}[H \mid H \leq h'].$$

Second, this function lies below r for low estimates. Define $\hat{h}$ by $\mathbb{E}[H \mid H < \hat{h}] = r$, which exists because $\mathbb{E}[H \mid H < h]$ rises continuously from $\underline{h}$ to μ_H. Informed types between r and $\hat{h}$ cannot use the formula, and they bid the reserve price instead. Types below r would lose money at any admissible bid and abstain. Third, the informed bidder's first-order condition for (14.56) is $G(b) = (h - b)G'(b)$ at $b = \sigma(h)$. Try $G(\sigma(h)) = F_H(h)$. Differentiating gives $G'(\sigma(h))\sigma'(h) = f_H(h)$, so the first-order condition becomes

$$\sigma'(h) = (h - \sigma(h))\, \frac{f_H(h)}{F_H(h)}.$$

The bid function from the first condition satisfies exactly this equation:

$$\sigma(h) = \frac{1}{F_H(h)} \int_{\underline{h}}^{h} x\, f_H(x)\, dx \quad \Longrightarrow \quad \sigma'(h) = \frac{h\, f_H(h)}{F_H(h)} - \frac{f_H(h)}{F_H(h)}\, \sigma(h) = (h - \sigma(h))\, \frac{f_H(h)}{F_H(h)}.$$

So the highest uninformed bid must be distributed exactly like the informed bid on the range above r.

Proposition 14.55 (Engelbrecht-Wiggans et al., 1983 and Hendricks and Porter, 1988, Theorem, p. 869)**.** *Let $c = 0$. A profile is an equilibrium of the first-price auction if and only if two conditions hold. The informed bidder uses*

$$\sigma^*(h) = \begin{cases} \mathbb{E}[H \mid H \leq h] & h > \hat{h}, \\ r & r \leq h \leq \hat{h}, \\ \text{no bid} & h < r. \end{cases}$$

The highest uninformed bid has the distribution function

$$G^*(b) = \begin{cases} F_H(\hat{h}) & 0 \leq b \leq r, \\ F_H(\phi^*(b)) & r < b < \mu_H, \\ 1 & b \geq \mu_H. \end{cases}$$

Here $\hat{h}$ solves $\mathbb{E}[H \mid H < \hat{h}] = r$ and ϕ^* is the inverse of σ^* on $(\hat{h}, \bar{h})$. The uninformed bidders earn zero expected profit. Their individual strategies are indeterminate, and only the distribution of their highest bid is pinned down.

Proof. We prove that the profile is an equilibrium. The converse is in Engelbrecht-Wiggans et al. (1983) and the Appendix of Hendricks and Porter (1988).

Uninformed bidders. Take uninformed bidder i and any profile of the others with highest bid distributed as G^*. For $b \in (r, \mu_H)$, $\phi^*(b)$ is well defined and $b = \mathbb{E}[H \mid H \le \phi^*(b)]$, so the first factor in (14.57) is zero. Every such bid earns zero. A bid of exactly r wins when $H < r$ and ties with informed types in $[r, \hat{h}]$. With random tie-breaking it earns at most

$$\mathbb{E}\left[(H - r)\mathbf{1}\{H < r\}\right] + \frac{1}{2}\mathbb{E}\left[(H - r)\mathbf{1}\{r \le H \le \hat{h}\}\right] = -\frac{1}{2}\mathbb{E}\left[(H - r)\mathbf{1}\{r \le H \le \hat{h}\}\right] \le 0,$$

times the probability that no other uninformed bidder bids more. The equality uses $\mathbb{E}[(H - r)\mathbf{1}\{H < \hat{h}\}] = 0$, which is the definition of $\hat{h}$. A bid $b \ge \mu_H$ wins for sure and earns $\mu_H - b \le 0$. Abstaining also earns zero. So every mixture over no bid and bids in (r, μ_H) is a best response.

Informed bidder. Against G^*, mimicking a type $x > \hat{h}$ gives the informed type h the payoff $\Pi(x; h) = (h - \sigma^*(x))F_H(x)$. Using $\sigma^{*\prime}(x)F_H(x) = (x - \sigma^*(x))f_H(x)$,

$$\frac{\partial \Pi(x; h)}{\partial x} = -\sigma^{*\prime}(x)F_H(x) + (h - \sigma^*(x))\, f_H(x) = f_H(x)\,(h - x).$$

So for $h > \hat{h}$ the best x is $x = h$. For $h \le \hat{h}$ the best $x \ge \hat{h}$ is $x = \hat{h}$, which yields $(h - r)F_H(\hat{h})$. This equals the payoff from bidding r, which wins exactly when no uninformed bidder bids, an event of probability $G^*(r) = F_H(\hat{h})$. Bids in $(r, \sigma^*(\hat{h}^+))$ do not exist, because $\sigma^*(\hat{h}^+) = r$. Bids above μ_H win for sure and are worse than bids just below μ_H. For $h \ge r$, bidding r beats abstaining because $(h - r)F_H(\hat{h}) \ge 0$. For $h < r$, every admissible bid $b \ge r > h$ loses money when it wins, so abstaining is optimal. □

Integrating by parts, $\int_{\underline{h}}^{h} x\, dF_H(x) = hF_H(h) - \int_{\underline{h}}^{h} F_H(x)\, dx$, so for $h > \hat{h}$

$$\sigma^*(h) = h - \frac{\int_{\underline{h}}^{h} F_H(x)\, dx}{F_H(h)}. \tag{14.58}$$

This is equation (4) of Hendricks and Porter (1988) with $c = 0$ (they write the lower limit as $-\infty$). The integral term is the amount by which the informed bidder shades its bid below its estimate. When the reserve price does not bind ($r = \underline{h}$, so $\hat{h} = \underline{h}$), (14.58) is the Riley-Samuelson bid (14.29) for two bidders with values drawn independently from F_H. The informed bidder behaves as if it faced one private-value rival whose value is an independent copy of its own. The uninformed bidders, taken together, replicate the bid distribution of that fictitious rival. The public signal matters for the shading term even when it adds nothing to the informed bidder's estimate, because it shapes the rivals' behavior (Hendricks and Porter, 1988, p. 870).

Why must the uninformed bidders randomize? If they used a predictable bid, the informed bidder would top it whenever the tract was worth more and stay out otherwise. The uninformed would then win only tracts worth less than their bids and lose money on average (Hendricks and Porter, 1988, p. 869). Randomization makes the informed bidder lose some profitable tracts. The mixed equilibrium can be read as the limit of pure-strategy equilibria of a game in

which the uninformed bidders have slightly informative private signals (Hendricks and Porter, 1988, pp. 869–870).

The model makes sharp predictions. The informed bidder wins when $h > \hat{h}$ and the highest uninformed bid is below $\sigma^*(h)$, which has probability $G^*(\sigma^*(h)) = F_H(h)$. It also wins when $r \le h \le \hat{h}$ and no uninformed bidder bids, which has probability $F_H(\hat{h})$. Its unconditional probability of winning is

$$\begin{aligned}\mathbb{P}(\text{informed wins}) &= \int_{\hat{h}}^{\bar{h}} F_H(h) f_H(h)\, dh + \left[F_H(\hat{h}) - F_H(r)\right] F_H(\hat{h}) \\ &= \frac{1}{2}\left[1 - F_H(\hat{h})^2\right] + F_H(\hat{h})^2 - F_H(\hat{h})F_H(r) \\ &= \frac{1}{2} + \frac{1}{2}F_H(\hat{h})^2 - F_H(\hat{h})F_H(r).\end{aligned}$$

Nobody bids with probability $F_H(r)F_H(\hat{h})$. Conditional on at least one bid, the informed bidder wins with probability

$$\frac{\frac{1}{2} + \frac{1}{2}F_H(\hat{h})^2 - F_H(\hat{h})F_H(r)}{1 - F_H(\hat{h})F_H(r)} = \frac{1}{2} + \frac{\frac{1}{2}F_H(\hat{h})\left[F_H(\hat{h}) - F_H(r)\right]}{1 - F_H(\hat{h})F_H(r)} \ge \frac{1}{2}, \tag{14.59}$$

which is the expression on p. 870 of Hendricks and Porter (1988). The second form follows by writing $\frac{1}{2} = \frac{\frac{1}{2}(1-F_H(\hat{h})F_H(r)) + \frac{1}{2}F_H(\hat{h})F_H(r)}{1-F_H(\hat{h})F_H(r)}$ and collecting terms. Hendricks and Porter (1988, pp. 870–871) list seven predictions, in the following order.

(a) The informed bidder abstains less often than the uninformed bidders do, since $F_H(r) \le F_H(\hat{h})$.

(b) The informed bidder wins at least half of the auctions with a bid, by (14.59).

(c) The uninformed bidders earn zero expected profit overall. They lose money on tracts where the informed bidder does not bid and earn money on tracts where it does.

(d) The informed bidder earns an information rent.

(e) The ex ante bid distributions, before X is realized, are approximately the same. In our version with $c = 0$, the informed bid is at most $\sigma^*(h)$ with probability $F_H(h)$ for $h > \hat{h}$, and $G^*(\sigma^*(h)) = F_H(h)$. Above r the informed bid and the highest uninformed bid therefore have the same distribution. They differ only in how the mass $F_H(\hat{h})$ at or below r splits between abstaining and bidding r.

(f) The number of uninformed bidders does not affect the informed bidder's strategy or the distribution of the highest uninformed bid. This is convenient empirically, because only uninformed bidders who choose to bid are observed.

(g) The informed bidder's bid rises with the public signal when a larger public signal is good news. By (14.58), a bidder with estimate $h > \hat{h}$ bids $\sigma^*(h) = \mathbb{E}[H \mid H < h]$, computed under the distribution of H given the public signal. When that distribution has the MLRP in the public signal, this conditional mean rises with the signal (Hendricks and Porter, 1988, p. 870).

A numerical example makes the predictions concrete (Figure 14.12). Let H be uniform on $[0, 1]$ and $r = 0.2$. Then $\mathbb{E}[H \mid H < \hat{h}] = \frac{\hat{h}}{2} = r$ gives $\hat{h} = 0.4$, and $\sigma^*(h) = \frac{h}{2}$ for $h > 0.4$.

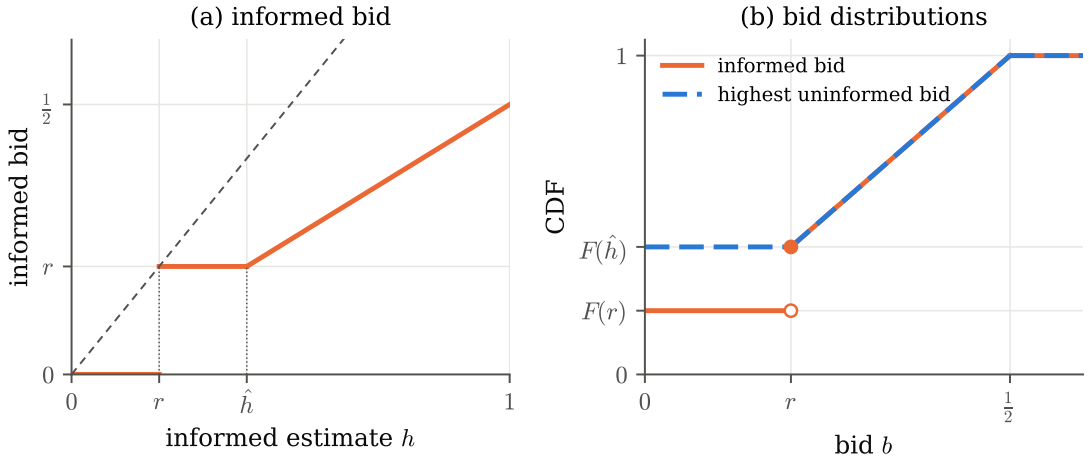

Figure 14.12: Equilibrium with one informed bidder, for H uniform on $[0,1]$ and reserve price $r = 0.2$. Panel (a): the informed bid function, which is zero (no bid) below r, equal to r on $[r, \hat{h}]$ with $\hat{h} = 0.4$, and $\frac{h}{2}$ above $\hat{h}$. Panel (b): the distribution functions of the informed bid and of the highest uninformed bid. They coincide above r and differ only in their masses at zero and at r.

The uninformed bidders abstain with probability 0.4, and otherwise their highest bid has distribution function $G^*(b) = 2b$ on $(0.2, 0.5]$. The informed bidder wins half of all auctions and 0.5435 of the auctions with a bid, by (14.59). Its expected profit is $\int_{0.4}^{1} \frac{h}{2}\, h\, dh + 0.4 \int_{0.2}^{0.4} (h - 0.2)\, dh = 0.156 + 0.008 = 0.164$. The tract is sold unless $H < r$ and no uninformed bidder bids, so expected surplus is $0.5 - 0.2 \times 0.4 \times 0.1 = 0.492$. The seller's expected revenue is $0.492 - 0.164 = 0.328$. The uninformed bidders lose 0.15 per tract on the tracts where the informed bidder abstains and gain 0.0375 per tract on the others, which nets to zero. These numbers come from the script `emw_example.py`, which also confirms them by simulation.

Propositions 14.54 and 14.55 make the same point from two sides. A bidder whose information is a garbling of a rival's information earns nothing, and a bidder with exclusive information earns a rent even against many rivals. The value of information in an auction lies in its privacy.

14.8.6 The English auction

Milgrom and Weber model the English auction as the Japanese button auction of Definition 14.2. The price rises continuously from zero, the price and the number of active bidders are displayed at all times, and exits are public and irrevocable. When one bidder remains, it wins and pays the price at which the last rival left. With two bidders the English and second-price auctions are strategically equivalent (Proposition 14.6). With three or more bidders, the prices at which bidders drop out convey information to those who remain, and the two formats differ.

Suppose k bidders have quit, at prices $p_1 \le \cdots \le p_k$. A strategy for bidder i specifies, for each such history, the price $\beta_k(s_i \mid p_1, \ldots, p_k) \ge p_k$ at which it will quit if nobody else quits first. Milgrom and Weber (1982, eqs. (5)–(6)) define the strategy $\beta^E = (\beta_0^E, \ldots, \beta_{n-2}^E)$ iteratively. Before any exit,

$$\beta_0^E(s) = \mathbb{E}\left[V_1 \mid S_1 = s,\ Y_1 = s, \ldots, Y_{n-1} = s\right]. \tag{14.60}$$

After $k = 1, \dots, n-2$ exits,

$$\beta_k^E(s \mid p_1, \dots, p_k) = \mathbb{E}\left[V_1 \mid S_1 = s,\ Y_1 = \cdots = Y_{n-k-1} = s,\ Y_{n-k} = y_{n-k}, \dots, Y_{n-1} = y_{n-1}\right]. \tag{14.61}$$

The signals of the bidders who quit are inferred from their exit prices. They solve $\beta_0^E(y_{n-1}) = p_1$, $\beta_1^E(y_{n-2} \mid p_1) = p_2$, and so on up to $\beta_{k-1}^E(y_{n-k} \mid p_1, \dots, p_{k-1}) = p_k$.

These strategies are myopic in a precise sense (Milgrom and Weber, 1982, p. 1105). Suppose nobody has quit and the price has reached $\beta_0^E(y)$. If all other bidders quit at that instant, bidder 1 would infer that $Y_1 = \cdots = Y_{n-1} = y$. It would then value the object at $\mathbb{E}[V_1 \mid S_1 = s, Y_1 = \cdots = Y_{n-1} = y]$, and its payoff from winning at the current price would be this value minus $\beta_0^E(y)$. By Proposition 14.16(iii) the difference is positive if $s > y$ and negative if $s < y$. So β_0^E keeps it active until the price at which it would be just indifferent between winning and losing. The later strategies β_k^E have the same interpretation, with the signals of those who quit inferred from their exit prices.

Proposition 14.56 (Milgrom and Weber, 1982, Theorem 10)**.** *Under Assumption 14.10, the profile in which every bidder uses β^E is an equilibrium of the English auction. If bidder 1 wins, it pays*

$$\bar{v}(Y_1, Y_1, Y_2, \dots, Y_{n-1}), \qquad \text{where } \bar{v}(s, y_1, \dots, y_{n-1}) = \mathbb{E}\left[V_1 \mid S_1 = s,\ Y_1 = y_1, \dots, Y_{n-1} = y_{n-1}\right], \tag{14.62}$$

evaluated at the realized order statistics.

Proof. Each β_k^E is increasing in its first argument, by Assumption 14.10(ii) and Proposition 14.16(iii). Exits therefore occur in increasing order of signals and reveal them. Let bidders $2, \dots, n$ use β^E. While bidder 1 is active, the history of exits consists only of rivals' exits, so its own strategy affects whether it wins and not the price it pays if it wins. If it outlasts everyone, the last rival to quit has signal Y_1. That rival quits at $\beta_{n-2}^E(Y_1 \mid p_1, \dots, p_{n-2})$, the expected value to a bidder with signal Y_1 given that the other remaining bidder also has signal Y_1 and given the revealed signals $Y_2, \dots, Y_{n-1}$. By the symmetry of u this equals $\bar{v}(Y_1, Y_1, Y_2, \dots, Y_{n-1})$, which proves (14.62).

Given its own signal and the rivals' signals, bidder 1 values the object at $\bar{v}(s, Y_1, \dots, Y_{n-1})$ in expectation. Its payoff from winning is therefore

$$\bar{v}(s, Y_1, Y_2, \dots, Y_{n-1}) - \bar{v}(Y_1, Y_1, Y_2, \dots, Y_{n-1}),$$

which is nonnegative if and only if $s \geq Y_1$, by monotonicity of $\bar{v}$ in its first argument. Under β^E it wins exactly when $s > Y_1$ (the event $s = Y_1$ has probability zero). It thus wins in every realization in which winning is profitable and in no other. No strategy can do better. □

The argument is pointwise. Bidder 1 would not regret its strategy even if it learned all rivals' signals, so the equilibrium is an *ex post equilibrium* (Krishna, 2010, Chapter 6). With private values, $\beta_k^E(s \mid \cdot) = s$ for every k, and the strategy reduces to staying in until the price reaches one's value, as in Athey and Haile (2007, eq. (2.6)) and Section 14.4.

With common values the equilibrium is not unique. Bikhchandani et al. (2002) show that there are many symmetric equilibria in strictly increasing, weakly undominated strategies, even with symmetric bidders. In every such equilibrium, a bidder who is one of the last two to exit quits at

$$\mathbb{E}\left[V_i \mid S_i = s_i,\ S_j = s_i \text{ for active } j \neq i,\ S_k = s_k \text{ for } k \in \mathcal{E}_i\right],$$

where $\mathcal{E}_i$ is the set of bidders who quit before it (Athey and Haile, 2007, eq. (2.7)). The Milgrom-Weber equilibrium is the one in which every bidder follows this rule at every stage.

The multiplicity concerns the earlier exits, those below the final price, so these exit prices have no unique interpretation. This complicates the use of losing bids in empirical work (Chapter 15).

Example 14.57 (Mineral rights, continued)**.** In Example 14.52, the posterior of V given any set of signals is uniform on $[\max_i s_i - \omega,\ \min_i s_i + \omega]$, so the posterior mean is the midpoint of the highest and lowest signals. Before anyone quits all signals in (14.60) equal s, so $\beta_0^E(s) = s$. After $k \geq 1$ exits the highest signal in (14.61) is s and the lowest is y_{n-1}, so $\beta_k^E(s \mid \cdot) = \frac{s+y_{n-1}}{2}$. The lowest bidder quits at its signal. The others then stay in until the midpoint between their own signal and that lowest signal. For $n \geq 3$ the winner pays $\frac{Y_1+Y_{n-1}}{2}$, the midpoint of the second-highest and the lowest signal. For $n = 2$ it pays Y_1.

14.8.7 The first-price auction

We first derive the necessary conditions for a symmetric equilibrium with an increasing, differentiable bid function β (Milgrom and Weber, 1982, p. 1106, following Wilson, 1977). Suppose bidders $2, \ldots, n$ use β. If bidder 1 has signal s and bids b, its expected payoff is

$$\begin{aligned}\Pi(b; s) &= \mathbb{E}\left[(V_1 - b)\mathbf{1}\{\beta(Y_1) < b\} \mid S_1 = s\right] \\ &= \mathbb{E}\left[\mathbb{E}\left[(V_1 - b)\mathbf{1}\{\beta(Y_1) < b\} \mid S_1, Y_1\right] \mid S_1 = s\right] \\ &= \mathbb{E}\left[(v(S_1, Y_1) - b)\,\mathbf{1}\{\beta(Y_1) < b\} \mid S_1 = s\right] \\ &= \int_{\underline{s}}^{\beta^{-1}(b)} (v(s, \alpha) - b)\, f_{Y_1}(\alpha \mid s)\, d\alpha.\end{aligned}$$

Differentiating with respect to b by Leibniz's rule,

$$\Pi_b(b; s) = \frac{\big(v(s, \beta^{-1}(b)) - b\big)\, f_{Y_1}(\beta^{-1}(b) \mid s)}{\beta'(\beta^{-1}(b))} - F_{Y_1}(\beta^{-1}(b) \mid s).$$

In equilibrium $\Pi_b(\beta(s); s) = 0$. Substituting $b = \beta(s)$ and rearranging yields the linear differential equation (Milgrom and Weber, 1982, eq. (7))

$$\beta'(s) = \big(v(s, s) - \beta(s)\big)\, \frac{f_{Y_1}(s \mid s)}{F_{Y_1}(s \mid s)}. \tag{14.63}$$

Two further necessary conditions fix the boundary. First, $v(s, s) - \beta(s) \geq 0$ for every s. Otherwise the payoff $\int_{\underline{s}}^{s} (v(s, \alpha) - \beta(s))\, f_{Y_1}(\alpha \mid s)\, d\alpha$ would be negative, since $v(s, \alpha) \leq v(s, s)$ for $\alpha \leq s$, and bidding zero would do better. Second, $v(\underline{s}, \underline{s}) - \beta(\underline{s}) \leq 0$. Otherwise the lowest type could raise its bid slightly above $\beta(\underline{s})$, win against rivals with low signals, and earn a positive payoff instead of zero. Together these give the boundary condition $\beta(\underline{s}) = v(\underline{s}, \underline{s})$.

Proposition 14.58 (Milgrom and Weber, 1982, Theorem 14)**.** *Under Assumption 14.10, the strategy*

$$\beta^{FP}(s) = \int_{\underline{s}}^{s} v(\alpha, \alpha)\, dL(\alpha \mid s), \qquad L(\alpha \mid s) = \exp\left(-\int_{\alpha}^{s} \frac{f_{Y_1}(t \mid t)}{F_{Y_1}(t \mid t)}\, dt\right), \tag{14.64}$$

used by every bidder is a symmetric equilibrium of the first-price auction. Equivalently,

$$\beta^{FP}(s) = v(s, s) - \int_{\underline{s}}^{s} L(\alpha \mid s)\, dv(\alpha, \alpha). \tag{14.65}$$

We follow Milgrom and Weber's conventions. The ratio $\frac{f_{Y_1}(t|t)}{F_{Y_1}(t|t)}$ is zero outside the support of Y_1, and $L(\alpha \mid s) = 0$ when the integral is infinite (their footnotes 22 and 23). We read $L(\cdot \mid s)$ as a distribution function on $[\underline{s}, s]$ that places any mass $L(\underline{s} \mid s)$ at $\underline{s}$, and the integral in (14.64) includes that atom.

Proof. Write $\zeta(t) = \frac{f_{Y_1}(t|t)}{F_{Y_1}(t|t)}$.

Solving the equation. Rewrite (14.63) as $\beta'(s) + \zeta(s)\beta(s) = \zeta(s)v(s,s)$. Fix an interior point s_0 and let $\Gamma(s) = \int_{s_0}^{s} \zeta(t)\,dt$. Multiplying by the integrating factor $e^{\Gamma(s)}$ gives

$$\frac{d}{ds}\left[\beta(s)e^{\Gamma(s)}\right] = \zeta(s)v(s,s)e^{\Gamma(s)}.$$

Integrating from $\underline{s}$ to s,

$$\beta(s)e^{\Gamma(s)} = \beta(\underline{s})e^{\Gamma(\underline{s})} + \int_{\underline{s}}^{s} \zeta(\alpha)v(\alpha,\alpha)e^{\Gamma(\alpha)}\,d\alpha.$$

Divide by $e^{\Gamma(s)}$. Note that $L(\alpha \mid s) = e^{\Gamma(\alpha)-\Gamma(s)}$ and $\frac{\partial L(\alpha|s)}{\partial \alpha} = \zeta(\alpha)L(\alpha \mid s)$. Imposing $\beta(\underline{s}) = v(\underline{s},\underline{s})$,

$$\beta(s) = v(\underline{s},\underline{s})L(\underline{s} \mid s) + \int_{\underline{s}}^{s} v(\alpha,\alpha)\frac{\partial L(\alpha \mid s)}{\partial \alpha}\,d\alpha,$$

which is (14.64) with the atom at $\underline{s}$. Integrating the second term by parts and using $L(s \mid s) = 1$,

$$\int_{\underline{s}}^{s} v(\alpha,\alpha)\frac{\partial L(\alpha \mid s)}{\partial \alpha}\,d\alpha = v(s,s) - v(\underline{s},\underline{s})L(\underline{s} \mid s) - \int_{\underline{s}}^{s} L(\alpha \mid s)\,dv(\alpha,\alpha).$$

The atom term cancels, which gives (14.65).

Monotonicity. As a function of α, $L(\cdot \mid s)$ is nondecreasing with $L(s \mid s) = 1$, so it is a distribution function on $[\underline{s}, s]$. It increases stochastically in s. For $s' > s$ and $\alpha \le s$, $L(\alpha \mid s') = L(\alpha \mid s)\exp(-\int_{s}^{s'} \zeta) \le L(\alpha \mid s)$, and for $\alpha \in (s, s']$, $L(\alpha \mid s') \le 1 = L(\alpha \mid s)$ once we extend $L(\cdot \mid s)$ by one above s. Since $v(\alpha,\alpha)$ is nondecreasing, its mean under $L(\cdot \mid s)$ rises with s, so β^{FP} is nondecreasing. Where $v(s,s) > \beta^{FP}(s)$, (14.63) shows that it is strictly increasing.

Sufficiency. Assume for now that $\beta = \beta^{FP}$ is continuous, and hence differentiable after a monotone rescaling of signals (Proposition 14.16(i)). A bidder with signal z need only consider bids in the range of β, since higher bids are dominated by $\beta(\bar{s})$ and lower bids never win. Let its bid be $\beta(x)$. Substituting $b = \beta(x)$ into Π_b and factoring,

$$\Pi_b(\beta(x); z) = \frac{f_{Y_1}(x \mid z)}{\beta'(x)}\left[\big(v(z,x) - \beta(x)\big) - \beta'(x)\frac{F_{Y_1}(x \mid z)}{f_{Y_1}(x \mid z)}\right].$$

At $z = x$ the bracket is zero by (14.63). Take $x < z$. Then $v(z,x) \ge v(x,x)$ by Corollary 14.49, and $\frac{F_{Y_1}(x|z)}{f_{Y_1}(x|z)} \le \frac{F_{Y_1}(x|x)}{f_{Y_1}(x|x)}$ by Lemma 14.50. With $\beta' \ge 0$, the bracket is at least $(v(x,x) - \beta(x)) - \beta'(x)\frac{F_{Y_1}(x|x)}{f_{Y_1}(x|x)} = 0$. For $x > z$ both inequalities reverse and the bracket is at most zero. So the payoff rises in x below z and falls above z, and $x = z$ is optimal.

Continuity. Milgrom and Weber (1982, p. 1108) show that β^{FP} can jump at x only if $F_{Y_1}(x \mid x + \epsilon) = 0$ for every $\epsilon > 0$. By affiliation and symmetry this means that if any signal exceeds x, all signals do. The game then splits into two subgames, one in which it is common knowledge that all signals exceed x and one in which none does. The argument above applies within each. □

A jump can occur (Milgrom and Weber, 1982, footnote 21). Let $n = 2$ and $V_i = S_i$. With probability $\frac{1}{2}$ both signals are drawn independently and uniformly from $[0, 1]$, and with probability $\frac{1}{2}$ from $[1, 2]$. A bidder's signal reveals the regime, and within each regime the auction is the uniform private values auction of Section 14.5. The equilibrium bid is $\frac{s}{2}$ on $[0, 1)$ and $1 + \frac{s-1}{2}$ on $(1, 2]$, so it jumps from $\frac{1}{2}$ to 1 at $s = 1$. The signals remain affiliated, because conditional on one signal being high the other is more likely to be high.

The first-price formula nests the private values case. With independent signals, $F_{Y_1}(t \mid s) = F(t)^{n-1}$ does not depend on s, so $\zeta(t) = \frac{(n-1)f(t)}{F(t)}$ and

$$L(\alpha \mid s) = \exp\left(-(n-1)\left[\ln F(s) - \ln F(\alpha)\right]\right) = \frac{F(\alpha)^{n-1}}{F(s)^{n-1}}.$$

This is the distribution function of Y_1 conditional on $Y_1 \le s$. Hence $\beta^{FP}(s) = \mathbb{E}[v(Y_1, Y_1) \mid Y_1 < s]$ with independent signals. With private values $v(\alpha, \alpha) = \alpha$, and we recover the Riley-Samuelson bid in its conditional-expectation form (14.30) without a reserve price. With $V = \frac{S_1+S_2}{2}$ and independent uniform signals, as in Example 14.44, $v(\alpha, \alpha) = \alpha$ again and $\beta^{FP}(s) = \frac{s}{2}$. With affiliated signals, $L(\cdot \mid s)$ is no longer a conditional distribution of Y_1, and this is where the formats come apart.

Example 14.59 (Mineral rights, continued)**.** In Example 14.52, given $S_1 = s$ the posterior of V is uniform on $[s - \omega, s + \omega]$, and given V each rival signal falls below s with probability $\frac{s-V+\omega}{2\omega}$. Substituting $t = s + \omega - V$,

$$F_{Y_1}(s \mid s) = \frac{1}{2\omega}\int_0^{2\omega}\left(\frac{t}{2\omega}\right)^{n-1} dt = \frac{1}{n},$$
$$f_{Y_1}(s \mid s) = \frac{1}{2\omega}\int_0^{2\omega}(n-1)\left(\frac{t}{2\omega}\right)^{n-2}\frac{1}{2\omega}\,dt = \frac{1}{2\omega}.$$

So $\zeta(t) = \frac{n}{2\omega}$ is constant and $L(\alpha \mid s) = e^{-\frac{n(s-\alpha)}{2\omega}}$. With $v(\alpha, \alpha) = \alpha - \omega\frac{n-2}{n}$ from (14.54), $dv(\alpha, \alpha) = d\alpha$, and (14.65) gives

$$\beta^{FP}(s) = s - \omega\frac{n-2}{n} - \int_{-\infty}^{s} e^{-\frac{n(s-\alpha)}{2\omega}}\,d\alpha = s - \omega\frac{n-2}{n} - \frac{2\omega}{n} = s - \omega. \tag{14.66}$$

One checks directly that $\beta^{FP\prime}(s) = 1 = \left(v(s, s) - \beta^{FP}(s)\right)\frac{n}{2\omega}$. The bid $s - \omega$ never loses money, since $V \ge s - \omega$ for every possible value. With a proper uniform prior the lower boundary changes the bid, but its effect dies out exponentially in the distance from the bottom. In the script `mineral_rights.py` with $n = 3$, the exact bid for a signal five units of ω above the bottom of the prior support differs from $s - \omega$ by about 0.001ω.

Example 14.60 (Affiliated private values, continued)**.** From (14.55), $f_{Y_1}(t \mid t) = \frac{2(1+t^2)}{2+t}$ and $F_{Y_1}(t \mid t) = \frac{t(2+t^2)}{2+t}$, so

$$\zeta(t) = \frac{2(1+t^2)}{t(2+t^2)}.$$

We decompose by partial fractions, $\frac{2+2t^2}{t(2+t^2)} = \frac{a}{t} + \frac{bt+c}{2+t^2}$. Multiplying out, $2 + 2t^2 = a(2 + t^2) + (bt + c)t = 2a + (a + b)t^2 + ct$. Matching coefficients gives $a = 1$, $c = 0$ and $b = 1$, so $\zeta(t) = \frac{1}{t} + \frac{t}{2+t^2}$. Integrating,

$$\int_\alpha^s \zeta(t)\,dt = \ln\frac{s}{\alpha} + \frac{1}{2}\ln\frac{2+s^2}{2+\alpha^2}, \qquad L(\alpha \mid s) = \frac{\alpha\sqrt{2+\alpha^2}}{s\sqrt{2+s^2}}.$$

Here $L(0 \mid s) = 0$, so there is no atom. With private values $v(\alpha, \alpha) = \alpha$, and (14.65) gives

$$\begin{aligned} \beta^{FP}(s) &= s - \frac{1}{s\sqrt{2+s^2}} \int_0^s \alpha\sqrt{2+\alpha^2}\, d\alpha \\ &= s - \frac{1}{s\sqrt{2+s^2}} \left[\frac{(2+\alpha^2)^{\frac{3}{2}}}{3} \right]_0^s = s - \frac{(2+s^2)^{\frac{3}{2}} - 2^{\frac{3}{2}}}{3s\sqrt{2+s^2}}. \end{aligned} \tag{14.67}$$

A symbolic check in `apv_example.py` confirms that (14.67) solves (14.63). As $s \to 0$ the ratio $\frac{\beta^{FP}(s)}{s}$ tends to $\frac{1}{2}$, so $\beta^{FP}(0) = 0 = v(0,0)$. At the top, $\beta^{FP}(1) = \frac{2\sqrt{6}}{9} \approx 0.544$.

Figure 14.13 plots the bids. The first-price bid lies slightly above the benchmark $\frac{s}{2}$ for independent uniform values. A cleaner comparison holds the marginal distribution fixed. With independent signals and the same marginal density $\frac{2}{5}(2+s)$, the Riley-Samuelson bid is $\frac{2s(s+3)}{3(s+4)}$. It exceeds the affiliated bid at low signals (0.1275 versus 0.1260 at $s = 0.25$) and falls below it at high signals (0.533 versus 0.544 at $s = 1$). A bidder with a high signal expects strong rivals and bids more aggressively. A bidder with a low signal expects weak rivals and shades more.

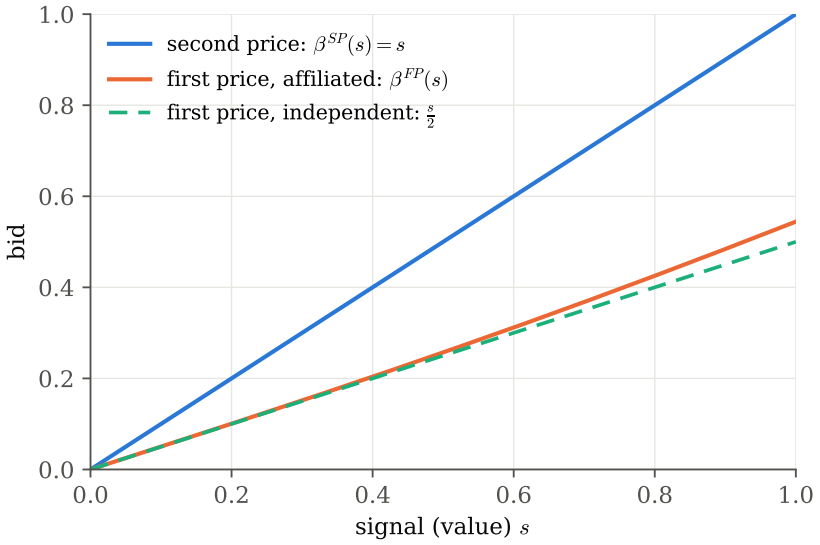

Figure 14.13: Equilibrium bids for the affiliated private values density $f(s_1, s_2) = \frac{4}{5}(1 + s_1 s_2)$ on $[0,1]^2$ with two bidders. The second-price bid is s. The first-price bid is (14.67). The dashed line is the first-price bid $\frac{s}{2}$ for independent uniform values.

The first-order condition can also be written in terms of the bid distribution, which is the form used for estimation. Consider affiliated private values, possibly asymmetric, and let $M_i = \max_{j \neq i} B_j$ be the highest rival bid. Bidder i with value v_i solves

$$\max_b \; \mathbb{E}\left[(v_i - b)\mathbf{1}\{M_i \le b\} \mid V_i = v_i\right] = \max_b \; (v_i - b)\mathbb{P}\left(M_i \le b \mid V_i = v_i\right).$$

The conditioning on v_i matters, because under affiliation a bidder's own value is informative about rivals' values and hence about their bids. The first-order condition is

$$-\mathbb{P}\left(M_i \le b \mid V_i = v_i\right) + (v_i - b)\frac{\partial \mathbb{P}\left(M_i \le b \mid V_i = v_i\right)}{\partial b} = 0,$$

which rearranges to

$$v_i = b + \frac{\mathbb{P}\left(M_i \le b \mid V_i = v_i\right)}{\frac{\partial}{\partial b}\mathbb{P}\left(M_i \le b \mid V_i = v_i\right)}.$$

The derivative is taken in the threshold b, holding the conditioning value fixed. In an equilibrium with strictly increasing strategies β_i, the events $\{V_i = v_i\}$ and $\{B_i = \beta_i(v_i)\}$ coincide. So $\mathbb{P}(M_i \le m \mid V_i = v_i) = G_{M|B}(m \mid b_i)$, where $G_{M|B}(m \mid b) = \mathbb{P}(M_i \le m \mid B_i = b)$ and $b_i = \beta_i(v_i)$. Let $g_{M|B}(m \mid b)$ be its density in m. At the equilibrium bid,

$$v_i = b_i + \frac{G_{M|B}(b_i \mid b_i)}{g_{M|B}(b_i \mid b_i)}. \tag{14.68}$$

Everything on the right side is a feature of the joint distribution of a bidder's own bid and the highest rival bid, which is observed when all bids are recorded. Chapter 15 uses (14.68) to recover values from bids (Li et al., 2002; Campo et al., 2003). With common values the same argument gives Athey and Haile (2007, eq. (2.4)), in which the left side is the pivotal expected value $\mathbb{E}[V_i \mid S_i = s_i,\ M_i = \beta(s_i)]$. In the symmetric Milgrom-Weber model this is $v(s, s)$. There, $G_{M|B}(b \mid b) = F_{Y_1}(s \mid s)$ and $g_{M|B}(b \mid b) = \frac{f_{Y_1}(s|s)}{\beta'(s)}$ at $b = \beta(s)$, and (14.68) becomes (14.63).

Existence and uniqueness of equilibrium are now well understood. The following theorem collects the results summarized by Athey and Haile (2007, Theorem 2.1).

Theorem 14.61 (Existence and uniqueness in first-price auctions)**.** *Suppose values have a compact, convex common support, signals are affiliated with a product support, and their joint density is strictly positive on the interior of the support.*

(i) An equilibrium in pure, nondecreasing strategies exists (Athey, 2001; Reny and Zamir, 2004). Strategies can be taken strictly increasing, except in common values models with asymmetric bidders and dependent signals. There, at most one bidder may bid the lowest winning bid with positive probability (McAdams, 2003).

(ii) With private values and either independence or symmetry, and a continuously differentiable density, the equilibrium is unique and in pure, strictly increasing, differentiable strategies (Lebrun, 1999; Maskin and Riley, 2003; McAdams, 2003, 2007).

(iii) With symmetric bidders and a continuously differentiable density, there is a unique equilibrium within the class of nondecreasing pure strategies. It is symmetric, strictly increasing and differentiable, and it is the equilibrium of Proposition 14.58 (McAdams, 2007).

We do not prove the theorem. Existence for asymmetric bidders rests on single-crossing arguments that go beyond this book. Part (iii) shows that, among monotone equilibria, the Milgrom-Weber first-price equilibrium is the only one in the symmetric model.

14.9 Affiliated Values II: The Linkage Principle, Revenue Ranking, and Information Disclosure

With independent private values the four standard formats raise the same expected revenue (Proposition 14.43). Affiliation breaks this equivalence in a systematic direction. This section explains why through the linkage principle, proves the ranking, and applies the same logic to the seller's disclosure of information, reserve prices and entry fees. It then asks which results survive risk aversion and closes with an assessment of the paper.

14.9.1 The linkage principle

Milgrom and Weber (1982, pp. 1110–1111) view each auction as a revelation game in which every bidder chooses a report x in place of a bid $\beta(x)$. No auction can set prices directly in terms of bidders' preferences and information. Prices can depend only on the reports and on the seller's information. If the price depends on variables other than the winner's own report, and those variables are affiliated with the winner's signal, then the price is statistically linked to that signal. The expected price, as a function of the winner's signal, rises more steeply than it otherwise would. In all three auctions the winner with the lowest signal expects to pay $v(\underline{s}, \underline{s})$. A steeper expected payment function therefore means higher prices and lower bidder profits.

To make this precise, consider a symmetric auction mechanism $\mathcal{M}$ with a symmetric, increasing equilibrium in which the highest signal wins. For bidder 1 with signal z who bids as if its signal were x, define the expected value it receives,

$$R(x, z) = \mathbb{E}\left[V_1 \mathbf{1}\{Y_1 < x\} \mid S_1 = z\right],$$

and its expected payment conditional on winning, $W^{\mathcal{M}}(x, z)$. Its expected payoff is $R(x, z) - W^{\mathcal{M}}(x, z) F_{Y_1}(x \mid z)$. In equilibrium $x = z$ is optimal, so the first-order condition holds at $x = z$ (Milgrom and Weber, 1982, eq. (9)):

$$0 = R_1(z, z) - W_1^{\mathcal{M}}(z, z) F_{Y_1}(z \mid z) - W^{\mathcal{M}}(z, z) f_{Y_1}(z \mid z), \tag{14.69}$$

where subscripts denote partial derivatives. The boundary condition is $W^{\mathcal{M}}(\underline{s}, \underline{s}) = v(\underline{s}, \underline{s})$. In the first-price auction the winner pays its own bid, so $W^{FP}(x, z) = \beta^{FP}(x)$. In the second-price auction it pays the highest rival bid, so $W^{SP}(x, z) = \mathbb{E}[v(Y_1, Y_1) \mid Y_1 < x,\ S_1 = z]$. The partial derivative $W_2^{\mathcal{M}}$ measures how much the expected price depends on the winner's true signal when its report is held fixed. We call it the *linkage* of the mechanism.

Proposition 14.62 (Linkage principle). *Let $\mathcal{M}$ and $\mathcal{M}'$ be two mechanisms as above that satisfy (14.69). Suppose $W^{\mathcal{M}}(\underline{s}, \underline{s}) = W^{\mathcal{M}'}(\underline{s}, \underline{s})$ and $W_2^{\mathcal{M}}(z, z) \geq W_2^{\mathcal{M}'}(z, z)$ for all z. Then $W^{\mathcal{M}}(z, z) \geq W^{\mathcal{M}'}(z, z)$ for all z, and $\mathcal{M}$ yields an expected revenue at least as large as $\mathcal{M}'$.*

Proof. Let $g(z) = W^{\mathcal{M}}(z, z)$ and $h(z) = W^{\mathcal{M}'}(z, z)$. Solving (14.69) for W_1 in each mechanism and subtracting,

$$W_1^{\mathcal{M}}(z, z) - W_1^{\mathcal{M}'}(z, z) = -\left[g(z) - h(z)\right] \frac{f_{Y_1}(z \mid z)}{F_{Y_1}(z \mid z)}.$$

By the chain rule $g'(z) = W_1^{\mathcal{M}}(z, z) + W_2^{\mathcal{M}}(z, z)$, and similarly for h. Therefore

$$g'(z) - h'(z) = -\left[g(z) - h(z)\right] \frac{f_{Y_1}(z \mid z)}{F_{Y_1}(z \mid z)} + \left[W_2^{\mathcal{M}}(z, z) - W_2^{\mathcal{M}'}(z, z)\right].$$

If $g(z) < h(z)$, the first term is positive and the second is nonnegative, so $g'(z) \geq h'(z)$. Since $g(\underline{s}) = h(\underline{s})$, Lemma 14.39 gives $g \geq h$ everywhere. By symmetry each bidder wins with probability $\frac{1}{n}$, so expected revenue is $n\,\mathbb{E}[W(S_1, S_1)\mathbf{1}\{S_1 > Y_1\}] = \mathbb{E}[W(S_1, S_1) \mid S_1 > Y_1]$, which is larger under $\mathcal{M}$. □

The principle explains where bidders' profits come from. A bidder earns a rent because the price cannot depend on its private signal except through its own report. Every channel that makes the price track its signal through other affiliated variables reduces that rent. General versions of the principle are in Milgrom (2004) and Krishna (2010, Chapter 7).

14.9.2 Revenue ranking

The ranking rests on one inequality, which also delivers the disclosure results of Section 14.9.3.

Lemma 14.63 (Information raises the second-price expected price)**.** *Let $\mathbf{Z}$ be a random vector such that $(\mathbf{Z}, S_1, Y_1)$ are affiliated, and let $w_{\mathbf{Z}}(s, y, z) = \mathbb{E}[V_1 \mid S_1 = s,\ Y_1 = y,\ \mathbf{Z} = z]$ be nondecreasing. Then*

$$\mathbb{E}\left[v(Y_1, Y_1) \mid S_1 > Y_1\right] \le \mathbb{E}\left[w_{\mathbf{Z}}(Y_1, Y_1, \mathbf{Z}) \mid S_1 > Y_1\right].$$

Proof. By the law of iterated expectations, for all x and y,

$$v(x, y) = \mathbb{E}\left[\mathbb{E}[V_1 \mid S_1, Y_1, \mathbf{Z}] \mid S_1 = x, Y_1 = y\right] = \mathbb{E}\left[w_{\mathbf{Z}}(x, y, \mathbf{Z}) \mid S_1 = x, Y_1 = y\right].$$

Now take $x > y$. Applying this identity at the point (y, y) and then Proposition 14.16(iii) to the nondecreasing function $w_{\mathbf{Z}}(y, y, \cdot)$,

$$v(y, y) = \mathbb{E}\left[w_{\mathbf{Z}}(y, y, \mathbf{Z}) \mid S_1 = y, Y_1 = y\right] \le \mathbb{E}\left[w_{\mathbf{Z}}(y, y, \mathbf{Z}) \mid S_1 = x, Y_1 = y\right].$$

Setting $y = Y_1$ and $x = S_1$ on the event $\{S_1 > Y_1\}$ and taking expectations,

$$\mathbb{E}\left[v(Y_1, Y_1) \mid S_1 > Y_1\right] \le \mathbb{E}\left[\mathbb{E}\left[w_{\mathbf{Z}}(Y_1, Y_1, \mathbf{Z}) \mid S_1, Y_1\right] \mid S_1 > Y_1\right] = \mathbb{E}\left[w_{\mathbf{Z}}(Y_1, Y_1, \mathbf{Z}) \mid S_1 > Y_1\right]. \qquad \square$$

Proposition 14.64 (Milgrom and Weber, 1982, Theorems 11 and 15)**.** *Let Assumption 14.10 hold, and consider the equilibria of Propositions 14.51, 14.56 and 14.58. The expected price in the English auction is at least that in the second-price auction. The expected price in the second-price auction is at least that in the first-price and Dutch auctions.*

Proof. Second price versus first price. Both equilibria satisfy (14.69), because $x = z$ is optimal in each. In the first-price auction $W^{FP}(x, z) = \beta^{FP}(x)$ does not depend on z, so $W_2^{FP} = 0$. In the second-price auction $W^{SP}(x, z) = \mathbb{E}[v(Y_1, Y_1) \mid Y_1 < x, S_1 = z]$. Since (S_1, Y_1) are affiliated, v is nondecreasing and the event $\{Y_1 < x\}$ is an interval, Proposition 14.16(iii) shows that W^{SP} is nondecreasing in z, so $W_2^{SP} \ge 0$. Both mechanisms satisfy the boundary condition $W(\underline{s}, \underline{s}) = v(\underline{s}, \underline{s})$. Proposition 14.62 gives $W^{SP}(z, z) \ge W^{FP}(z, z)$ for all z, and the expected prices are $\mathbb{E}[W(S_1, S_1) \mid S_1 > Y_1]$.

English versus second price. When bidder 1 wins, it pays $\bar{v}(Y_1, Y_1, Y_2, \ldots, Y_{n-1})$ in the English auction (Proposition 14.56) and $v(Y_1, Y_1)$ in the second-price auction. Apply Lemma 14.63 with $\mathbf{Z} = (Y_2, \ldots, Y_{n-1})$. Then $w_{\mathbf{Z}} = \bar{v}$, which is nondecreasing by Corollary 14.49, and $(S_1, Y_1, \ldots, Y_{n-1})$ are affiliated by Proposition 14.16(iv) and (ii).

Dutch versus first price. The two are strategically equivalent (Proposition 14.4). $\square$

The English auction proceeds in two phases (Milgrom and Weber, 1982, p. 1105). In the first, the $n - 2$ bidders with the lowest signals reveal them publicly by dropping out. In the second, the last two bidders play what amounts to a second-price auction with this public information. Lemma 14.63 says that public information affiliated with the bidders' signals raises the expected second-price price. The first phase therefore raises the expected price above the second-price level. In the language of linkage, the English price is linked to the signals of all losing bidders. The second-price price is linked only to the highest losing signal, and the first-price price to no other signal at all.

The mineral rights example (Examples 14.52, 14.57 and 14.59) makes the ranking explicit. Write $S_i = V + \omega(2U_i - 1)$ with U_i i.i.d. uniform on $[0, 1]$. The k-th lowest of n uniforms has mean $\frac{k}{n+1}$, so the k-th lowest signal has mean

$$\mathbb{E}\left[S_{(k:n)}\right] = V + \omega\left(\frac{2k}{n+1} - 1\right) = V + \omega\,\frac{2k - n - 1}{n+1}.$$

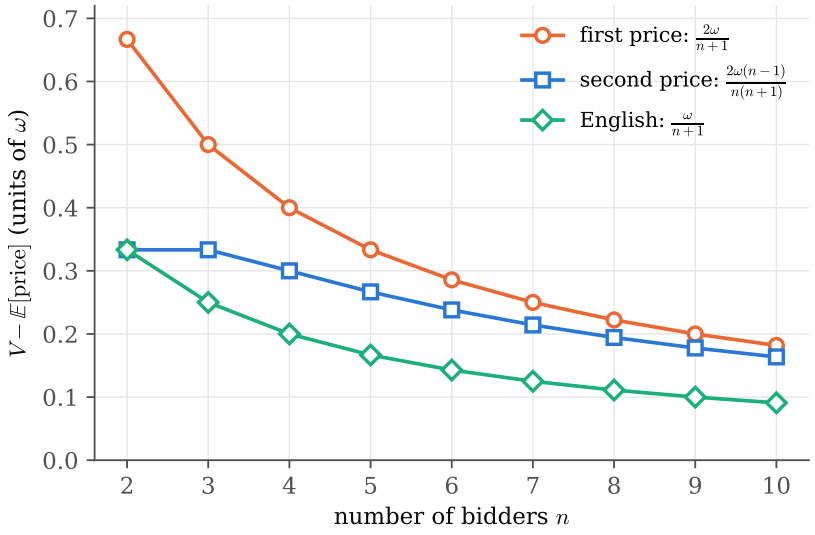

Figure 14.14: Expected bidder rents $V - \mathbb{E}[\text{price}]$, in units of ω, in the mineral rights model with uniform noise (Example 14.52) and a diffuse prior. The formulas are derived in the text, and a Monte Carlo check is in `mineral_rights.py`.

The first-price winner pays $S_{(n:n)} - \omega$, by (14.66). Its expected payment is

$$V + \omega\,\frac{n-1}{n+1} - \omega = V - \frac{2\omega}{n+1}.$$

The second-price winner pays $v(S_{(n-1:n)}, S_{(n-1:n)}) = S_{(n-1:n)} - \omega\frac{n-2}{n}$, by (14.54). Its expected payment is

$$V + \omega\,\frac{n-3}{n+1} - \omega\,\frac{n-2}{n} = V + \omega\,\frac{n(n-3) - (n-2)(n+1)}{n(n+1)} = V - \frac{2\omega(n-1)}{n(n+1)}.$$

The English winner pays $\frac{S_{(n-1:n)}+S_{(1:n)}}{2}$, with expectation

$$V + \frac{\omega}{2}\left(\frac{n-3}{n+1} + \frac{1-n}{n+1}\right) = V - \frac{\omega}{n+1}.$$

The expected bidder rents are therefore $\frac{2\omega}{n+1}$, $\frac{2\omega(n-1)}{n(n+1)}$ and $\frac{\omega}{n+1}$. They are ranked as Proposition 14.64 predicts, because $1 \geq \frac{n-1}{n}$ and $2(n-1) \geq n$. The English and second-price auctions tie at $n = 2$, as they must. Figure 14.14 plots the rents. The first-price rent is twice the English rent for every n.

The affiliated private values example (Examples 14.53 and 14.60) shows that interdependent values are not needed. The second-price (and English) revenue is $\mathbb{E}[\min\{S_1, S_2\}]$. By symmetry,

$$\mathbb{E}[\min\{S_1, S_2\}] = 2\int_0^1 \int_0^{s_1} s_2\,\frac{4}{5}(1+s_1 s_2)\,ds_2\,ds_1 = \frac{8}{5}\int_0^1 \left(\frac{s_1^2}{2} + \frac{s_1^4}{3}\right) ds_1 = \frac{8}{5}\cdot\frac{7}{30} = \frac{28}{75} \approx 0.3733.$$

We compute the first-price revenue $\mathbb{E}[\beta^{FP}(\max\{S_1, S_2\})]$ by numerical integration and obtain 0.3676. The gap is small because the correlation is only 0.054, but its sign is the one the theory

predicts. Compare Example 14.44, which has interdependent values $V = \frac{S_1+S_2}{2}$ and independent uniform signals. There both formats raise $\frac{1}{3}$. The ranking comes from the affiliation of the signals. Interdependence of values alone does not produce it. Table 14.8 collects the numbers.

Table 14.8: Equilibrium bids and expected revenue in the two running examples

Panel A. Mineral rights with uniform noise, diffuse prior

Format	Bid or price	$V - \mathbb{E}[\text{price}]$	$n = 3$
First price	bid $s - \omega$	$\frac{2\omega}{n+1}$	0.500ω
Second price	bid $s - \omega\frac{n-2}{n}$	$\frac{2\omega(n-1)}{n(n+1)}$	0.333ω
English	price $\frac{Y_1+Y_{n-1}}{2}$	$\frac{\omega}{n+1}$	0.250ω
Second price, S_0 disclosed	bid $w(s, s, s_0)$	numerical	0.192ω
English, S_0 disclosed	price $\frac{\max\{Y_1,S_0\}+\min\{Y_{n-1},S_0\}}{2}$	$\frac{n\omega}{(n+1)(n+2)}$	0.150ω

Panel B. Affiliated private values, $f(s_1, s_2) = \frac{4}{5}(1 + s_1 s_2)$, $n = 2$

Format	Bid	Revenue	Bidder surplus
First price	(14.67)	0.3676	0.3257
Second price, English	s	$\frac{28}{75} \approx 0.3733$	0.3200
Independent uniform values	$\frac{s}{2}$ (first), s (second)	$\frac{1}{3}$	$\frac{1}{3}$

Notes: In Panel A the seller's signal is $S_0 = V + \epsilon_0$ with ϵ_0 uniform on $[-\omega, \omega]$ and independent of the bidders' noise. The closed forms are derived in the text. The disclosed second-price rent is computed by numerical integration (0.167ω, 0.192ω, 0.191ω and 0.182ω for $n = 2, \ldots, 5$). In Panel B, expected total surplus is $\mathbb{E}[\max\{S_1, S_2\}] = \frac{52}{75}$ with affiliation and $\frac{2}{3}$ with independent uniform values. The first-price revenue is computed by numerical integration. Source: scripts `mineral_rights.py` and `apv_example.py`.

Table 14.9 maps the paper's results to the places where this chapter states and proves them.

14.9.3 Information disclosure by the seller

Suppose the seller observes a variable S_0 that is affiliated with $(\boldsymbol{A}, \boldsymbol{S})$, such as an expert appraisal. Can the seller gain by revealing it? We assume that the seller can commit to a reporting policy and that its reports are credible. Credibility is plausible if a buyer has recourse after a false announcement, or if the seller is an institution, such as an auction house, that values its reputation for truthfulness (Milgrom and Weber, 1982, footnote 18).

Define $w(s, y, s_0) = \mathbb{E}[V_1 \mid S_1 = s, Y_1 = y, S_0 = s_0]$, which is nondecreasing by Proposition 14.16(iii). After $S_0 = s_0$ is announced, the conditional density of $(\boldsymbol{A}, \boldsymbol{S})$ given s_0 is proportional to $f(\boldsymbol{a}, \boldsymbol{s}, s_0)$ with s_0 held fixed. It satisfies (14.7), since the inequality for f holds in particular for pairs of points with the same value of s_0. So the analysis of Section 14.8 applies conditionally. In the second-price auction the equilibrium bid becomes $\beta^{SP}(s; s_0) = w(s, s, s_0)$, a function of both private and public information (Milgrom and Weber, 1982, p. 1102).

Proposition 14.65 (Milgrom and Weber, 1982, Theorems 8, 12 and 16)**.** *Let Assumption 14.10 hold, and let S_0 be affiliated with $(\boldsymbol{A}, \boldsymbol{S})$.*

(i) In the second-price auction, the expected price without disclosure, $\mathcal{R}_N^{SP} = \mathbb{E}[v(Y_1, Y_1) \mid S_1 > Y_1]$, is at most the expected price with public disclosure of S_0, $\mathcal{R}_I^{SP} = \mathbb{E}[w(Y_1, Y_1, S_0) \mid S_1 > Y_1]$.

(ii) In the English auction, the expected price without disclosure, $\mathcal{R}_N^E = \mathbb{E}[\bar{v}(Y_1, Y_1, Y_2, \dots, Y_{n-1}) \mid S_1 > Y_1]$*, is at most the expected price with disclosure,* $\mathcal{R}_I^E = \mathbb{E}[\bar{w}(Y_1, Y_1, Y_2, \dots, Y_{n-1}, S_0) \mid S_1 > Y_1]$*, where* $\bar{w}(s, y_1, \dots, y_{n-1}, s_0) = \mathbb{E}[V_1 \mid S_1 = s,\ Y_1 = y_1, \dots, Y_{n-1} = y_{n-1},\ S_0 = s_0]$.

(iii) In the first-price auction, public disclosure of S_0 *cannot lower, and may raise, the expected price.*

Proof. Part (i). By symmetry the expected price equals the expected price paid by bidder 1 when it wins, which is $v(Y_1, Y_1)$ without disclosure and $w(Y_1, Y_1, S_0)$ with it. Apply Lemma 14.63 with $\boldsymbol{Z} = S_0$. The vector (S_0, S_1, Y_1) is affiliated by Proposition 14.16(iv) and (ii), with S_0 counted among the variables $\boldsymbol{A}$, and w is nondecreasing.

Part (ii). The argument of Lemma 14.63 goes through with $(Y_2, \dots, Y_{n-1})$ added to every conditioning set. For $x > y_1$,

$$\begin{aligned}\bar{v}(y_1, y_1, y_2, \dots, y_{n-1}) &= \mathbb{E}\left[\bar{w}(y_1, y_1, \dots, y_{n-1}, S_0) \mid S_1 = y_1, Y_1 = y_1, \dots\right] \\ &\le \mathbb{E}\left[\bar{w}(y_1, y_1, \dots, y_{n-1}, S_0) \mid S_1 = x, Y_1 = y_1, \dots\right],\end{aligned}$$

where the dots stand for $Y_2 = y_2, \dots, Y_{n-1} = y_{n-1}$. Taking expectations over $\{S_1 > Y_1\}$ gives the result.

Part (iii), sketch. Let $\beta(\cdot; s_0)$ be the first-price equilibrium after $S_0 = s_0$ is announced. It solves the analogue of (14.63) with $w(s, s, s_0)$ in place of $v(s, s)$ and the ratio $\zeta(s; s_0) = \frac{f_{Y_1}(s|s,s_0)}{F_{Y_1}(s|s,s_0)}$, with boundary value $w(\underline{s}, \underline{s}, s_0)$. A variant of Lemma 14.50 shows that $\zeta(s; s_0)$ is nondecreasing in s_0, and w is nondecreasing in s_0. For $s_0' > s_0$, let $g = \beta(\cdot; s_0')$ and $h = \beta(\cdot; s_0)$. Then $g(\underline{s}) \ge h(\underline{s})$, and $g(x) < h(x)$ implies $g'(x) = (w(x, x, s_0') - g(x))\zeta(x; s_0') \ge (w(x, x, s_0) - h(x))\zeta(x; s_0) = h'(x)$. By Lemma 14.39, $\beta(x; s_0)$ is nondecreasing in s_0. Now define $W^*(x, z) = \mathbb{E}[\beta(x; S_0) \mid Y_1 < x,\ S_1 = z]$,

the expected payment of a winner with signal z who bids as if x whatever S_0 turns out to be. By Proposition 14.16(iii), $W_2^* \geq 0 = W_2^{FP}$. The boundary value is $W^*(\underline{s}, \underline{s}) = \mathbb{E}[w(\underline{s}, \underline{s}, S_0) \mid Y_1 = S_1 = \underline{s}] = v(\underline{s}, \underline{s})$. A bidder who commits to the report x before S_0 is announced chooses $x = z$, because $x = z$ is optimal for every realization of S_0. So W^* satisfies (14.69). Proposition 14.62 gives $W^*(z, z) \geq \beta^{FP}(z)$, and the expected price is higher with disclosure. □

Could the seller do better by censoring, that is, reporting S_0 only when it is favorable? No. If the policy is known, rational bidders interpret the absence of a report as bad news. More generally, let the seller's report be $S_0' = \varrho(S_0, Z)$, where Z is uniform on $[0, 1]$ and independent of everything else. The report may depend both on the seller's information and on the spin of a roulette wheel. Since the policy is known, we can assume without loss that the seller always makes some report, possibly a blank page (Milgrom and Weber, 1982, p. 1103).

Proposition 14.66 (Milgrom and Weber, 1982, Theorems 9, 13 and 17)**.** *In the second-price, English and first-price auctions, no reporting policy yields a higher expected price than always reporting S_0.*

Proof. Let $g(s_0' \mid s_0)$ be the conditional density of the report given S_0 and $g(s_0')$ its marginal. Given $S_0' = s_0'$, the conditional density of $(\boldsymbol{A}, \boldsymbol{S}, S_0)$ is $\frac{f(\boldsymbol{a}, \boldsymbol{s}, s_0)\, g(s_0' \mid s_0)}{g(s_0')}$ (Milgrom and Weber, 1982, footnote 19). For fixed s_0', this is the product of the affiliated density f and a nonnegative function of s_0 alone. A function of one variable satisfies (14.7) with equality, so the product is affiliated by Proposition 14.12. Conditional on $S_0' = s_0'$, Proposition 14.65 therefore says that revealing S_0 as well raises the expected price. Revealing both S_0 and S_0' leads to the same bidding as revealing S_0 alone, because S_0' carries no information about $(\boldsymbol{A}, \boldsymbol{S})$ beyond S_0. Averaging over S_0' completes the proof. □

Full disclosure links the price to S_0, a variable affiliated with the winner's signal that the winner cannot influence. It dilutes the winner's informational advantage and so lowers its rent (Milgrom and Weber, 1982, p. 1117). The results offer an explanation for the expert appraisals and catalog estimates that reputable auction houses publish.

The mineral rights example quantifies the effect (Panel A of Table 14.8). Let the seller observe $S_0 = V + \epsilon_0$, with ϵ_0 uniform on $[-\omega, \omega]$ and independent of the bidders' noise. In the English auction with S_0 public, the posterior of V at the last exit is uniform. Its support runs from the largest signal minus ω to the smallest signal plus ω, where S_0 now counts as a signal. The winner pays $\frac{\max\{Y_1, S_0\} + \min\{Y_{n-1}, S_0\}}{2}$. In uniform units, $\min\{U_{(1:n)}, U_0\}$ is the minimum of $n + 1$ uniforms, with mean $\frac{1}{n+2}$. The maximum $\max\{U_{(n-1:n)}, U_0\}$ has distribution function $x\Lambda_n(x)$, where $\Lambda_n(x) = nx^{n-1}(1 - x) + x^n$ is the distribution function of $U_{(n-1:n)}$. Its mean is

$$1 - \int_0^1 x\Lambda_n(x)\, dx = 1 - n\left(\frac{1}{n+1} - \frac{1}{n+2}\right) - \frac{1}{n+2} = 1 - \frac{2n+1}{(n+1)(n+2)}.$$

Converting back with $S = V + \omega(2U - 1)$, the price is

$$V + \omega\left(\max\{U_{(n-1:n)}, U_0\} + \min\{U_{(1:n)}, U_0\} - 1\right),$$

so the expected rent is

$$V - \mathbb{E}[\text{price}] = \omega\left[\frac{2n+1}{(n+1)(n+2)} - \frac{1}{n+2}\right] = \frac{n\omega}{(n+1)(n+2)}.$$

Disclosure multiplies the English rent $\frac{\omega}{n+1}$ by $\frac{n}{n+2}$. For $n = 2$ it halves the rent, from $\frac{\omega}{3}$ to $\frac{\omega}{6}$. In the second-price auction the price becomes $w(Y_1, Y_1, S_0)$, the mean of a density proportional to $(Y_1 + \omega - V)^{n-2}$ on $[\max\{Y_1, S_0\} - \omega,\ \min\{Y_1, S_0\} + \omega]$. Numerical integration gives a rent of 0.192ω for $n = 3$, against 0.333ω without disclosure.

14.9.4 Reserve prices and entry fees

So far no reserve price or entry fee has played a role. Bids were restricted to be nonnegative, which amounts to a reserve price of zero that never binds, because values are nonnegative (Milgrom and Weber, 1982, footnote 25). Without any reserve, other symmetric equilibria can appear, as Section 14.5 shows for uniform private values.

A reserve price r above $v(\underline{s}, \underline{s})$ changes the analysis in one way. Only bidders whose signals exceed a *screening level* participate, where (Milgrom and Weber, 1982, eq. (10))

$$s^*(r) = \inf\{s :\ \mathbb{E}[V_1 \mid S_1 = s,\ Y_1 < s] \geq r\}. \tag{14.70}$$

The marginal participant wins only when every rival's signal lies below s^*, so that no rival bids, and then it pays r. It must therefore be indifferent between participating and staying out, which is the condition $\mathbb{E}[V_1 \mid S_1 = s^*, Y_1 < s^*] = r$. The conditional mean is nondecreasing in s by Proposition 14.16(iii), so the screening level rises with r.

The equilibrium strategies adapt in a simple way (Milgrom and Weber, 1982, p. 1111). In the first-price auction the bid solves (14.63) on $[s^*, \bar{s}]$ with boundary condition $\beta(s^*) = r$. Repeating the integrating-factor argument from s^* in place of $\underline{s}$,

$$\beta^{FP}(s) = r\, L(s^* \mid s) + \int_{s^*}^{s} v(\alpha, \alpha)\, dL(\alpha \mid s) \quad \text{for } s \geq s^*,$$

and types below s^* bid less than r or not at all. In the second-price auction the bid is $v(s, s)$ for $s \geq s^*$, and types below s^* do not bid. When at least two bidders participate, the winner pays the highest rival bid. A sole participant pays r. The marginal type's expected payoff is $F_{Y_1}(s^* \mid s^*)\,(\mathbb{E}[V_1 \mid S_1 = s^*, Y_1 < s^*] - r) = 0$, so the same screening level applies. The same set of bidders participates in all three auctions with the same reserve price. The revenue ranking of Proposition 14.64 survives a fixed reserve price (Milgrom and Weber, 1982, p. 1112).

The second-price auction with a reserve has a curious feature (Milgrom and Weber, 1982, footnote 26). By Proposition 14.17, $v(s^*, s^*) \geq \mathbb{E}[V_1 \mid S_1 = s^*, Y_1 < s^*] = r$. When the inequality is strict, bids jump from nothing below s^* to $v(s^*, s^*) > r$ at s^*, so no bids fall in a neighborhood above r. The marginal participant bids above the reserve because winning against a participating rival is better news than winning alone.

Seller information interacts with the reserve price. If the seller fixes a reserve price and then reveals S_0, the revelation changes the screening level and hence the set of competitors. Favorable news attracts bidders and unfavorable news deters them. The seller can offset this by adjusting the reserve to the announcement. Fix a reserve $\bar{r}$ and let $s^*(r \mid s_0)$ be the screening level when $S_0 = s_0$ is announced and the reserve is r. It is nondecreasing in r and nonincreasing in s_0. Let $r(s_0 \mid \bar{r})$ be the reserve that keeps the screening level fixed, so that $s^*(r(s_0 \mid \bar{r}) \mid s_0) = s^*(\bar{r})$.

Proposition 14.67 (Milgrom and Weber, 1982, Theorem 18)**.** *For any reserve price $\bar{r}$ in the first-price, second-price or English auction, announcing S_0 and setting the reserve $r(S_0 \mid \bar{r})$ raises the expected price.*

Proof for the second-price auction. Let $s^* = s^*(\bar{r})$ and $Y_1^* = \max\{Y_1, s^*\}$. Define $v^*(x,y) = \mathbb{E}[V_1 \mid S_1 = x, Y_1^* = y]$ and $w^*(x,y,s_0) = \mathbb{E}[V_1 \mid S_1 = x, Y_1^* = y, S_0 = s_0]$. Bidder 1 wins exactly when $S_1 > Y_1^*$. Without disclosure it then pays $v(Y_1, Y_1)$ if $Y_1 \geq s^*$ and $\bar{r}$ if $Y_1 < s^*$. Both cases equal $v^*(Y_1^*, Y_1^*)$, because $\bar{r} = \mathbb{E}[V_1 \mid S_1 = s^*, Y_1 < s^*] = v^*(s^*, s^*)$ by (14.70). With disclosure and the adjusted reserve it pays $w(Y_1, Y_1, S_0)$ or $r(S_0 \mid \bar{r}) = \mathbb{E}[V_1 \mid S_1 = s^*, Y_1 < s^*, S_0]$, which both equal $w^*(Y_1^*, Y_1^*, S_0)$. The map $Y_1 \mapsto \max\{Y_1, s^*\}$ is nondecreasing, so (S_0, S_1, Y_1^*) are affiliated by Proposition 14.16(i), and v^*, w^* are nondecreasing. The argument of Lemma 14.63, with Y_1^* in place of Y_1, then gives $\mathbb{E}[v^*(Y_1^*, Y_1^*) \mid S_1 > Y_1^*] \leq \mathbb{E}[w^*(Y_1^*, Y_1^*, S_0) \mid S_1 > Y_1^*]$. The English case is the same with $Y_2, \ldots, Y_{n-1}$ added, and the first-price case adapts the argument of Proposition 14.65(iii) (Milgrom and Weber, 1982, p. 1112). □

As with Proposition 14.66, no partial reporting policy beats full revelation with an adjusted reserve.

Entry fees add a second instrument. With a reserve price r and an entry fee e paid by every participant, the screening level becomes

$$s^*(r,e) = \inf\{s : \mathbb{E}[(V_1 - r)\mathbf{1}\{Y_1 < s\} \mid S_1 = s] \geq e\}.$$

The left side is the expected profit of the marginal participant, who wins only when nobody else enters and then pays r. It need not be true that exactly the bidders above $s^*(r,e)$ choose to enter. In a first-price auction, a bidder with a signal well above $s^*(r,e)$ may stay out if its chance of winning, $F_{Y_1}(s \mid s)$, is small (Milgrom and Weber, 1982, p. 1112).

Definition 14.68 (Regular reserve price and entry fee)**.** A reserve price and entry fee pair (r,e) is *regular* for an auction if, in equilibrium, the bidders who participate are exactly those with signals above $s^*(r,e)$.

A zero entry fee is always regular. Milgrom and Weber (1982, footnote 27) give an irregular pair. Let $n = 2$ and $V_i = S_i$. With probability $\frac{1}{2}$ both signals are drawn independently and uniformly from $[0,2]$, and with probability $\frac{1}{2}$ from $[1,2]$. Take $r = 0$ and $e = 0.32$. For $s < 1$ only the first regime is possible, $F_{Y_1}(s \mid s) = \frac{s}{2}$, and $s \cdot \frac{s}{2} = 0.32$ gives $s^* = 0.8$. Just above $s = 1$, Bayes' rule puts posterior probability $\frac{1}{3}$ on the first regime. Then $F_{Y_1}(s \mid s)$ drops from $\frac{1}{2}$ to $\frac{1}{3} \cdot \frac{1}{2} = \frac{1}{6}$ (the printed footnote reports $\frac{1}{4}$, and the conclusion is the same). A bidder with s slightly above 1 expects a gross payoff of at most $sF_{Y_1}(s \mid s) \approx \frac{1}{6} < 0.32$, so it stays out although its value exceeds s^*.

Proposition 14.69 (Milgrom and Weber, 1982, Theorem 19)**.** *Fix the first-price, second-price or English auction, and let (r,e) be regular. Let $(\tilde{r},\tilde{e})$ have the same screening level, $s^*(r,e) = s^*(\tilde{r},\tilde{e})$, and $\tilde{e} < e$. Then $(\tilde{r},\tilde{e})$ is regular, and its expected revenue is at most that of (r,e).*

Sketch. Let $P(x,z)$ and $\tilde{P}(x,z)$ be bidder 1's expected payments (not conditional on winning) under the two pairs when its signal is z and it bids as if x. With R as in Section 14.9.1, the equilibrium conditions are $P_1(z,z) = R_1(z,z) = \tilde{P}_1(z,z)$ for $z \geq s^*$ and $P(s^*,s^*) = R(s^*,s^*) = \tilde{P}(s^*,s^*)$. Since $\tilde{e} < e$ at the same screening level, $\tilde{r} > r$. In the first-price auction, $P(x,z) = b(x)F_{Y_1}(x \mid z) + e$ and $\tilde{P}(x,z) = \tilde{b}(x)F_{Y_1}(x \mid z) + \tilde{e}$, where b and $\tilde{b}$ solve the same differential equation with $b(s^*) = r < \tilde{r} = \tilde{b}(s^*)$. Solutions of a first-order equation cannot cross, so $b < \tilde{b}$ everywhere. Hence

$$P_2(x,x) - \tilde{P}_2(x,x) = \left[b(x) - \tilde{b}(x)\right] \frac{\partial F_{Y_1}(x \mid z)}{\partial z}\Big|_{z=x} \geq 0,$$

because affiliation makes $F_{Y_1}(x \mid z)$ nonincreasing in z. In the second-price and English auctions the payments differ only when the bidder pays the reserve price, that is, when $Y_1 < s^*$. Then $P_2(x,z) - \tilde{P}_2(x,z) = (r - \tilde{r})\frac{\partial F_{Y_1}(s^* \mid z)}{\partial z} \geq 0$. In each case the argument of Proposition 14.62, built on Lemma 14.39, gives $P(z,z) \geq \tilde{P}(z,z)$ for all $z \geq s^*$. Participants therefore pay more on average under (r,e). Under $(\tilde{r},\tilde{e})$ they earn $R(z,z) - \tilde{P}(z,z) \geq R(z,z) - P(z,z) \geq 0$ and so participate. Types below s^* still prefer to stay out, which uses the quasiconcavity of the bidder's problem and affiliation once more (Milgrom and Weber, 1982, pp. 1113–1114). □

The intuition is again linkage. An entry fee is paid whatever the bidder's signal. The reserve price is paid only when nobody else participates, an event whose probability $F_{Y_1}(s^* \mid z)$ falls as the bidder's signal rises. Replacing reserve-price revenue with entry-fee revenue removes this negative link between the payment and the bidder's signal. It makes the expected payment rise more steeply with the signal, which lowers bidders' rents.

14.9.5 Risk aversion

With independent private values and risk-averse bidders, the first-price auction raises more expected revenue than the second-price auction (Proposition 14.40). In Milgrom and Weber's version of the argument (Milgrom and Weber, 1982, eq. (11)), a risk-averse bidder's first-price bid function rises at least as fast as the risk-neutral one wherever it lies below it. The second-price bid is unaffected by risk aversion. Together with Proposition 14.64, this has a sharp consequence. With both affiliation and risk aversion, the first-price and second-price auctions cannot be ranked in general (Milgrom and Weber, 1982, p. 1114). Affiliation favors the second-price auction, and risk aversion favors the first-price auction.

Let bidders have a utility of money $\mathcal{U}$ that is increasing, concave and differentiable, with $\mathcal{U}(0) = 0$, and let reserve prices and entry fees be zero. The second-price analysis extends once v is redefined as a certainty equivalent. Let $v(x,y)$ solve $\mathbb{E}\left[\mathcal{U}\left(V_1 - v(x,y)\right) \mid S_1 = x, Y_1 = y\right] = \mathcal{U}(0)$. The proof of Proposition 14.51 carries over, and $\beta^{SP}(x) = v(x,x)$ remains an equilibrium (Milgrom and Weber, 1982, p. 1115). Define $w(x,y,s_0)$ in the same way with $S_0 = s_0$ added to the conditioning set.

With risk neutrality, the disclosure results rest on the inequality $\mathbb{E}[w(S_1,Y_1,S_0) \mid S_1,Y_1] \geq v(S_1,Y_1)$, which holds with equality. For risk-averse bidders the inequality says that resolving uncertainty by releasing information lowers the risk premium that bidders demand. If the information resolves all uncertainty, the premium falls to zero. Partial resolution need not lower it. To state the issue formally, take a pair (V,X) of a value and a signal. Define $\chi(x)$ by $\mathbb{E}[\mathcal{U}(V - \chi(X)) \mid X = x] = \mathcal{U}(0)$ and $\bar{\chi}$ by $\mathbb{E}[\mathcal{U}(V - \bar{\chi})] = \mathcal{U}(0)$. These are the willingness to pay with and without the information X. Revealing X *raises average willingness to pay* if $\mathbb{E}[\chi(X)] \geq \bar{\chi}$.

Proposition 14.70 (Milgrom and Weber, 1982, Theorem 20)**.** *Let $\mathcal{U}$ be increasing. Revealing X raises average willingness to pay for every pair (V,X) if and only if the coefficient of absolute risk aversion $-\frac{\mathcal{U}''}{\mathcal{U}'}$ is a nonnegative constant.*

Proof of sufficiency and sketch of necessity. Sufficiency. Under risk neutrality the claim is immediate. Adding a constant to $\mathcal{U}$ does not change χ or $\bar{\chi}$, so with constant absolute risk aversion $\kappa > 0$ we may take $\mathcal{U}(x) = -e^{-\kappa x}$, with $\mathcal{U}(0) = -1$. Factor the utility as

$\mathcal{U}(V - \bar{\chi}) = e^{\kappa(\bar{\chi} - \chi(X))}\,\mathcal{U}(V - \chi(X))$. Then

$$\begin{aligned}\mathcal{U}(0) &= \mathbb{E}\left[\mathcal{U}(V - \bar{\chi})\right] = \mathbb{E}\left[e^{\kappa(\bar{\chi} - \chi(X))}\,\mathbb{E}\left[\mathcal{U}(V - \chi(X)) \mid X\right]\right] \\ &= \mathbb{E}\left[e^{\kappa(\bar{\chi} - \chi(X))}\right]\mathcal{U}(0).\end{aligned}$$

Since $\mathcal{U}(0) \neq 0$, $\mathbb{E}[e^{\kappa(\bar{\chi} - \chi(X))}] = 1$. By Jensen's inequality, $e^{\kappa(\bar{\chi} - \mathbb{E}[\chi(X)])} \leq \mathbb{E}[e^{\kappa(\bar{\chi} - \chi(X))}] = 1$, so $\bar{\chi} \leq \mathbb{E}[\chi(X)]$.

Necessity, sketch. Normalize $\mathcal{U}(0) = 0$. Let X take the values 0 and 1 with probability $\frac{1}{2}$ each, let $V_a = X(Z + a)$, and let Z be independent of X with $\mathbb{E}[\mathcal{U}(Z)] = 0$. Then $\chi_a(0) = 0$, $\chi_a(1) = a$ and $\mathbb{E}[\chi_a(X)] = \frac{a}{2}$. If revealing X always raises willingness to pay, then $\bar{\chi}_a \leq \frac{a}{2}$. Since $\mathcal{U}$ is increasing,

$$0 = \mathbb{E}\left[\mathcal{U}(V_a - \bar{\chi}_a)\right] = \frac{1}{2}\mathbb{E}\left[\mathcal{U}(Z + a - \bar{\chi}_a)\right] + \frac{1}{2}\mathcal{U}(-\bar{\chi}_a) \geq \frac{1}{2}\mathbb{E}\left[\mathcal{U}\left(Z + \frac{a}{2}\right)\right] + \frac{1}{2}\mathcal{U}\left(-\frac{a}{2}\right).$$

The last expression is zero at $a = 0$, so it is maximized there, for every admissible Z. The first- and second-order conditions give $\mathbb{E}[\mathcal{U}'(Z)] = \mathcal{U}'(0)$ and $\mathbb{E}[\mathcal{U}''(Z)] + \mathcal{U}''(0) \leq 0$. Varying Z shows that $\mathcal{U}'$ composed with $\mathcal{U}^{-1}$ must be affine, so $\mathcal{U}' = c\,\mathcal{U} + \mathcal{U}'(0)$. The solutions are linear or exponential utilities, and the second-order condition leaves only those with constant, nonnegative absolute risk aversion (Milgrom and Weber, 1982, pp. 1115–1116). □

Proposition 14.71 (Milgrom and Weber, 1982, Theorem 21)**.** *Suppose bidders are risk averse with constant absolute risk aversion.*

(i) In the second-price and English auctions, public disclosure of S_0 raises the expected price.

(ii) Among all reporting policies, full disclosure yields the highest expected price in these two auctions.

(iii) The expected price in the English auction is at least that in the second-price auction.

Proof of (i) for the second-price auction. A corollary of Proposition 14.70, applied conditionally on $S_1 = x$ and $Y_1 = y$, is $\mathbb{E}[w(S_1, Y_1, S_0) \mid S_1 = x, Y_1 = y] \geq v(x, y)$. Since w is nondecreasing, for all $x > y$,

$$\begin{aligned}v(y, y) &\leq \mathbb{E}\left[w(S_1, Y_1, S_0) \mid S_1 = y, Y_1 = y\right] = \mathbb{E}\left[w(Y_1, Y_1, S_0) \mid S_1 = y, Y_1 = y\right] \\ &\leq \mathbb{E}\left[w(Y_1, Y_1, S_0) \mid S_1 = x, Y_1 = y\right],\end{aligned}$$

where the last step uses Proposition 14.16(iii). Taking expectations over $\{S_1 > Y_1\}$ gives $\mathbb{E}[v(Y_1, Y_1) \mid S_1 > Y_1] \leq \mathbb{E}[w(Y_1, Y_1, S_0) \mid S_1 > Y_1]$. □

The proof separates two effects of disclosure (Milgrom and Weber, 1982, p. 1117). The second inequality is the risk-neutral effect. Disclosure dilutes the winner's informational advantage and lowers its profit. The first inequality is new. With constant absolute risk aversion, disclosure also raises bidders' average willingness to pay. Milgrom and Weber argue that disclosure lowers average willingness to pay only when the range of possible wealth outcomes is large and much uncertainty remains unresolved. They judge that combination unusual for auction houses, so the result may account for the prevalence of English auctions and of published expert appraisals.

14.9.6 Assessment of Milgrom and Weber (1982)

Contribution. The paper built one framework that nests the independent private values model and the common value model, together with the intermediate cases that real auctions present. It identified affiliation as the property that organizes the theory. Affiliation is weak enough to cover the leading examples and strong enough to sign every comparison. With it, the paper derived equilibria in closed form for the second-price, English and first-price auctions, and it ranked the formats by expected revenue. It explained two features of practice that the private values theory could not, the prevalence of ascending auctions and sellers' willingness to publish appraisals. The linkage principle gave a single intuition for all of these results. Krishna (2010) and Milgrom (2004) build their textbook treatments of interdependent values on this framework.

Limitations and critiques. Symmetry is essential. With asymmetric bidders, equilibria lack closed forms, the first-price auction can allocate inefficiently, and the revenue ranking can fail (Section 14.10 and Maskin and Riley, 2000). The linkage principle need not extend to multi-unit auctions. Perry and Reny (1999) show by example that it can fail when bidders demand more than one unit. Affiliation is a strong form of positive dependence. It requires the inequality (14.7) at every pair of points and rules out negatively dependent signals. One-dimensional signals are a further restriction (Milgrom and Weber, 1982, footnote 14). In the English auction with common values the equilibrium is not unique (Bikhchandani et al., 2002), so the revenue comparison selects one equilibrium among many. Milgrom and Weber themselves list open problems in their Section 9 (pp. 1117–1118). Auctions in use account for hundreds of billions of dollars of trade every year, yet the theory was still poorly developed. Bidding for weapons systems is affected by expected renegotiation. The assumption that each auction can be studied in isolation also fails at times. The Department of the Interior may offer about 200 oil tracts at once, and a bidder on many tracts may worry about winning too many as well as too few. Examples by Engelbrecht-Wiggans and Weber (1979) suggest that the optimal strategy may then place high bids on a few tracts and low bids on several others of comparable value. Resale markets for drilling rights raise similar issues. Lumber mill owners who bid repeatedly against each other for timber may collude, which raises the question of which formats are least vulnerable (Section 14.12). Their footnote 9 (p. 1090) adds that collusion had received no attention in theoretical studies, despite many allegations of collusion in bidding for timber rights (Mead, 1967). Milgrom and Weber treat bidding syndicates as a further collusion issue. They ask why large oil companies sometimes bid jointly with smaller ones and how such syndicates affect prices. They also note that auctions for shares of a divisible object had received relatively little attention (Milgrom and Weber, 1982, p. 1118). Laboratory evidence also qualifies the rationality assumption. Kagel and Levin (1986) find that subjects in common value auctions often fail to correct fully for the winner's curse, especially in larger groups. Where bidders fall prey to the curse, public information can lower revenue by helping them correct it, contrary to the theory's prediction.

Empirical relevance. The model also delimits what auction data can reveal. Athey and Haile (2007, Section 7) normalize signals so that $\mathbb{E}[V_i \mid S_i = \max_{j \neq i} S_j = s] = s$ (their eq. (7.1)). The first-price condition (14.68) then states that $s_i = b_i + \frac{G_{M|B}(b_i|b_i)}{g_{M|B}(b_i|b_i)}$ (their eq. (7.2)). With common values, first-price bids identify only the distribution of the pivotal values $v(S_i, S_i)$. With a fixed number of bidders and no reserve price, common values and private values cannot be distinguished (Laffont and Vuong, 1996; Guerre et al., 2000). Ascending auctions are harder

still. In Athey and Haile (2007, Theorem 7.1), three bidders have uniform signals and either $V = \frac{S_1+S_2+S_3}{3}$ or $V = \frac{S_{(1:3)}}{3} + \frac{S_{(2:3)}}{6} + \frac{S_{(3:3)}}{2}$. The two models produce the same distribution of exit prices in the Milgrom-Weber equilibrium, yet they imply different optimal reserve prices. Progress requires more structure or more data. Variation in the number of bidders allows tests of private against common values, and ex post measures of the value help in auctions of offshore oil leases (Hendricks and Porter, 1988; Hendricks et al., 2003). Chapter 15 develops these approaches.

14.10 Asymmetric Bidders

The models of Sections 14.5, 14.8 and 14.9 treat every bidder as a draw from the same population, and the assessment in Section 14.9.6 noted that symmetry is essential to the Milgrom-Weber results. Many auctions instead pit different kinds of firms against each other. In the timber sales studied by Athey et al. (2011), sawmills with their own manufacturing capacity compete with independent loggers who must resell the timber. In public procurement, domestic firms compete with foreign firms, and incumbents compete with entrants. This section develops the private values model with bidders who draw their values from different distributions.

The mechanism-design results of Section 14.6 already allow bidder-specific distributions. Revenue equivalence therefore still holds for any two auctions that allocate the object in the same way. Asymmetry matters because it makes the first-price auction allocate the object differently from the second-price and ascending auctions. We show how the allocation changes, who gains and who loses, and why the revenue comparison becomes ambiguous.

14.10.1 The asymmetric private values model

Assumption 14.72 (Asymmetric independent private values)**.** There are $n \geq 2$ risk-neutral bidders, $i \in \mathcal{N} = \{1, \ldots, n\}$. Bidder i's value V_i is drawn from a distribution F_i with a continuous density f_i that is strictly positive on the support $[\underline{v}, \bar{v}_i]$. Values are independent across bidders and private. The distributions $F_1, \ldots, F_n$ and the set of bidders are common knowledge. The reserve price equals the common lower bound of the supports, $r = \underline{v}$.

The common lower bound and the choice $r = \underline{v}$ follow the model of Athey et al. (2011, Section II.A), where every support has the form $[\underline{v} = r, \bar{v}_i]$. The upper bounds may differ. When there are two classes of bidders, we call them *strong* (subscript s) and *weak* (subscript w). The ordering that gives these labels content is the following.

Definition 14.73 (Stochastic orders)**.** Let F_s and F_w have the common lower bound $\underline{v}$, and set $f_i(v) = 0$ and $F_i(v) = 1$ for $v > \bar{v}_i$. The distribution F_s dominates F_w in the *reverse hazard rate order* if

$$\frac{f_s(v)}{F_s(v)} \geq \frac{f_w(v)}{F_w(v)} \qquad \text{for all } v > \underline{v}. \tag{14.71}$$

It dominates in the *hazard rate order* if $\frac{f_s(v)}{1-F_s(v)} \leq \frac{f_w(v)}{1-F_w(v)}$ wherever both ratios are defined. It dominates in the *likelihood ratio order* if $\frac{f_s(v)}{f_w(v)}$ is nondecreasing. It dominates in the sense of *first-order stochastic dominance* if $F_s(v) \leq F_w(v)$ for all v.

The ratio $\frac{f(v)}{F(v)}$ is the *reverse hazard rate*. It is the density of the value at v conditional on the value not exceeding v. Condition (14.71) says that, conditional on both values lying below any

level v, the strong value is more concentrated near the top. Since $\frac{f}{F} = \frac{d}{dv} \ln F$, condition (14.71) is equivalent to

$$\frac{d}{dv} \ln \frac{F_s(v)}{F_w(v)} \geq 0, \qquad \text{so that } \frac{F_s(v)}{F_w(v)} \text{ is nondecreasing in } v. \tag{14.72}$$

The likelihood ratio order implies both the reverse hazard rate order and the hazard rate order, and each of these implies first-order dominance (see Krishna, 2010). Proposition B.190 proves this chain, and Section B.9.5 restates the four orders for reference. The reverse hazard rate order is the one that signs equilibrium bids in the first-price auction (Maskin and Riley, 2000; Athey et al., 2011). A reader of the original papers should note one difference in names. Athey et al. (2011, Section II.A, p. 212) assume that F_M dominates F_L "according to a hazard rate order," with mills M strong and loggers L weak. Their condition is $\frac{f_M(v)}{F_M(v)} \geq \frac{f_L(v)}{F_L(v)}$, which is the reverse hazard rate order (14.71) of our definition.

Lemma 14.74. *If F_s dominates F_w in the reverse hazard rate order, then $\bar{v}_s \geq \bar{v}_w$ and $F_s(v) \leq F_w(v)$ for all v. Strong values first-order stochastically dominate weak values.*

Proof. Suppose first that $\bar{v}_s < \bar{v}_w$. For $v \in (\bar{v}_s, \bar{v}_w)$ the left side of (14.71) is zero, because $f_s(v) = 0$, while the right side is strictly positive. This contradicts (14.71), so $\bar{v}_s \geq \bar{v}_w$.

By (14.72), the ratio $\frac{F_s}{F_w}$ is nondecreasing on $(\underline{v}, \bar{v}_s]$. At $v = \bar{v}_s$ both distributions equal one, because $\bar{v}_s \geq \bar{v}_w$. Hence, for every $v \in (\underline{v}, \bar{v}_s]$,

$$\frac{F_s(v)}{F_w(v)} \leq \frac{F_s(\bar{v}_s)}{F_w(\bar{v}_s)} = 1.$$

Multiplying by $F_w(v) > 0$ gives $F_s(v) \leq F_w(v)$. Above $\bar{v}_s$ both distributions equal one. □

Two examples recur below. First, let F_i be uniform on $[0, \bar{v}_i]$ with $\bar{v}_s > \bar{v}_w$. Then $\frac{f_i(v)}{F_i(v)} = \frac{1}{v}$ for both bidders on $(0, \bar{v}_w]$. Above $\bar{v}_w$ the weak bidder's reverse hazard rate is zero and the strong bidder's is $\frac{1}{v}$. Condition (14.71) holds, with equality on the common part of the supports. Second, let $F_i(v) = \left(\frac{v}{\bar{v}}\right)^{\gamma_i}$ on a common support $[0, \bar{v}]$. The reverse hazard rate is $\frac{\gamma_i}{v}$, so F_s dominates F_w exactly when $\gamma_s \geq \gamma_w$.

14.10.2 Second-price and ascending auctions with asymmetric bidders

Asymmetry leaves the second-price and ascending auctions unchanged in their essentials. The dominance argument of Proposition 14.22 uses only private values. Each bidder therefore still bids its value in the second-price auction and stays in the button auction until the price reaches its value (Athey et al., 2011, Section II.B). The highest-value bidder wins, so both auctions are *efficient*. The price is the second-highest value, because $r = \underline{v}$.

The distribution of the price follows from counting. Let $V^{(2)}$ denote the second-highest of the n values. It is at most t when all values are at most t, or when exactly one value exceeds t:

$$\mathbb{P}\left(V^{(2)} \leq t\right) = \prod_{j=1}^{n} F_j(t) + \sum_{i=1}^{n} \big(1 - F_i(t)\big) \prod_{j \neq i} F_j(t). \tag{14.73}$$

Expected revenue is $R^{SP} = \underline{v} + \int_{\underline{v}}^{\bar{v}} \left[1 - \mathbb{P}(V^{(2)} \leq t)\right] dt$ with $\bar{v} = \max_i \bar{v}_i$. Bidder i of type v wins with probability $Q_i^{SP}(v) = \prod_{j \neq i} F_j(v)$. The lowest type earns zero, so Lemma 14.42 gives its

interim expected surplus,

$$\pi_i^{SP}(v) = \int_{\underline{v}}^{v} \prod_{j \neq i} F_j(t)\, dt. \tag{14.74}$$

14.10.3 The first-price auction: first-order conditions

Suppose every rival j uses a strictly increasing, differentiable bid function β_j with inverse $\phi_j = \beta_j^{-1}$. Rival j bids less than b with probability

$$G_j(b) = \mathbb{P}\big(\beta_j(V_j) < b\big) = F_j\big(\phi_j(b)\big), \tag{14.75}$$

which is Athey et al. (2011, eq. (1)). Let $g_j = G_j'$ be the density of j's bid. Bid distributions are continuous, so ties occur with probability zero. Bidder i with value v_i wins with bid b when every rival bids less, and independence gives the expected payoff

$$U_i(b; v_i) = (v_i - b) \prod_{j \neq i} G_j(b). \tag{14.76}$$

The payoff is the product of a margin and a win probability. Taking logarithms turns the product into a sum,

$$\ln U_i(b; v_i) = \ln(v_i - b) + \sum_{j \neq i} \ln G_j(b).$$

Differentiating with respect to b and setting the derivative to zero at the optimal bid b_i gives

$$-\frac{1}{v_i - b_i} + \sum_{j \neq i} \frac{g_j(b_i)}{G_j(b_i)} = 0.$$

Rearranging yields the first-order condition of the asymmetric first-price auction:

$$\frac{1}{v_i - b_i} = \sum_{j \neq i} \frac{g_j(b_i)}{G_j(b_i)}. \tag{14.77}$$

This is Athey et al. (2011, eq. (2)). The left side is the proportional loss in the margin from raising the bid. The right side is the proportional gain in the win probability, summed over the rivals who might be outbid. Solving (14.77) for the value gives the inverse form

$$v_i = b_i + \left[\sum_{j \neq i} \frac{g_j(b_i)}{G_j(b_i)} \right]^{-1}. \tag{14.78}$$

Equation (14.78) expresses each bidder's value through its own bid and the distributions of its rivals' bids. With $n - 1$ identical rivals the sum equals $(n-1)\frac{g}{G}$, and (14.78) reduces to the symmetric condition (14.34). Chapter 15 uses (14.78) to recover asymmetric value distributions from bids.

The system of differential equations. The first-order conditions hold for every bidder at every bid, so they jointly determine the inverse bid functions. Write $\nu_j(b) = \frac{g_j(b)}{G_j(b)}$ for the reverse hazard

rate of j's bid and $\bar{v}(b) = \sum_{j=1}^{n} v_j(b)$ for their sum. Here v is unrelated to the taste shocks of the demand chapters. At bid b, bidder i's value is $\phi_i(b)$, so (14.77) reads

$$\bar{v}(b) - v_i(b) = \frac{1}{\phi_i(b) - b}, \qquad i = 1, \dots, n. \tag{14.79}$$

Summing (14.79) over the n bidders gives $n\bar{v}(b) - \bar{v}(b) = \sum_j \frac{1}{\phi_j(b)-b}$, and therefore

$$\bar{v}(b) = \frac{1}{n-1} \sum_{j=1}^{n} \frac{1}{\phi_j(b) - b}.$$

Substituting back into (14.79) isolates each bidder's own term:

$$v_i(b) = \frac{1}{n-1} \sum_{j=1}^{n} \frac{1}{\phi_j(b) - b} - \frac{1}{\phi_i(b) - b}.$$

By (14.75), $v_i(b) = \frac{f_i(\phi_i(b))\,\phi_i'(b)}{F_i(\phi_i(b))}$. Solving for $\phi_i'(b)$ gives the system

$$\phi_i'(b) = \frac{F_i\big(\phi_i(b)\big)}{f_i\big(\phi_i(b)\big)} \left[\frac{1}{n-1} \sum_{j=1}^{n} \frac{1}{\phi_j(b) - b} - \frac{1}{\phi_i(b) - b} \right], \qquad i = 1, \dots, n. \tag{14.80}$$

With two bidders the bracket equals $\frac{1}{\phi_1 - b} + \frac{1}{\phi_2 - b} - \frac{1}{\phi_i - b}$, so the system collapses to

$$\phi_i'(b) = \frac{F_i\big(\phi_i(b)\big)}{f_i\big(\phi_i(b)\big)} \frac{1}{\phi_j(b) - b}, \qquad i, j \in \{1, 2\},\ j \neq i. \tag{14.81}$$

Each bidder's inverse bid function depends on its rival's through the rival's margin $\phi_j(b) - b$. An equivalent form, used repeatedly below, is

$$\frac{d}{db} \ln G_j(b) = \frac{1}{\phi_i(b) - b} \qquad \text{(two bidders, } j \neq i\text{)}. \tag{14.82}$$

The system needs boundary conditions. At the bottom, every bidder bids the reserve price, $\phi_i(r) = r$ for all i (Athey et al., 2011, Section II.B). At the top, all bidders share a common highest bid $\bar{b}$, at which each bidder's highest type bids, so $\phi_i(\bar{b}) = \bar{v}_i$ (Proposition 14.75 below). The top bid $\bar{b}$ is itself unknown. The problem is therefore a two-point boundary value problem with a free endpoint. The right side of (14.80) is singular at $b = r$, where every margin $\phi_j(b) - b$ vanishes. Numerical methods therefore guess $\bar{b}$, integrate backward from the top and adjust the guess until the solution reaches (r, r) (Marshall et al., 1994; Bajari, 2001).

Type-symmetric bidding. In the application of Athey et al. (2011) the participants consist of n_L weak bidders (loggers) and n_M strong bidders (mills), with $\boldsymbol{n} = (n_L, n_M)$ and $n = n_L + n_M$. Bidders of the same type use the same bid function. We write $G_L(\cdot; \boldsymbol{n})$ and $G_M(\cdot; \boldsymbol{n})$ for the bid distributions of one logger and one mill, and ϕ_L and ϕ_M for the inverse bid functions. A logger faces $n_L - 1$ other loggers and n_M mills, and a mill faces n_L loggers and $n_M - 1$ other mills. Condition (14.77) becomes

$$\frac{1}{\phi_L(b) - b} = (n_L - 1)\frac{g_L(b; \boldsymbol{n})}{G_L(b; \boldsymbol{n})} + n_M \frac{g_M(b; \boldsymbol{n})}{G_M(b; \boldsymbol{n})}, \tag{14.83}$$

$$\frac{1}{\phi_M(b) - b} = n_L \frac{g_L(b; \boldsymbol{n})}{G_L(b; \boldsymbol{n})} + (n_M - 1)\frac{g_M(b; \boldsymbol{n})}{G_M(b; \boldsymbol{n})}. \tag{14.84}$$

Applying the solution of (14.79) with n_L copies of ϕ_L and n_M copies of ϕ_M gives, for $k \in \{L, M\}$,

$$\frac{g_k(b;\boldsymbol{n})}{G_k(b;\boldsymbol{n})} = \frac{1}{n-1}\left[\frac{n_L}{\phi_L(b)-b} + \frac{n_M}{\phi_M(b)-b}\right] - \frac{1}{\phi_k(b)-b}. \tag{14.85}$$

When $\phi_L = \phi_M = \phi$, the right side equals $\frac{1}{(n-1)(\phi(b)-b)}$. This recovers the symmetric condition $v = b + \frac{G(b)}{(n-1)g(b)}$, as it should.

14.10.4 Common support of the bid distributions

The boundary condition at the top rests on the following result.

Proposition 14.75 (Common bid support)**.** *Consider an equilibrium of the first-price auction in strictly increasing bid functions under Assumption 14.72. Let $\bar{b}_i$ be the highest bid of bidder i.*

(a) With two bidders, $\bar{b}_1 = \bar{b}_2$, whether or not the value supports coincide.

(b) (Athey and Haile, 2007, Theorem 2.2) With $n \geq 2$ bidders whose values share the support $[\underline{v}, \bar{v}]$, all bidders have the same bid support $[r, \bar{b}]$.

Proof. (a) Suppose $\bar{b}_j > \bar{b}_i$. Every bid $b \in (\bar{b}_i, \bar{b}_j]$ wins against bidder i with probability one. A type of bidder j that bids such a b could lower its bid to any level in $(\bar{b}_i, b)$, still win with probability one and pay less. So no type of j bids above $\bar{b}_i$, which contradicts $\bar{b}_j > \bar{b}_i$.

(b) We follow Athey and Haile (2007, proof of Theorem 2.2). With independence, the inverse bid function of bidder i is the right side of (14.78),

$$\xi_i(b) = b + \left[\sum_{k \neq i} \frac{g_k(b)}{G_k(b)}\right]^{-1}.$$

Part (a) covers $n = 2$, so let $n > 2$ and suppose $\bar{b}_i < \bar{b}_j$. The highest type $\bar{v}$ of bidder i bids $\bar{b}_i$, so

$$\bar{v} = \xi_i(\bar{b}_i) = \bar{b}_i + \left[\sum_{k \in \mathcal{N} \setminus \{i\}} \frac{g_k(\bar{b}_i)}{G_k(\bar{b}_i)}\right]^{-1}.$$

Bidder j's inverse bid function must be continuous at $\bar{b}_i$. Otherwise a strictly increasing strategy would leave a gap in j's values, which contradicts an interval support. Just above $\bar{b}_i$ bidder i never bids, so $G_i = 1$ and $g_i = 0$ there, and bidder i drops out of j's sum. The remaining sum omits the strictly positive term $\frac{g_j(\bar{b}_i)}{G_j(\bar{b}_i)}$ that appears in bidder i's sum. Hence

$$\bar{v} = \xi_i(\bar{b}_i) < \bar{b}_i + \left[\sum_{k \in \mathcal{N} \setminus \{i,j\}} \frac{g_k(\bar{b}_i)}{G_k(\bar{b}_i)}\right]^{-1} = \xi_j(\bar{b}_i).$$

So bidder j's type that bids $\bar{b}_i$ has a value above $\bar{v}$, which contradicts the common support. All highest bids are therefore equal. Standard arguments show that every bid support starts at r, which gives the common support $[r, \bar{b}]$. □

Part (b) needs the common value support when $n > 2$. Athey and Haile (2007, footnote 15) give a three-bidder example with different value supports in which the bid supports differ. With two bidders, part (a) shows that the top bid is common even when $\bar{v}_s > \bar{v}_w$, as in the uniform example below.

Existence and uniqueness. Athey and Haile (2007, Theorem 2.1) summarize the results for first-price auctions in which values have a compact, convex support and signals are affiliated with a positive density. An equilibrium in pure, nondecreasing strategies exists, by Athey (2001) and Reny and Zamir (2004) (Athey and Haile, 2007, footnote 10). An equilibrium in strictly increasing strategies exists in every such model except common values with asymmetric bidders and dependent signals. With independent private values and a continuously differentiable density, the equilibrium is unique, and it is in pure, strictly increasing and differentiable strategies (Athey and Haile, 2007, Theorem 2.1(ii)). In that case all equilibria are monotone. The uniqueness results are due to Lebrun (1999), Bajari (2001) and Maskin and Riley (2003) (Athey and Haile, 2007, footnote 11). Lebrun (1999) also gives an alternative proof of the common bid support of Proposition 14.75 (Athey and Haile, 2007, footnote 14). Lebrun (1996) had earlier proved existence in strictly increasing bid functions for asymmetric independent private values. The first-order conditions and the boundary condition $\phi_i(r) = r$ then characterize the equilibrium bids for any set of participants (Athey et al., 2011, Section II.B).

14.10.5 Strong bidders shade more: the Maskin-Riley properties

The main qualitative results compare the two classes of bidders. They hold under the reverse hazard rate order and are due to Maskin and Riley (2000). We state and prove them for two bidders. Athey et al. (2011, Section II.B) state properties (i) and (ii) for type-symmetric equilibria with any numbers of mills and loggers.

Proposition 14.76 (Maskin and Riley 2000)**.** *Let there be one strong and one weak bidder satisfying Assumption 14.72, with F_s dominating F_w in the reverse hazard rate order. In the equilibrium of the first-price auction with strictly increasing bid functions:*

(i) The strong bidder shades more. At every bid the strong bidder's value is at least the weak bidder's, $\phi_s(b) \geq \phi_w(b)$ for $b \in [r, \bar{b}]$. Equivalently, $\beta_s(v) \leq \beta_w(v)$ for every $v \in [\underline{v}, \bar{v}_w]$.

(ii) The strong bidder bids higher in distribution, $G_s(b) \leq G_w(b)$ for every b. Moreover $\frac{g_s(b)}{G_s(b)} \geq \frac{g_w(b)}{G_w(b)}$, so the bid distributions inherit the reverse hazard rate order.

(iii) The strong bidder never wins with the lower value. If $\phi_s(b) > \phi_w(b)$ on a set of bids of positive length, the weak bidder wins with the lower value with positive probability. The weak bidder then wins more often than in the efficient allocation.

(iv) Every type of the weak bidder earns at least as much in the first-price auction as in the second-price auction. Every type of the strong bidder earns at most as much.

Proof. Step 1 (log bid distributions). By (14.82), the first-order conditions of the two bidders read

$$\frac{d}{db} \ln G_s(b) = \frac{1}{\phi_w(b) - b}, \qquad \frac{d}{db} \ln G_w(b) = \frac{1}{\phi_s(b) - b}, \qquad b \in (r, \bar{b}]. \tag{14.86}$$

The weak bidder's condition involves the strong bidder's bid distribution, and conversely.

Step 2 (part i). Suppose the set $D = \{b \in (r, \bar{b}) : \phi_w(b) > \phi_s(b)\}$ is nonempty and pick $b_0 \in D$. At the top, $\phi_w(\bar{b}) = \bar{v}_w \leq \bar{v}_s = \phi_s(\bar{b})$ by Lemma 14.74. Let $b_1 = \inf\{b > b_0 : \phi_w(b) \leq \phi_s(b)\} \leq \bar{b}$.

By continuity, $\phi_w(b_1) = \phi_s(b_1) \equiv x$, and $\phi_w > \phi_s$ on $[b_0, b_1)$. Fix $b \in [b_0, b_1)$ and integrate (14.86) over $[b, b_1]$. Because $\phi_w(t) - t > \phi_s(t) - t$ on this interval,

$$\ln \frac{G_s(b_1)}{G_s(b)} = \int_b^{b_1} \frac{dt}{\phi_w(t) - t} < \int_b^{b_1} \frac{dt}{\phi_s(t) - t} = \ln \frac{G_w(b_1)}{G_w(b)}.$$

Exponentiating and rearranging gives $\frac{G_s(b)}{G_s(b_1)} > \frac{G_w(b)}{G_w(b_1)}$. Now substitute $G_k = F_k \circ \phi_k$ from (14.75), and use $\phi_w(b) > \phi_s(b)$ with F_w strictly increasing:

$$\frac{F_s(\phi_s(b))}{F_s(x)} > \frac{F_w(\phi_w(b))}{F_w(x)} > \frac{F_w(\phi_s(b))}{F_w(x)}.$$

With $y = \phi_s(b) < x$, the outer inequality says $\frac{F_s(y)}{F_w(y)} > \frac{F_s(x)}{F_w(x)}$. This contradicts (14.72), which says that $\frac{F_s}{F_w}$ is nondecreasing. Hence D is empty and $\phi_s \geq \phi_w$ on $[r, \bar{b}]$.

For the equivalent statement, fix $v \leq \bar{v}_w$ and let $b = \beta_w(v)$. Then $\phi_s(b) \geq \phi_w(b) = v$. Since β_s is increasing, $\beta_s(v) \leq \beta_s\big(\phi_s(b)\big) = b = \beta_w(v)$.

Step 3 (part ii). Subtracting the two equations in (14.86) and using part (i),

$$\frac{d}{db} \ln \frac{G_s(b)}{G_w(b)} = \frac{1}{\phi_w(b) - b} - \frac{1}{\phi_s(b) - b} \geq 0.$$

This is the reverse hazard rate ordering of the bids. The ratio $\frac{G_s}{G_w}$ is therefore nondecreasing on $(r, \bar{b}]$, and it equals one at $\bar{b}$ by Proposition 14.75. So $G_s(b) \leq G_w(b)$ for all b.

Step 4 (part iii). If $v_s < v_w$, part (i) gives $\beta_s(v_s) \leq \beta_w(v_s) < \beta_w(v_w)$, so the weak bidder wins. The strong bidder therefore wins only when $v_s > v_w$. The weak bidder wins whenever $\beta_s(v_s) < \beta_w(v_w)$, that is, whenever

$$v_s < \phi_s\big(\beta_w(v_w)\big). \tag{14.87}$$

Part (i) gives $\phi_s(\beta_w(v_w)) \geq \phi_w(\beta_w(v_w)) = v_w$. The event (14.87) thus contains $\{v_s < v_w\}$ together with the band $v_w \leq v_s < \phi_s(\beta_w(v_w))$, in which the weak bidder wins with the lower value. The band has positive probability when the gap $\phi_s - \phi_w$ is positive on a set of positive length.

Step 5 (part iv). Both auctions give the lowest type zero surplus. By the revelation principle, the equilibrium of each auction defines an incentive-compatible direct mechanism. By Lemma 14.42, a type's expected surplus is then the integral of its win probability from the bottom of the support. In the first-price auction, the weak bidder of type t wins with probability $Q_w^{FP}(t) = G_s(\beta_w(t)) = F_s\big(\phi_s(\beta_w(t))\big)$. Since $\phi_s(\beta_w(t)) \geq t$, this is at least $F_s(t) = Q_w^{SP}(t)$. Integrating,

$$\pi_w^{FP}(v) = \int_{\underline{v}}^{v} Q_w^{FP}(t)\, dt \;\geq\; \int_{\underline{v}}^{v} F_s(t)\, dt = \pi_w^{SP}(v).$$

For the strong bidder, $\beta_s(t) \leq \beta_w(t)$ implies $\phi_w(\beta_s(t)) \leq t$ for $t \leq \bar{v}_w$. Hence $Q_s^{FP}(t) = F_w\big(\phi_w(\beta_s(t))\big) \leq F_w(t) = Q_s^{SP}(t)$. For $t > \bar{v}_w$ the inequality holds because $Q_s^{SP}(t) = 1$. Integrating gives $\pi_s^{FP}(v) \leq \pi_s^{SP}(v)$. □

The intuition is a comparison of the competition each bidder faces. The strong bidder's rival is weak, so the strong bidder wins often even after a deep cut in its bid. The weak bidder's rival is strong, so the weak bidder must bid aggressively to have any chance. At a given value, the weak bidder therefore bids more. The strong bidder still bids more on average, because its

values are higher. Property (ii) is a testable restriction on observed bids. Athey et al. (2011, Section II.B) call it "a testable implication of the model." Property (iii) is the sense in which the first-price auction favors weaker bidders. It is the source of the first-price auction's inefficiency and, through entry, of the format effects in Section 14.11. Property (iv) states who prefers which format. With a fixed set of participants, the strong bidder prefers the open auction and the weak bidder prefers the sealed first-price auction. Athey et al. (2011, Section II.D, p. 215) give the argument for loggers and mills. Mills shade their bids more than loggers in the sealed bid equilibrium. A logger therefore has a greater chance to win, and hence higher expected profit, than in the open auction, where the allocation is efficient. The argument is reversed for mills. The proof above is our own, and Maskin and Riley (2000) contain related comparisons.

14.10.6 A closed-form example: uniform values with different supports

Closed-form asymmetric equilibria are rare. The leading exception has two bidders with uniform values on intervals with a common lower bound (Griesmer et al., 1967; Plum, 1992; Krishna, 2010). We derive it step by step and then compute its revenue, allocation and welfare.

Example 14.77 (Uniform values with different supports)**.** Let $V_w \sim U[0, \bar{v}_w]$ and $V_s \sim U[0, \bar{v}_s]$ with $\bar{v}_s > \bar{v}_w$, and $r = 0$. Then $F_i(v) = \frac{v}{\bar{v}_i}$ and $\frac{F_i(v)}{f_i(v)} = v$, so the system (14.81) becomes

$$\phi_s'(b) = \frac{\phi_s(b)}{\phi_w(b) - b}, \qquad \phi_w'(b) = \frac{\phi_w(b)}{\phi_s(b) - b}, \tag{14.88}$$

with $\phi_s(0) = \phi_w(0) = 0$, $\phi_s(\bar{b}) = \bar{v}_s$ and $\phi_w(\bar{b}) = \bar{v}_w$.

A first integral. Multiply each equation in (14.88) by its denominator and add:

$$\phi_s'(\phi_w - b) + \phi_w'(\phi_s - b) = \phi_s + \phi_w.$$

Subtract $(\phi_w - b) + (\phi_s - b)$ from both sides:

$$(\phi_s' - 1)(\phi_w - b) + (\phi_w' - 1)(\phi_s - b) = 2b.$$

The left side is the derivative of $(\phi_s - b)(\phi_w - b)$. Integrating from 0, where both inverse bids vanish, gives

$$\big(\phi_s(b) - b\big)\big(\phi_w(b) - b\big) = b^2. \tag{14.89}$$

The top bid. Evaluating (14.89) at $\bar{b}$ gives $(\bar{v}_s - \bar{b})(\bar{v}_w - \bar{b}) = \bar{b}^2$. Expanding, the $\bar{b}^2$ terms cancel and $\bar{v}_s\bar{v}_w - \bar{b}(\bar{v}_s + \bar{v}_w) = 0$. Hence

$$\bar{b} = \frac{\bar{v}_s\bar{v}_w}{\bar{v}_s + \bar{v}_w}. \tag{14.90}$$

The inverse bid functions. By (14.89), $\phi_w - b = \frac{b^2}{\phi_s - b}$. Substituting into the first equation of (14.88) gives a Bernoulli equation,

$$\phi_s' = \frac{\phi_s(\phi_s - b)}{b^2} = \frac{\phi_s^2}{b^2} - \frac{\phi_s}{b}.$$

Let $u = \frac{1}{\phi_s}$, so that $u' = -\frac{\phi_s'}{\phi_s^2} = -\frac{1}{b^2} + \frac{u}{b}$. The linear equation $u' - \frac{u}{b} = -\frac{1}{b^2}$ has integrating factor $\frac{1}{b}$:

$$\frac{d}{db}\left(\frac{u}{b}\right) = \frac{u'}{b} - \frac{u}{b^2} = -\frac{1}{b^3}.$$

Integrating, $\frac{u}{b} = \frac{1}{2b^2} + \frac{k_s}{2}$ for a constant k_s, so $u = \frac{1+k_s b^2}{2b}$. The same steps apply to the weak bidder. Therefore

$$\phi_i(b) = \frac{2b}{1 + k_i b^2}, \qquad i \in \{s, w\}. \tag{14.91}$$

Every such function satisfies $\phi_i(0) = 0$. The top conditions $\phi_i(\bar{b}) = \bar{v}_i$ give $1 + k_i \bar{b}^2 = \frac{2\bar{b}}{\bar{v}_i}$. Using (14.90), $\frac{2\bar{b}}{\bar{v}_w} - 1 = \frac{\bar{v}_s - \bar{v}_w}{\bar{v}_s + \bar{v}_w}$, and dividing by $\bar{b}^2$ yields

$$k_w = \frac{1}{\bar{v}_w^2} - \frac{1}{\bar{v}_s^2} > 0, \qquad k_s = \frac{1}{\bar{v}_s^2} - \frac{1}{\bar{v}_w^2} = -k_w < 0. \tag{14.92}$$

Verification. Differentiating (14.91) gives $\phi_i'(b) = \frac{2(1-k_i b^2)}{(1+k_i b^2)^2}$. With $k_j = -k_i$,

$$\phi_j(b) - b = \frac{2b}{1 - k_i b^2} - b = \frac{b(1 + k_i b^2)}{1 - k_i b^2}, \qquad \text{so} \qquad \frac{\phi_i(b)}{\phi_j(b) - b} = \frac{2b}{1 + k_i b^2} \cdot \frac{1 - k_i b^2}{b(1 + k_i b^2)} = \phi_i'(b).$$

Both equations of (14.88) hold. A symbolic check in the script `asym_uniform.py` confirms the system, the boundary conditions and (14.89).

The bid functions. Inverting $v = \frac{2b}{1+k_i b^2}$ means solving the quadratic $k_i v b^2 - 2b + v = 0$. The root that tends to $\frac{v}{2}$ as $k_i \to 0$ is

$$\beta_i(v) = \frac{1 - \sqrt{1 - k_i v^2}}{k_i v}. \tag{14.93}$$

Because $\sqrt{1-x} < 1 - \frac{x}{2}$ for $x \neq 0$, we get $\beta_w(v) > \frac{v}{2} > \beta_s(v)$. The weak bidder bids more than in the symmetric auction with two weak bidders, and the strong bidder bids less, in line with Proposition 14.76(i). When $\bar{v}_s = \bar{v}_w$, both constants vanish and $\beta_i(v) = \frac{v}{2}$.

Numbers for $\bar{v}_w = 1$ and $\bar{v}_s = 2$. Now $k_w = \frac{3}{4}$, $k_s = -\frac{3}{4}$ and $\bar{b} = \frac{2}{3}$. The bid distributions are $G_w(b) = \phi_w(b) = \frac{2b}{1+\frac{3}{4}b^2}$ and $G_s(b) = \frac{\phi_s(b)}{2} = \frac{b}{1-\frac{3}{4}b^2}$ on $[0, \frac{2}{3}]$. A weak bidder with value 1 bids $\frac{2}{3}$, while a strong bidder with the same value bids only 0.43. At value $\frac{1}{2}$ the bids are 0.263 and 0.239.

Expected revenue in the first-price auction is the expected highest bid,

$$R^{FP} = \int_0^{\bar{b}} \left[1 - G_w(b) G_s(b)\right] db, \qquad G_w(b) G_s(b) = \frac{2b^2}{1 - \frac{9}{16} b^4}.$$

Partial fractions give $\frac{2b^2}{1-\frac{9}{16}b^4} = \frac{4}{3}\left[\frac{1}{1-\frac{3}{4}b^2} - \frac{1}{1+\frac{3}{4}b^2}\right]$. With $c = \frac{\sqrt{3}}{2}$ and $c\bar{b} = \frac{1}{\sqrt{3}}$, the two standard integrals are

$$\int_0^{\frac{2}{3}} \frac{db}{1 - c^2 b^2} = \frac{1}{2c} \ln \frac{1 + \frac{1}{\sqrt{3}}}{1 - \frac{1}{\sqrt{3}}} = \frac{\ln(2 + \sqrt{3})}{\sqrt{3}}, \qquad \int_0^{\frac{2}{3}} \frac{db}{1 + c^2 b^2} = \frac{1}{c} \arctan \frac{1}{\sqrt{3}} = \frac{\pi}{3\sqrt{3}}.$$

Collecting terms,

$$R^{FP} = \frac{2}{3} - \frac{4 \ln(2 + \sqrt{3})}{3\sqrt{3}} + \frac{4\pi}{9\sqrt{3}} \approx 0.4590. \tag{14.94}$$

In the second-price auction revenue is the expected lower value. Since $\mathbb{P}(\min\{V_w, V_s\} > t) = (1-t)\left(1-\frac{t}{2}\right)$ on $[0,1]$,

$$R^{SP} = \int_0^1 (1-t)\left(1-\frac{t}{2}\right)dt = 1 - \frac{3}{4} + \frac{1}{6} = \frac{5}{12} \approx 0.4167.$$

The weak bidder wins the first-price auction with probability

$$\mathbb{P}(B_s < B_w) = \int_0^{\bar{b}} G_s(b) g_w(b)\, db = \int_0^{\frac{2}{3}} \frac{2b}{\left(1+\frac{3}{4}b^2\right)^2} db = \frac{4}{3}\left[1 - \frac{1}{1+\frac{1}{3}}\right] = \frac{1}{3},$$

where we used $g_w(b) = \frac{2(1-\frac{3}{4}b^2)}{(1+\frac{3}{4}b^2)^2}$. In the efficient allocation the weak bidder wins with probability $\mathbb{P}(V_s < V_w) = \int_0^1 \frac{v}{2} dv = \frac{1}{4}$. The strong bidder never wins with the lower value, so the first-price allocation is inefficient with probability $\frac{1}{3} - \frac{1}{4} = \frac{1}{12}$, or 8.3 percent of auctions.

Expected total surplus in the efficient allocation is $\mathbb{E}[\max\{V_w, V_s\}]$. The maximum is at most t with probability $\frac{t^2}{2}$ on $[0,1]$ and $\frac{t}{2}$ on $[1,2]$, so

$$\mathbb{E}[\max\{V_w, V_s\}] = \int_0^1 \left(1 - \frac{t^2}{2}\right)dt + \int_1^2 \left(1 - \frac{t}{2}\right)dt = \frac{5}{6} + \frac{1}{4} = \frac{13}{12}.$$

The first-price auction loses $\mathbb{E}\left[(V_s - V_w)\mathbf{1}\{\text{weak wins}, V_s > V_w\}\right]$. By (14.87) and the first integral, the boundary of the inefficient region is $\hat{s}(v_w) = \phi_s(\beta_w(v_w)) = \frac{v_w \beta_w(v_w)}{v_w - \beta_w(v_w)}$. The loss equals $\frac{1}{4}\int_0^1 (\hat{s}(v) - v)^2 dv \approx 0.0205$, so surplus is 1.0628. Bidder payoffs follow from (14.74) in the second-price auction and from direct integration in the first-price auction. Table 14.10 collects the results and Figure 14.15 plots the bids and the inefficient region.

Table 14.10: Asymmetric uniform example: $V_w \sim U[0,1]$, $V_s \sim U[0,2]$, no reserve price

	First-price	Second-price or ascending
Highest bid	$\bar{b} = \frac{2}{3}$	$\bar{v}_s = 2$
Expected revenue	0.4590	$\frac{5}{12} \approx 0.4167$
Probability that the weak bidder wins	$\frac{1}{3} \approx 0.3333$	$\frac{1}{4} = 0.2500$
Probability of an inefficient allocation	$\frac{1}{12} \approx 0.0833$	0
Expected total surplus	1.0628	$\frac{13}{12} \approx 1.0833$
Expected payoff of the weak bidder	0.0969	$\frac{1}{12} \approx 0.0833$
Expected payoff of the strong bidder	0.5069	$\frac{7}{12} \approx 0.5833$

Notes: Exact values are derived in the text. Decimal values for the first-price auction are computed by numerical integration in `figures/ch14/src/asym_uniform.py` and confirmed by a Monte Carlo simulation with two million auctions. In each column revenue equals total surplus minus the two bidders' payoffs.

The example shows every effect of Proposition 14.76. The strong bidder's payoff falls by 0.0764 when we move from the second-price to the first-price auction. The weak bidder's payoff rises by 0.0136, and total surplus falls by 0.0205. Revenue is total surplus minus payoffs, so revenue rises by $0.0764 - 0.0136 - 0.0205 = 0.0423$. The first-price auction extracts more from the strong bidder than it gives away to the weak bidder and to inefficiency.

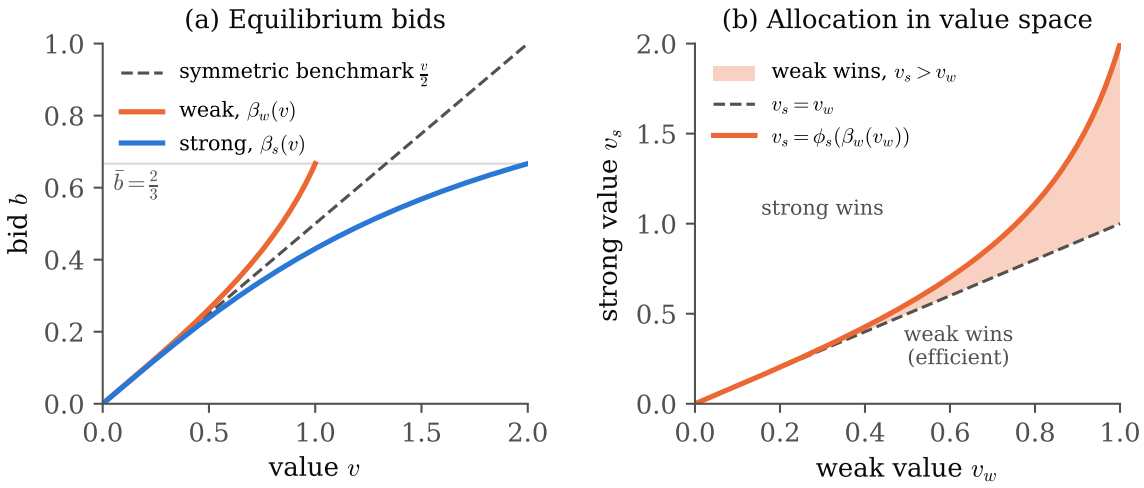

Figure 14.15: Asymmetric first-price auction with $V_w \sim U[0,1]$ and $V_s \sim U[0,2]$. Panel (a): the equilibrium bid functions (14.93) and the symmetric benchmark $\frac{v}{2}$. Both bidders' bids end at the common top bid $\bar{b} = \frac{2}{3}$. Panel (b): the weak bidder wins below the curve $v_s = \phi_s(\beta_w(v_w))$. In the shaded band between that curve and the diagonal the weak bidder wins although the strong bidder values the object more.

14.10.7 Revenue comparisons with asymmetric bidders

The decomposition used in the example holds in general:

$$\text{expected revenue} = \text{expected total surplus} - \sum_i \mathbb{E}\big[\pi_i(V_i)\big]. \tag{14.95}$$

Moving from the open auction to the first-price auction lowers total surplus, by Proposition 14.76(iii). It raises the weak bidder's rents and lowers the strong bidder's rents, by part (iv). The net effect on revenue has no general sign. Maskin and Riley (2000) give sufficient conditions on the value distributions under which the first-price auction yields higher revenue, and others under which the open auction does. In the uniform example the first-price auction raises more revenue. Athey et al. (2011, Section II.D) stress that "there is no general theoretical comparison of expected revenue, even with fixed participation."

The optimal auction of Section 14.7 explains why the first-price auction often does well. In the same example, Section 14.7.6 showed that the optimal mechanism of Myerson (1981) gives the weak bidder a head start of $\frac{1}{2}$, because $\psi_w(v) = 2v - 1$ exceeds $\psi_s(v) = 2v - 2$ at every value. It earns $\frac{31}{48} \approx 0.646$, well above both standard formats. The first-price auction tilts the allocation in the same direction as the optimal mechanism, without design, and it captures part of the gain. Athey and Haile (2007, Section 7) summarize the trade-off. First-price auctions may allocate inefficiently with asymmetric bidders, but they "tend to raise more revenue in private values settings."

14.11 Participation and Entry

So far the set of bidders has been fixed. In practice, bidding is costly. A timber bidder must cruise the tract to estimate its volume and quality, and a construction firm must prepare a

detailed cost estimate. Firms decide whether to incur these costs before the auction. The number of bidders is then an equilibrium outcome, and the auction format can affect it.

Two timing assumptions organize the theory. In the first, a bidder knows its value before deciding whether to pay the entry cost. In the second, a bidder learns its value only after paying the cost. Samuelson (1985) studies the first timing, and Levin and Smith (1994) study the second. The second timing underlies the empirical work of Athey et al. (2011), where the entry cost is the cost of cruising the tract. The two timings give the entry cost different meanings (Hortaçsu and Perrigne, 2021, Section 2.2, p. 91). When bidders know their values, entry is *selective*, since only bidders with high enough values enter, and K is a cost of preparing a bid. When bidders learn their values after entry, entry is *nonselective*, and K also covers the cost of acquiring information. Roberts and Sweeting (2016) nest both cases. In their model each potential bidder observes a noisy signal of its value before it decides whether to enter. The model of Levin and Smith (1994) is the case of signals independent of values, and the model of Samuelson (1985) is the case of perfect correlation (Hortaçsu and Perrigne, 2021, footnote 9, p. 92). Throughout this section, $K > 0$ is the entry cost, N is the number of potential bidders, and p denotes an entry probability. Elsewhere p is the clock price (Section 14.2) or a probability of winning (Section 14.6.1).

14.11.1 Entry with values known in advance

Suppose each of N symmetric potential bidders knows its value v_i, drawn independently from F on $[\underline{v}, \bar{v}]$. A bidder who pays K may bid in a standard auction with reserve price r. We look for a symmetric equilibrium in which a bidder enters if and only if its value is at least a cutoff v^*.

The cutoff type is pinned down by a simple observation. A bidder with value v^* wins only if no rival enters, because any entrant has a value above v^*. That happens with probability $F(v^*)^{N-1}$, and then the lone bidder pays the reserve price. In the second-price auction this is immediate. In the first-price auction the cutoff type also bids r, because it wins only when it is alone and any higher bid would only raise its payment. Indifference of the cutoff type requires

$$(v^* - r)\, F(v^*)^{N-1} = K. \tag{14.96}$$

Let $\Phi(v) = (v - r)F(v)^{N-1}$. It is zero at $v = r$ and strictly increasing, with $\Phi'(v) = F(v)^{N-1} + (v - r)(N - 1)F(v)^{N-2} f(v) > 0$. So a unique interior cutoff exists whenever $\bar{v} - r > K$. Types above v^* strictly prefer to enter, because a bidder's expected surplus rises with its value at the rate of its win probability.

Implicit differentiation of (14.96) gives the comparative statics:

$$\frac{dv^*}{dK} = \frac{1}{\Phi'(v^*)} > 0, \qquad \frac{dv^*}{dr} = \frac{F(v^*)^{N-1}}{\Phi'(v^*)} \in (0, 1), \qquad \frac{dv^*}{dN} = -\frac{(v^* - r)F(v^*)^{N-1} \ln F(v^*)}{\Phi'(v^*)} > 0,$$

where the last expression treats N as continuous. The entry cost and the reserve price both screen out low-value bidders. A higher reserve raises the cutoff by less than one for one. The entry cost differs from a reserve price in one respect. It is a resource cost borne by every entrant, and the seller collects none of it.

Example 14.78 (Cutoffs with uniform values)**.** Let F be uniform on $[0, 1]$, $N = 5$ and $r = 0$. Equation (14.96) becomes $(v^*)^5 = K$, so $v^* = K^{\frac{1}{5}}$. With $K = 0.05$ the cutoff is 0.549, each potential bidder enters with probability 0.451, and 2.25 bidders enter on average. With $K = 0.10$ the

cutoff is 0.631 and 1.85 bidders enter on average. Raising the reserve to $r = 0.25$ raises the cutoffs to 0.610 and 0.690. These values come from `entry_example.py`.

With values known in advance, the entrants are a selected sample of high-value bidders. This complicates both theory and estimation. Athey et al. (2011, Section II.F) note that with asymmetric bidders who have prior private information, "the ex ante rankings of strong and weak bidders may fail to hold conditional on entry." This is one reason they adopt the second timing.

14.11.2 Entry with values learned after entry: the Levin-Smith model

Now suppose a bidder learns its value only after paying K. Before entry, all N potential bidders are identical. Entrants observe the number of other entrants before bidding (Athey and Haile, 2007, Section 6.3.2). Let $\pi(k)$ be the expected profit, gross of K, of an entrant when k bidders enter in total, so that it faces $k-1$ rivals. We study the symmetric equilibrium in which each potential bidder enters with probability p.

Given that the other $N-1$ potential bidders each enter with probability p, the number of rival entrants is binomial. An entrant's ex ante expected profit is therefore

$$\Pi(p) = \sum_{k=1}^{N} \binom{N-1}{k-1} p^{k-1}(1-p)^{N-k}\, \pi(k). \tag{14.97}$$

A potential bidder enters with probability one if $\Pi(p) > K$, stays out if $\Pi(p) < K$, and is willing to randomize if $\Pi(p) = K$.

Lemma 14.79. *In the symmetric private values model with any standard auction and reserve price r, the gross profit of an entrant is*

$$\pi(k) = \int_{r}^{\bar{v}} F(t)^{k-1}\big(1 - F(t)\big)\, dt, \tag{14.98}$$

which is strictly decreasing in k. With values uniform on $[0,1]$ and $r = 0$, $\pi(k) = \frac{1}{k(k+1)}$.

Proof. By revenue equivalence, an entrant's interim surplus is the same in every standard auction. By Lemma 14.42, a type $v \geq r$ facing $k-1$ rivals earns $\int_r^v F(t)^{k-1}dt$, and types below r earn zero. Taking expectations and exchanging the order of integration,

$$\pi(k) = \int_r^{\bar{v}} \left[\int_r^{v} F(t)^{k-1} dt\right] f(v)\, dv = \int_r^{\bar{v}} F(t)^{k-1} \left[\int_t^{\bar{v}} f(v)\, dv\right] dt = \int_r^{\bar{v}} F(t)^{k-1}\big(1-F(t)\big)\, dt.$$

Since $F(t) < 1$ on the interior of the support, the integrand falls strictly in k. In the uniform case, $\pi(k) = \int_0^1 t^{k-1}(1-t)\, dt = \frac{1}{k} - \frac{1}{k+1} = \frac{1}{k(k+1)}$. □

Proposition 14.80 (Symmetric entry equilibrium)**.** *Suppose $\pi(k)$ is strictly decreasing in k and $N \geq 2$. Then $\Pi(p)$ is strictly decreasing in p, and there is a unique symmetric entry equilibrium p^*. If $\pi(N) \geq K$, then $p^* = 1$. If $\pi(1) \leq K$, then $p^* = 0$. Otherwise $p^* \in (0,1)$ solves $\Pi(p^*) = K$.*

Proof. Let $X \sim \text{Binomial}(N-1, p)$ be the number of rival entrants, so $\Pi(p) = \mathbb{E}[\pi(1+X)]$. A binomial random variable is stochastically increasing in its success probability. Since π is strictly decreasing, $\mathbb{E}[\pi(1+X)]$ is strictly decreasing in p. The function is continuous, with $\Pi(0) = \pi(1)$ and $\Pi(1) = \pi(N)$. The three cases follow from the intermediate value theorem and strict monotonicity. □

When $p^* \in (0,1)$, entrants earn zero expected profit net of the entry cost. This has a striking consequence. Let the seller value the object at v_0, and let $S(k)$ be the expected gain from trade when k bidders enter, measured relative to the seller keeping the object. It equals the expected value of the winner minus v_0 when a sale occurs, and zero otherwise. The seller's expected gain, revenue minus v_0 times the probability of sale, equals expected gains from trade minus bidders' expected gross rents. Gross rents sum to $Np^*\Pi(p^*) = Np^*K$. Hence

$$\text{seller's expected gain} = \mathbb{E}\big[S(X^*)\big] - Np^*K, \qquad X^* \sim \text{Binomial}(N, p^*). \tag{14.99}$$

The right side is expected social welfare. The seller captures all of the social surplus, net of entry costs. With $v_0 = 0$ the seller's gain is its expected revenue.

Proposition 14.81 (Levin and Smith 1994)**.** *Consider symmetric private values, a seller who values the object at v_0, and an efficient standard auction with reserve price $r = v_0$. Then:*

(i) Social welfare $W(p) = \mathbb{E}[S(X)] - NpK$, with $X \sim$ Binomial(N, p), satisfies $W'(p) = N\big(\Pi(p) - K\big)$. The equilibrium entry probability maximizes welfare among symmetric entry probabilities.

(ii) If $p^* \in (0,1)$ at $r = v_0$, no reserve price gives the seller a higher expected gain than $r = v_0$.

Proof. (i) Write $X = \sum_{j=1}^{N} \epsilon_j$ with independent entry indicators ϵ_j that equal one with probability p_j. Differentiating $\mathbb{E}[S(X)]$ with respect to p_j gives $\mathbb{E}[S(Y_{-j}+1) - S(Y_{-j})]$, where Y_{-j} counts the other entrants. At $p_j = p$ for all j, summing over j yields

$$\frac{d}{dp}\mathbb{E}[S(X)] = N\,\mathbb{E}\big[S(Y+1) - S(Y)\big], \qquad Y \sim \text{Binomial}(N-1, p).$$

With $r = v_0$ and an efficient auction, $S(k) = \mathbb{E}\big[(\max\{V_1, \dots, V_k\} - v_0)^+\big]$. The increment $S(k+1) - S(k)$ is then the expected marginal contribution of one more bidder, $\mathbb{E}\big[(V_{k+1} - \max\{V_1, \dots, V_k, v_0\})^+\big]$. In a second-price auction with reserve v_0, this is exactly the bidder's expected surplus when it faces k rivals, which is $\pi(k+1)$. By revenue equivalence the same holds in any efficient standard auction with reserve v_0. Therefore $\frac{d}{dp}\mathbb{E}[S(X)] = N\,\mathbb{E}[\pi(Y+1)] = N\,\Pi(p)$, and $W'(p) = N(\Pi(p) - K)$. Since Π is decreasing, W is concave, and its maximizer over $[0,1]$ is the p^* of Proposition 14.80.

(ii) Let $R(r)$ and $W_r(p)$ denote the seller's expected gain and welfare with reserve r, and let $p^*(r)$ be the equilibrium entry probability. Net bidder rents are never negative in equilibrium, so $R(r) \le W_r(p^*(r))$. For any fixed p, the reserve v_0 allocates the object efficiently among the entrants and the seller, so $W_r(p) \le W_{v_0}(p)$. By part (i), $W_{v_0}(p) \le W_{v_0}(p^*(v_0))$. Finally, (14.99) gives $W_{v_0}(p^*(v_0)) = R(v_0)$ when $p^*(v_0) \in (0,1)$. Chaining the inequalities, $R(r) \le R(v_0)$. □

Part (ii) reverses the logic of Corollary 14.47. With a fixed number of bidders, the seller sets a reserve above its own value to extract rents. With endogenous entry and zero expected rents, there are no rents left to extract. A reserve above v_0 then only discourages entry and distorts the allocation. Hortaçsu and Perrigne (2021, Section 2.2, p. 91) state the contrast between the two entry models. Under nonselective entry of the Levin-Smith type, the optimal reserve price is the seller's own value. Under selective entry it is given by the formula (14.51) of the fixed-participation model. The proofs here are our own. Levin and Smith (1994) also show that the random entry of the mixed equilibrium wastes resources. Sometimes too many bidders enter and sometimes too few. A seller who could limit the number of potential bidders, and charge an entry fee if needed, would earn more.

Example 14.82 (Levin-Smith entry with uniform values)**.** Let values be uniform on $[0, 1]$, $r = v_0 = 0$ and $N = 5$. By Lemma 14.79, $\pi(1), \ldots, \pi(5) = \frac{1}{2}, \frac{1}{6}, \frac{1}{12}, \frac{1}{20}, \frac{1}{30}$, so $\Pi(1) = \pi(5) = \frac{1}{30} \approx 0.033$. Every entry cost between $\frac{1}{30}$ and $\pi(1) = \frac{1}{2}$ therefore produces a mixed equilibrium. For $K \geq \frac{1}{2}$ nobody enters. With $K = 0.05$, solving $\Pi(p) = K$ numerically gives $p^* = 0.816$, so 4.08 bidders enter on average. Expected revenue equals expected welfare, 0.592. With $K = 0.10$, $p^* = 0.559$, 2.79 bidders enter on average, nobody enters with probability 0.017, and revenue is 0.425. Figure 14.16(a) shows the two solutions.

The value of limiting entry is visible in Figure 14.16(b). With $K = 0.05$ and $N = 4$ potential bidders, $\pi(4) = \frac{1}{20} = K$, so all four enter and revenue is $\frac{3}{5} = 0.600$. Adding a fifth potential bidder lowers revenue to 0.592, and ten potential bidders lower it to 0.574. With $K = 0.10$, revenue peaks at 0.452 with $N = 3$. The losses are modest here, but they have the sign that Levin and Smith (1994) emphasize. All numbers come from `entry_example.py`.

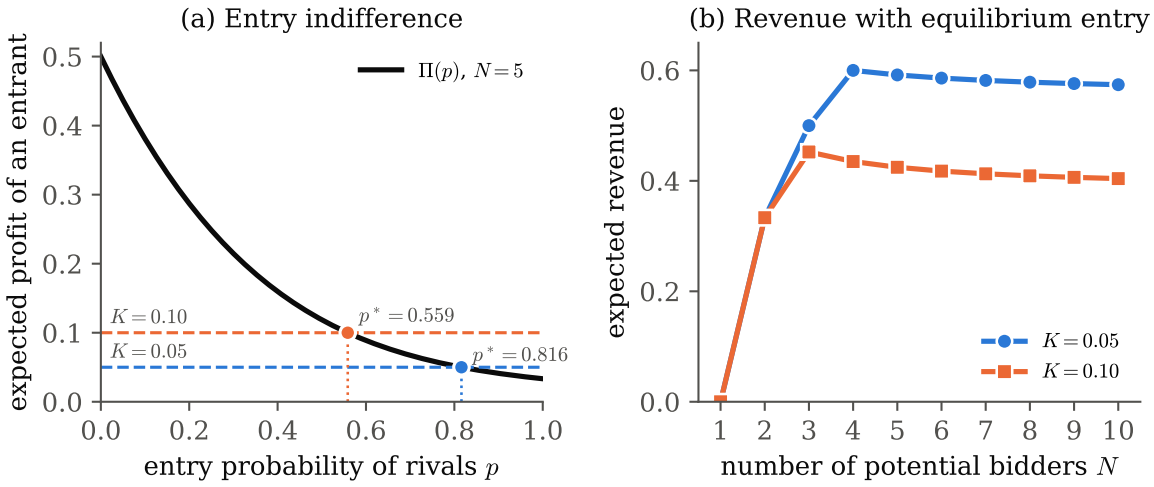

Figure 14.16: Levin-Smith entry with uniform values and no reserve price. Panel (a): the ex ante profit of an entrant $\Pi(p)$ in (14.97) for $N = 5$, and the equilibrium entry probabilities for $K = 0.05$ and $K = 0.10$. Panel (b): expected revenue in the symmetric entry equilibrium as a function of the number of potential bidders N.

14.11.3 Asymmetric bidders and type-symmetric entry equilibria

Athey et al. (2011) combine the Levin-Smith timing with the asymmetric model of Section 14.10. There are N_L potential loggers with value distribution F_L and N_M potential mills with value distribution F_M. Mills are strong: F_M dominates F_L in the reverse hazard rate order. Each firm decides independently whether to pay K, learns its value if it does, and learns which rivals entered before bidding (Athey et al., 2011, Section II.A).

The model omits two features that could also matter for the format comparison. Bidders may have a common value component, from private estimates of timber quality and volume or from differing beliefs about future market conditions. They may also be risk averse. Athey et al. (2011, Section II.F) abstract from both for two reasons. The format differences they observe are qualitatively different from those that common values or risk aversion would imply, and including either feature significantly complicates the analysis. They also restrict attention to

type-symmetric equilibria, which they regard as a convenient assumption that allows point identification of entry costs.

Let $\pi_L^\tau(n_L, n_M)$ and $\pi_M^\tau(n_L, n_M)$ be the expected profits, gross of K, of a participating logger and mill in format $\tau \in \{\text{o}, \text{s}\}$ (open or sealed). The superscript τ indexes the format and is unrelated to the payment rule τ_i of Section 14.6. The participants are n_L loggers and n_M mills, and these counts include the bidder itself. Following Athey et al. (2011, eq. (4)), bidder i's ex ante profit from entering is

$$\Pi_i^\tau(\boldsymbol{p}) = \sum_{\boldsymbol{n}} \pi_i^\tau(n_L, n_M)\, \mathbb{P}\big[n_L, n_M \mid i \text{ enters, rivals play } \boldsymbol{p}_{-i}\big], \tag{14.100}$$

where $\boldsymbol{p}$ is the profile of entry probabilities. When all loggers enter with probability p_L and all mills with probability p_M, the probabilities are binomial. Write $\text{bin}(k; m, p) = \binom{m}{k} p^k (1-p)^{m-k}$. For a logger and a mill, respectively,

$$\Pi_L^\tau(p_L, p_M) = \sum_{n_L=1}^{N_L} \sum_{n_M=0}^{N_M} \text{bin}(n_L - 1; N_L - 1, p_L)\, \text{bin}(n_M; N_M, p_M)\, \pi_L^\tau(n_L, n_M), \tag{14.101}$$

$$\Pi_M^\tau(p_L, p_M) = \sum_{n_L=0}^{N_L} \sum_{n_M=1}^{N_M} \text{bin}(n_L; N_L, p_L)\, \text{bin}(n_M - 1; N_M - 1, p_M)\, \pi_M^\tau(n_L, n_M). \tag{14.102}$$

Definition 14.83 (Type-symmetric entry equilibrium)**.** A *type-symmetric entry equilibrium* (Athey et al., 2011, Section II.A) consists of bid strategies $b_L(\cdot; \boldsymbol{n})$, $b_M(\cdot; \boldsymbol{n})$ and entry probabilities p_L, p_M with three properties.

(i) All loggers use (b_L, p_L) and all mills use (b_M, p_M).

(ii) Each bidder's bid strategy maximizes its profit conditional on entering, for every set of participants.

(iii) Each bidder enters if and only if its expected profit from entry (14.100) is at least K. It may randomize when the two are equal.

Bid strategies in the open auction are $b_k(v; \boldsymbol{n}) = v$. In the sealed auction they solve (14.83) and (14.84) with $b_k(r; \boldsymbol{n}) = r$. A type-symmetric entry equilibrium exists in both formats, but it need not be unique (Athey et al., 2011, Section II.C). The following condition restores uniqueness. For the proof we maintain that a participant's expected profit falls when a rival is added, strictly in expectation. In the open auction this holds auction by auction, since a bidder's surplus $(v - \max\{\text{rival values}, r\})^+$ can only fall when a rival is added.

Proposition 14.84 (Athey, Levin and Seira 2011, Proposition 1)**.** *Suppose that for all n_L, n_M,*

$$\pi_M^{\text{s}}(n_L, n_M + 1) > \pi_L^{\text{s}}(n_L, n_M). \tag{14.103}$$

Then there is a unique type-symmetric entry equilibrium for both auction formats. In equilibrium, either $p_L = 0$ or $p_M = 1$.

Condition (14.103) compares a mill and a logger that face the same n_M mills. The mill faces n_L loggers, while the logger faces only $n_L - 1$ other loggers. The condition requires the mill to earn more despite its extra rival. In the words of Athey et al. (2011, Section II.C), "mills have a sufficient value advantage over loggers to outweigh the effects of facing an additional bidder." They call the condition "rather strong" as theory, and they verify it for every tract in their estimated model (Chapter 15).

Proof sketch. Mills earn more than loggers at every entry profile. Fix (p_L, p_M). A logger who enters faces $X_L \sim \text{Binomial}(N_L - 1, p_L)$ other loggers and $X_M \sim \text{Binomial}(N_M, p_M)$ mills. A mill who enters faces $X_L + \epsilon_L$ loggers and $X_M - \epsilon_M$ other mills. Here ϵ_L is an indicator with success probability p_L, independent of everything else, and ϵ_M is the entry indicator of one of the N_M mills counted in X_M. Then $X_L + \epsilon_L \sim \text{Binomial}(N_L, p_L)$ and $X_M - \epsilon_M \sim \text{Binomial}(N_M - 1, p_M)$, as a mill's counts require. Using monotonicity, then (14.103), then monotonicity again,

$$\pi_M(X_L{+}\epsilon_L,\, X_M{-}\epsilon_M{+}1) \geq \pi_M(X_L{+}1,\, X_M{-}\epsilon_M{+}1) > \pi_L(X_L{+}1,\, X_M{-}\epsilon_M) \geq \pi_L(X_L{+}1,\, X_M).$$

Taking expectations gives $\Pi_M(p_L, p_M) > \Pi_L(p_L, p_M)$ for every profile.

Either $p_L = 0$ or $p_M = 1$. If loggers enter with positive probability, then $\Pi_L \geq K$. The previous step gives $\Pi_M > K$, so mills enter with probability one.

Uniqueness. Candidate equilibria have either $p_M = 1$ and p_L solving the logger's condition, or $p_L = 0$ and $p_M < 1$ solving the mill's condition. Each family has at most one member, because $\Pi_L(\cdot, 1)$ and $\Pi_M(0, \cdot)$ are strictly decreasing. Suppose an equilibrium with $p_L = 0$ and $p_M < 1$ exists. Then $\Pi_M(0, p_M) \leq K$ when $p_M = 0$, or $\Pi_M(0, p_M) = K$ when $p_M > 0$. In either case $\Pi_M(p_L, 1) < \Pi_M(0, p_M) \leq K$ for every p_L, so no equilibrium with $p_M = 1$ exists. Only one candidate survives.

Both formats. For any participant set, mills earn more and loggers less in the open auction than in the sealed auction (Athey et al., 2011, Section II.D). This is the many-bidder analogue of Proposition 14.76(iv). Hence $\pi_M^{\text{o}}(n_L, n_M + 1) \geq \pi_M^{\text{s}}(n_L, n_M + 1) > \pi_L^{\text{s}}(n_L, n_M) \geq \pi_L^{\text{o}}(n_L, n_M)$, and the argument applies to the open auction as well. □

The empirically relevant equilibrium has every mill entering and loggers randomizing, $p_M = 1$ and $p_L \in (0, 1)$. Athey et al. (2011, Section II.C) motivate this case with their data: they "observe logger entry in more than 85% of sales and always more potential logger entrants than actual logger entrants."

The homogeneous benchmark. If $F_L = F_M$, every bidder is the same and revenue equivalence applies conditional on the number of entrants. Each format then produces the same $\pi(k)$, given by (14.98), and the same entry condition. Athey et al. (2011, Section II.D) conclude that the two formats have "(i) the same expected entry, (ii) the same allocation, and (iii) the same expected revenue." Format differences in entry therefore require asymmetric bidders.

Proposition 14.85 (Athey, Levin and Seira 2011, Proposition 2)**.** *For any type-symmetric entry equilibrium of the sealed bid auction, there is a type-symmetric entry equilibrium of the open auction with the following properties.*

(i) Loggers are less likely to enter.

(ii) Mills are more likely to enter.

(iii) It is less likely that a logger wins.

Proof sketch for the empirically relevant case. Assume (14.103), so each format has a unique equilibrium, and suppose the sealed equilibrium has $p_M^{\text{s}} = 1$ and $p_L^{\text{s}} \in (0, 1)$. For every participant set, a logger earns weakly less in the open auction. Hence $\Pi_L^{\text{o}}(p_L, 1) \leq \Pi_L^{\text{s}}(p_L, 1)$ for every p_L. At p_L^{s} the sealed condition holds with equality, so $\Pi_L^{\text{o}}(p_L^{\text{s}}, 1) \leq K$. Because $\Pi_L^{\text{o}}(\cdot, 1)$ is decreasing, the open-auction solution satisfies $p_L^{\text{o}} \leq p_L^{\text{s}}$. This is (i). Mills earn weakly more in the open auction and face fewer loggers, so $\Pi_M^{\text{o}}(p_L^{\text{o}}, 1) \geq \Pi_M^{\text{s}}(p_L^{\text{s}}, 1) \geq K$. Mills still enter with probability one, which gives (ii) with equality. For (iii), two effects reinforce each other. For a fixed set of participants, a logger wins less often in the open auction, which is efficient, than in the sealed

auction, by Proposition 14.76(iii). In the open auction, fewer logger entrants also mean a lower chance that the highest value belongs to a logger. □

The general statement allows multiple equilibria, which is why it is phrased as existence of a suitable open-auction equilibrium. Under the uniqueness condition, the prediction is sharp: "open bidding leads to less logger entry, equivalent mill entry and a lower chance that a logger wins" (Athey et al., 2011, Section II.D). The revenue comparison remains ambiguous. Sealed bidding attracts more loggers, which raises competition, but it allocates inefficiently. The sealed auction is "inefficient even conditional on participation," while the efficient type-symmetric outcome is an equilibrium of the open auction (Athey et al., 2011, Section II.D, citing Athey et al., 2004b). The idea that sealed bids encourage entry by weaker bidders is emphasized by Klemperer (2004) in the context of spectrum auctions (Athey et al., 2011, footnote 4, p. 215). Athey and Haile (2007, Section 7) likewise list entry among the factors that govern the choice of format. The format "also affects bidder entry when bidders are asymmetric," and they cite Klemperer (2002) and Athey et al. (2004b). The mechanism is the one of Proposition 14.85. An ascending auction deters entry by bidders who expect to be outbid by a stronger rival. Klemperer (2002) proposes hybrid formats that end with a sealed-bid stage.

Example 14.86 (One mill and one potential logger)**.** Take the values of Example 14.77: the mill draws from $U[0,2]$, the logger from $U[0,1]$, and $r = 0$. With both present, Table 14.10 gives $\pi_L^{\mathrm{s}} = 0.0969$, $\pi_L^{\mathrm{o}} = \frac{1}{12} \approx 0.0833$, $\pi_M^{\mathrm{s}} = 0.5069$ and $\pi_M^{\mathrm{o}} = \frac{7}{12}$. A mill alone pays the reserve and earns $\mathbb{E}[V_M] = 1$, and a logger alone earns $\mathbb{E}[V_L] = \frac{1}{2}$. Condition (14.103) holds, since $0.5069 > 0.5$. Let $K = 0.09$. In the sealed auction the mill enters and the logger enters too, because $0.0969 > 0.09$. Revenue is 0.459, the logger wins with probability $\frac{1}{3}$, and welfare is $1.0628 - 2K = 0.883$. In the open auction the logger stays out, because $0.0833 < 0.09$. The mill wins at the reserve price, so revenue is zero and welfare is $1 - K = 0.91$. The sealed auction raises far more revenue through entry, and the open auction is more efficient.

The example is extreme because $r = 0$, but it isolates the mechanism of Proposition 14.85. The weak bidder's expected profit is higher under sealed bidding, so it enters more often. That entry disciplines the strong bidder, whose price would otherwise be set by the reserve.

From entry decisions to entry costs. The indifference of randomizing bidders carries empirical content. For any bidder who randomizes, expected profit from entry equals K. Athey and Haile (2007, Section 6.3.2) write this as

$$K = \sum_{\mathcal{A}:\, i \in \mathcal{A}} \mathbb{P}\big(\tilde{\mathcal{N}} = \mathcal{A} \mid i \in \tilde{\mathcal{N}}\big)\, \pi_i(\mathcal{A}), \tag{14.104}$$

where $\tilde{\mathcal{N}}$ is the random set of entrants. Here $\pi_i(\mathcal{A})$ is bidder i's expected gross profit when the participant set is $\mathcal{A}$,

$$\pi_i(\mathcal{A}) = \mathbb{E}\Big[\big(V_i - \beta_i(V_i;\mathcal{A})\big)\, G_{M_i|B_i}\big(\beta_i(V_i;\mathcal{A}) \,\big|\, \beta_i(V_i;\mathcal{A});\mathcal{A}\big)\Big], \tag{14.105}$$

with $G_{M_i|B_i}$ the distribution of the highest rival bid given bidder i's own bid. The notation follows Athey and Haile (2007, Section 6.3.2), who write Π_i for what we call π_i. The post-entry profits are identified from bids, and the entry probabilities are observed. The level of the entry cost is then identified in dollars. This contrasts with entry models that infer profits only from entry decisions (Athey and Haile, 2007, Section 6.3.2). Chapter 15 develops the estimator.

14.12 Collusion and the Choice of Format

Collusion among bidders is a long-standing concern in auction design. Gifford Pinchot, the first chief of the US Forest Service, advocated sealed bidding for timber. He described a sale on sealed bids as "thereby preventing the customary collusion between bidders" (Pinchot, 1998, p. 209), as quoted by Athey et al. (2011, footnote 2). Milgrom and Weber (1982, Section 9) name the same setting as a limit of their noncooperative theory. They judge it less reasonable for timber rights on federal land, where "the bidders (owners of lumber mills) are members of a trade association and bid repeatedly against each other" (Milgrom and Weber, 1982, p. 1118). This section explains why the format matters for collusion. The general theory of cartels is in Chapter 12, and prosecuted bidding rings are studied in Chapter 13.

14.12.1 Rings in second-price and ascending auctions

A *bidding ring* is a group of bidders who agree to suppress competition among themselves. Consider the private values model with a ring $C \subset N$ of $m \geq 2$ members. Suppose for now that members know each other's values. The simplest agreement designates the member with the highest value, bidder d, to bid. The other members abstain or bid the reserve price. Bidders outside the ring bid as usual.

Proposition 14.87 (Robinson 1985)**.** *In a second-price or ascending auction with private values, the ring agreement in which the highest-value member bids its value and the other members abstain is self-enforcing. No member gains by deviating within the auction, whatever the values and whether or not the members meet again.*

Proof. Outsiders bid their values, which is weakly dominant by Proposition 14.22. The designated bidder d bids v_d, which is also weakly dominant. Consider a member $j \neq d$, with $v_j \leq v_d$. Bidder j wins only with a bid above v_d, since d stays in until the price reaches v_d. A winning deviation then pays at least $v_d \geq v_j$, so its payoff is at most zero. Abstaining yields zero. Hence no deviation is profitable. □

The ring gains because it removes the price pressure that members exert on each other. Let $V^C_{(1)} \geq V^C_{(2)}$ be the two highest member values and $V^O_{(1)}$ the highest outsider value. Competitive bidding sets the price at the second-highest value overall. Under the ring, the price is $\max\{V^O_{(1)}, r\}$ whenever a member wins. The price falls only when the two highest values both belong to members, and then by

$$\Delta P = \left(V^C_{(2)} - \max\left\{ V^O_{(1)}, r \right\} \right)^+ . \tag{14.106}$$

The ring does not change who wins, so the allocation stays efficient. The ring transfers surplus from the seller to its members.

Hortaçsu and Perrigne (2021, Section 2.5, p. 96) draw the practical lesson from Proposition 14.87. Open auctions may favor collusion, because bidders meet face to face and can react at once to each other's behavior. If the ring allocates the object to its highest-value member, no other member gains by deviating, since that member can always outbid the deviator. For this reason auction theorists recommend first-price auctions. The issue is practical. Collusion at U.S. Forest Service timber sales was suspected in the 1970s, and it was the subject of allegations and of a congressional hearing in 1977, though few cases were prosecuted. In 1976 the federal government recommended first-price sealed bids over ascending auctions, mainly to reduce

collusion (Hortaçsu and Perrigne, 2021, Section 2.4, p. 96). Sealed bids are no cure, however. The same survey reviews collusion in first-price procurement auctions of construction contracts (their Section 3.4), and Chapter 13 studies such rings.

14.12.2 Rings in first-price auctions

The first-price auction is different. To gain, the designated bidder must bid less than the price that competition would produce. Every other member with a value above that bid then has a unilateral incentive to bid slightly more and win. In a one-shot auction, the designated bid must exceed the values of all other members to deter such deviations. With known values, the ring must therefore pay at least $V^C_{(2)}$ whenever it wins. The price suppression of (14.106) cannot be sustained within a single sealed-bid auction.

Sustaining a first-price ring requires the threat of future punishment. A member who undercuts the designated bidder is detected only after the bids are opened, and the ring can respond only in later auctions. The agreement survives if the one-time gain from undercutting is smaller than the discounted loss from the ring's collapse, a condition of the kind derived in Chapter 12. The open auction needs no such condition. A deviation there is observed as it happens, and the designated bidder answers it by continuing to bid. Athey and Haile (2007, Section 7) summarize the comparison: first-price auctions "may be less susceptible to collusion (detection and response to defections are more difficult than in an ascending auction)." This is why sealed bids appear in Table 14.13 as the format less prone to collusion. Robinson (1985) draws the policy conclusion that a seller worried about rings should prefer the first-price format.

14.12.3 Ring size, leakage and secret deviations

The two formats also differ in who gains from a ring that does not include every bidder. Marshall and Marx (2012, ch. 8, p. 176) put the contrast as follows. In the ascending auction the highest-value member stays in up to its value, exactly as it would without the ring. An outsider who wins pays what it would have paid without collusion, so the ring captures all the gains. In the sealed-bid auction the designated member bids strictly less than its noncollusive bid. Outsiders then sometimes win auctions that they would have lost under competition. Part of the collusive gain spills over to the outsiders, which Marshall and Marx (2012, p. 181) call *leakage*. The following example computes the ascending-auction side of the comparison in closed form.

Example 14.88 (Ring size with uniform values)**.** Let n bidders have values that are independent and uniform on $[0,1]$, with $r = v_0 = 0$. A ring of $k \geq 1$ members bids in an ascending auction as in Proposition 14.87, and the other $m = n - k$ bidders bid their values. We compute the expected price and the expected surplus of each bidder.

Step 1 (price reduction). By (14.106) with $r = 0$, the ring lowers the price by $(C_2 - O_1)^+$. Here C_2 is the second-highest member value and O_1 the highest outsider value, with $O_1 = 0$ when $m = 0$. The density of C_2 is $k(k-1)x^{k-2}(1-x)$ on $[0,1]$, and $\mathbb{P}(O_1 \leq y) = y^m$. For a fixed x,

$$\mathbb{E}\big[(x - O_1)^+\big] = \int_0^x \mathbb{P}(O_1 \leq y)\, dy = \int_0^x y^m\, dy = \frac{x^{m+1}}{m+1}.$$

Integrating over C_2 and using $k + m = n$,

$$\mathbb{E}[\Delta P] = \frac{k(k-1)}{m+1}\int_0^1 x^{n-1}(1-x)\,dx = \frac{k(k-1)}{m+1}\left(\frac{1}{n} - \frac{1}{n+1}\right) = \frac{k(k-1)}{(n-k+1)\,n\,(n+1)}.$$

Step 2 (price). Without a ring the expected price is $\mathbb{E}[V_{(n-1:n)}] = \frac{n-1}{n+1}$, so the expected price with a ring of k members is

$$\mathbb{E}[P_k] = \frac{n-1}{n+1} - \frac{k(k-1)}{(n-k+1)\,n\,(n+1)}. \tag{14.107}$$

With $k = 2$ the fall is $\frac{2}{(n-1)n(n+1)}$.

Step 3 (surplus). An outsider wins only with the highest value overall, and it then pays the second-highest value overall, ring or no ring. Its expected surplus is therefore unchanged at $\frac{1}{n}\mathbb{E}\left[V_{(n:n)} - V_{(n-1:n)}\right] = \frac{1}{n(n+1)}$. Members keep their competitive surplus $\frac{k}{n(n+1)}$ and gain $\mathbb{E}[\Delta P]$ in addition. Per member,

$$\frac{1}{k}\left[\frac{k}{n(n+1)} + \frac{k(k-1)}{(n-k+1)n(n+1)}\right] = \frac{1}{n(n+1)}\cdot\frac{n}{n-k+1} = \frac{1}{(n+1)(n-k+1)}.$$

An all-inclusive ring, $k = n$, pays nothing, and each member earns $\frac{1}{n+1} = \frac{1}{n}\mathbb{E}[V_{(n:n)}]$.

Table 14.11 reproduces Table 8.1 of Marshall and Marx (2012, ch. 8, p. 182), which compares the two formats with five bidders. The ascending columns follow from Example 14.88. For example, with $n = 5$ and $k = 3$, (14.107) gives $\frac{4}{6} - \frac{6}{3\cdot 30} = 0.600$, and each member earns $\frac{1}{6\cdot 3} \approx 0.056$. In the first-price auction the ring is a single strong bidder whose value is the highest of k uniform draws. That asymmetric auction has no closed form. Marshall and Marx take its values from Marshall et al. (1994, Table III), who compute them by Monte Carlo with 100,000 draws.

Table 14.11: Rings of different sizes with five bidders and uniform values

	Expected price		Surplus per ring member		Surplus per outsider	
Ring size k	Ascending	First price	Ascending	First price	Ascending	First price
1	0.667	0.667	0.033	0.033	0.033	0.033
2	0.650	0.651	0.042	0.035	0.033	0.037
3	0.600	0.609	0.056	0.041	0.033	0.049
4	0.467	0.506	0.083	0.057	0.033	0.086
5	0.000	0.000	0.167	0.167	–	–

Notes: Five bidders with values independent and uniform on $[0, 1]$, and a reserve price of zero. A ring of size one means competitive bidding. The ascending columns and the first-price row for $k = 1$ are analytic. The other first-price entries are from Marshall et al. (1994, Table III). Source: Marshall and Marx (2012, ch. 8, Table 8.1, p. 182).

The table shows three effects. First, outsiders gain from a ring only in the sealed-bid auction. Their surplus rises from 0.033 to 0.037, 0.049 and 0.086 as the ring grows from two to four members. Members of a larger ring bid lower, and outsiders win more often and pay less (Marshall and Marx, 2012, p. 181). The leakage also creates inefficiency. With a ring of four against one outsider, the outsider bids about 0.40 when its value is about 0.54. The ring bids

about 0.40 only when its highest value is about 0.76 (Marshall and Marx, 2012, pp. 183–184, using Figure 2 of Marshall et al., 1994). The outsider then wins whenever the ring's highest value lies between 0.54 and 0.76.

Second, a ring that excludes some bidders hurts the seller more in the ascending auction. With two, three and four members the expected price is 0.650, 0.600 and 0.467 there, against 0.651, 0.609 and 0.506 in the first-price auction. Each member also gains more, 0.042, 0.056 and 0.083 against 0.035, 0.041 and 0.057. In this example the incentive to collude is therefore stronger in the ascending auction (Marshall and Marx, 2012, p. 181). Marshall and Marx stress in their footnote 21 that this ranking is not a general result.

Third, leakage affects who wants to join. In the ascending auction there is no leakage, so outsiders always want to join, and with symmetric bidders the ring wants to admit them (Marshall and Marx, 2012, p. 177). In the sealed-bid auction an outsider may prefer to stay out. With 101 bidders, an outsider facing a ring of 99 earns 0.0159 in the first-price auction. As a member of a ring of 100 it would earn only 0.0025. The last outsider facing a ring of 100 earns 0.0412, more than the 0.0098 it would earn in the all-inclusive ring (Marshall and Marx, 2012, Table 8.2, pp. 185–186). Example 14.88 reproduces their ascending entries, a member surplus of $\frac{1}{102 \cdot 3} \approx 0.0033$, $\frac{1}{102 \cdot 2} \approx 0.0049$ and $\frac{1}{102} \approx 0.0098$.

The same contrast governs enforcement. A *secret deviation* is a clandestine bid at the main auction, contrary to the ring's recommendation, that cannot be traced to the member without substantial cost (Marshall and Marx, 2012, ch. 9, pp. 187–188). Secret deviations are a major concern in sealed-bid auctions and a lesser one in ascending auctions. In the ascending auction the highest-value member can stay active up to its value, as it would without the ring, so there is no room for a profitable deviation. In the sealed-bid auction the designated member bids below its noncooperative bid, which opens the door to deviations by other members. Marshall and Marx conclude that pricing and enforcement structures are harder to implement in sealed-bid auctions, while the structures for allocating the gains are much the same in the two formats (Marshall and Marx, 2012, p. 198).

14.12.4 Knockouts and side payments

The agreement above assumed that members know each other's values. In practice, a ring must elicit values and divide the gains. Rings often hold a private auction among their members, called a *knockout*, before or after the real one. The winner of the knockout gets the object or the right to bid for it, and side payments compensate the losers.

Graham and Marshall (1987) study knockouts for second-price and English auctions. In a knockout of the type they analyze, each member reports a value to a ring center. The highest reporter bids its report in the main auction. If it wins at price P, it pays the center the amount by which the second-highest report exceeds P. Its total outlay is $P + (\hat{z}_{(2)} - P)^+ = \max\{P, \hat{z}_{(2)}\}$, where $\hat{z}_{(2)}$ is the second-highest report. Each member thus faces a second-price auction against the other reports and the outside bids, so truthful reporting is weakly dominant. The center's collections are returned to members as transfers fixed in advance, which keeps incentives intact and balances the budget in expectation.

McAfee and McMillan (1992) study rings in first-price auctions. A *weak cartel* cannot make side payments. Its best scheme has every member with a value above the reserve bid the reserve price, with the winner chosen at random among them. A *strong cartel* can make side payments. It can allocate the object to the member with the highest value through a first-price knockout whose winner pays its knockout bid to the other members in equal shares.

Marshall and Marx (2012, ch. 9, pp. 191–192) describe a strong cartel of this kind. From 1895 the cast-iron pipe makers of the Addyston Pipe cartel met before each sealed-bid procurement in their pay territories and held a knockout. The high bidder in the knockout was selected to bid at the procurement. Its knockout bid was distributed among all the ring members, in shares that varied with their production capacities (Marshall and Marx, 2012, p. 191, footnote 7). The other members either stayed out or submitted deliberately losing bids. In one procurement in St. Louis, Howard-Harrison won with a bid of \$24, while Addyston and Dennis Long protected it with bids of \$24.37 and \$24.57. The Chattanooga foundry could have supplied the pipe at \$17 or \$18 and still made a profit (Marshall and Marx, 2012, p. 192). Marshall and Marx describe this mechanism in stylized form, and their footnote 6 attributes the stylized model to McAfee and McMillan (1992). The cartel thus ran a version of the McAfee and McMillan knockout. With symmetric bidders that knockout lets the ring suppress all competition among its members.

Knockouts used in practice need not be incentive compatible. Asker (2010) studies a ring of eleven wholesale stamp dealers that operated in the 1990s at ascending auctions, mainly at New York auction houses (Marshall and Marx, 2012, ch. 9, p. 192). Before each auction the members reported values to a ring center, in effect a sealed-bid knockout. The center bid for the member with the highest report, and the other members stayed out. If the ring won, side payments depended on the reports and on the price P (Marshall and Marx, 2012, ch. 9, pp. 192–194). Rank the reports as $r_1 > r_2 > \cdots > r_k > P$, where member 1 is the winner and all other reports lie below P. Write $\rho_l = r_l$ for $l \le k$ and $\rho_{k+1} = P$. Each increment $\rho_l - \rho_{l+1}$ with $2 \le l \le k$ is split in half. The winner keeps one half and pays out the other half, which is shared equally by the $l-1$ losing members whose reports are at least ρ_l (Marshall and Marx, 2012, p. 193). Losing member $j \in \{2, \ldots, k\}$ therefore receives

$$t_j = \sum_{l=j}^{k} \frac{\rho_l - \rho_{l+1}}{2(l-1)}, \tag{14.108}$$

and members whose reports lie below P receive nothing. These are the transfers of Table 9.1 of Marshall and Marx (2012, p. 193). Summing over j counts the term of increment l once for each of the $l-1$ members $j \le l$, so

$$\sum_{j=2}^{k} t_j = \sum_{l=2}^{k} (l-1)\,\frac{\rho_l - \rho_{l+1}}{2(l-1)} = \sum_{l=2}^{k} \frac{\rho_l - \rho_{l+1}}{2} = \frac{\rho_2 - P}{2}.$$

The sum equals $\frac{r_2 - P}{2}$ when at least one losing member reports more than P, and zero otherwise. It is exactly the winner's payment in Table 9.1, so the rule balances the budget. Members with higher reports receive larger payments. The rule also rewards overreporting. Only the term $l = j$ of (14.108) contains r_j. A losing member therefore raises its transfer at the rate $\frac{1}{2(j-1)}$ by raising its report, as long as the report stays below r_{j-1}. A member whose value lies below P can likewise collect a share by reporting more than P. Marshall and Marx note, as Graham et al. (1990) had pointed out, that such rules give members an incentive to overreport. Inflated reports can lead the ring to win lots that an outsider valued more, at prices above the ring's own highest value. In the model with unobserved heterogeneity, Asker (2010, Section VII.C and Table 10) estimates that this happened in 19 percent of the auctions the ring won. Chapter 13 analyzes this ring in detail.

A ring at ascending auctions where members can see who holds the high bid needs no communication before the auction. Its members follow one rule. No member raises the bid

when another member is the current high bidder (Marshall and Marx, 2012, ch. 9, p. 194). The items that members win are then reallocated at a knockout held after the auction. Marshall and Marx (2012, ch. 3, pp. 61–64) give a fictional account of such a ring at antique auctions, with footnotes that tie its features to known cases. At the knockout, members submit *bonus bids*, offers in excess of the price paid at the main auction. The highest bonus bidder reimburses the member who bought the item and puts the bonus "into the hat." The hat money is divided equally among the members at the end of the day. In their example, ten members shared about $500,000, or $50,000 each. A ring whose members differ in strength can run a *nested knockout*. The three members of an inner ring do not bid against each other at the first knockout. The items they win there go to a second knockout among the inner ring alone. Suppose an inner member wins the first knockout with a bonus of $5,000 and the second with a bonus of $10,000. The first amount is split among all ten members, and the second among the inner three (Marshall and Marx, 2012, ch. 3, p. 63). Equal sharing again invites overbidding. A member may raise the bonus on an item it does not want, because it receives a share of every bonus. The cases behind the account include rings in antiques, used industrial machinery and real estate (Marshall and Marx, 2012, ch. 3, p. 55, and ch. 9, p. 194).

14.12.5 Collusion and entry: Athey, Levin and Seira's Proposition 3

Athey et al. (2011, Section II.E) add collusion to the entry model of Section 14.11. They cite a long record of concern about collusion in open Forest Service sales, including the empirical study of oral timber auctions by Baldwin et al. (1997). Collusive schemes take many forms, so they assume for concreteness that participating mills in an open auction cooperate perfectly. "The participating mill with the highest value bids his value, while the other mills register as participants but do not actively bid. Loggers simply bid up to their value." Entry decisions remain independent, so mills anticipate cooperating with whichever mills enter but do not coordinate entry. We call this the *mill-collusive* open auction.

Proposition 14.89 (Athey, Levin and Seira 2011, Proposition 3)**.** *For any type-symmetric entry equilibrium of the open auction, there is a type-symmetric collusive equilibrium with the following properties.*

(i) Loggers are less likely to enter.

(ii) Mills are more likely to enter.

(iii) It is less likely that a logger wins.

Thus, for any type-symmetric entry equilibrium of the sealed bid auction, there is a type-symmetric collusive equilibrium of the open auction in which properties (i) to (iii) hold. In the empirically relevant case, with $p_M = 1$ and $p_L \in (0, 1)$, collusion leaves entry and the allocation unchanged and only lowers prices.

Proof sketch. Fixed participants. The highest-value mill still bids its value and loggers bid theirs, so the participant with the highest value wins, as in the competitive open auction. A logger's payoff is $(v_L - \max\{\text{other participants' values}, r\})^+$. It depends on the mills only through the highest mill value, which remains in the auction. Logger profits are therefore unchanged, $\pi_L^{\text{oc}}(\boldsymbol{n}) = \pi_L^{\text{o}}(\boldsymbol{n})$, where oc denotes the mill-collusive open auction. When a mill wins, it pays weakly less, and a mill that does not win earns zero in both cases. Hence $\pi_M^{\text{oc}}(\boldsymbol{n}) \geq \pi_M^{\text{o}}(\boldsymbol{n})$.

Entry. Loggers' entry incentives are unchanged at any entry profile, while mills' incentives rise. The argument of Proposition 14.85, with the collusive open auction in place of the

open auction and the open auction in place of the sealed one, delivers properties (i) to (iii). Combining with Proposition 14.85 gives the comparison with the sealed auction.

The empirically relevant case. If $p_M = 1$ in the competitive open auction, mills also enter with probability one under collusion, since their profits are higher. The logger's entry condition $\Pi_L^{oc}(p_L, 1) = \Pi_L^{o}(p_L, 1) = K$ is unchanged, so p_L is unchanged. Entry and the allocation are identical, and only the price differs. □

The price falls exactly in the configurations described by (14.106), with the mills as the ring. Let $V_{(1)}^M \geq V_{(2)}^M$ be the two highest participating mill values and $V_{(1)}^L$ the highest logger value. The competitive price is the second-highest participant value. The collusive price is the second-highest value among the top mill and the loggers. The two prices differ only when at least two mills participate and the two highest values both belong to mills. The price reduction is

$$\Delta P = \left(V_{(2)}^M - \max\left\{ V_{(1)}^L, r \right\} \right)^+, \tag{14.109}$$

with the conventions that $\Delta P = 0$ when fewer than two mills participate and that the maximum equals r when no logger participates.

Example 14.90 (Size of the collusive price reduction)**.** Let one logger with $V_L \sim U[0,1]$ and two mills with $V_{M1}, V_{M2} \sim U[0,2]$ participate in an open auction with $r = 0$. The second-highest mill value $Y = \min\{V_{M1}, V_{M2}\}$ has density $1 - \frac{y}{2}$ on $[0,2]$. The price changes when $Y > V_L$, which has probability

$$\int_0^1 \left(1 - \frac{l}{2}\right)^2 dl = \frac{2}{3}\left(1 - \frac{1}{8}\right) = \frac{7}{12}.$$

The expected reduction is $\mathbb{E}[(Y - V_L)^+] = \int_0^1 \int_l^2 (y - l)\left(1 - \frac{y}{2}\right) dy\, dl$. The substitution $u = 2 - y$ turns the inner integral into $\int_0^{2-l} (2 - l - u)\frac{u}{2} du = \frac{(2-l)^3}{12}$, so

$$\mathbb{E}[\Delta P] = \int_0^1 \frac{(2-l)^3}{12} dl = \frac{16 - 1}{48} = \frac{5}{16} \approx 0.313.$$

The competitive expected price is $\frac{19}{24} \approx 0.792$, so collusion lowers it to $\frac{23}{48} \approx 0.479$, a fall of 39 percent. The script `collusion_example.py` confirms these values by exact integration and simulation.

Proposition 14.89 yields a sharp test. If mills collude in open auctions, the open-auction price shortfall relative to sealed bidding should be concentrated in sales where at least two mills participate. A sale with a single mill carries no information about mill collusion. Athey et al. (2011, Section I) report that the price differential "is observed mainly in sales where multiple mills are competing." Chapter 15 presents their evidence.

The two sides of the format choice now stand side by side. The open auction allocates efficiently among participants but discourages weak bidders' entry and invites collusion. The sealed auction allocates inefficiently but attracts weak bidders and resists collusion. Which effect dominates is an empirical question. Athey et al. (2011) answer it for timber, and Chapter 15 reports their findings.

14.13 Procurement Auctions

In a *procurement auction* a buyer, often a government agency, asks firms to bid for the right to supply a good or carry out a project. The lowest bid wins. Government procurement is a major source of auction data, and first-price formats are particularly common there (Athey and Haile, 2007, Section 1). Procurement is the mirror image of the selling auctions studied so far. Every result carries over with costs in place of values and with the inequalities reversed. This section derives the main results directly, because empirical work on procurement uses them in this form.

14.13.1 The model and the equilibrium bid

There are n risk-neutral firms. Firm i's cost of performing the contract is c_i, drawn independently from F_c with a positive density f_c on $[\underline{c}, \bar{c}]$. Costs are private information. In the first-price (low-bid) auction the lowest bidder wins and is paid its bid. A firm that bids b earns

$$(b - c_i)\,\mathbf{1}\Big\{b < \min_{j \neq i} b_j\Big\}. \tag{14.110}$$

The buyer accepts any bid up to $\bar{c}$, so the reserve price does not bind.

Proposition 14.91 (Symmetric procurement equilibrium)**.** *The unique symmetric equilibrium in strictly increasing, differentiable bid functions is*

$$\beta(c) = c + \frac{\int_c^{\bar{c}} \big(1 - F_c(t)\big)^{n-1} dt}{\big(1 - F_c(c)\big)^{n-1}}, \tag{14.111}$$

with $\beta(\bar{c}) = \bar{c}$. Equivalently, $\beta(c) = \mathbb{E}\big[Y \mid Y > c\big]$, where $Y = \min_{j \neq i} C_j$ is the lowest rival cost.

Proof. Necessity. Suppose the rivals use a strictly increasing bid function β with inverse ϕ. A rival bids above b when its cost exceeds $\phi(b)$, which has probability $1 - F_c(\phi(b))$. The firm with cost c therefore maximizes

$$(b - c)\big(1 - F_c(\phi(b))\big)^{n-1}.$$

Write $H(c) = (1 - F_c(c))^{n-1}$, so that $H'(c) = -(n-1)(1 - F_c(c))^{n-2} f_c(c)$. The first-order condition is

$$H(\phi(b)) + (b - c)\, H'(\phi(b))\, \phi'(b) = 0.$$

In a symmetric equilibrium the optimal bid is $b = \beta(c)$, so $\phi(b) = c$ and $\phi'(b) = \frac{1}{\beta'(c)}$. Multiplying by $\beta'(c)$ gives the differential equation

$$H(c)\beta'(c) = -\big(\beta(c) - c\big)H'(c).$$

Moving terms gives $H(c)\beta'(c) + H'(c)\beta(c) = cH'(c)$, that is,

$$\frac{d}{dc}\big[\beta(c)H(c)\big] = cH'(c).$$

Integrate from c to $\bar{c}$ and use $H(\bar{c}) = 0$:

$$-\beta(c)H(c) = \int_c^{\bar{c}} tH'(t)\,dt = \big[tH(t)\big]_c^{\bar{c}} - \int_c^{\bar{c}} H(t)\,dt = -cH(c) - \int_c^{\bar{c}} H(t)\,dt.$$

Dividing by $-H(c)$ gives (14.111). As $c \to \bar{c}$, the ratio in (14.111) tends to zero by l'Hôpital's rule, so $\beta(\bar{c}) = \bar{c}$.

Sufficiency. A firm with cost c that bids as if its cost were z earns $(\beta(z)-c)H(z)$. Its derivative in z is $\beta'(z)H(z)+(\beta(z)-c)H'(z)$. Using the differential equation at z, $\beta'(z)H(z) = -(\beta(z)-z)H'(z)$, so the derivative equals $(z-c)H'(z)$. Since $H' < 0$, it is positive for $z < c$ and negative for $z > c$. Mimicking one's own type is optimal, and bids outside the range of β are dominated.

Conditional expectation. The lowest rival cost satisfies $\mathbb{P}(Y > t) = H(t)$. Hence $\mathbb{E}[Y \mid Y > c] = c + \int_c^{\bar{c}} \frac{\mathbb{P}(Y>t)}{\mathbb{P}(Y>c)} dt$, which is (14.111). □

Each firm bids the expected cost of its strongest rival, conditional on that rival having a higher cost. This mirrors (14.30), where a bidder bids the expected highest rival value conditional on that value being lower. The markup $\beta(c) - c$ falls with n and vanishes as $n \to \infty$.

Example 14.92 (Uniform costs)**.** Let F_c be uniform on $[0,1]$. Then $H(t) = (1-t)^{n-1}$ and $\int_c^1 (1-t)^{n-1} dt = \frac{(1-c)^n}{n}$, so

$$\beta(c) = c + \frac{1-c}{n} = \frac{1+(n-1)c}{n}. \tag{14.112}$$

The expected price paid by the buyer is $\mathbb{E}[\beta(C_{(1:n)})]$, where $C_{(1:n)}$ is the lowest cost, with mean $\frac{1}{n+1}$. Hence the expected price is $\frac{1}{n+1} + \frac{1}{n}\left(1 - \frac{1}{n+1}\right) = \frac{2}{n+1}$.

14.13.2 The first-order condition in terms of the bid distribution

Let G be the distribution of one rival's equilibrium bid and g its density. A firm with cost c chooses b to maximize $(b-c)(1-G(b))^{n-1}$. The first-order condition is

$$\big(1-G(b)\big)^{n-1} - (b-c)(n-1)\big(1-G(b)\big)^{n-2} g(b) = 0.$$

Dividing by $(n-1)(1-G(b))^{n-2} g(b)$ and solving for the cost gives

$$c = b - \frac{1-G(b)}{(n-1)\,g(b)}. \tag{14.113}$$

Equation (14.113) is the procurement counterpart of (14.34). It recovers each firm's cost from its bid and the observable distribution of bids. With uniform costs, (14.112) implies that bids are uniform on $[\frac{1}{n}, 1]$, with $G(b) = \frac{nb-1}{n-1}$ and $g(b) = \frac{n}{n-1}$. Then $\frac{1-G(b)}{(n-1)g(b)} = \frac{1-b}{n-1}$, and (14.113) gives $c = \frac{nb-1}{n-1}$, which inverts (14.112). With asymmetric firms, the condition generalizes as in (14.78): $c_i = b_i - \left[\sum_{j \neq i} \frac{g_j(b_i)}{1-G_j(b_i)}\right]^{-1}$.

14.13.3 The oligopoly analogy

The procurement bidder's problem has the structure of a pricing problem. Define the win probability $\mathcal{W}(b) = (1-G(b))^{n-1}$. The firm maximizes $(b-c)\mathcal{W}(b)$, just as a firm with marginal cost c chooses a price p to maximize $(p-c)q(p)$. The bid plays the role of the price and the win probability plays the role of the quantity sold. The first-order condition $\mathcal{W}(b)+(b-c)\mathcal{W}'(b) = 0$ can be written as

$$\frac{b-c}{b} = \frac{1}{\eta_{\mathcal{W}}(b)}, \qquad \eta_{\mathcal{W}}(b) = -\frac{\mathcal{W}'(b)\,b}{\mathcal{W}(b)} = (n-1)\frac{b\,g(b)}{1-G(b)}. \tag{14.114}$$

This is the inverse elasticity rule of Chapter 2, with the elasticity of the win probability in place of the demand elasticity. The bidder trades off the margin against the probability of winning, as a firm trades off its markup against its sales. In the uniform example with $n = 4$, a firm with cost 0.2 bids 0.4. There $\eta_W(0.4) = \frac{3\times0.4}{0.6} = 2$, and the margin $\frac{0.4-0.2}{0.4} = \frac{1}{2}$ equals $\frac{1}{\eta_W}$.

The analogy extends to empirical method. In Chapter 4 we recover marginal costs by inverting a pricing first-order condition with an estimated demand system. Equation (14.113) recovers costs in the same way, with the bid distribution in the role of demand. The auction setting is cleaner. The "demand" facing a bidder is the distribution of rival bids, which the researcher observes directly.

14.13.4 Other formats, reserve prices and preferences

In a second-price procurement auction the lowest bidder wins and is paid the second-lowest bid. Bidding one's cost is weakly dominant, by the mirror of Proposition 14.22. The expected price is the expected second-lowest cost, $\mathbb{E}[C_{(2:n)}]$. With uniform costs this equals $\frac{2}{n+1}$, the same as in Example 14.92, as revenue equivalence requires.

Procurement agencies often refuse bids above a maximum acceptable price, frequently set with reference to an internal engineer's estimate of the project's cost. This price is the procurement analogue of a reserve price. The optimal maximum price mirrors Corollary 14.47. Changing variables from costs to values $v = -c$ turns the virtual valuation (14.48) into the *virtual cost*

$$J(c) = c + \frac{F_c(c)}{f_c(c)}. \tag{14.115}$$

A buyer who values the project at u_0 should procure from the firm with the lowest virtual cost if that cost is below u_0. With a regular cost distribution (J increasing), any standard auction with maximum acceptable price r^* solving $J(r^*) = u_0$ is optimal. With uniform costs on $[0, 1]$, $J(c) = 2c$ and $r^* = \frac{u_0}{2}$ whenever $u_0 \leq 2$.

With asymmetric firms, the strong firm is the one with the lower costs. Under the change of variables $v = -c$, the reverse hazard rate order on values becomes a hazard rate order on costs. The strong firm's cost distribution has the higher hazard rate $\frac{f_c(c)}{1-F_c(c)}$ at every c. The results of Section 14.10 then carry over. Low-cost firms inflate their bids more, the first-price auction sometimes awards the contract to a higher-cost firm, and the optimal auction favors high-cost firms. McAfee and McMillan (1989) apply this logic to government purchasing and international trade. A price preference for high-cost firms, such as domestic firms facing foreign rivals, makes the non-favored firms bid more aggressively against the strengthened favored bids. Competition rises and the procurement cost falls (Hortaçsu and Perrigne, 2021, Section 3.10, p. 123). Under a typical preference, the bids of non-favored firms are scaled up by a factor $\lambda > 1$ before the comparison with favored bids (Hortaçsu and Perrigne, 2021, p. 122).

Hortaçsu and Perrigne (2021, p. 123) note that the argument neglects the effect of the preference on the participation of low-cost firms that are not favored. Krasnokutskaya and Seim (2011) estimate an entry model of the Levin-Smith type with cost asymmetries for California highway procurement. With fixed participation, the procurement cost varies little with the level of the preference. With endogenous participation, the cost is minimized by a preference toward the large, low-cost firms, because it raises their participation. Marion (2007) studies the 5 percent preference ($\lambda = 1.05$) for small businesses in California road contracts. He compares state-funded contracts, which carry the preference, with federally funded ones, which do not. Small businesses participate and win more often in the former. A structural counterfactual

based on the inversion of Chapter 15 shows that the preference raises procurement costs by 3.8 percent. The main reason is that large, low-cost firms participate less (Hortaçsu and Perrigne, 2021, Section 3.10, p. 122). With entry, the logic of Section 14.11 can thus reverse the fixed-participation case for favoring weak bidders.

Procurement auctions appear throughout the empirical chapters. Detecting bid rigging in highway procurement (Porter and Zona, 1993) is studied in Chapter 13. Procurement auctions with unobserved project heterogeneity (Krasnokutskaya, 2011) are studied in Chapter 15. A merger between two bidders creates a bidder whose value is the larger of the two values, or whose cost is the smaller of the two costs. Its effect on prices has the structure of (14.106), and Chapter 11 discusses merger analysis more generally.

14.14 From Theory to Data

This section collects what auction theory hands to empirical work. Auctions are attractive to empirical economists because the elements of the game can be described with "an unusually high degree of confidence" (Athey and Haile, 2007, Section 1). Four features of the theory make this confidence useful.

First, the game form is known. The seller writes the rules of allocation and payment, and the researcher reads them. In Chapter 3 conduct was a free parameter to be estimated. In an auction the only behavioral assumption is equilibrium play under the stated information structure.

Table 14.12: From equilibrium to data: the inversions used in empirical work

Model and format	Equilibrium bid	Equation that inverts it	Use in Chapter 15
Private values, second-price or ascending	$\beta(v) = v$	Bids equal values. The price is $V_{(n-1:n)}$, with CDF (14.17)	Order-statistic inversion
Symmetric IPV, first-price	(14.29)	$v = b + \frac{G(b)}{(n-1)g(b)}$ (14.34)	Guerre et al. (2000)
Affiliated private values, first-price	Proposition 14.58	$v = b + \frac{G_{M\|B}(b\|b)}{g_{M\|B}(b\|b)}$ (14.68)	Li et al. (2002)
Asymmetric IPV, first-price	System (14.80)	$v_i = b_i + \left[\sum_{j\neq i} \frac{g_j(b_i)}{G_j(b_i)}\right]^{-1}$ (14.78)	Athey et al. (2011)
Asymmetric APV, first-price	No closed form	(14.68) for each bidder type, $v_i = b_i + \frac{G_{M_i\|B_i}(b_i\|b_i)}{g_{M_i\|B_i}(b_i\|b_i)}$	Campo et al. (2003)
Procurement, first-price	(14.111)	$c = b - \frac{1-G(b)}{(n-1)g(b)}$ (14.113)	Krasnokutskaya (2011)
Costly entry, mixed strategies	$\Pi(p) = K$ (14.97)	K equals expected post-entry profit (14.104)	Entry costs in Athey et al. (2011)
Common values, first-price	Proposition 14.58	Identifies only the distribution of $v(s,s)$	Tests of common values

Notes: G and g are the distribution and density of a rival's bid. $G_{M|B}$ is the distribution of the highest rival bid conditional on one's own bid. In each first-price row the right side depends only on observable bid distributions.

Second, equilibrium maps primitives into bids in ways that can be inverted. In second-price and ascending auctions with private values, dominant strategies make bids equal values. In first-price auctions, the first-order conditions (14.34), (14.68), (14.78) and (14.113) express each value or cost as the bid plus or minus a markdown. The markdown depends only on the

Table 14.13: Revenue and efficiency across auction formats: a synthesis

Environment	Expected revenue	Allocation	Results
Symmetric IPV, risk neutral	First-price = Dutch = second-price = English	All efficient	Proposition 14.43
Symmetric IPV, risk averse	First-price = Dutch > second-price = English	All efficient	Proposition 14.40
Symmetric affiliated values	English ≥ second-price ≥ first-price = Dutch	All efficient	Proposition 14.64
Asymmetric IPV	No general ranking. First-price higher in the uniform example	First-price inefficient and favors weak bidders. Open efficient	Proposition 14.76, Table 14.10
Symmetric entry, values learned after entry	Equal across standard formats. Seller earns welfare net of entry costs	Efficient among entrants. Entry random	Proposition 14.81
Asymmetric entry	No general ranking. Sealed bids attract weak entrants	Open efficient among entrants	Proposition 14.85
Collusion	Open and second-price auctions more vulnerable. Rings self-enforcing there	Ring leaves the open-auction allocation unchanged	Proposition 14.87, Proposition 14.89

Notes: IPV denotes independent private values. "Efficient" refers to the allocation among participating bidders in the symmetric increasing equilibrium. The ranking with risk aversion is due to Holt (1980) and Maskin and Riley (1984). Rankings for affiliated values hold in the symmetric model of Milgrom and Weber (1982).

distribution of rival bids. Since the bid distribution is observable, each bid can be converted into a value. Table 14.12 lists these inversions and where Chapter 15 uses them.

Third, the theory implies testable restrictions. Bid functions are increasing. Strong bidders' bids dominate weak bidders' bids in the reverse hazard rate order (Proposition 14.76). Formats are ranked by revenue under specific conditions, as Table 14.13 summarizes. Entry responds to format in predictable directions (Proposition 14.85), and collusion in open auctions leaves a footprint in sales with several strong bidders (Proposition 14.89).

Fourth, the theory marks the limits of what data can reveal. Athey and Haile (2007, Section 1) note that "identification of models with common values, risk aversion, or unobserved heterogeneity can be obtained only with strong a priori restrictions," particularly in ascending auctions. With common values, the first-order condition identifies only the distribution of the pivotal expected value $v(s,s)$ (Section 14.8). Private and common values cannot be distinguished from first-price bids with a fixed number of bidders and no reserve price (Athey and Haile, 2007, Section 7).

The choice of format illustrates how these pieces combine. Athey and Haile (2007, Section 7) list the considerations a seller must weigh. With asymmetries, first-price auctions may allocate inefficiently. They also tend to raise more revenue with private values, may be less susceptible to collusion and may be cheaper to administer. The format also changes entry when bidders are asymmetric. "In trading off these factors, a seller must understand the underlying structure of bidder demand and information that determines the significance of each factor." The theory in this chapter identifies the forces. Measuring their size requires the econometric methods of Chapter 15.

14.15 Bibliographic notes

Modern auction theory begins with Vickrey (1961). He introduced the second-price auction, noted the equivalence of the Dutch and first-price auctions and solved the first-price auction

with uniform values. Vickrey (1962) and Ortega-Reichert (1968) found that the standard formats raise the same expected revenue with independent private values. Wilson (1967, 1977) introduced common values and showed that prices can aggregate dispersed information. Milgrom (1979, 1981b) extended the aggregation result, and Milgrom (1981a) formalized good news. The self-selection approach of Harris and Raviv (1981), Myerson (1981) and Riley and Samuelson (1981) explained revenue equivalence and solved the optimal auction. Bulow and Roberts (1989) recast the optimal auction as monopoly pricing, and Bulow and Klemperer (1996) showed that one more bidder is worth more than optimal design. Holt (1980) and Maskin and Riley (1984) established the advantage of the first-price auction with risk-averse bidders, and Che and Gale (1998) studied budget constraints. Milgrom and Segal (2002) give the general envelope theorem behind the payment identity.

Milgrom and Weber (1982) is the central paper of the field. Its affiliated values model, its linkage principle and its disclosure results organize most later work on interdependent values. Engelbrecht-Wiggans et al. (1983) solved the first-price auction with one informed bidder, and Hendricks and Porter (1988) took that model to offshore drainage leases. Later work clarified the limits of the theory. The linkage principle can fail with multi-unit demand (Perry and Reny, 1999), and the English auction with common values has many equilibria (Bikhchandani et al., 2002). Existence of monotone equilibria in general settings is due to Athey (2001), McAdams (2003) and Reny and Zamir (2004). Uniqueness results are in Lebrun (1999), Maskin and Riley (2003) and McAdams (2007). Kagel and Levin (1986) documented the winner's curse in the laboratory.

Asymmetric first-price auctions were first solved in closed form by Griesmer et al. (1967) and Plum (1992). Maskin and Riley (2000) derived the general comparisons between strong and weak bidders, and Lebrun (1996, 1999) proved existence and uniqueness. Marshall et al. (1994) and Bajari (2001) developed numerical methods. Endogenous entry was introduced by Samuelson (1985) for bidders who know their values and by Levin and Smith (1994) for bidders who learn them after entry. Athey et al. (2011) combined entry with asymmetric bidders and derived the format comparisons that Chapter 15 tests, and Klemperer (2002, 2004) drew the policy lessons for format design. The theory of bidding rings starts with Robinson (1985), Graham and Marshall (1987) and McAfee and McMillan (1992). Marshall and Marx (2012) give a book-length account of rings, leakage and the mechanisms that real rings use. McAfee and McMillan (1989) studied preferences in government procurement, and Marion (2007) and Krasnokutskaya and Seim (2011) measured their costs once entry responds.

Krishna (2010) is the standard graduate textbook, and Milgrom (2004) presents the theory with an eye to practical design. McAfee and McMillan (1987) and Klemperer (1999) survey the literature of their time. Athey and Haile (2007) restate the theory in the form that econometric work needs and are the natural bridge to Chapter 15. Hortaçsu and Perrigne (2021, p. 84) list the main surveys of empirical work. Hendricks and Porter (2007) link auction theory, empirical practice and policy questions. Hortaçsu and Perrigne (2021) organize the empirical literature by the type of good sold, from timber, procurement and oil leases to online advertising, electricity, securities and spectrum. The methodological companion to their survey, Perrigne and Vuong (2021), covers the identification and estimation of auction models.

14.16 Exercises

1. *Power distributions.* Values are independent with $F(v) = v^\gamma$ on $[0, 1]$, where $\gamma > 0$, and there are $n \geq 2$ bidders.

(a) Use (14.23) to show that the expected revenue of the second-price auction without a reserve price is $1 - \frac{n}{\gamma(n-1)+1} + \frac{n-1}{\gamma n+1}$.

(b) Use the bid function of Example 14.34 to compute the expected revenue of the first-price auction. Show that both revenues equal $\frac{\gamma^2 n(n-1)}{(\gamma(n-1)+1)(\gamma n+1)}$, and explain why Proposition 14.43 predicts this.

(c) Compute each bidder's ex ante expected surplus. How does the relative shading $\frac{v-\beta(v)}{v}$ depend on γ, and why?

(d) Assume $\gamma \geq 1$ and $v_0 = 0$. Show that F is regular and that the optimal reserve price is $r^* = (1+\gamma)^{-\frac{1}{\gamma}}$. Check that $r^* = \frac{1}{2}$ when $\gamma = 1$.

2. *Reserve prices or more bidders?* Values are exponential with rate λ, and the seller's value is $v_0 = 0$.

(a) Use Corollary 14.47 to show that $r^* = \frac{1}{\lambda}$ for every number of bidders.

(b) With two bidders, use (14.23) to show that the second-price auction with reserve price r^* raises expected revenue $\frac{1}{\lambda}\left(2e^{-1} - \frac{1}{2}e^{-2}\right) \approx \frac{0.668}{\lambda}$, against $\frac{1}{2\lambda}$ without a reserve price.

(c) Show that a second-price auction with three bidders and no reserve price raises $\frac{5}{6\lambda}$. Relate the comparison to Proposition 14.48, and explain what the proposition assumes about the cost of attracting the third bidder.

3. *Risk aversion with general distributions.* Bidders have the utility $\mathcal{U}(x) = x^a$ with $0 < a \leq 1$, and values are independent with distribution F on $[0, \bar{v}]$.

(a) Use (14.40) to show that the symmetric first-price bid is $\beta_u(v) = v - \int_0^v \left(\frac{F(t)}{F(v)}\right)^{\frac{n-1}{a}} dt$.

(b) Interpret this formula. A bidder with relative risk aversion $1 - a$ bids like a risk-neutral bidder who faces how many rivals?

(c) Use the argument of Proposition 14.36 to show that β_u falls in a. Deduce that the first-price auction raises more expected revenue than the second-price auction whenever $a < 1$, and check the result against Example 14.38.

4. *Asymmetric bidders in the open auction.* Use the example of Example 14.77 with $V_w \sim U[0,1]$ and $V_s \sim U[0,2]$.

(a) Use (14.74) to show that in the second-price auction the weak bidder's ex ante expected payoff is $\frac{1}{12}$ and the strong bidder's is $\frac{7}{12}$.

(b) Verify that expected revenue equals expected total surplus minus the two payoffs, and that it equals $\frac{5}{12}$.

(c) Explain, using Proposition 14.76, why the weak bidder gains and the strong bidder loses when the seller switches to the first-price auction. Which bidder would lobby for each format?

5. *Entry with two potential bidders.* Two potential bidders with values uniform on $[0,1]$ decide whether to pay an entry cost K before learning their values. Entrants bid in a second-price auction with no reserve price, and $v_0 = 0$.

(a) Use Lemma 14.79 to show that $\Pi(p) = \frac{1}{2} - \frac{p}{3}$. Derive the symmetric entry equilibrium p^* for every $K > 0$.

(b) For $K \in \left(\frac{1}{6}, \frac{1}{2}\right)$, show that expected revenue is $\frac{(p^*)^2}{3}$ and that it equals expected welfare $\mathbb{E}[S(X)] - 2p^*K$, as (14.99) states.

(c) For the same range of K, use Proposition 14.81 to show that no reserve price above zero raises the seller's expected revenue. Explain the difference from Corollary 14.47, and explain why the conclusion can fail when $K < \frac{1}{6}$.

6. *A merger of bidders.* In a second-price auction with $n \geq 3$ bidders and values independent and uniform on $[0, 1]$, bidders 1 and 2 merge. The merged bidder's value is $\max\{V_1, V_2\}$, and the other bidders are unaffected.

(a) Show that the price changes only when bidders 1 and 2 hold the two highest values, and that the price then falls from the second-highest to the third-highest value.

(b) Show that the expected price falls by $\frac{2}{n(n-1)(n+1)}$. Check the answer for $n = 3$ by computing the expected minimum of the merged bidder's value and V_3 directly.

(c) Compare the merger with a bidding ring of two members (Proposition 14.87). Then explain why the effect of the same merger on a first-price auction is harder to compute. Relate your answer to the merger simulations of Chapter 11.

7. *What auction data reveal.* Answer in words, citing the relevant results of this chapter.

(a) Under symmetric independent private values, explain why the distribution of transaction prices in English auctions with a known number of bidders determines F. Which step of the argument fails when values are affiliated?

(b) In the first-price auction, explain why the inversion (14.34) does not distinguish private from common values when the number of bidders is fixed.

(c) Explain why, under Proposition 14.89, a timber sale with a single participating mill carries no information about collusion among mills. Which sales are informative, and what pattern of prices would reveal collusion?

8. *Ring size, leakage and side payments.* Use Example 14.88, with n bidders whose values are independent and uniform on $[0, 1]$. The reserve price is zero except in part (a).

(a) Extend Example 14.88 to a reserve price $r \in (0, 1)$ and a ring of $k \geq 2$ members. Use (14.106) to show that, with $m = n - k$, the expected price reduction is

$$\mathbb{E}[\Delta P] = \frac{k(k-1)}{m+1} \int_r^1 x^{k-2}(1-x)\left(x^{m+1} - r^{m+1}\right) dx.$$

Show that it falls as r rises and that it reduces to Step 1 of the example when $r = 0$. Explain why a reserve price limits the damage that a ring does to the seller.

(b) Use the surplus expressions of Example 14.88. Compare the expected surplus of an outsider facing a ring of $k < n$ members with its expected surplus as a member of a ring of $k + 1$. Show that the outsider gains by joining and that each existing member gains by admitting it. Explain why every outsider wants to join a ring that operates at an ascending auction.

(c) Use the first-price columns of Table 14.11 to explain why outsiders gain from a ring at a sealed-bid auction. Explain why this leakage can lead an outsider to refuse to join a large ring.

(d) A ring uses the payment rule (14.108). Four members report 10, 8, 6 and 5 for a lot that the ring wins at the price $P = 4$. Show that the three losing members receive $\frac{17}{12}$, $\frac{5}{12}$ and $\frac{1}{6}$, and that these sum to the winner's payment $\frac{r_2 - P}{2} = 2$. Show that the member who reported 6 gains $\frac{1}{4}$ for each unit by which it raises its report, as long as the report stays below 8. Explain how such overreporting can lead the ring to pay more than any member's value.

Chapter 15

Identification and Estimation of Single-Object Auctions

Auctions are the setting in which the structural program of empirical industrial organization, outlined in Chapter 1, works best. In Chapter 3 the way firms compete was itself unknown, so conduct entered the model as a parameter to be estimated. In an auction the seller writes down the rules. The researcher knows who wins and what each bidder pays as a function of the bids. The only behavioral assumption left is that bidders play an equilibrium (Athey and Haile, 2007, Section 1). Chapter 14 derived how bidders behave, given the joint distribution of their values and information. This chapter runs the argument in reverse. It asks what observed bids reveal about the distribution that generated them and how to estimate that distribution. It then uses the estimates to answer questions about reserve prices, auction formats, entry and collusion.

The central idea fits in one display. In a first-price auction with n symmetric bidders whose values are independent, let G and g be the distribution and density of a rival's bid. A bidder who bids b must then have the value

$$v = b + \frac{G(b)}{(n-1)\, g(b)}.$$

The right side involves only the bid and the distribution of bids, which the data reveal. Each bid therefore maps into the value that rationalizes it, and no equilibrium needs to be computed. The formula is the auction counterpart of recovering marginal cost from a pricing first-order condition once demand has been estimated (Chapters 4 and 8). Here the distribution of rival bids plays the role of the demand curve. Much of the chapter extends this inversion to richer models and asks what remains identified when the data are poorer.

Five questions organize the chapter. Which primitives are identified from which data? How should they be estimated, and how fast do the estimators converge? How can the information structure be tested, in particular private against common values? How should we handle heterogeneity that bidders see and the econometrician does not, and participation that responds to the auction's features? What does a complete application look like, from reduced-form evidence to counterfactual policy?

The chapter is organized as follows. Section 15.1 defines the primitives, the observables, and what identification and testability mean. Section 15.2 treats second-price and ascending auctions, where bids equal values but some bids are never observed. It also covers the bounds that survive when the button model of the English auction fails. Sections 15.3 and 15.4 turn to first-price auctions. The first studies direct parametric methods and the simulated estimator

of Laffont et al. (1995). The second develops the indirect approach of Guerre et al. (2000) in full. Sections 15.5 to 15.8 relax the maintained assumptions one at a time. They cover affiliated and asymmetric private values, common values, unobserved auction heterogeneity, and entry, dynamics and risk aversion. Section 15.9 then follows the timber study of Athey et al. (2011) from question to counterfactuals. Section 15.10 reviews tests for collusion and the auction designs that make bidding rings harder to run. Section 15.11 turns to divisible goods, such as Treasury bills and central bank loans, for which bidders submit demand schedules. Section 15.12 collects the identification results in one map. Table 15.2 summarizes the plan. Apart from the short treatment of divisible goods in Section 15.11, this book treats single-unit auctions only. Auctions of several different objects, such as spectrum licenses, raise separate problems.

The chapter leans on the rest of the book in several places. Chapter 14 supplies the equilibrium theory, and we recall its results by reference instead of deriving them again. The analysis of bidding rings connects to the cartel theory of Chapter 12 and to the bid-rigging and knockout studies of Chapter 13. Appendix A reviews the econometric tools used here, including kernel density estimation, the delta method, the bootstrap, simulation estimators and matching. Appendix B collects the results on order statistics, characteristic functions, affiliation and log-concavity. Most sections close with the empirical magnitudes found in timber, procurement and offshore oil auctions. For studies that we summarize without a full treatment, we rely on the survey of Hortaçsu and Perrigne (2021) and cite its pages.

15.1 The Structural Approach to Auction Data

This section sets up the framework that the rest of the chapter uses. It defines the primitives and the observables, states the sampling assumptions, gives precise definitions of identification and testability, and previews the two broad estimation strategies that the later sections develop.

Auctions suit this program for the reasons given in Section 14.1.1. Bids, prices, the number of bidders and often the identities of the bidders are recorded. Above all, the seller writes down the rules, so the mapping from bids to the allocation and to payments is known to the researcher. Athey and Haile (2007, Section 1) observe that the primitives of any strategic model are the players, the information structure, the rules of play and the players' objectives. In auction markets these elements can be described with unusual confidence. The only behavioral assumption left is equilibrium play.

The structural approach targets questions that bids alone cannot answer. Athey and Haile (2007, Section 1) list several. Some concern the division of rents in auctions of public resources, the adequacy of reserve prices in government auctions, and the effects of mergers between bidders on procurement costs. The last is a merger simulation of the kind studied in Chapter 11, with the advantage that the game form is known. Others concern the revenue consequences of changing the auction rules, the efficiency of bundling procurement contracts and the value of seller reputations. Still others concern information-acquisition costs, adverse selection created by private information, and risk aversion. Each question needs the distribution functions that describe bidders' demand and information. They add a methodological point. Economic theory shapes many parts of an empirical model, but it rarely says anything about the distributions of unobservables. Much of what auction data can teach us does not depend on such distributional assumptions (Athey and Haile, 2007, Section 1).

15.1.1 Primitives and observables

A single indivisible object is sold to one of $n \geq 2$ risk-neutral bidders. Bidder i has a value V_i for the object and private information summarized by a signal S_i. Upper-case letters denote random variables and lower-case letters their realizations. The general model of Section 14.3 specifies the joint distribution of values and signals. The two classes of models in Definition 14.8 differ in whether a rival's signal is informative about one's own value. In a *private values* (PV) model it is not, and we normalize $S_i = V_i$. The primitive is then the joint distribution F_V of the vector of values $\boldsymbol{V} = (V_1, \ldots, V_n)$. In the *independent private values* (IPV) model, $F_V(\boldsymbol{v}) = \prod_{i=1}^{n} F_i(v_i)$. In the *symmetric* IPV model (SIPV), every F_i equals a common F with density f. In a *common values* (CV) model a bidder would revise her expected value if she learned a rival's signal (Athey and Haile, 2002, p. 2110). Its primitive is the joint distribution of values and signals.

We maintain the setting of Athey and Haile (2002, Section 2.1) unless a section says otherwise. The number of bidders is common knowledge and there is no reserve price. Bidders play a Bayesian Nash equilibrium in weakly undominated strategies, symmetric when bidders are symmetric. Ascending auctions follow the button model of Definition 14.2, in which bidders exit observably and irrevocably as the price rises.

The data never contain values. Athey and Haile (2002, Section 2.2) distinguish what is always observed from what is sometimes observed. The econometrician always sees the number of bidders n_t and the transaction price P_t of each auction t. With asymmetric bidders, the set of participants is also known. The following may or may not be available:

(i) bids other than the transaction price,

(ii) bidder identities, in particular the identity I_t of the winner,

(iii) *auction covariates* Z_t, such as the appraised value of the object or its realized ex post value,

(iv) *bidder covariates* W_{it}, such as firm size, location, distance to the project or backlog.

The format determines which bids exist. A sealed-bid auction can record every bid. A Dutch auction stops at the first bid, so only the winning bid exists. An ascending auction ends when the next-to-last bidder drops out, so the price at which the winner would have exited is never revealed (Section 14.4.4).

A last type of information is variation in the number of bidders. Participation is *exogenous* if the joint distribution of the signals of any subset of bidders does not depend on which other bidders participate (Athey and Haile, 2002, p. 2113). Exogenous variation arises, for example, when potential bidders draw participation costs that are independent of their values, when a seller restricts participation, or by design in field experiments.

Throughout, we observe T auctions indexed by $t = 1, \ldots, T$, and T_n of them have n bidders. Two sampling assumptions underlie everything that follows. First, auctions are independent, and the values and signals in each auction are drawn from the same distribution, conditional on any auction covariates. Second, the same equilibrium is played in all auctions with the same observables. Without the second assumption, the observed distribution of rivals' bids would mix several equilibria and would not represent the beliefs of a bidder in any one auction (Athey and Haile, 2007, footnote 18). Dependence across auctions, such as the effect of a backlog of contracts won earlier, is excluded here and studied in Section 15.8. Values and bids have continuous distributions, so ties occur with probability zero. All asymptotic statements let $T \to \infty$, with $T_n \to \infty$ for every n that is used.

15.1.2 Identification and testability

The general notion of identification in Appendix A specializes neatly to auctions. Let $\mathbb{F}$ be a set of joint distributions of the latent variables (values and signals). Let $\mathbb{H}$ be the set of all joint distributions of the observable variables. Let Γ be a collection of mappings $\gamma : \mathbb{F} \to \mathbb{H}$. Each γ sends a distribution of primitives to the distribution of observables that equilibrium play in a given auction game implies. Following Athey and Haile (2002, p. 2114), a *model* is a pair $(\mathbb{F}, \Gamma)$. Implicit in the specification is the assumption that the model contains the true structure.

Definition 15.1 (Identification, Athey and Haile, 2002)**.** A model $(\mathbb{F}, \Gamma)$ is *identified* if for every $(F, \tilde{F}) \in \mathbb{F}^2$ and $(\gamma, \tilde{\gamma}) \in \Gamma^2$, the equality $\gamma(F) = \tilde{\gamma}(\tilde{F})$ implies $(F, \gamma) = (\tilde{F}, \tilde{\gamma})$.

Definition 15.2 (Testability, Athey and Haile, 2002)**.** A model $(\mathbb{F}, \Gamma)$ is *testable* if $\bigcup_{\gamma \in \Gamma,\, F \in \mathbb{F}} \gamma(F) \neq \mathbb{H}$, that is, if some distributions of observables cannot be generated by the model.

In most of this chapter Γ contains a single mapping, the equilibrium of a given auction game. Identification then means that the distribution of observables determines F uniquely. A model is *partially identified* when the observables determine only some features of F, or only bounds on it (Athey and Haile, 2007, Section 1). Testability means that equilibrium behavior in the model places refutable restrictions on the data.

Three remarks clarify how these definitions are used. First, equilibrium bidding is maintained throughout. A rejection is therefore read as evidence against the assumptions on primitives, such as independence or symmetry. Equilibrium play itself is never the hypothesis under test (Athey and Haile, 2002, p. 2114). Second, identification and estimation are distinct questions. Identification asks what the observables could reveal with an infinite sample. Estimation asks how to approximate that answer in a finite sample, and it may well use parametric families. When a model is identified nonparametrically, a parametric specification becomes a parsimonious approximation rather than a maintained hypothesis about the true structure (Athey and Haile, 2002, p. 2109, following Roehrig, 1988). Third, a nonidentification result is informative as well. It shows which models generate the same data, and so which conclusions rest on assumptions rather than on evidence.

15.1.3 Two routes from bids to primitives

There are two broad ways to estimate the primitives, and Figure 15.1 contrasts them. The *direct* route specifies a parametric family $F(\cdot; \theta)$, solves for the equilibrium bid function $\beta(\cdot; \theta)$, derives the implied likelihood or moments of the bids, and fits them to the data (Paarsch, 1992; Donald and Paarsch, 1996; Laffont et al., 1995). The *indirect* route of Guerre et al. (2000) starts from the bids. It estimates their distribution, inverts each bidder's first-order condition to recover the value that rationalizes each bid, and then estimates F from these *pseudo-values*. In second-price and ascending auctions with private values both routes are simple, because the bid function is the identity. The difficulty there is that some bids are not observed (Section 15.2). In first-price auctions the two routes differ sharply (Section 15.3 and Section 15.4).

Table 15.1 collects the notation of the chapter. It follows Table 14.2 with three changes. We write order statistics with a superscript, $V^{(k:n)}$, which frees the subscript for the auction index t. We write V_i and S_i where Athey and Haile (2002, 2007) write U_i and X_i. The symbol ξ denotes an inverse bid function written through the bid distribution, a local use unrelated to the unobserved product quality ξ_{jt} of the demand chapters. Table 15.2 previews the chapter.

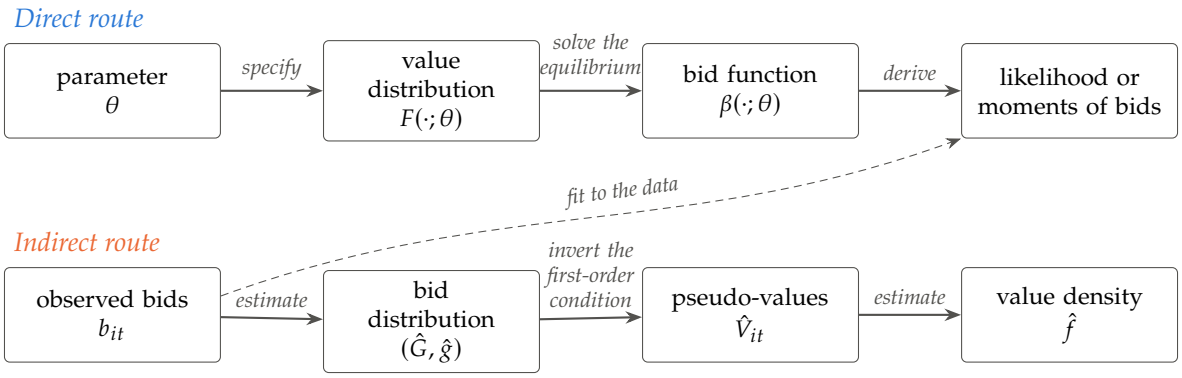

Figure 15.1: Two routes from bids to the value distribution. The direct route solves the equilibrium for every trial parameter and compares implied and observed bids. The indirect route inverts the bidders' first-order condition once, bid by bid, and never solves for the equilibrium.

Table 15.1: Notation for the empirical analysis of auctions

Symbol	Meaning
t, T, T_n	auction index, number of auctions, number of auctions with n bidders
n, N	number of participating bidders and of potential bidders (entry and reserve sections)
V_{it}, v	value (random variable and realization)
S_{it}	signal
$F, f, F_i, F_{\mathbf{V}}$	value distribution and density, bidder-specific version, joint distribution
B_{it}, b	bid (random variable and realization)
G, g, G_i	CDF and density of one bidder's equilibrium bid, bidder-specific version
$M_{it} = \max_{j\neq i} B_{jt}$	highest rival bid
$V^{(k:n)}, B^{(k:n)}$	k-th lowest of n values or bids
$F_{(k:n)}$	CDF of $V^{(k:n)}$
$\Lambda_{k:n}, \Lambda_n \equiv \Lambda_{n-1:n}$	map from $F(v)$ to $F_{(k:n)}(v)$, (15.1)
P_t, B_t^w, I_t	transaction price, winning bid of a first-price or Dutch auction, identity of the winner
$\xi(b;G,n), \xi_i$	inverse bid function written through bid distributions
$\hat{V}_{it}$	pseudo-value
$\mathcal{K}, h$	kernel and bandwidth
r, v_0	reserve price and seller's value for the object
Z_t, W_{it}	auction covariates and bidder covariates (never instruments in this chapter)
ω_t	auction heterogeneity known to bidders but not to the econometrician
A_{it}	idiosyncratic component of a value or cost
θ	parameter of a parametric value distribution (Section 15.3)
C_{it}, c, F_c	procurement cost and its distribution
K	entry (information acquisition) cost

Table 15.2: Roadmap of the chapter

Section	Format and data	Main result	Key papers
15.2	ascending or second price, with the price and possibly other bids, identities and covariates	IPV identified from the price alone, correlated PV not identified from incomplete bids, bounds without the button model	Athey and Haile (2002), Haile and Tamer (2003)
15.3	first price or Dutch, winning bid or all bids, parametric F	non-regular likelihood, simulated least squares through revenue equivalence	Donald and Paarsch (1996), Laffont et al. (1995)
15.4	first price, all bids	inversion of the first-order condition, optimal nonparametric rates	Guerre et al. (2000)
15.5	first price, all bids or the top two	affiliated and asymmetric private values	Li et al. (2002), Campo et al. (2003)
15.6	all formats, variation in n, ex post values	common values not identified, tests of private against common values	Athey and Haile (2002), Hendricks and Porter (1988)
15.7	first price, two or more bids, reserve prices	unobserved auction heterogeneity	Krasnokutskaya (2011), Roberts (2013)
15.8	all formats, potential bidders	entry costs, dynamics and risk aversion	Jofre-Bonet and Pesendorfer (2003)
15.9, 15.10	sealed and open timber sales, bid records of suspected rings	asymmetry, heterogeneity, entry and collusion in one application, tests for rings	Athey et al. (2011), Marshall and Marx (2012)
15.11	divisible goods sold by uniform or discriminatory pricing, step demand schedules	marginal values recovered step by step from the distribution of the clearing price	Kastl (2011), Cassola et al. (2013)
15.12	all formats	an identification map	Athey and Haile (2007)

15.2 Second-Price and Ascending Auctions

With private values, bidding one's value is weakly dominant in the second-price sealed-bid auction (Proposition 14.22). Exiting at one's value is weakly dominant in the button auction (Proposition 14.26). The bid function is the identity, so there is no inverse bid function to estimate. Identification is nonetheless not trivial. An ascending auction stops as soon as one bidder remains, so the only information about the winner's value is the censoring point, the transaction price (Athey and Haile, 2007, Section 4.1). The question in this section is therefore which order statistics of the bids are observed, and what each data configuration reveals under each model. We start with the richest data and remove pieces.

15.2.1 All bids observed in a second-price auction

Proposition 15.3 (All bids in a second-price auction)**.** *In a second-price sealed-bid auction with private values, suppose all bids and the bidders' identities are observed. Then the joint distribution of values $F_{\mathbf{V}}$ is identified. In the SIPV model, $F(v) = \mathbb{P}(B_{it} \le v)$.*

Proof. By Proposition 14.22, $B_{it} = V_{it}$ for every bidder, whatever the joint distribution of values. The observed joint distribution of the vector of bids, indexed by identity, is therefore $F_{\mathbf{V}}$. Under SIPV each bid is a draw from F. □

The natural estimator in the SIPV model pools all bids,

$$\hat{F}(v) = \frac{1}{\sum_{t=1}^{T} n_t} \sum_{t=1}^{T} \sum_{i=1}^{n_t} \mathbf{1}(b_{it} \le v).$$

It is unbiased. By the Glivenko-Cantelli theorem it converges to F uniformly with probability one, and at each v the scaled error $\big(\sum_t n_t\big)^{\frac{1}{2}}\big(\hat{F}(v) - F(v)\big)$ is asymptotically normal with variance $F(v)\big(1 - F(v)\big)$. If values may be correlated within an auction, the estimator remains consistent for the marginal distribution. Standard errors must then treat the auction as the unit of observation, for example by resampling whole auctions (Section A.9.2).

Three remarks place the result. First, it needs private values but neither symmetry nor independence, because truthful bidding is dominant for any distribution of values. Second, with all bids observed the unrestricted PV model is identified but not testable. For a fixed n, any distribution of bids is rationalized by setting the distribution of values equal to it (Athey and Haile, 2002, p. 2118, citing Laffont and Vuong, 1996). Restricted models are testable. Under IPV bids within an auction must be independent, and under symmetry their joint distribution must be exchangeable. Third, second-price sealed-bid auctions are rare in practice (Athey and Haile, 2007, footnote 2). Proxy bidding on internet platforms resembles a second-price auction, but bidders there can often observe and react to rivals' bids, so the analogy is only approximate (Athey and Haile, 2007, footnote 2). Earlier work cited by Athey and Haile (2002, footnote 2) treats such bids as coming from standard second-price auctions.

15.2.2 Only the transaction price: order-statistic inversion

Consider now an SIPV button auction in which only the transaction price and the number of bidders are recorded. By (14.22), with no reserve price the price is the second-highest value,

$P_t = V_t^{(n-1:n)}$. The distribution of any order statistic of n i.i.d. draws is a known function of the parent distribution (Proposition 14.21):

$$F_{(k:n)}(v) = \Lambda_{k:n}\big(F(v)\big), \qquad \Lambda_{k:n}(x) \equiv \frac{n!}{(n-k)!\,(k-1)!}\int_0^x s^{k-1}(1-s)^{n-k}\,ds. \tag{15.1}$$

This is equation (5) of Athey and Haile (2002) and the case $k = n-1$ is (14.17). The derivative

$$\Lambda'_{k:n}(x) = \frac{n!}{(n-k)!\,(k-1)!}\,x^{k-1}(1-x)^{n-k}$$

is the beta density with parameters k and $n-k+1$. It is positive on $(0,1)$, so $\Lambda_{k:n}$ is the beta CDF, a strictly increasing bijection of $[0,1]$. We write $\Lambda_n \equiv \Lambda_{n-1:n}$, which equals $\Lambda_n(x) = nx^{n-1} - (n-1)x^n$, with $\Lambda'_n(x) = n(n-1)x^{n-2}(1-x)$. Figure 15.2 plots Λ_n for several n.

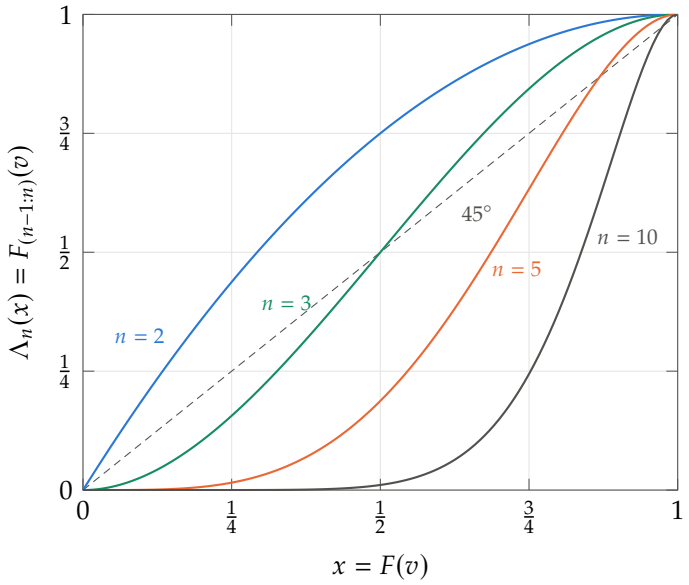

Figure 15.2: The map Λ_n from the value distribution to the distribution of the transaction price, $\Lambda_n(x) = nx^{n-1} - (n-1)x^n$. Each curve is strictly increasing, so the price distribution determines F. The curves are flat near $x = 0$ when n is large, which is why the lower tail of F is hard to recover from prices.

Theorem 15.4 (Athey and Haile, 2002, Theorem 1)**.** *In the SIPV model of the ascending or second-price auction:*

(i) F is identified from the distribution of the transaction price, and more generally from the distribution of any single order statistic $B^{(k:n)}$ with known n.

(ii) The model is testable if either (a) more than one bid per auction is observed, or (b) transaction prices are observed from auctions with exogenously varying numbers of bidders.

Proof. (i) Bids equal values, so $B^{(k:n)} = V^{(k:n)}$ and the observed CDF of $B^{(k:n)}$ in n-bidder auctions, $G_B^{(k:n)}$, equals $F_{(k:n)}$. By (15.1),

$$G_B^{(k:n)}(v) = \Lambda_{k:n}\big(F(v)\big) \quad \text{for all } v.$$

Since $\Lambda_{k:n}$ is strictly increasing and continuous, it has a continuous inverse, and

$$F(v) = \Lambda_{k:n}^{-1}\big(G_B^{(k:n)}(v)\big).$$

The transaction price is $B^{(n-1:n)}$, the case $k = n-1$. Under SIPV the marginal F determines $F_V = \prod_i F(v_i)$.

(ii) Suppose the distributions of two order statistics $B^{(k:n)}$ and $B^{(k':n')}$ are observed, with $(k,n) \neq (k',n')$. Under the model each implies a value distribution, and the two must coincide:

$$\Lambda_{k:n}^{-1}\big(G_B^{(k:n)}(v)\big) = \Lambda_{k':n'}^{-1}\big(G_B^{(k':n')}(v)\big) \quad \text{for all } v.$$

Pairs of distributions that violate this equality are easy to construct, so the restriction is refutable. Case (a) supplies two order statistics from the same auctions. In case (b), exogenous participation guarantees that the same F governs auctions with different n. □

The result rests on independence and symmetry, and both can fail in ways the test detects. Independence is testable even with a single bid per auction, because (15.1) dictates exactly how the price distribution must move with n. The restriction fails in natural examples with asymmetric or strictly affiliated values (Athey and Haile, 2002, footnote 20). The test also has power against the button model itself. In free-form oral auctions recorded bids often understate willingness to pay. Comparing estimates from low-ranked bids with estimates from high-ranked bids then measures how far bidders fall short of their values (Athey and Haile, 2002, footnote 19).

Example 15.5 (Two and three bidders)**.** With $n = 2$, the price is the lower of two values and $\Lambda_2(x) = 2x - x^2$. Let H_2 denote the CDF of the price in two-bidder auctions. Then

$$1 - H_2(v) = 1 - 2F(v) + F(v)^2 = \big(1 - F(v)\big)^2, \qquad \text{so} \qquad F(v) = 1 - \sqrt{1 - H_2(v)}.$$

The survival function of the minimum is the square of the survival function of one value. With $n = 3$, $\Lambda_3(x) = 3x^2 - 2x^3$, and $F(v)$ is the unique root in $[0,1]$ of the cubic $3x^2 - 2x^3 = H_3(v)$. Since $\Lambda_3(\frac{1}{2}) = \frac{3}{4} - \frac{1}{4} = \frac{1}{2}$, the median price in three-bidder auctions equals the median value. The second-highest of three draws is their median, and the median of three draws has the same median as each draw.

Estimation. The identification argument is constructive. Following Athey and Haile (2007, Section 4.2), let

$$\hat{H}_n(v) = \frac{1}{T_n} \sum_{t=1}^{T} \mathbf{1}\big(n_t = n,\ P_t \le v\big)$$

be the empirical CDF of prices in n-bidder auctions. Its population counterpart is the price CDF $H_n(v) = \Lambda_n\big(F(v)\big)$. The estimator is $\hat{F}(v) = \Lambda_n^{-1}\big(\hat{H}_n(v)\big)$. It is computed at each v by bisection, which is fast because Λ_n is monotone. Uniform consistency of $\hat{H}_n$ carries over to $\hat{F}$ through the continuity of Λ_n^{-1}.

The delta method (Theorem A.59) gives the precision of $\hat{F}$. At a point v with $H_n(v) \in (0,1)$, the empirical CDF satisfies

$$\sqrt{T_n}\big(\hat{H}_n(v) - H_n(v)\big) \xrightarrow{d} N\Big(0,\ H_n(v)\big(1 - H_n(v)\big)\Big).$$

The inverse function rule gives the derivative of the transformation,

$$\left.\frac{d\Lambda_n^{-1}(y)}{dy}\right|_{y=H_n(v)} = \frac{1}{\Lambda_n'\big(\Lambda_n^{-1}(H_n(v))\big)} = \frac{1}{\Lambda_n'\big(F(v)\big)}.$$

Therefore

$$\sqrt{T_n}\big(\hat{F}(v) - F(v)\big) \xrightarrow{d} N\left(0,\ \frac{H_n(v)\big(1-H_n(v)\big)}{\Lambda_n'\big(F(v)\big)^2}\right), \qquad \Lambda_n'(x) = n(n-1)x^{n-2}(1-x). \tag{15.2}$$

The formula shows where prices are informative. In the lower tail, write $x = F(v)$ and let $x \to 0$. Then $H_n \approx nx^{n-1}$ and $\Lambda_n'(x) \approx n(n-1)x^{n-2}$, so the asymptotic variance in (15.2) behaves like

$$\frac{nx^{n-1}}{n^2(n-1)^2x^{2n-4}} = \frac{x^{3-n}}{n(n-1)^2}.$$

It vanishes with x when $n = 2$, stays at $\frac{1}{12}$ when $n = 3$, and explodes when $n \geq 4$. A low value sets the price only if $n-1$ values are low, an event of probability of order x^{n-1}, so prices carry little information about the lower tail. The upper tail is also poorly estimated. Expanding around $x = 1$ gives $1 - \Lambda_n(x) \approx \frac{n(n-1)}{2}(1-x)^2$ and $\Lambda_n'(x) \approx n(n-1)(1-x)$, so the asymptotic variance tends to $\frac{1}{2n(n-1)}$. The estimator from all n bids has asymptotic variance $\frac{x(1-x)}{n}$ per auction, which vanishes at both ends. With $n = 2$ the ratio of the two variances is $\frac{2-x}{2(1-x)}$, equal to one in the lower tail and unbounded in the upper tail. The price never reveals the winner's value.

Figure 15.3 illustrates these properties on simulated data. Panel (a) shows that 500 transaction prices from four-bidder auctions recover F well. Panel (b) shows that the delta-method formula tracks the bootstrap standard error closely. Compare it with the benchmark in which all bids are observed. At the median value the price-only standard error is 24 percent larger, and at $v = 0.5$, where $F = 0.08$, it is more than four times larger (our calculation from the simulation).

Exogenous variation in n yields one estimator $\Lambda_n^{-1}(\hat{H}_n)$ for each value of n in the data. If losing bids also follow the button model, each further order statistic yields another estimator through $\Lambda_{k:n}^{-1}$. An efficient estimator would take an optimally weighted average of these estimators and impose monotonicity of the estimated CDF (Athey and Haile, 2007, Section 4.2). The differences among them are the basis of the specification tests in Theorem 15.4(ii).

15.2.3 Asymmetric independent private values: competing risks

Independence alone suffices for identification from a single bid, provided we also observe who won. The argument borrows from the statistics of *competing risks*. A system fails as soon as one of its components fails, and we observe the failure time and the component that failed. Up to a change of sign, this is the same as observing the highest bid and the identity of the highest bidder (Athey and Haile, 2002, footnote 21).

Theorem 15.6 (Athey and Haile, 2002, Theorem 2)**.** *In the asymmetric IPV model, assume that each F_i is continuous and that the support of F_i is the same for all i. Each F_i is identified if either*

(a) the transaction price $B^{(n-1:n)}$ and the identity of the winner are observed, or

(b) in a second-price auction, the highest bid $B^{(n:n)}$ and the identity of the winner are observed.

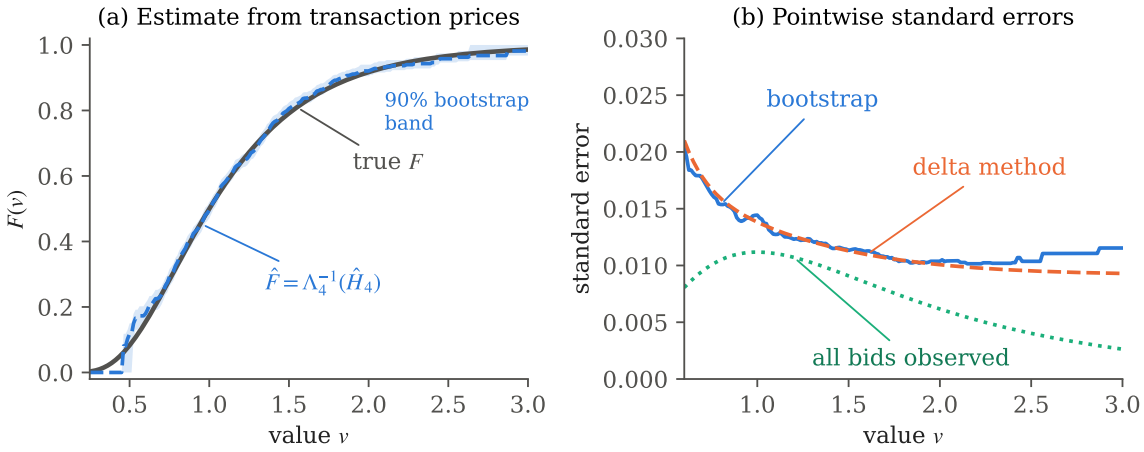

Figure 15.3: Price-only inversion in simulated button auctions. Our simulation: $T = 500$ auctions with $n = 4$ bidders, values lognormal with $\mu = 0$ and $\sigma = \frac{1}{2}$, seed 15201. Panel (a): true F, the estimate $\hat{F} = \Lambda_4^{-1}(\hat{H}_4)$, and a pointwise 90 percent band from 500 bootstrap samples of whole auctions. Panel (b): bootstrap standard error, the delta-method formula (15.2), and the standard error of the empirical CDF if all $4T$ values were observed. Panel (b) starts at $v = 0.6$ because few prices fall below that level.

Given (a) or (b), the model is testable in either of two cases.

(i) Participation is exogenous, and each bidder faces at least two different sets of opponents.

(ii) The auction is second price, and both (a) and (b) hold.

Independence is maintained in the theorem. What is relaxed relative to Theorem 15.4 is symmetry. We prove part (b) for any n, part (a) for $n = 2$, and then show the structure of part (a) for $n = 3$. The general case of part (a) is due to Meilijson (1981, Theorem 1 and Section 4), and part (b) follows from results collected by Prakasa Rao (1992, Theorem 7.3.1).

Proof of part (b). Let $\bar{u}$ be the upper end of the common support. For each bidder i define the observable sub-distribution

$$\tilde{G}_i(t) = \mathbb{P}\big(B^{(n:n)} \le t,\ I = i\big) = \int_{-\infty}^{t} f_i(x) \prod_{j \neq i} F_j(x)\, dx,$$

since bidder i wins with bid x when her value is x and every rival's value is below x. The CDF of the highest bid is $H(t) = \prod_j F_j(t) = \sum_i \tilde{G}_i(t)$, also observable. Differentiating $\tilde{G}_i$,

$$\tilde{g}_i(t) = f_i(t) \prod_{j \neq i} F_j(t) = H(t)\, \frac{f_i(t)}{F_i(t)}.$$

So the reverse hazard rate of V_i equals the observable ratio $\frac{\tilde{g}_i(t)}{H(t)}$. Since $\frac{f_i}{F_i} = \frac{d}{dt} \ln F_i$ and $\ln F_i(\bar{u}) = 0$, integrating from t to $\bar{u}$ gives

$$F_i(t) = \exp\left(- \int_t^{\bar{u}} \frac{\tilde{g}_i(x)}{H(x)}\, dx \right).$$

The right side is a functional of the distribution of observables. □

Proof of part (a) for $n = 2$. With two bidders the price is the lower value and the winner is the bidder with the higher value. For the event that bidder 2 wins at a price of at most t,

$$\tilde{G}_2(t) = \mathbb{P}\big(V_1 \le t,\ V_1 < V_2\big) = \int_{-\infty}^{t} f_1(x)\big(1 - F_2(x)\big)\,dx.$$

The price exceeds t only if both values do, so its CDF H satisfies $1 - H(t) = \big(1 - F_1(t)\big)\big(1 - F_2(t)\big)$. Dividing the density of $\tilde{G}_2$ by $1 - H$ gives

$$\frac{\tilde{g}_2(t)}{1 - H(t)} = \frac{f_1(t)\big(1 - F_2(t)\big)}{\big(1 - F_1(t)\big)\big(1 - F_2(t)\big)} = \frac{f_1(t)}{1 - F_1(t)},$$

the hazard rate of V_1. Integrating the hazard from the bottom of the support gives $F_1(t) = 1 - \exp\big(-\int_{-\infty}^{t} \frac{\tilde{g}_2(x)}{1-H(x)}\,dx\big)$. The same steps with the roles reversed identify F_2. □

With $n = 3$ the argument of Athey and Haile (2007, Section 4.1) shows the structure of the general case. Let $\underline{u}$ be the lower end of the support. Bidder 3 wins at a price of at most t in two disjoint cases. Either both rivals are below t and bidder 3 is above t, or bidder 3 is below t and above both rivals:

$$\begin{aligned}\tilde{G}_3(t) &= \mathbb{P}\big(V_1 \le t,\ V_2 \le t,\ V_3 \ge t\big) + \mathbb{P}\big(V_1 \le V_3,\ V_2 \le V_3,\ V_3 \le t\big) \\ &= F_1(t)F_2(t)\big(1 - F_3(t)\big) + \int_{\underline{u}}^{t} F_1(x)F_2(x)\,dF_3(x).\end{aligned}$$

Integration by parts gives $\int_{\underline{u}}^{t} F_1F_2\,dF_3 = F_1(t)F_2(t)F_3(t) - \int_{\underline{u}}^{t}(F_1F_2)'F_3\,dx$. Substituting and writing $F_1(t)F_2(t) = \int_{\underline{u}}^{t}(F_1F_2)'\,dx$,

$$\tilde{G}_3(t) = \int_{\underline{u}}^{t} \big(F_1(x)F_2(x)\big)'\big(1 - F_3(x)\big)\,dx.$$

Differentiating and rearranging, $(F_1F_2)' = \frac{\tilde{g}_3}{1-F_3}$. Integrating and taking logarithms,

$$\ln F_1(t) + \ln F_2(t) = \ln \int_{\underline{u}}^{t} \frac{\tilde{g}_3(x)}{1 - F_3(x)}\,dx \equiv R_3(t),$$

and cyclically $\ln F_1 + \ln F_3 = R_2$ and $\ln F_2 + \ln F_3 = R_1$. The coefficient matrix of this system in $(\ln F_1, \ln F_2, \ln F_3)$ has rows $(1,1,0)$, $(1,0,1)$ and $(0,1,1)$, and its determinant is -2. If the right sides were known, the system would give, for example, $\ln F_1 = \frac{1}{2}(R_3 + R_2 - R_1)$. The right sides themselves depend on the unknown distributions through $1 - F_j$, so the system is a fixed-point problem. Meilijson (1981) shows that it has a unique solution.

Testability follows the logic of Theorem 15.4. With exogenous participation, each set of opponents that bidder i faces delivers its own version of F_i, and the versions must agree. In a second-price auction with both (a) and (b), the two constructions above must deliver the same F_i.

Estimation. The structure suggests a likelihood (Athey and Haile, 2007, equation (4.7)). Bidder i wins at price p when some rival j has value exactly p, every other rival k has a value below

p, and V_i exceeds p. The density of this event is $\big(1 - F_i(p)\big) \sum_{j \neq i} f_j(p) \prod_{k \neq i,j} F_k(p)$, and the likelihood of a sample of prices p_t and winners I_t is

$$\mathcal{L} = \prod_{t=1}^{T} \big(1 - F_{I_t}(p_t)\big) \sum_{j \neq I_t} f_j(p_t) \prod_{k \neq I_t, j} F_k(p_t).$$

Parametric or semi-nonparametric maximum likelihood can be applied to it. Brendstrup and Paarsch (2006) develop a semi-nonparametric estimator of this kind. Nonparametric estimators from the competing-risks literature, such as the Kaplan-Meier estimator, are natural alternatives. Athey and Haile (2007, Section 3.3.1) make this suggestion for the closely related problem of Dutch auctions with asymmetric bidders.

15.2.4 Covariates

Real auctions sell heterogeneous objects, and bidders differ in observable ways. Covariates are usually a nuisance, but they can also be a source of identification.

Theorem 15.7 (Athey and Haile, 2002, Theorem 3)**.** *Let private values be $V_i = g_i(A_i, Z)$, where each g_i is an unknown function strictly increasing in A_i. Each F_{A_i} is continuous with the same support for all i. The auction covariates Z and the transaction price are observed, together with the identity of the winner if bidders are asymmetric.*

(i) If $A_1, \dots, A_n$ are independent conditional on Z, each conditional distribution $F_{V_i}(\cdot \mid z)$ is identified.

(ii) If $g_i(A_i, Z) = A_i + g_0(Z)$ for all i, and $A_1, \dots, A_n$ are mutually independent and independent of Z, then the distribution of $\boldsymbol{A}$ and the function g_0 are identified up to location.

(iii) The symmetric models in (i) and (ii) are testable with more than one bid per auction, or with transaction prices from auctions with exogenously varying numbers of bidders.

Proof. (i) Fix $Z = z$. Values are independent given z, so Theorem 15.4 (symmetric case) or Theorem 15.6 (asymmetric case) applies conditional on z.

(ii) Consider the symmetric case. Given $Z = z$ the price is $A^{(n-1:n)} + g_0(z)$, so its conditional CDF is

$$H_n(b \mid z) = \mathbb{P}\big(A^{(n-1:n)} \leq b - g_0(z)\big) = F_{A,(n-1:n)}\big(b - g_0(z)\big),$$

where $F_{A,(n-1:n)}$ is the CDF of the second-highest of the A_i. Let $q_\tau(z)$ be the τ-quantile of the price given z, and a_τ the τ-quantile of $A^{(n-1:n)}$. Then $q_\tau(z) = g_0(z) + a_\tau$, so

$$g_0(z) - g_0(z') = q_\tau(z) - q_\tau(z') \quad \text{for all } z, z',$$

and g_0 is identified up to an additive constant. A location normalization, such as $g_0(z_0) = 0$ at a reference point, fixes the constant. The price net of $g_0(Z)$ is then $A^{(n-1:n)}$, whose distribution identifies F_A by Theorem 15.4. The asymmetric case uses Theorem 15.6 instead.

(iii) Two order statistics, or two values of n, give two versions of $F_V(\cdot \mid z)$ in (i), or of F_A in (ii), and these must coincide. □

Part (ii) is the basis of *homogenization*. Write the price in auction t as

$$P_t = g_0(Z_t) + A_t^{(n_t - 1:n_t)} = \kappa(n_t) + g_0(Z_t) + \varepsilon_t, \qquad \kappa(n) = \mathbb{E}\big[A^{(n-1:n)}\big], \quad \mathbb{E}[\varepsilon_t \mid Z_t, n_t] = 0.$$

A regression of prices on covariates and on indicators for n estimates g_0, parametrically or flexibly. The homogenized prices $P_t - \hat{g}_0(Z_t)$ are then treated as prices of identical objects, and the inversion of Section 15.2.2 estimates F_A (Athey and Haile, 2007, equation (6.6)). If g_0 is estimated at the parametric rate, the first step does not change the asymptotic distribution of the nonparametric second step. The function g_0 is often of interest in its own right, since it measures how observables shift valuations. In first-price auctions the same idea requires that equilibrium bidding preserve the additive structure, which Lemma 15.49 establishes (Section 15.7.2 applies it to bids). Here it is immediate because bids equal values. Alternatives to homogenization are kernel smoothing over covariates, which Haile and Tamer (2003) apply to ascending auctions, and flexible mixtures for the conditional price distribution (Athey and Haile, 2007, Section 6.1.1).

Bidder covariates do more. They can identify models with arbitrary correlation among values, which the next subsection shows are not identified from bids alone. The idea comes from the Roy model, in which a worker chooses the sector that offers the highest wage, and we observe only that wage and the chosen sector (Athey and Haile, 2002, footnote 29). Suppose $V_i = g_i(W_i) + A_i$ and suppose for a moment that the maximum value is observed. Then

$$\mathbb{P}\big(V^{(n:n)} \le u \mid \boldsymbol{w}\big) = \mathbb{P}\big(A_i \le u - g_i(w_i)\ \forall i\big) = F_{\boldsymbol{A}}\big(u - g_1(w_1), \dots, u - g_n(w_n)\big).$$

The joint distribution of values is observed only along its diagonal. Variation in the indices $g_i(w_i)$, however, moves the point at which $F_{\boldsymbol{A}}$ is evaluated over all of $\mathbb{R}^n$. When $g_j(w_j)$ is very negative for every $j \neq i$, bidder i has the highest value with probability close to one, and variation in w_i traces out g_i (Athey and Haile, 2007, Section 6.2.1). The following result shows that the same logic works for any single order statistic, including the transaction price of an ascending auction.

Theorem 15.8 (Athey and Haile, 2007, Theorem 6.1)**.** *Assume the following.*

(i) $V_i = g_i(W_i) + A_i$ *for* $i = 1, \dots, n$.

(ii) $F_{\boldsymbol{A}}$ *has support* $\mathbb{R}^n$ *and a continuously differentiable density* $f_{\boldsymbol{A}}$.

(iii) A_i *and* W_j *are independent for all* i, j.

(iv) The support of $\big(g_1(W_1), \dots, g_n(W_n)\big)$ *is* $\mathbb{R}^n$.

(v) Each g_i *is continuously differentiable, with* $g_i(w) \to \infty$ *as* $w \to \infty$ *and* $g_i(w) \to -\infty$ *as* $w \to -\infty$.

Then $F_{\boldsymbol{A}}$ *and each* g_i *are identified up to location from the distribution of* $\big(V^{(j:n)}, \boldsymbol{W}\big)$*, for any single* $j \in \{1, \dots, n\}$.

The theorem allows arbitrary dependence among the A_i and arbitrary asymmetry. It is a slight modification of Theorem 5 of Athey and Haile (2002) that corrects a minor error in its proof (Athey and Haile, 2007, footnote 55). We give a direct proof for scalar covariates.

Proof. Write $\boldsymbol{z}(u, \boldsymbol{w}) = \big(u - g_1(w_1), \dots, u - g_n(w_n)\big)$. For a set of bidders $\mathcal{T} \subseteq \{1, \dots, n\}$ define

$$\bar{F}^{\mathcal{T}}(\boldsymbol{a}) = \mathbb{P}\big(A_i > a_i\ \forall i \in \mathcal{T},\ A_k \le a_k\ \forall k \notin \mathcal{T}\big),$$

so that $\bar{F}^{\emptyset} = F_{\boldsymbol{A}}$.

Step 1. The j-th lowest value is at most u exactly when at least j values are at most u. Equivalently, the set $\mathcal{T}$ of bidders with $V_i > u$ has at most $n - j$ members. Since $V_i > u$ if and only if $A_i > u - g_i(w_i)$,

$$\mathbb{P}\big(V^{(j:n)} \le u \mid \boldsymbol{w}\big) = \sum_{\mathcal{T}\,:\,|\mathcal{T}|\le n-j} \bar{F}^{\mathcal{T}}\big(\boldsymbol{z}(u,\boldsymbol{w})\big).$$

Step 2. Write $\bar{F}^{\mathcal{T}}$ as an integral of $f_{\boldsymbol{A}}$ over $a_i > z_i$ for $i \in \mathcal{T}$ and $a_k \le z_k$ for $k \notin \mathcal{T}$. Differentiating once in each z_k gives a plus sign for upper limits and a minus sign for lower limits, so

$$\frac{\partial^n \bar{F}^{\mathcal{T}}(\boldsymbol{z})}{\partial z_1 \cdots \partial z_n} = (-1)^{|\mathcal{T}|} f_{\boldsymbol{A}}(\boldsymbol{z}).$$

Step 3. Since $\frac{\partial z_k}{\partial w_k} = -g_k'(w_k)$, the chain rule gives

$$\frac{\partial^n}{\partial w_1 \cdots \partial w_n} \bar{F}^{\mathcal{T}}\big(\boldsymbol{z}(u,\boldsymbol{w})\big) = (-1)^{|\mathcal{T}|} f_{\boldsymbol{A}}(\boldsymbol{z}) \prod_{k=1}^{n} \big(-g_k'(w_k)\big).$$

Step 4. Summing over the sets in Step 1, there are $\binom{n}{m}$ sets of size m. The identity $\sum_{m=0}^{K}(-1)^m\binom{n}{m} = (-1)^K\binom{n-1}{K}$ follows from Pascal's rule by telescoping. With $K = n - j$ and the case $\mathcal{T} = \emptyset$ of Step 3,

$$\frac{\partial^n}{\partial w_1 \cdots \partial w_n} \mathbb{P}\big(V^{(j:n)} \le u \mid \boldsymbol{w}\big) = (-1)^{n-j}\binom{n-1}{n-j} \frac{\partial^n}{\partial w_1 \cdots \partial w_n} F_{\boldsymbol{A}}\big(\boldsymbol{z}(u,\boldsymbol{w})\big).$$

Step 5. Integrate each $\tilde{w}_k$ from w_k to ∞. As $\tilde{w}_k \to \infty$, $g_k(\tilde{w}_k) \to \infty$, so $z_k \to -\infty$ and $F_{\boldsymbol{A}} \to 0$. Repeated use of the fundamental theorem of calculus gives

$$\int_{w_1}^{\infty} \cdots \int_{w_n}^{\infty} \frac{\partial^n F_{\boldsymbol{A}}\big(\boldsymbol{z}(u,\tilde{\boldsymbol{w}})\big)}{\partial \tilde{w}_1 \cdots \partial \tilde{w}_n}\, d\tilde{w}_n \cdots d\tilde{w}_1 = (-1)^n F_{\boldsymbol{A}}\big(\boldsymbol{z}(u,\boldsymbol{w})\big).$$

Combining with Step 4,

$$F_{\boldsymbol{A}}\big(\boldsymbol{z}(u,\boldsymbol{w})\big) = \frac{(-1)^j}{\binom{n-1}{n-j}} \int_{w_1}^{\infty} \cdots \int_{w_n}^{\infty} \frac{\partial^n \mathbb{P}\big(V^{(j:n)} \le u \mid \tilde{\boldsymbol{w}}\big)}{\partial \tilde{w}_1 \cdots \partial \tilde{w}_n}\, d\tilde{w}_n \cdots d\tilde{w}_1,$$

which is equation (6.17) of Athey and Haile (2007). The right side is observable.

Step 6. Let $w_k \to -\infty$ for every $k \neq i$. Then $z_k \to \infty$ and the left side tends to $F_{A_i}\big(u - g_i(w_i)\big)$. This function of (u, w_i) is known. Since F_{A_i} is strictly increasing, any two points with the same value satisfy $u - g_i(w_i) = u' - g_i(w_i')$, so $g_i(w_i) - g_i(w_i') = u - u'$. Hence g_i is identified up to an additive constant. With the g_i known, condition (iv) lets us choose u and $\boldsymbol{w}$ with $\boldsymbol{z}(u,\boldsymbol{w})$ equal to any point $\boldsymbol{a} \in \mathbb{R}^n$, which identifies $F_{\boldsymbol{A}}(\boldsymbol{a})$. □

Two order statistics give two expressions for $F_{\boldsymbol{A}}$, and their equality is a testable restriction (Athey and Haile, 2002, Theorem 5(ii)). The result needs large support: bidder covariates must push every bidder's value far above and far below the others'. Estimators that exploit it had not been developed when Athey and Haile (2007, Section 6.2.1) wrote.

15.2.5 Correlated values: what incomplete bids cannot reveal

The positive results above lean on independence or on rich covariates. Without either, the picture changes.

Theorem 15.9 (Athey and Haile, 2002, Theorem 4)**.** *In the symmetric private values model:*

(i) F_V *is not identified from the vector of bids in an ascending auction.*

(ii) In a second-price auction, F_V *is not identified unless all bids are observed.*

Proof. We construct two exchangeable distributions that generate the same observables. Suppose f_V is positive on a neighborhood of $[0,5]^n$. Let the k-th order statistic be the one that is not observed, where $k = n$ in an ascending auction because the winner never exits. Fix $0 < \varepsilon < \frac{1}{2}$ and write $Q(c)$ for the cube of half-width ε centered at c.

Start with $n = 2$ and $k = 2$, so only $\min(V_1, V_2)$ is observed. Let

$$c(v) = \mathbf{1}_{Q(1,3)}(v) + \mathbf{1}_{Q(3,1)}(v) - \mathbf{1}_{Q(1,2)}(v) - \mathbf{1}_{Q(2,1)}(v),$$

and $\tilde{f}_V = f_V + \gamma c$ with $\gamma > 0$ below the minimum of f_V on the four squares. Then $\tilde{f}_V \geq 0$, and it integrates to one because the squares have equal areas. It is symmetric in (v_1, v_2), so it is exchangeable. On $Q(1,2)$ and $Q(1,3)$ the minimum is v_1, and the perturbation adds and removes the same uniform mass for v_1 on $[1-\varepsilon, 1+\varepsilon]$. The same holds on $Q(2,1)$ and $Q(3,1)$ with the roles of the coordinates reversed. Hence the distribution of $\min(V_1, V_2)$ is unchanged. The marginal density of V_1, however, gains $2\varepsilon\gamma$ on $[3-\varepsilon, 3+\varepsilon]$ and loses $2\varepsilon\gamma$ on $[2-\varepsilon, 2+\varepsilon]$. Two different joint distributions, with different marginals, generate the same observables.

For general n and k, partition the bidders into one bidder i, a set of $k-1$ bidders and a set of $n-k$ bidders. Consider the point at which the $k-1$ bidders have value 1, bidder i has value 2, and the $n-k$ bidders have value 4. Shift mass γ from the cube around this point to the cube around the point at which bidder i has value 3 instead. Repeat for every such partition, which preserves exchangeability. Each shift moves only the k-th order statistic, from near 2 to near 3, while every other order statistic keeps the same local distribution. The joint distribution of the observed order statistics is therefore unchanged (Athey and Haile, 2002, proof of Theorem 4). □

Figure 15.4 draws the construction. The intuition is a matter of dimension. Even under exchangeability, F_V is an n-dimensional distribution, and identifying it from data of dimension $n-1$ or lower requires additional restrictions (Athey and Haile, 2007, Section 3.3.2). The result generalizes a classic finding of the competing-risks literature, in which the joint distribution of risks is not identified from the distribution of the first failure time alone (Athey and Haile, 2002, footnote 26). Affiliation does not rescue identification, because a small enough perturbation preserves strict affiliation (Athey and Haile, 2002, footnote 27). The marginal F itself is not identified, so even the distribution of a single bidder's value is out of reach.

Taken together, Theorems 15.4, 15.6, 15.8 and 15.9 describe a trade-off. One may relax the data, observing only the transaction price, if values are independent. One may relax the model, allowing correlation, if the data are richer: all bids, or bidder covariates with large support. One cannot relax both at once. Aradillas-López et al. (2013) study the case in between. With correlated private values and transaction prices from auctions with exogenously varying numbers of bidders, F_V is not point identified. They show that the reserve-price question does not need all of F_V (Hortaçsu and Perrigne, 2021, pp. 88–89). In an ascending auction with

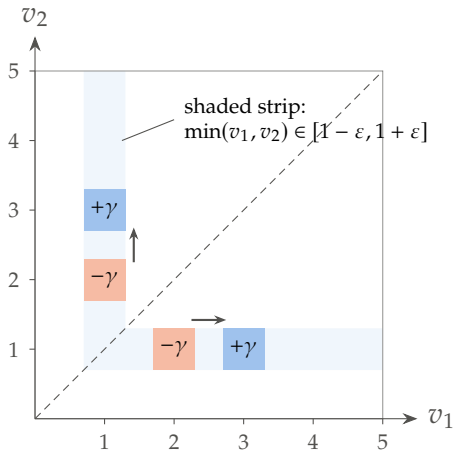

Figure 15.4: The construction behind Theorem 15.9 for $n = 2$. Mass γ moves from the orange squares to the blue squares, symmetrically about the diagonal. All four squares lie in the shaded strip, and within each pair the minimum has the same distribution. The law of $\min(V_1, V_2)$, the only observable in a two-bidder ascending auction, is therefore unchanged, while the marginal distribution of each value changes.

reserve r and seller value v_0, a sale occurs when $V^{(n:n)} \geq r$, at the price $\max\{V^{(n-1:n)}, r\}$. The seller's expected profit is therefore

$$\pi(r) = \mathbb{E}\left[(V^{(n-1:n)} - v_0)\mathbf{1}\{V^{(n-1:n)} \geq r\}\right] + (r - v_0)\mathbb{P}\left(V^{(n-1:n)} < r \leq V^{(n:n)}\right),$$

and the last probability equals $F_{(n-1:n)}(r) - F_{(n:n)}(r)$. Transaction prices identify $F_{(n-1:n)}$. Only the distribution of the highest value at the single point r is missing. It lies between $F_{(n-1:n)}(r)$ and, under their assumptions, the value $\left[\Lambda^{-1}_{n-1:n}\left(F_{(n-1:n)}(r)\right)\right]^n$ that independence would imply. For $r \geq v_0$ the profit falls in $F_{(n:n)}(r)$, so these limits bound $\pi(r)$. The bounds are wide. Exogenous variation in n tightens them, because the joint law of any $m < n$ values drawn at random must then be the same in auctions of every size (p. 89, footnote 5). Section 15.2.7 reports their estimates for timber sales.

15.2.6 An incomplete model of ascending auctions

The button model is a stylized description of an English auction. In many oral auctions bidders call out prices themselves and nontrivial minimum increments are common. A bidder may jump bid, or stay silent until the auction is about to end (Athey and Haile, 2007, Section 4.3). Bidders then fail to reveal their full willingness to pay, and some never bid. Losing bids need not equal values, and the price need not equal the second-highest value. Haile and Tamer (2003) replace the button model by two weak behavioral assumptions.

Assumption 15.10 (Haile and Tamer, 2003)**.** Values are SIPV and the number of bidders n is observed. Let $\Delta \geq 0$ be the minimum bid increment.

(HT1) Bidders do not bid more than they are willing to pay: $b_i \leq v_i$ for every bidder.

(HT2) Bidders do not allow an opponent to win at a price they are willing to beat: every losing bidder has $v_i \leq b^{(n:n)} + \Delta$, where $b^{(n:n)}$ is the winning bid.

The assumptions allow the dominant-strategy behavior of the button model but do not require it. Bids need not be monotone in values. The model is *incomplete*: it restricts the relation

between values and bids without fully characterizing behavior. It cannot identify F, but it bounds it. Let $G_B^{(i:n)}$ be the CDF of the i-th lowest bid in n-bidder auctions, and let $G_\Delta^{(n:n)}$ be the CDF of $B^{(n:n)} + \Delta$.

Theorem 15.11 (Haile and Tamer, 2003 and Athey and Haile, 2007, Theorem 4.3)**.** *Under Assumption 15.10, $F^-(v) \le F(v) \le F^+(v)$ for all v, where*

$$F^+(v) = \min_n \min_{1\le i\le n} \Lambda_{i:n}^{-1}\big(G_B^{(i:n)}(v)\big), \qquad F^-(v) = \max_n \Lambda_{n-1:n}^{-1}\big(G_\Delta^{(n:n)}(v)\big).$$

Proof. Upper bound. By HT1, $b_i \le v_i$ for every i. The value $v^{(i:n)}$ is at least as large as i of the values, and the bids of those i bidders are no larger than their values. So at least i bids are at most $v^{(i:n)}$, which means $b^{(i:n)} \le v^{(i:n)}$. Hence the event $\{V^{(i:n)} \le v\}$ implies $\{B^{(i:n)} \le v\}$, and

$$G_B^{(i:n)}(v) \ge F_{(i:n)}(v) = \Lambda_{i:n}\big(F(v)\big).$$

Applying the increasing function $\Lambda_{i:n}^{-1}$ to both sides gives $\Lambda_{i:n}^{-1}\big(G_B^{(i:n)}(v)\big) \ge F(v)$. This holds for every i and every n, so it holds for the minimum.

Lower bound. By HT2, all $n-1$ losing bidders have values at most $b^{(n:n)} + \Delta$. At least $n-1$ values are therefore below this level, so $v^{(n-1:n)} \le b^{(n:n)} + \Delta$. The event $\{B^{(n:n)} + \Delta \le v\}$ implies $\{V^{(n-1:n)} \le v\}$, and

$$G_\Delta^{(n:n)}(v) \le F_{(n-1:n)}(v) = \Lambda_{n-1:n}\big(F(v)\big).$$

Applying $\Lambda_{n-1:n}^{-1}$ gives $\Lambda_{n-1:n}^{-1}\big(G_\Delta^{(n:n)}(v)\big) \le F(v)$ for every n, hence for the maximum. □

Several features of the bounds matter in practice. If only the transaction price is recorded, the upper bound uses $i = n$ alone. The number of bidders must be observed, which holds when bidders must register or qualify, as in the timber auctions studied by Haile and Tamer (2003). If the data satisfy the button model and $\Delta \to 0$, the bounds collapse to F. Conversely, imposing the button model when it is false need not produce an estimate inside the bounds, even in large samples. Imposing false structure to obtain point identification differs from selecting a point inside the bounds of a correct incomplete model (Athey and Haile, 2007, Section 4.3.1).

Estimation replaces each CDF by its empirical counterpart. Each component $\Lambda_{i:n}^{-1}(\hat{G}_B^{(i:n)})$ is consistent and asymptotically normal, but the minimum and maximum have non-normal limits, and inference uses the bootstrap. The minimum of several consistent estimators tends to select one with a downward sampling error, and the maximum one with an upward error. The estimated bounds are therefore too narrow in finite samples and may even cross. Haile and Tamer (2003) replace the minimum and maximum by smooth weighted averages that approach them as the sample grows.

Bounds on the optimal reserve price. The seller's main policy instrument in the SIPV model is the reserve price. Let v_0 be the seller's value. By Corollary 14.47, the optimal reserve r^* solves $r^* - \frac{1-F(r^*)}{f(r^*)} = v_0$. Bounds on F place no restriction on its derivative at a point, so plugging F^+ or F^- into this equation does not bound r^*. A detour through an objective function works. Define

$$\pi(r) = (r - v_0)\big(1 - F(r)\big).$$

Then $\pi'(r) = \big(1 - F(r)\big) - (r - v_0)f(r) = -f(r)\big[\psi(r) - v_0\big]$, where ψ is the virtual valuation (14.48). So π has the same maximizer as the seller's expected profit, although it is not that profit when $n > 1$ (Athey and Haile, 2007, footnote 34). For $r \ge v_0$, the bounds on F imply

$$\pi_1(r) \equiv (r - v_0)\big(1 - F^+(r)\big) \le \pi(r) \le \pi_2(r) \equiv (r - v_0)\big(1 - F^-(r)\big).$$

Let r_1^* maximize π_1, let $\pi_1^* = \pi_1(r_1^*)$, and define

$$r^- = \sup\{r < r_1^* : \pi_2(r) \le \pi_1^*\}, \qquad r^+ = \inf\{r > r_1^* : \pi_2(r) \le \pi_1^*\}.$$

Proposition 15.12 (Haile and Tamer, 2003 and Athey and Haile, 2007, Theorem 4.4)**.** *Suppose π is continuously differentiable and strictly quasi-concave. Then $r^* \in [r^-, r^+]$. Given the bounds F^+ and F^-, the bounds r^- and r^+ are sharp.*

Proof of the inclusion. We treat the nontrivial case $r^- < r_1^* < r^+$ and assume π_2 is continuous. Athey and Haile (2007, Section 4.3.2) discuss the degenerate cases, in which $r^- = r^+ = r_1^*$. The true objective satisfies $\pi(r^*) \ge \pi(r_1^*) \ge \pi_1(r_1^*) = \pi_1^*$. Suppose $r^* < r^-$. Then r^- lies strictly between r^* and r_1^*, and strict quasi-concavity gives

$$\pi(r^-) > \min\{\pi(r^*), \pi(r_1^*)\} \ge \pi_1^*.$$

By continuity $\pi_2(r^-) \le \pi_1^*$, so $\pi(r^-) \le \pi_2(r^-) \le \pi_1^*$, a contradiction. The case $r^* > r^+$ is symmetric. □

Figure 15.5 applies the bounds to simulated auctions. Losing bidders stop between 80 and 100 percent of their values, and the price may fall up to one increment below the second-highest value. The bounds contain the true F over most of the range where the data are informative. The naive estimator that treats losing bids as values lies above the upper bound, because it ignores the fact that bidders stopped short. The implied interval for the optimal reserve is $[0.53, 1.04]$, and it contains the true optimum 0.77 (our simulation).

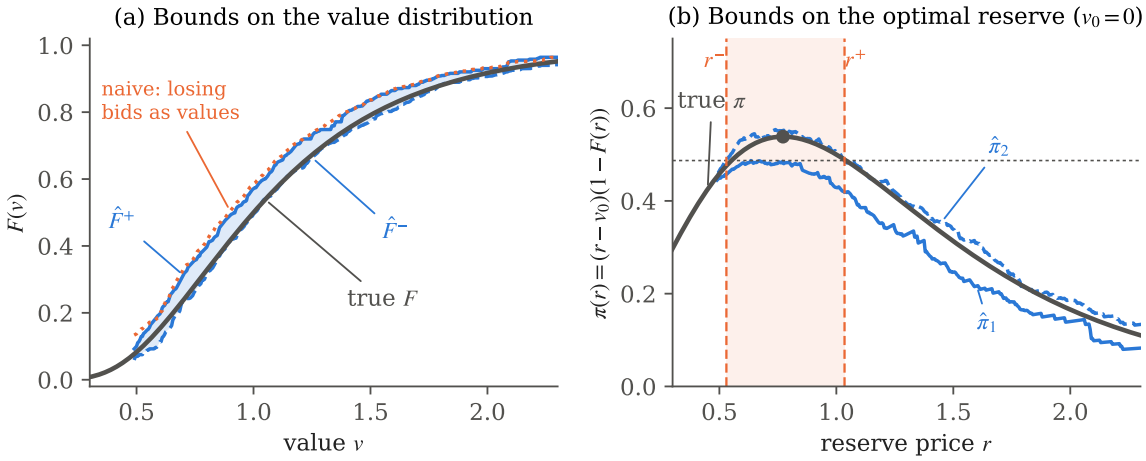

Figure 15.5: Bounds from an incomplete model of ascending auctions. Our simulation: 500 auctions with $n = 3$ and 500 with $n = 5$, values lognormal with $\mu = 0$ and $\sigma = \frac{1}{2}$, increment $\Delta = 0.05$, seed 15202. Losing bidders record bids equal to their values times a uniform draw on $[0.8, 1]$. The winning bid lies between the second-highest value minus Δ and that value, and is at least every losing bid. Panel (a): $\hat{F}^+$, $\hat{F}^-$, the true F and the naive estimate that inverts the highest losing bid as if it were the second-highest value. An order statistic is used at v only if at least 1 percent of its observations lie on each side of v, and curves are drawn where both bounds are informative. Panel (b): $\hat{\pi}_1$, $\hat{\pi}_2$ and the true π for $v_0 = 0$, with the interval $[r^-, r^+]$ shaded and the true optimum marked by a dot.

The approach extends in principle to asymmetric and affiliated private values, but the bounds are then likely to be wide. Bounds on realized values reveal little about their correlation structure, and many policy questions need that structure (Athey and Haile, 2007, Section 4.3.3).

15.2.7 Binding reserve prices

A reserve price r inside the support of values, with $F(r) \in (0,1)$, separates potential bidders from actual bidders. In this subsection N is the number of potential bidders and n_t the number who participate. With private values a bidder participates exactly when her value is at least r. Under independence, the participants' values are therefore i.i.d. draws from the truncated distribution

$$F(v \mid r) = \frac{F(v) - F(r)}{1 - F(r)}, \qquad v \geq r \tag{15.3}$$

(Athey and Haile, 2007, equation (6.18)). In an ascending auction with $n_t \geq 2$ participants, the price is the second-highest of n_t draws from $F(\cdot \mid r)$. With $n_t = 1$ the price equals r.

Proposition 15.13 (Athey and Haile, 2002, Corollary 3 and Athey and Haile, 2007, Corollary 6.1 and Theorem 6.3)**.** *Consider the SIPV model of a first-price, second-price or ascending auction with reserve price r and $F(r) \in (0,1)$.*

(i) If one bid from each auction and the number of participants are observed, $F(\cdot \mid r)$ is identified on $[r, \infty)$.

(ii) The model is testable if two bids from each auction are observed, or if one bid is observed in auctions with different numbers of participants.

(iii) If N is fixed and the number of participants is observed, N and $F(r)$ are identified. Combined with (i), $F(v)$ is then identified for every $v \geq r$.

Proof. Parts (i) and (ii) apply Theorem 15.4 to the truncated distribution (15.3), conditioning on the number of participants. For first-price auctions they apply the result of Section 15.4 instead. For part (iii), each potential bidder participates independently with probability $1 - F(r)$, so the number of participants is binomial with parameters N and $1 - F(r)$. Its distribution determines both parameters. Exchangeability gives a convenient formula. The probability that a given bidder stays out is the same for every bidder. It therefore equals the expected fraction of bidders who stay out:

$$F(r) = \mathbb{P}(\text{bidder 1 does not bid}) = \frac{\mathbb{E}[N - n_t]}{N} = \sum_{k=1}^{N} \frac{k}{N} \mathbb{P}\big(n_t = N - k\big),$$

which is equation (6.19) of Athey and Haile (2007). Finally, (15.3) gives $F(v) = F(r) + \big(1 - F(r)\big)F(v \mid r)$ for $v \geq r$. □

The sample analog of the last formula, $\hat{F}(v) = \hat{F}(r) + \big(1 - \hat{F}(r)\big)\hat{F}(v \mid r)$, is consistent. Below the reserve the data are silent without parametric assumptions. Is the truncated distribution enough for the reserve-price question? The next result says that it usually is.

Proposition 15.14 (Athey and Haile, 2007, Theorem 6.2)**.** *For a univariate CDF Φ, let $\pi(\tilde{r}; \Phi) = (\tilde{r} - v_0)\big(1 - \Phi(\tilde{r})\big)$ and let $p^*(\Phi)$ maximize $\pi(\cdot; \Phi)$ over the support of Φ. Suppose $\pi(\cdot; F)$ is continuously differentiable and strictly quasi-concave, and write $F_{|r} = F(\cdot \mid r)$.*

(i) If $r < p^*(F)$, then $p^*(F_{|r}) = p^*(F)$.

(ii) If $r \geq p^*(F)$, then $p^*(F_{|r}) = r$.

Proof. For $\tilde{r} \geq r$, (15.3) gives $1 - F(\tilde{r} \mid r) = \frac{1-F(\tilde{r})}{1-F(r)}$, so

$$\pi(\tilde{r}; F_{|r}) = \frac{\pi(\tilde{r}; F)}{1 - F(r)} \qquad \text{for all } \tilde{r} \geq r.$$

On the support of $F_{|r}$ the two objectives differ by a positive multiplicative constant. If $r < p^*(F)$, the unconstrained maximizer lies in $[r, \infty)$ and both objectives peak there. If $r \geq p^*(F)$, strict quasi-concavity makes $\pi(\cdot; F)$ decreasing on $[r, \infty)$, so the truncated objective peaks at its lower end r. □

In the SIPV model, the optimal reserve computed from participants alone, ignoring the selection created by the reserve, is the true optimum unless the actual reserve already exceeds it. The data reveal when that happens, because the estimated optimum then sits at the actual reserve. Variation in reserve prices across auctions does more. Suppose reserves vary for reasons unrelated to values. Data from auctions with low reserves then reveal F over a longer range, and a reserve below the lower end of the support reveals all of F (Athey and Haile, 2007, Section 6.3.1). Reserve prices may instead respond to features of the object that bidders see and the econometrician does not. A reserve then signals unobserved quality, and treating it as an exogenous truncation point is a mistake. Roberts (2013) builds an identification strategy on this observation (Section 15.7). With a reserve price, the tests of private against common values in Section 15.6 remain available, because truncation at a common reserve preserves exchangeability (Athey and Haile, 2002, Corollary 4).

Applications to timber sales. Timber sales have been the main testing ground for these methods (Hortaçsu and Perrigne, 2021, Section 2.1). The estimates agree on one point. Observed reserve prices are low relative to the optimum that most models imply, and the gain from raising them depends on the information structure.

Paarsch (1997) studies ascending timber auctions in British Columbia with a parametric model (pp. 87–88). He treats the winning bid as the second-highest value, as in the button model. Bids are per species on estimated volumes, while payments follow harvested volumes. He therefore rewrites each value in terms of an average harvesting cost, and the winner is the bidder with the lowest cost. He specifies a parametric cost function and a Weibull distribution. The estimated optimal reserve is then on average 3.4 to 4.2 times the observed reserve, as the seller's value v_0 ranges from zero to the appraisal value of the timber.

Haile and Tamer (2003) apply Theorem 15.11 and Proposition 15.12 to Forest Service ascending auctions, with data from Oregon (p. 88). They estimate bounds on the optimal reserve and on the implied gain. The increase in the seller's profit ranges from little to 34 percent, depending on v_0. At high values of v_0 the optimal reserve leaves more than 90 percent of tracts unsold. Aradillas-López et al. (2013) use Oregon data as well (p. 89). Their estimated bounds on the seller's profit are smaller than the profit computed under independent values, and independence also overstates bidders' surplus. A reserve computed under independence would be too high and could even lower the seller's profit. The authors note that an optimal reserve would conflict with the Forest Service's mandate to sell about 85 percent of the tracts it offers. The mandate may explain why observed reserves are low.

Coey et al. (2017) exploit the asymmetry between loggers and mills of Section 15.9 to tighten the bounds in California sales (p. 89). The lower bound on the optimal reserve is similar, while the upper bound is 10 to 15 percent lower. Coey et al. (2019) turn to the *bidder exclusion effect*, the expected fall in revenue when one of N bidders is excluded at random (pp. 89–90). In an ascending auction with private values the price is the second-highest value. Excluding a

bidder lowers it to the third-highest value exactly when the excluded bidder holds one of the two highest values, which happens with probability $\frac{2}{N}$. The exclusion effect is therefore

$$\frac{2}{N}\,\mathbb{E}\big[B^{(N-1:N)} - B^{(N-2:N)}\big],$$

which needs two order statistics and the number of potential bidders. Under exogenous participation the observed fall in revenue, $\mathbb{E}[B^{(N-1:N)}] - \mathbb{E}[B^{(N-2:N-1)}]$, must equal this effect. The difference is their test statistic. A negative value is consistent with common values, and a zero value with private values, as Athey and Haile (2002) show (Hortaçsu and Perrigne, 2021, footnote 6). The same effect bounds the gain from an optimal reserve without computing the reserve. By Proposition 14.48, an optimal reserve with $N-1$ bidders raises less revenue than one more bidder without a reserve. In California sales the average revenue gain from an optimal reserve is at most 13 percent. Exogenous participation is rejected, with positive selection, since values tend to be higher in auctions with more participants (p. 90).

The first-price evidence points the same way. Li and Perrigne (2003) study French public timber sales by first-price sealed bid with a secret reserve (p. 90). They model the reserve as random, equal to the seller's value and independent of bidders' values, which are independent private values. The inversion of Guerre et al. (2000), developed in Section 15.4, recovers the value distribution. The optimal announced reserve is on average 46 percent higher than the secret one. It lowers the number of successful sales and raises total revenue only slightly, but it doubles the seller's net profit.

15.3 First-Price Auctions I: The Inversion Problem and Direct Methods

In first-price and Dutch auctions bidders shade their bids below their values, and the amount of shading depends on the distribution of values. This section explains why that makes identification and estimation harder. It then studies the direct route, maximum likelihood with its non-regularity and the simulated estimator of Laffont et al. (1995). It closes with a comparison of direct and indirect methods that motivates Section 15.4.

15.3.1 Why first-price auctions are harder

In the SIPV model with reserve price r, a bidder with value $v \geq r$ bids (Proposition 14.31)

$$\beta(v) = v - \frac{\int_r^v F(t)^{n-1}\,dt}{F(v)^{n-1}}.$$

Bids are observed and values are not. The bid function depends on the unknown F, the very object we want to estimate (Athey and Haile, 2007, Section 3.1). The distribution of bids $G(b) = F\big(\beta^{-1}(b)\big)$ therefore depends on F in two ways, directly through the distribution of values and indirectly through the equilibrium strategy (Guerre et al., 2000, p. 529). Even a closed-form bid function does not tell us how to recover F from G.

The economics of shading also suggests the way out. A bidder trades off the probability of winning against the surplus she earns when she wins. In a procurement auction a firm with cost c chooses its bid b to maximize $(b-c)\mathbb{P}(\text{win} \mid b)$, exactly as an oligopolist chooses its price to maximize $(p-c)q(p)$. The win probability plays the role of residual demand, and

the first-order condition is an inverse elasticity rule (see (14.113) and (14.114), and Chapter 2). In demand estimation we recover marginal costs from the pricing first-order condition once demand is estimated (Chapters 4 and 8). In auctions we can recover values from the bidding first-order condition once the distribution of rivals' bids is estimated. That is the indirect route of Section 15.4. The literature first took the direct route, which we study now.

15.3.2 Maximum likelihood and its non-regularity

Let $F(\cdot;\theta)$ be a parametric family with density $f(\cdot;\theta)$, $\theta \in \Theta \subset \mathbb{R}^K$, and suppose for simplicity that there is no binding reserve price. Each bid is $B_{it} = \beta(V_{it};\theta)$ with β strictly increasing, so $G(b;\theta) = F\big(\beta^{-1}(b;\theta);\theta\big)$. Differentiating gives the bid density

$$g(b;\theta) = \frac{f\big(\beta^{-1}(b;\theta);\theta\big)}{\beta'\big(\beta^{-1}(b;\theta);\theta\big)}, \qquad b \in \big[\beta(\underline{v};\theta),\ \beta(\bar{v}(\theta);\theta)\big]. \tag{15.4}$$

The equilibrium differential equation (14.32) gives $\beta'(v) = (n-1)\big(v-\beta(v)\big)\frac{f(v)}{F(v)}$. Substituting it, with $\xi = \beta^{-1}(b;\theta)$,

$$g(b;\theta) = \frac{F(\xi;\theta)}{(n-1)(\xi - b)}.$$

The log-likelihood of all bids is $\ell(\theta) = \sum_t \sum_i \ln g(b_{it};\theta)$. If only the winning bid is recorded, as in a Dutch auction, its CDF is $H(b;\theta) = F(\xi;\theta)^n$. Its density is

$$h(b;\theta) = \frac{nF(\xi;\theta)^{n-1} f(\xi;\theta)}{\beta'(\xi;\theta)} = \frac{n}{n-1}\,\frac{F(\xi;\theta)^n}{\xi - b},$$

which is equation (7) of Laffont et al. (1995). With a binding reserve price the object goes unsold with probability $F(r;\theta)^n$, and the likelihood takes a Tobit form with a mass point at r.

Maximum likelihood faces three obstacles. The first is computation. Each evaluation of $\ell(\theta)$ requires $\beta^{-1}(b_{it};\theta)$ for every bid and every trial value of θ. The bid function involves an integral and has no closed form for most families. With asymmetric or affiliated values it solves a system of differential equations, such as (14.77), which must be solved anew at each θ. The second obstacle is regularity. The upper end of the support of bids, $\beta(\bar{v}(\theta);\theta)$, depends on θ. With only the winning bid, the support is $[r, \mathbb{E}\max(Y, r)]$, where Y is the largest of $n-1$ draws from F (Laffont et al., 1995, p. 958). A parameter-dependent support violates the standard conditions for maximum likelihood (Section A.6.7). The third obstacle is that practical applications were confined to families with closed-form bid functions and to the SIPV model (Athey and Haile, 2007, Section 3.2). Donald and Paarsch (1993, 1996) study the non-regular problem. They derive non-standard asymptotic distributions and propose estimators built on extreme order statistics of the bids. The following example shows what goes wrong.

Example 15.15 (Maximum likelihood with power-distributed values)**.** Let $F(v;\theta) = \big(\frac{v}{\theta}\big)^{\gamma}$ on $[0,\theta]$ with $\gamma > 0$ known and θ unknown, and let there be no reserve price. As in Example 14.34, rescaled to the support $[0,\theta]$,

$$\int_0^{v} \left(\frac{t}{\theta}\right)^{\gamma(n-1)} dt = \frac{v}{\gamma(n-1)+1}\left(\frac{v}{\theta}\right)^{\gamma(n-1)}.$$

Substituting into (14.29) gives

$$\beta(v) = v - \frac{v}{\gamma(n-1)+1} = c\,v, \qquad c = \frac{\gamma(n-1)}{\gamma(n-1)+1}.$$

Bids $B = cV$ have CDF $G(b;\theta) = \left(\frac{b}{c\theta}\right)^{\gamma}$ on $[0, c\theta]$ and density $g(b;\theta) = \gamma b^{\gamma-1}(c\theta)^{-\gamma}$. With nT bids the likelihood is

$$L(\theta) = \prod_{t=1}^{T}\prod_{i=1}^{n} \gamma\, b_{it}^{\gamma-1}(c\theta)^{-\gamma}\,\mathbf{1}\big(b_{it} \le c\theta\big) = \Big[\prod_{t,i}\gamma\, b_{it}^{\gamma-1}\Big](c\theta)^{-\gamma nT}\,\mathbf{1}\Big(\theta \ge \frac{\max_{t,i} b_{it}}{c}\Big).$$

The likelihood is zero for θ below $\frac{1}{c}\max_{t,i} b_{it}$ and strictly decreasing above it, so

$$\hat{\theta} = \frac{1}{c}\max_{t,i} b_{it}.$$

Its distribution follows from that of the maximum of nT independent bids. For $0 \le x \le T\theta$,

$$\mathbb{P}\big(T(\theta - \hat{\theta}) > x\big) = \mathbb{P}\Big(\max_{t,i} B_{it} < c\Big(\theta - \frac{x}{T}\Big)\Big) = \Big(1 - \frac{x}{T\theta}\Big)^{\gamma nT} \longrightarrow e^{-\frac{\gamma n}{\theta}x}.$$

So $T(\theta - \hat{\theta})$ converges to an exponential distribution with mean $\frac{\theta}{\gamma n}$.

The estimator converges at rate T, faster than the usual $\sqrt{T}$, and its limit is not normal. The information equality fails. The score of one bid is $\frac{\partial}{\partial\theta}\ln g(b;\theta) = -\frac{\gamma}{\theta}$, whose mean is not zero, because the support moves with θ. Standard errors from the inverse information matrix are therefore invalid, and the nonparametric bootstrap fails for the sample maximum (Proposition A.47 and Section A.9.5). The estimator also rests entirely on the largest bid, so a single error in the top bid moves it. The same structure arises whenever the upper end of the bid support depends on the parameters, which is the rule in first-price auctions.

15.3.3 Laffont, Ossard and Vuong (1995): simulated nonlinear least squares

Question. Laffont et al. (1995) ask how to estimate a general parametric distribution of private values from first-price or Dutch auctions in which only the winning bid is observed. They want to allow heterogeneity across auctions and an unknown number of bidders, and to avoid computing the equilibrium bid function. Earlier structural work by Paarsch (1992) had relied on families with closed-form bid functions (Laffont et al., 1995, p. 954).

Model. The model of their Section 2 is the SIPV first-price auction with reserve price r_t and n bidders. The equilibrium bid (their eq. (1)) is (14.29). The winning bid is $\beta\big(V_t^{(n:n)}\big)$ when $V_t^{(n:n)} \ge r_t$ (eq. (2)), and the optimal reserve solves $r^* = v_0 + \frac{1-F(r^*)}{f(r^*)}$ (eq. (4), Corollary 14.47). Heterogeneity enters through observed characteristics z_t:

$$F_t(\cdot) = F(\cdot \mid z_t, \theta) \qquad \text{(their eq. (5))}.$$

The reserve price is not among the characteristics, which fits their application, where buyers and sellers have the same information about market conditions (Laffont et al., 1995, p. 957). To avoid a discontinuity when the object is unsold, they set the winning bid equal to the reserve in that case (eq. (6)):

$$b_t^{w} = \beta_t\big(V_t^{(n:n)}\big)\,\mathbf{1}\big(V_t^{(n:n)} \ge r_t\big) + r_t\,\mathbf{1}\big(V_t^{(n:n)} < r_t\big).$$

Its distribution has a mass $F_t(r_t)^n$ at r_t and the density h_t above r_t. Bidders draw new independent values in every auction, which rules out the dynamic incentives of repeated auctions.

Revenue equivalence as an estimation device. The key step replaces the intractable bid function by a conditional expectation that is easy to simulate.

Lemma 15.16 (Laffont et al., 1995, eq. (12))**.** *For $v \geq r$, $\beta(v) = \mathbb{E}\big[\max\{V^{(n-1:n)}, r\} \mid V^{(n:n)} = v\big]$.*

Proof. Given that the highest of n i.i.d. values equals v, the other $n-1$ values are i.i.d. draws from F truncated to lie below v. Their maximum $V^{(n-1:n)}$ then has CDF $\big(\frac{F(y)}{F(v)}\big)^{n-1}$ on $y \leq v$. This is the distribution of the highest rival value Y_1 conditional on $Y_1 < v$. Hence the right side equals $\mathbb{E}\big[\max\{Y_1, r\} \mid Y_1 < v\big]$, which is $\beta(v)$ by (14.30). □

Applying the lemma at $v = V_t^{(n:n)}$ gives $b_t^w = \mathbb{E}\big[\max\{V_t^{(n-1:n)}, r_t\} \mid V_t^{(n:n)}\big]$. The equality also holds when the object is unsold, since both sides then equal r_t. Taking expectations conditional on $x_t = (r_t, z_t)$ yields the moment that drives the estimator (their eqs. (13)–(15)):

$$\begin{aligned} m_t(\theta) \equiv \mathbb{E}\big[b_t^w \mid x_t\big] &= \mathbb{E}\big[\max\{V_t^{(n-1:n)}, r_t\} \mid x_t\big] \\ &= \int \cdots \int \max\{u^{(n-1:n)}, r_t\} \prod_{i=1}^{n} f_t(u_i)\, du_1 \cdots du_n, \end{aligned} \tag{15.5}$$

where $u^{(n-1:n)}$ is the second highest of $(u_1, \ldots, u_n)$. This is revenue equivalence (Proposition 14.43). The expected winning bid in a first-price auction equals the expected price in an English auction with the same reserve. The right side needs no bid function: draw n values, take the second highest, and compare it with the reserve.

The simulator. Laffont et al. (1995) use importance sampling. For each auction they choose a known density g_t whose support contains that of f_t. Before estimation they draw S independent samples $\boldsymbol{u}_t^s = (u_{1t}^s, \ldots, u_{nt}^s)$, $s = 1, \ldots, S$, with each u_{it}^s drawn from g_t. Their eqs. (16)–(17) define

$$X_{st}(\theta) = \max\big\{u_{(n-1:n)t}^s,\, r_t\big\} \prod_{i=1}^{n} \frac{f_t(u_{it}^s; \theta)}{g_t(u_{it}^s)}, \qquad \bar{X}_t(\theta) = \frac{1}{S} \sum_{s=1}^{S} X_{st}(\theta).$$

By construction $\mathbb{E}\big[\bar{X}_t(\theta) \mid x_t\big] = m_t(\theta)$. The draws do not depend on θ and are independent of b_t^w given x_t. Because θ enters only through the weights, outside the maximum, $\bar{X}_t(\theta)$ is twice continuously differentiable in θ whenever f is. Standard derivative-based optimization then applies, and the asymptotic theory is simpler than for discontinuous simulators (Laffont et al., 1995, p. 961).

The bias of naive simulated least squares. Nonlinear least squares with the exact mean would minimize $\frac{1}{T}\sum_t \big(b_t^w - m_t(\theta)\big)^2$. Replacing m_t by its simulator gives the naive criterion $Q_S(\theta) = \frac{1}{T}\sum_t \big(b_t^w - \bar{X}_t(\theta)\big)^2$ (their eq. (8)). To find its limit, decompose

$$b_t^w - \bar{X}_t(\theta) = \big(b_t^w - m_t(\theta_0)\big) + \big(m_t(\theta_0) - m_t(\theta)\big) + \big(m_t(\theta) - \bar{X}_t(\theta)\big).$$

Given x_t, the first and third terms have mean zero and are independent of each other, and the second is fixed. Every cross product therefore has conditional mean zero, and

$$\mathbb{E}\Big[\big(b_t^w - \bar{X}_t(\theta)\big)^2 \,\Big|\, x_t\Big] = \sigma_0^2(x_t) + \big(m_t(\theta_0) - m_t(\theta)\big)^2 + \frac{1}{S}\,\omega_t(\theta),$$

where $\sigma_0^2(x_t) = \mathrm{Var}(b_t^w \mid x_t)$ and $\omega_t(\theta) = \mathrm{Var}\big(X_{st}(\theta) \mid x_t\big)$. The first term does not depend on θ and the second is minimized at θ_0. The third term, the simulation variance, does depend on θ. The naive estimator converges to the minimizer of the sum of the last two terms, which is generally not θ_0 (their eq. (9)). It favors parameter values at which the simulator is less noisy, and it is inconsistent for any fixed S.

The fix subtracts an unbiased estimate of the simulation variance. The sample variance of the draws, divided by S, satisfies $\mathbb{E}\big[\frac{1}{S(S-1)}\sum_s \big(X_{st}(\theta)-\bar{X}_t(\theta)\big)^2 \mid x_t\big] = \frac{1}{S}\omega_t(\theta)$. The simulated nonlinear least squares (SNLS) criterion is therefore (their eq. (11))

$$Q_S^*(\theta) = \frac{1}{T}\sum_{t=1}^{T}\left[\big(b_t^w - \bar{X}_t(\theta)\big)^2 - \frac{1}{S(S-1)}\sum_{s=1}^{S}\big(X_{st}(\theta)-\bar{X}_t(\theta)\big)^2\right]. \tag{15.6}$$

Each bracket has conditional mean $\sigma_0^2(x_t) + \big(m_t(\theta_0) - m_t(\theta)\big)^2$, the same as the criterion of exact nonlinear least squares. Section A.7.4 treats the estimator in the general framework of simulation estimators.

Asymptotic properties. Their Proposition 1 shows that for any fixed S the SNLS estimator $\hat{\theta}$ is strongly consistent as $T \to \infty$, provided θ_0 is identified from the first moment of the winning bid. The minimized criterion $Q_S^*(\hat{\theta})$ consistently estimates the mean squared error of the model. Proposition 2 gives asymptotic normality. Let $\mu_t = \frac{\partial m_t(\theta_0)}{\partial \theta}$ and $Y_{st} = \frac{\partial X_{st}(\theta_0)}{\partial \theta}$, and let ω_t, Ω_t and C_t be the conditional variances of $X_{st}(\theta_0)$ and Y_{st} and their conditional covariance. Then $\Sigma^{-\frac{1}{2}}\sqrt{T}(\hat{\theta}-\theta_0) \xrightarrow{d} N(0, I_K)$ with $\Sigma = A^{-1}BA^{-1}$ and

$$A = \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}\big[\mu_t\mu_t^\top\big],$$

$$B = \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}\left[\sigma_0^2(x_t)\mu_t\mu_t^\top + \frac{1}{S}\Big(\sigma_0^2(x_t)\Omega_t + \omega_t\mu_t\mu_t^\top\Big) + \frac{1}{S(S-1)}\Big(\omega_t\Omega_t + C_tC_t^\top\Big)\right].$$

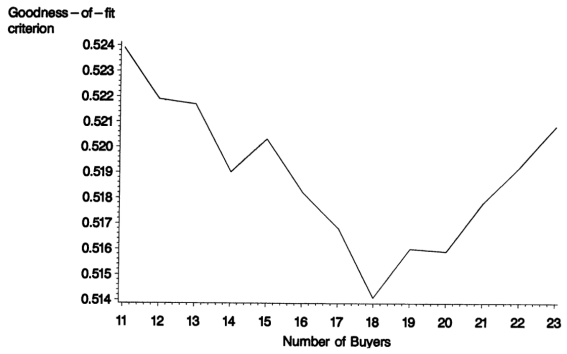
The first term of B alone gives the sandwich of exact nonlinear least squares. Simulation inflates the variance by a term of order $\frac{1}{S}$, which vanishes as S grows. Proposition 3 gives a heteroskedasticity-robust estimator of Σ that is consistent for fixed S and requires neither σ_0^2 nor exact moments. Competing simulated estimators, such as simulated maximum likelihood, are inconsistent for fixed S, because they simulate a nonlinear function of an expectation (Laffont et al., 1995, p. 962).

An unknown number of bidders. Bidders in a Dutch auction who never bid leave no trace, so n may be unknown. Their Proposition 4 treats the true n_0 as a parameter in a bounded set $\mathcal{J}$ of integers. For each $n \in \mathcal{J}$ compute $\hat{\theta}_n$ and $Q_{S,n}^*(\hat{\theta}_n)$, and let $\hat{n}$ minimize the criterion over $\mathcal{J}$. Then $(\hat{n}, \hat{\theta}_{\hat{n}})$ converges almost surely to (n_0, θ_0) for fixed S. Since $\hat{n}$ is discrete it converges faster than $\hat{\theta}$, and inference on θ can proceed as if n were known (their footnote 14). Identification of n here rests on the parametric family. Without n, the distribution of the winning bid does not even determine the distribution of a single bid (Athey and Haile, 2007, Section 3.3.1), as Section 15.4.8 shows.

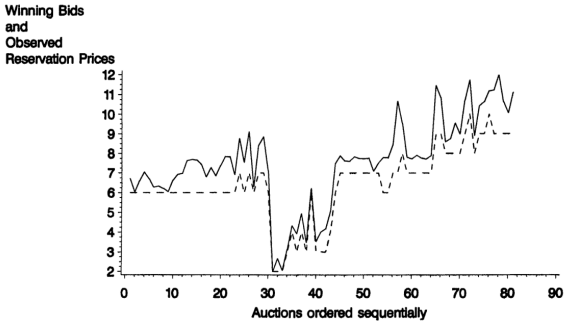
Extensions. Three extensions broaden the method. First, if the econometrician observes only part z_{1t} of the characteristics $z_t = (z_{1t}, z_{2t})$ that bidders see, a parametric model $h(z_2 \mid r, z_1; \gamma)$ for the omitted part can be integrated out. The simulator then draws z_{2t} along with the values (their eqs. (24)–(25)). Second, the lemma lets us simulate $\beta(v)$ itself, by averaging $\max\{V^{(n-1:n)}, r\}$ over draws given $V^{(n:n)} = v$. Higher moments of the winning bid then become available for a method of simulated moments. Third, the moment (15.5) is the expected price of any standard auction with the same reserve, so the estimator applies equally to English and second-price auctions (Laffont et al., 1995, p. 959).

Setting and data. The application is a descending auction of greenhouse eggplants in Marmande, France. The sellers are farmers, and the buyers are resale trading firms acting for retailers who placed orders at given prices before the market opened. These prices are the buyers' valuations, which supports the private values assumption. In each round a case of 15 to 350 kilos is offered. The seller announces a reserve price per kilo, and the clock starts high, for example at fifteen francs when the usual price is about ten francs per kilo. The first buyer to stop the clock wins and pays the current price (Laffont et al., 1995, p. 967).

The data cover daily sales in the summer of 1990, from June to October. To avoid dynamic incentives within a day, the authors keep only days on which a single case of a given size category was offered. Eggplants deteriorate quickly, so one day's supply can be treated as independent of the previous day's trade. The sample has 81 auctions. The winning bid averages 7.52 francs per kilo (standard deviation 2.21, range 2.00 to 11.98), and the reserve price averages 6.43 (standard deviation 1.81, range 2.00 to 10.00). The correlation between winning bids and reserves is 0.962 (Laffont et al., 1995, Appendix B).



(a) Criterion $Q_S^*(\hat{\theta}_n)$ against the assumed number of buyers n.



(b) Winning bids (solid) and reserve prices (dashed), auctions in chronological order.

Figure 15.6: The Marmande eggplant auctions. Panel (a) selects the number of buyers by minimizing the simulated criterion. Panel (b) shows that winning bids and reserve prices move together. Source: Laffont, Ossard and Vuong (1995), Figures 1 and 3.

Specification. Values are lognormal, a family without a closed-form bid function. The mean of log values is linear in six characteristics (their eq. (26)):

$$\mathbb{E}\ln V_{it} = \mu_t = \theta_1 + \theta_2\,\text{seller}_t + \theta_3\,\text{size1}_t + \theta_4\,\text{size2}_t + \theta_5\,\text{period}_t + \theta_6\,\text{date}_t + \theta_7\,\text{supply}_t.$$

The seller dummy is zero for the seller with the better reputation for quality (19 of the 81 lots come from the other seller). The size dummies mark the middle category, 300 to 400 grams per eggplant (10 lots), and the largest category, above 400 grams (34 lots). The period dummy is zero from the beginning of August until the first week of September, when a large supply of substitute eggplants depresses prices, and one otherwise (68 lots). The date variable records the time of the auction within 1990 divided by 100, so June 25 corresponds to 1.76. Supply is the quantity of eggplants of all categories supplied at Marmande that day, in tons (mean 1.39).

The standard deviation σ of $\ln V$ is not estimated. Retail prices for a given lot have a standard deviation of about 5 percent of their mean. Setting $\frac{\text{sd}(V)}{\mathbb{E}(V)} = (e^{\sigma^2} - 1)^{\frac{1}{2}} = 0.05$ gives $\sigma \approx 0.05$ (Laffont et al., 1995, p. 969). Their footnote 18 explains the choice. Reserve prices were low and every lot was sold. Write $V = e^{\mu+\sigma U}$ with U standard normal. Then $\mathbb{E}[b^w] = e^{\mu}\kappa(\sigma, \ln r - \mu)$, where $\kappa(\sigma, a) = \mathbb{E}\big[\exp\big(\max\{\sigma U^{(n-1:n)}, a\}\big)\big]$ for i.i.d. standard normal draws. As the reserve

becomes irrelevant, $\mathbb{E}[b^w]$ approaches $e^{\mu}\kappa(\sigma, -\infty)$, and the constant in μ cannot be separated from σ. The estimator uses $S = 20$ simulations per auction, and 30 give similar results. The importance density for each auction is lognormal, centered at a preliminary consistent estimate and with standard deviation 0.05.

Results. The authors consider two hypotheses about the number of bidders. Eleven buyers attend regularly, but one buyer wins almost half of the auctions and may act for several traders. They search over $n = 11, \dots, 23$, and the criterion is smallest at $n = 18$ (Figure 15.6a). The large buyer would then represent 8 traders, consistent with a market share slightly below one half (Laffont et al., 1995, p. 970). Table 15.3 reproduces their estimates for $n = 11$ and $n = 18$.

Table 15.3: Simulated nonlinear least squares estimates for the Marmande eggplant auctions

	$n = 11$		$n = 18$	
	Estimate	(t)	Estimate	(t)
Constant	0.1297	(0.02)	0.0286	(0.06)
Seller	−0.0107	(−0.17)	−0.0240	(−0.51)
Size 1 (300–400 g)	0.2402	(3.57)	0.2402	(4.39)
Size 2 (above 400 g)	0.1373	(1.39)	0.1213	(1.60)
Period	1.2404	(2.16)	1.1998	(2.90)
Date	0.3115	(3.04)	0.3202	(4.03)
Supply	−0.0340	(−0.59)	−0.0357	(−0.81)
Criterion value $Q_S^*(\hat{\theta})$	0.52395		0.51401	
Simulations per auction S	20		20	
Auctions T	81		81	

Notes. Reproduced from Laffont et al. (1995, Table I). The coefficients are those of the mean of log values, μ_t in their eq. (26), with $\sigma = 0.05$ imposed. Parentheses contain t-statistics computed from the robust covariance estimator of their Proposition 3, not standard errors. Bids are in francs per kilo.

With a lognormal distribution and fixed σ, $\ln \mathbb{E}[V_t] = \mu_t + \frac{\sigma^2}{2}$, so each coefficient is $\theta_k = \frac{1}{\mathbb{E}[V]} \frac{\partial \mathbb{E}[V]}{\partial x_k}$, a proportional effect on the expected value of the lot (Laffont et al., 1995, p. 970). With $n = 18$, they read the size coefficients as midsize eggplants being worth 24 percent more than small ones and large ones 12 percent more. The size variables are dummies, so the exact proportional effects are $e^{0.240} - 1 = 27$ percent and $e^{0.121} - 1 = 13$ percent (our calculation). This agrees with the conventional view that midsize eggplants are of the highest quality. The seller coefficient is negative, so the seller with the better reputation commands higher values, but the effect is small and insignificant. The period coefficient is large and significant. Values fall sharply during the August glut, when Figure 15.6b shows winning bids dropping from about 7 francs to between 2 and 4 francs. The sample contains 13 lots with the period dummy equal to zero (Laffont et al., 1995, Appendix B), which matches the length of that run of low bids. Values also trend upward over the season (date). Local supply has no significant effect, which the authors attribute to buyers serving several markets, with national supply movements captured by the period and date variables. The fit is good: with $n = 18$, $R^2 = 1 - \frac{Q_S^*(\hat{\theta})}{\widehat{\mathrm{Var}}(b^w)} = 0.895$ (Laffont et al., 1995, p. 971). The slope coefficients barely change between $n = 11$ and $n = 18$, while the constant falls from 0.13 to 0.03. With more bidders the expected second-highest value is higher, so a lower level of values fits the same winning bids.

Assessment. The paper made three contributions. It brought simulation-based estimation to structural auction models, with an estimator that is consistent for a fixed number of simulations. It turned revenue equivalence into an estimation device. It showed how to handle unobserved heterogeneity and an unknown number of bidders within the same framework. Its limits are equally clear. The value distribution is parametric, and its dispersion was imposed from retail data rather than estimated. The device relies on revenue equivalence, which fails with asymmetric bidders, affiliated values or risk aversion. The dominant buyer is accommodated by inflating n, an assumption that holds only if that buyer bids for each trader independently. Only the first moment of the winning bid is used.

Figure 15.6b also raises a deeper issue. Winning bids and reserve prices move in tandem. If the reserve were an exogenous truncation point, variation in reserves would change the fraction of lots sold, yet every lot was sold. A more natural reading is that lots differ in ways that the seller and the buyers recognize and the econometrician does not (Roberts, 2013, p. 7). The authors anticipate the point in their conclusion. A seller may set the reserve with better information than buyers, so that the reserve both truncates and shifts the distribution of values (Laffont et al., 1995, p. 973). Roberts (2013) builds an identification strategy for unobserved heterogeneity on exactly this co-movement (Section 15.7).

15.3.4 From direct to indirect methods

Direct methods confront two burdens: solving the equilibrium for every trial parameter and a likelihood whose support moves with the parameters. Simulated least squares removes the first burden with revenue equivalence and the second by working with a smooth moment. Its reach is limited to models in which revenue equivalence holds. The indirect approach of Guerre et al. (2000) removes both burdens in a different way. It estimates the distribution of bids first and inverts the first-order condition (14.34) bid by bid, so no equilibrium is ever computed. It also requires no parametric family (Section 15.4).

Between the two lie hybrid two-step methods that specify a parametric first stage for bids conditional on covariates, invert the first-order condition, and then work with the implied values (Jofre-Bonet and Pesendorfer, 2003; Athey et al., 2011). They include covariates parsimoniously. A fully parametric two-step method must keep the parametric families for bids and for values mutually consistent, because the equilibrium bid function links them (Perrigne and Vuong, 1999). Making only one step parametric avoids that problem (Athey and Haile, 2007, Section 3.2). Theory also implies that bid distributions have compact support, so a parametric first stage should impose an upper bound on bids (Athey and Haile, 2007, footnote 19). Table 15.4 summarizes the comparison.

15.4 First-Price Auctions II: The Guerre-Perrigne-Vuong Approach

The direct methods of Section 15.3 start from a parametric value distribution and solve for the equilibrium at every trial parameter. Guerre et al. (2000), henceforth GPV, reversed the direction of the argument. They start from the distribution of observed bids and recover the value that rationalizes each bid. No equilibrium is ever computed, and no parametric family is assumed. This section develops their approach in full. It is the template for almost every structural method for first-price auctions that later sections use.

The question. GPV pose three questions about the symmetric independent private values (SIPV) model of the first-price auction (Guerre et al., 2000, p. 526). Does the model restrict

Table 15.4: Direct and indirect approaches to first-price auction data

	Maximum likelihood	Simulated least squares	Two-step nonparametric	Two-step, parametric first stage
Examples	Paarsch (1992), Donald and Paarsch (1996)	Laffont et al. (1995)	Guerre et al. (2000)	Jofre-Bonet and Pesendorfer (2003), Athey et al. (2011)
Value distribution	parametric $F(\cdot;\theta)$	parametric $F(\cdot;\theta)$	unrestricted, smooth	implied by a parametric bid distribution
Equilibrium computation	solve and invert $\beta(\cdot;\theta)$ for every bid and every θ	none, since the moment $\mathbb{E}\max\{V^{(n-1:n)}, r\}$ is simulated	none, since the first-order condition is inverted	none, since the first-order condition is inverted
Regularity and rate	support depends on θ, rate T and non-normal limits	regular, $\sqrt{T}$ for fixed S, variance excess of order $\frac{1}{S}$	nonparametric rates slower than $\sqrt{T}$	$\sqrt{T}$ for the bid parameters
Data used	all bids or the winning bid	winning bid, n may be unknown	all bids (the winning bid suffices under SIPV)	all bids with covariates
Asymmetry, affiliation, heterogeneity	a system of differential equations at every θ	excluded where revenue equivalence fails, heterogeneity by integration	extends to all three (Sections 15.5 and 15.7)	asymmetry, dynamics, heterogeneity and entry
Main drawback	computation, closed forms needed in practice	one moment, parametric family	dimensionality and boundary trimming	consistency of bid and value families, support bounds

the distribution of observable bids, so that it can be tested? Does identification of the value distribution require parametric assumptions? Can one estimate the value distribution without parametric assumptions and without solving for the equilibrium? Their answers are yes, no and yes. The model places two testable restrictions on bids. The value distribution is identified nonparametrically and constructively. A two-step kernel estimator recovers it, and no estimator can converge uniformly at a faster rate.

Data. The method needs, for each auction $t = 1, \dots, T$, all submitted bids $B_{1t}, \dots, B_{n_t t}$, the number of bidders n_t, and the observed characteristics Z_t of the object. These are the records of a sealed-bid first-price auction, such as a timber sale, a highway procurement or an offshore oil lease sale. GPV illustrate the method on simulated data, and we follow them in Section 15.4.6. Applications to field data appear in Sections 15.5, 15.7 and 15.9.

15.4.1 Setting and the inversion

We first state the model and the assumptions on the data-generating process, following GPV, Section 3.1. A single indivisible object is sold in each auction by a first-price sealed-bid auction. The highest bidder wins and pays her bid. Throughout Sections 15.4.1 to 15.4.6 the reserve price does not bind, so every potential bidder submits a bid and n_t is the number of bidders who could have participated. Section 15.4.7 treats a binding reserve price.

Let $Z_t \in \mathbb{R}^d$ collect the continuous characteristics of the object in auction t, and let $\mathcal{I}$ denote the set of possible numbers of bidders. The characteristics Z_t are common knowledge among bidders. Their role is to absorb observed heterogeneity across auctions. They are not instruments.

Assumption 15.17 (Sampling, GPV Assumption A1)**.** (i) The vectors (Z_t, n_t), $t = 1, 2, \dots$, are independent and identically distributed with density $f_{Zn}(z, n)$. (ii) In each auction t, the values $V_{1t}, \dots, V_{n_t t}$ are independent and identically distributed conditional on (Z_t, n_t), with distribution $F(\cdot \mid Z_t, n_t)$ and density $f(\cdot \mid Z_t, n_t)$.

Assumption 15.18 (Regularity, GPV Assumption A2)**.** The set $\mathcal{I}$ is a bounded subset of $\{2, 3, \dots\}$, and the following hold. (i) For each $n \in \mathcal{I}$, the support of (V, Z) is $\{(v, z) : z \in [\underline{z}, \bar{z}],\ v \in [\underline{v}(z), \bar{v}(z)]\}$ with $\underline{z} < \bar{z}$. (ii) $f(v \mid z, n) \geq c_f > 0$ on this support, and $f_{Zn}(z, n) \geq c_f > 0$ on the support of (Z, n). (iii) For each $n \in \mathcal{I}$, $F(\cdot \mid \cdot, n)$ and $f_{Zn}(\cdot, n)$ have $R + 1$ continuous bounded partial derivatives on their supports, with $R \geq 1$.

Assumption 15.17 rules out dependence of values across auctions. Such dependence would create dynamic incentives that the static equilibrium ignores. It allows the number of bidders to depend on the characteristics of the object. Part (iii) of Assumption 15.18 implies that the value density $f(\cdot \mid z, n)$ has R bounded continuous derivatives. The integer R measures smoothness and governs every rate of convergence below. The density is bounded away from zero, which keeps the bid density away from zero as well (Proposition 15.24). GPV also assume, in the spirit of the theory, that Z_t contains everything that bidders know about the object (Guerre et al., 2000, footnote 11). Unobserved heterogeneity is the subject of Section 15.7.

Equilibrium. Fix an auction with characteristics z and n bidders, and suppress (z, n) when no confusion arises. Set the reserve price equal to $\underline{v}$. By Proposition 14.31, which gives the bid function of Riley and Samuelson (1981), the unique symmetric equilibrium bid is

$$\beta(v) = v - \frac{1}{F(v)^{n-1}} \int_{\underline{v}}^{v} F(u)^{n-1}\, du, \tag{15.7}$$

which is (14.29) with $r = \underline{v}$ (GPV, eqs. (1) and (8)). It solves the differential equation

$$1 = \big(v - \beta(v)\big)(n-1)\frac{f(v)}{F(v)}\frac{1}{\beta'(v)} \tag{15.8}$$

with the boundary condition $\beta(\underline{v}) = \underline{v}$ (GPV, eq. (2)). This is (14.32) divided by $\beta'(v)F(v)^{n-1}$. The bid function is strictly increasing on $[\underline{v}, \bar{v}]$.

Why identification is not obvious. As Section 15.3.1 explained, the bid distribution G depends on F in two ways. It depends on F directly, because values are drawn from F. It also depends on F through the strategy β, which by (15.7) is itself a functional of F. A direct method must untangle both channels for every trial value of F.

The inversion. GPV observe that the first-order condition can be written so that the derivative β', the distribution F and the density f disappear together. We derive the resulting formula step by step. Let $[\underline{b}, \bar{b}] = [\beta(\underline{v}), \beta(\bar{v})]$ denote the support of bids, and note that $\underline{b} = \underline{v}$.

Step 1. We express the bid distribution through F and β. For $b \in [\underline{b}, \bar{b}]$, the strict monotonicity of β gives

$$G(b) = \mathbb{P}(B_i \le b) = \mathbb{P}\big(V_i \le \beta^{-1}(b)\big) = F\big(\beta^{-1}(b)\big).$$

Step 2. We differentiate. By the inverse function rule,

$$g(b) = f\big(\beta^{-1}(b)\big)\frac{d\beta^{-1}(b)}{db} = \frac{f\big(\beta^{-1}(b)\big)}{\beta'\big(\beta^{-1}(b)\big)}.$$

Step 3. We take the ratio. Write $v = \beta^{-1}(b)$. Dividing the result of Step 2 by that of Step 1 gives

$$\frac{g(b)}{G(b)} = \frac{1}{\beta'(v)}\,\frac{f(v)}{F(v)}.$$

Step 4. We substitute into the equilibrium condition. The right side of Step 3 is exactly the product that appears in (15.8). Replacing it there and using $\beta(v) = b$ gives

$$1 = (v - b)(n-1)\frac{g(b)}{G(b)}.$$

Step 5. We solve for the value. Dividing by $(n-1)\frac{g(b)}{G(b)}$ and adding b to both sides yields

$$v = \xi(b; G, n) \equiv b + \frac{1}{n-1}\,\frac{G(b)}{g(b)}. \tag{15.9}$$

This is GPV's equation (3), and it coincides with (14.34). With covariates, G and g are replaced by $G(\cdot \mid z, n)$ and $g(\cdot \mid z, n)$ (GPV, eq. (9)).

Equation (15.9) expresses each value through the bid, the bid distribution, the bid density and the number of bidders. All four are observable or estimable. If bids are equilibrium bids, the value behind each bid must satisfy (15.9). We call $\xi(\cdot; G, n)$ the *inverse bid function*. In equilibrium it equals β^{-1}, and it has been obtained without solving (15.8). We use the symbol ξ for this object throughout the chapter, as GPV do (Table 15.1).

The same equation follows from the bidder's problem written in terms of bids, which is how Section 14.5.5 derived (14.34). A bidder with value v facing rivals whose bids are i.i.d. with distribution G maximizes $(v - b)G(b)^{n-1}$. The first-order condition rearranges to (15.9).

The derivation above shows that the two routes agree. It also shows why the bid-based form is the right one for identification: it contains only objects that the data reveal.

The markdown. The term $\frac{G(b)}{(n-1)g(b)} = v - b$ is the bidder's *markdown*, the shading of the bid below the value. By (14.35), the relative markdown $\frac{v-b}{b}$ equals the inverse of the elasticity of the win probability $G(b)^{n-1}$ with respect to the bid. A bidder is a monopsonist facing the residual supply curve traced out by the highest rival bid. Equation (15.9) makes the oligopoly analogy of Section 15.3.1 exact. The distribution of rival bids plays the role of the demand system, and the econometrician observes it directly.

Credit and precursors. The idea first appeared in print in Laffont and Vuong (1993), who attribute it to an early draft of GPV (Athey and Haile, 2007, Section 3.1). Similar formulas appear earlier in decision-theoretic models of bidding, starting with Friedman (1956). There each bidder optimizes against an exogenous distribution of rival bids, so the value distribution and the bid distribution need not be linked by $F = G \circ \beta$ (Guerre et al., 2000, footnote 3). In (15.9) the link holds because bidders' beliefs about rival bids are correct in equilibrium.

15.4.2 Identification and testable restrictions

We now state GPV's identification theorem. Let $\mathcal{P}$ denote the set of distributions on $\mathbb{R}_+$ that are absolutely continuous with an interval support. The support of a distribution in $\mathcal{P}$ is the closure of the set where its density is positive, so every member of $\mathcal{P}$ is strictly increasing on its support (Guerre et al., 2000, footnote 4). Let $\mathbf{G}$ denote the joint distribution of the n bids $(B_1, \ldots, B_n)$ in an auction. As in GPV, we restrict attention to strictly increasing and differentiable equilibrium strategies.

Theorem 15.19 (Guerre et al., 2000, Theorem 1)**.** *Let $n \geq 2$, and let $\mathbf{G}$ belong to $\mathcal{P}^n$ with support $[\underline{b}, \bar{b}]^n$. Consider a first-price sealed-bid auction with symmetric independent private values and a nonbinding reserve price. There exists a value distribution $F \in \mathcal{P}$ whose equilibrium bids have joint distribution $\mathbf{G}$ if and only if the following two conditions hold.*

(C1) $\mathbf{G}(b_1, \ldots, b_n) = \prod_{i=1}^{n} G(b_i)$ *for some distribution G.*

(C2) The function $\xi(\cdot; G, n)$ defined in (15.9) is strictly increasing on $[\underline{b}, \bar{b}]$, and its inverse is differentiable on $[\underline{v}, \bar{v}] \equiv [\xi(\underline{b}; G, n), \xi(\bar{b}; G, n)]$.

When such an F exists, it is unique, its support is $[\underline{v}, \bar{v}]$, and

$$F(v) = G\big(\xi^{-1}(v; G, n)\big) \qquad \text{for all } v \in [\underline{v}, \bar{v}]. \tag{15.10}$$

Moreover, $\xi(\cdot; G, n)$ is the inverse of the equilibrium strategy: $\xi(b; G, n) = \beta^{-1}(b)$ for all $b \in [\underline{b}, \bar{b}]$.

Proof. We follow GPV, Appendix A.1, and add the global optimality argument that their footnote 5 assumes. Write $\xi(b)$ for $\xi(b; G, n)$.

Necessity of (C1). Suppose $F \in \mathcal{P}$ with support $[\underline{v}, \bar{v}]$ rationalizes $\mathbf{G}$, and let β be the equilibrium strategy. Each bid is $B_i = \beta(V_i)$, a fixed function of an independent draw from F. Hence the bids are i.i.d., and (C1) holds with $G(b) = F(\beta^{-1}(b))$.

Necessity of (C2). The strategy β solves (15.8). Steps 1 to 5 of Section 15.4.1 show that (15.8) implies $\xi(\beta(v)) = v$ for every $v \in [\underline{v}, \bar{v}]$. Setting $b = \beta(v)$ gives $\xi(b) = \beta^{-1}(b)$ on $[\underline{b}, \bar{b}]$. The inverse of a strictly increasing function is strictly increasing, so ξ is strictly increasing. Its inverse is β, which is differentiable on $[\underline{v}, \bar{v}] = [\xi(\underline{b}), \xi(\bar{b})]$. Hence (C2) holds.

Sufficiency, Step 1: the lower boundary. Assume (C1) and (C2). We show that

$$\lim_{b \downarrow \underline{b}} \xi(b) = \underline{b}. \tag{15.11}$$

Since ξ is strictly increasing, the limit exists. Since $\frac{G}{g} \geq 0$, we have $\xi(b) \geq b$, so the limit equals $\underline{b} + c$ for some $c \geq 0$. Suppose that $c > 0$. By (15.9),

$$\frac{G(b)}{g(b)} = (n-1)\big(\xi(b) - b\big) \longrightarrow (n-1)c > 0 \qquad \text{as } b \downarrow \underline{b}.$$

Hence there is $\delta > 0$ with $\frac{g(b)}{G(b)} \leq \frac{2}{(n-1)c}$ on $(\underline{b}, \underline{b} + \delta)$. Because $\frac{d}{db} \ln G(b) = \frac{g(b)}{G(b)}$, integrating over $[b, \underline{b} + \delta]$ gives

$$\ln G(b) \geq \ln G(\underline{b} + \delta) - \frac{2\delta}{(n-1)c} \qquad \text{for all } b \in (\underline{b}, \underline{b} + \delta).$$

The right side is a finite constant, yet $\ln G(b) \to -\infty$ as $b \downarrow \underline{b}$ because $G(\underline{b}) = 0$. This contradiction shows that $c = 0$.

Sufficiency, Step 2: a candidate distribution. Set $\underline{v} = \xi(\underline{b}) = \underline{b}$, using (15.11), and $\bar{v} = \xi(\bar{b})$. Define F on $[\underline{v}, \bar{v}]$ by (15.10). By (C2), ξ^{-1} is strictly increasing and differentiable. Since G is strictly increasing on $[\underline{b}, \bar{b}]$ and absolutely continuous, F is strictly increasing and absolutely continuous, with $F(\underline{v}) = G(\underline{b}) = 0$ and $F(\bar{v}) = G(\bar{b}) = 1$. Hence $F \in \mathcal{P}$ with support $[\underline{v}, \bar{v}]$.

Sufficiency, Step 3: the candidate strategy solves the equilibrium equation. Let $s = \xi^{-1}$. By Step 1, $s(\underline{v}) = \underline{v}$. By construction $F(v) = G(s(v))$, so $f(v) = g(s(v))s'(v)$ and

$$\frac{f(v)}{F(v)} = s'(v)\,\frac{g\big(s(v)\big)}{G\big(s(v)\big)}.$$

Evaluating (15.9) at $b = s(v)$ gives $v = s(v) + \frac{G(s(v))}{(n-1)g(s(v))}$, which rearranges to

$$1 = \big(v - s(v)\big)(n-1)\frac{g\big(s(v)\big)}{G\big(s(v)\big)} = \big(v - s(v)\big)(n-1)\frac{f(v)}{F(v)}\frac{1}{s'(v)}.$$

This is (15.8) with the boundary condition $s(\underline{v}) = \underline{v}$. By Step 5 of the proof of Proposition 14.31, its unique solution is the bid function (15.7) associated with F. Hence $s = \beta$.

Sufficiency, Step 4: the candidate strategy is a best response. Suppose the rivals use s and draw values from F. Each rival bid then has distribution $F(s^{-1}(b)) = F(\xi(b)) = G(b)$. A bidder with value v who bids $b \in [\underline{b}, \bar{b}]$ earns $(v-b)G(b)^{n-1}$. Its derivative is

$$\frac{d}{db}\Big[(v-b)G(b)^{n-1}\Big] = G(b)^{n-2}\Big[(n-1)g(b)(v-b) - G(b)\Big] = (n-1)g(b)G(b)^{n-2}\big[v - \xi(b)\big].$$

By (C2) the bracket is positive for $b < s(v)$ and negative for $b > s(v)$. The payoff therefore rises up to $b = s(v)$ and falls after it, so $s(v)$ is the best bid in $[\underline{b}, \bar{b}]$. A bid above $\bar{b}$ wins with certainty, like $\bar{b}$, but costs more. A bid below $\underline{b}$ never wins and earns zero, which is at most $(v - s(v))G(s(v))^{n-1} \geq 0$. Hence s is a symmetric equilibrium. The resulting joint distribution of bids is $\prod_i G(b_i) = \mathbf{G}$ by (C1).

Uniqueness. The necessity part shows that any rationalizing F has an equilibrium strategy with $\beta = \xi^{-1}$. Then $F(v) = G(\beta(v)) = G(\xi^{-1}(v))$, which is (15.10). The right side depends only on G and n, so F is unique. Its support is $[\xi(\underline{b}), \xi(\bar{b})] = [\underline{b}, \xi(\bar{b})]$ by (15.11). □

Step 4 of the proof shows the role of (C2) beyond invertibility. The derivative of the payoff factors into a positive term and the gap $v - \xi(b)$. Monotonicity of ξ is exactly the condition under which the first-order condition picks the global maximum. GPV assume second-order conditions in their footnote 5. In the SIPV model (C2) delivers them. Athey and Haile (2007, Section 5.1) use the same single-crossing logic for the affiliated private values model with independence or symmetry (Theorem 15.29 below).

Remark 15.20 (An equivalent form of (C2)). Suppose g is differentiable on $(\underline{b}, \bar{b})$. Differentiating (15.9) by the quotient rule gives

$$\xi'(b) = 1 + \frac{1}{n-1}\,\frac{g(b)^2 - G(b)g'(b)}{g(b)^2} = \frac{n}{n-1} - \frac{1}{n-1}\,\frac{G(b)g'(b)}{g(b)^2}.$$

The derivative of $\frac{g}{G^n}$ is

$$\frac{d}{db}\frac{g(b)}{G(b)^n} = \frac{g'(b)G(b)^n - nG(b)^{n-1}g(b)^2}{G(b)^{2n}} = \frac{G(b)g'(b) - ng(b)^2}{G(b)^{n+1}}.$$

Comparing the two displays,

$$\xi'(b) = -\frac{G(b)^{n+1}}{(n-1)g(b)^2}\,\frac{d}{db}\frac{g(b)}{G(b)^n}.$$

The factor in front is negative, so ξ is strictly increasing if and only if $\frac{g}{G^n}$ is strictly decreasing (Guerre et al., 2000, footnote 6). A sufficient condition is that G is *log-concave*, that is, $\frac{g}{G}$ is decreasing. Indeed $\frac{g}{G^n} = \frac{g}{G}\cdot G^{-(n-1)}$ is then the product of a positive decreasing function and a positive strictly decreasing function. GPV state this sufficient condition on p. 530. Log-concavity is a property of the bid data, so it can be checked directly.

Condition (C2) has content. Bid distributions with deep U-shaped densities can violate it, and so can some sharply peaked multimodal densities (Guerre et al., 2000, p. 530). The next example, due to GPV, makes the point concrete.

Example 15.21 (Bids that no value distribution rationalizes)**.** Let $n = 2$ and let bids be i.i.d. with distribution

$$G(b) = \left(\frac{b}{5-4b}\right)^{\frac{1}{5}}, \qquad b \in [0,1].$$

This is a valid distribution: $G(0) = 0$, $G(1) = 1$, and $\frac{b}{5-4b}$ is strictly increasing. We compute the inverse bid function in four steps. First, take logarithms:

$$\ln G(b) = \frac{1}{5}\Big[\ln b - \ln(5-4b)\Big].$$

Second, differentiate:

$$\frac{g(b)}{G(b)} = \frac{1}{5}\left[\frac{1}{b} + \frac{4}{5-4b}\right] = \frac{1}{5}\cdot\frac{5-4b+4b}{b(5-4b)} = \frac{1}{b(5-4b)}.$$

Third, substitute into (15.9) with $n-1 = 1$:

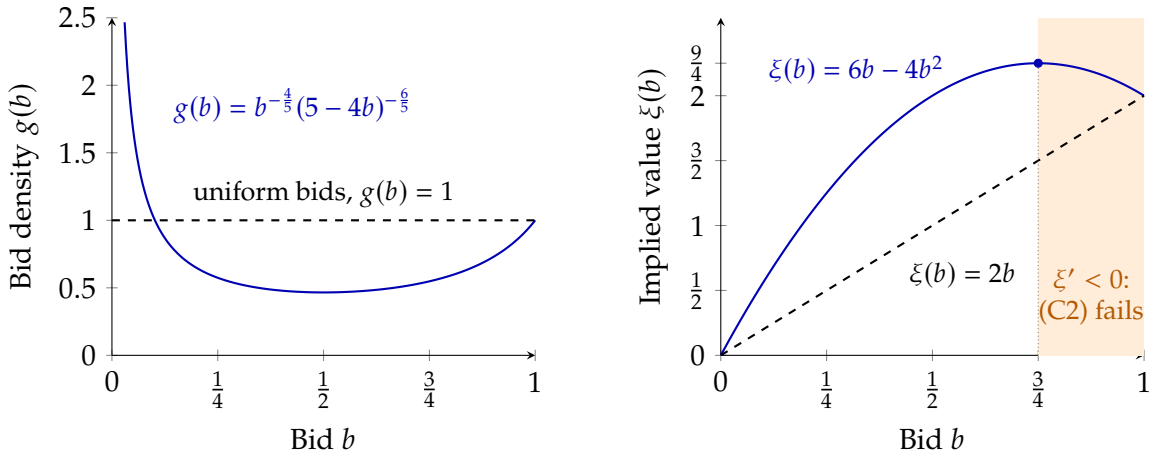
$$\xi(b) = b + b(5-4b) = 6b - 4b^2.$$

Fourth, differentiate: $\xi'(b) = 6 - 8b$, which is negative for $b > \frac{3}{4}$. Condition (C2) fails. The implied value peaks at $\xi(\frac{3}{4}) = \frac{9}{4}$ and falls to $\xi(1) = 2$. A bidder who bids 0.9 would need a lower value, 2.16, than a bidder who bids 0.8, whose implied value is 2.24. Both cannot be best responses to the same distribution of rival bids, so no value distribution generates these bids in equilibrium.

The density behind this example is U-shaped. Multiplying the second step by G gives $g(b) = b^{-\frac{4}{5}}(5 - 4b)^{-\frac{6}{5}}$. Its logarithmic derivative is $-\frac{4}{5b} + \frac{24}{5(5-4b)}$, which vanishes at $b = \frac{1}{2}$. The density falls from infinity at $b = 0$ to $g(\frac{1}{2}) \approx 0.47$ and rises to $g(1) = 1$. The mass of high bids is too thin relative to the mass just below them. Consistently with Remark 15.20, the function $\frac{g}{G^2} = b^{-\frac{6}{5}}(5 - 4b)^{-\frac{4}{5}}$ falls on $(0, \frac{3}{4})$ and rises on $(\frac{3}{4}, 1)$.

For contrast, let bids be uniform on $[0, 1]$ with $n = 2$. Then $\frac{G}{g} = b$ and $\xi(b) = 2b$, which is strictly increasing. Formula (15.10) gives $F(v) = G(\frac{v}{2}) = \frac{v}{2}$ on $[0, 2]$. These bids come from values uniform on $[0, 2]$, with $\beta(v) = \frac{v}{2}$, as Example 14.32 confirms after rescaling.

The exponent $\frac{1}{5}$ matters. With exponent $\frac{3}{2}$ instead, the second step gives $\frac{G}{g} = \frac{b(5-4b)}{7.5}$ and $\xi'(b) = 1 + \frac{5-8b}{7.5} \geq 1 - \frac{3}{7.5} > 0$, so (C2) would hold. Figure 15.7 plots both bid densities and both inverse bid functions of the example.



(a) Bid densities

(b) Inverse bid functions

Figure 15.7: The counterexample of Guerre et al. (2000, p. 530). Two bidders, bids i.i.d. with $G(b) = (\frac{b}{5-4b})^{\frac{1}{5}}$ on $[0, 1]$ (solid), against bids uniform on $[0, 1]$ (dashed). The U-shaped bid density in panel (a) implies an inverse bid function that falls for $b > \frac{3}{4}$ (shaded region in panel (b)), so no value distribution rationalizes these bids. Uniform bids imply $\xi(b) = 2b$ and values uniform on $[0, 2]$.

Remark 15.22 (What kind of identification result this is). Four features of Theorem 15.19 deserve emphasis. First, identification is nonparametric: no family of distributions is assumed. It implies identification within any parametric family. A parametric specification then serves only as an approximation and plays no role in identification (Section 15.1.2). Second, the proof is constructive, since (15.10) gives F explicitly. Third, the result is global. It does not rest on conditions in a neighborhood of a particular distribution (Guerre et al., 2000, footnote 7). Fourth, the theorem characterizes the testable content of the model: (C1) and (C2) are all the restrictions that the SIPV first-price model places on bids from auctions with a fixed n. Section 15.4.9 turns them into tests.

Remark 15.23 (One equilibrium in all auctions). The inversion uses the distribution of rival bids observed across auctions as the belief of each bidder in each auction. This relies on the sampling assumption of Section 15.1.1 that the same equilibrium is played in all auctions with the same observables. In the SIPV model the equilibrium is unique, so the assumption holds automatically (Athey and Haile, 2007, Section 3.1).

15.4.3 The bid density is smoother than the value density

The estimator of Section 15.4.4 replaces G and g in (15.9) by estimates. How well they can be estimated depends on their smoothness. GPV show that the bid density has one more derivative than the value density.

Proposition 15.24 (Guerre et al., 2000, Proposition 1)**.** *Under Assumption 15.18, the conditional bid distribution $G(\cdot \mid \cdot,\cdot)$ satisfies the following. (i) For each $n \in \mathcal{I}$, its support is $\{(b,z) : z \in [\underline{z},\bar{z}],\ b \in [\underline{b}(z,n), \bar{b}(z,n)]\}$ with $\inf_z[\bar{b}(z,n) - \underline{b}(z,n)] > 0$. The boundaries $\underline{b}(\cdot,n)$ and $\bar{b}(\cdot,n)$ have $R+1$ continuous bounded derivatives, and $\underline{b}(z,n) = \underline{v}(z)$. (ii) $g(b \mid z,n) \geq c_g > 0$ on the support. (iii) $G(\cdot \mid \cdot,n)$ has $R+1$ continuous bounded partial derivatives on the support. (iv) On any closed subset of the interior of the support, $g(\cdot \mid \cdot,n)$ has $R+1$ continuous bounded partial derivatives.*

Part (iv) is the striking one. The value density has R derivatives, and the bid density has $R+1$ on inner sets. The intuition comes from rearranging (15.9):

$$g(b \mid z,n) = \frac{G(b \mid z,n)}{(n-1)\big(\xi(b;z,n) - b\big)} \tag{15.12}$$

(Guerre et al., 2000, p. 536). The same formula appeared in Section 15.3.2 as the bid density of a parametric model. The bid function (15.7) involves F and its integral, so it has the $R+1$ derivatives of F. Its inverse ξ inherits them. The distribution G also has $R+1$ derivatives by part (iii). On inner sets the denominator of (15.12) is bounded away from zero, so g has $R+1$ derivatives there. The bidding strategy acts as a smoothing operator. Each bid aggregates information about the whole lower tail of F through the integral in (15.7).

Formula (15.12) also explains part (ii) and the behavior of g at the edges of its support. At the top, $G(\bar{b}) = 1$, so $g(\bar{b}) = \frac{1}{(n-1)(\bar{v}-\bar{b})}$. At the bottom, both G and $\xi(b) - b$ vanish. To find the limit we expand near $\underline{v}$. Because $f(\underline{v}) > 0$, we have $F(u) = f(\underline{v})(u - \underline{v})(1 + o(1))$ as $u \downarrow \underline{v}$. Substituting into (15.7),

$$v - \beta(v) = \frac{\int_{\underline{v}}^{v} f(\underline{v})^{n-1}(u-\underline{v})^{n-1}du}{f(\underline{v})^{n-1}(v-\underline{v})^{n-1}}\big(1+o(1)\big) = \frac{v-\underline{v}}{n}\big(1+o(1)\big).$$

Hence, at $b = \beta(v)$,

$$g(b) = \frac{F(v)}{(n-1)\big(v-\beta(v)\big)} = \frac{f(\underline{v})(v-\underline{v})}{(n-1)\frac{v-\underline{v}}{n}}\big(1+o(1)\big) \longrightarrow \frac{n}{n-1}\,f(\underline{v})$$

as $v \downarrow \underline{v}$. For values uniform on $[0,1]$, bids are uniform on $[0, \frac{n-1}{n}]$ with density $\frac{n}{n-1}$, which matches the formula.

The consequence for estimation is immediate. By Stone (1982), a function with $R+1$ derivatives in $d+1$ dimensions can be estimated uniformly at the rate $(\frac{T}{\log T})^{\frac{R+1}{2R+d+3}}$. The bid density, and with it the inverse bid function on inner sets, can therefore be estimated faster than the value density could be estimated even if values were observed. The difficulty lies elsewhere, as Section 15.4.5 shows.

15.4.4 The two-step estimator

Theorem 15.19 suggests an estimator that mirrors identification. In the first step we estimate G and g nonparametrically and use (15.9) to build a *pseudo-sample* of values, one pseudo-value per bid (Section 15.1.3). In the second step we treat the pseudo-values as a sample from F and estimate its density by kernel smoothing. Kernel density estimation, bandwidths and boundary effects are reviewed in Appendix A. Throughout, kernels are normalized to have support $[-1, 1]$.

Homogeneous auctions. Suppose first that all T auctions sell identical objects with the same number n of bidders. The first step estimates the bid distribution by its empirical counterpart and the bid density by a kernel estimator (GPV, eqs. (4)–(5)):

$$\hat{G}(b) = \frac{1}{nT} \sum_{t=1}^{T} \sum_{i=1}^{n} \mathbf{1}(B_{it} \le b), \tag{15.13}$$

$$\hat{g}(b) = \frac{1}{nTh_g} \sum_{t=1}^{T} \sum_{i=1}^{n} \mathcal{K}\Big(\frac{b - B_{it}}{h_g}\Big), \tag{15.14}$$

where $\mathcal{K}$ is a kernel and h_g a bandwidth. All nT bids enter, because bids are i.i.d. within and across auctions under (C1).

Boundary bias. A kernel density estimator is biased near the edges of the support, and the bias contaminates the pseudo-values. We derive the bias at the top of the support, following GPV, p. 531. Take a symmetric kernel with support $[-1, 1]$ and a bid $b = \bar{b} - \lambda h_g$ with $\lambda \in [0, 1)$. Then

$$\mathbb{E}\big[\hat{g}(b)\big] = \frac{1}{h_g} \int_{\underline{b}}^{\bar{b}} \mathcal{K}\Big(\frac{b - y}{h_g}\Big) g(y)\, dy.$$

We change variables to $u = \frac{b-y}{h_g}$, so that $y = b - h_g u$ and $dy = -h_g\, du$. The upper limit $y = \bar{b}$ becomes $u = \frac{b-\bar{b}}{h_g} = -\lambda$. The lower limit $y = \underline{b}$ becomes $u = \frac{b-\underline{b}}{h_g}$, which exceeds one once h_g is small. Hence

$$\mathbb{E}\big[\hat{g}(b)\big] = \int_{-\lambda}^{1} \mathcal{K}(u)\, g(b - h_g u)\, du \longrightarrow g(\bar{b}) \int_{-\lambda}^{1} \mathcal{K}(u)\, du \qquad \text{as } h_g \to 0.$$

For $\lambda < 1$ the integral of the kernel is less than one, and at $\lambda = 0$ it equals $\frac{1}{2}$. Within one bandwidth of $\bar{b}$, the estimator therefore underestimates the density, by up to one half at the edge. The same argument applies within one bandwidth of $\underline{b}$.

The effect on the pseudo-values is large. At the top, $\hat{G} \approx 1$ while $\hat{g} \approx \frac{1}{2} g(\bar{b})$, so the estimated markdown is about twice the true markdown $\bar{v} - \bar{b}$. The pseudo-value of the top bid is then about $\bar{b} + 2(\bar{v} - \bar{b}) = 2\bar{v} - \bar{b}$, well above the largest possible value. Figure 15.9 shows the effect in a simulated sample.

Trimming. Let $B_{\min}$ and $B_{\max}$ be the smallest and largest of the nT bids. Because $\underline{b} \le B_{\min}$ and $B_{\max} \le \bar{b}$, the estimator $\hat{g}$ is asymptotically unbiased on $[B_{\min} + h_g, B_{\max} - h_g]$. GPV define the pseudo-values as (GPV, eq. (6))

$$\hat{V}_{it} = \begin{cases} B_{it} + \dfrac{1}{n-1} \dfrac{\hat{G}(B_{it})}{\hat{g}(B_{it})} & \text{if } B_{\min} + h_g \le B_{it} \le B_{\max} - h_g, \\ +\infty & \text{otherwise.} \end{cases} \tag{15.15}$$

Setting a trimmed pseudo-value to $+\infty$ removes it from the second step, because a kernel with bounded support assigns it zero weight.

Second step. The density of values is estimated by (GPV, eq. (7))

$$\hat{f}(v) = \frac{1}{nTh_f} \sum_{t=1}^{T} \sum_{i=1}^{n} \mathcal{K}_f\Big(\frac{v - \hat{V}_{it}}{h_f}\Big), \tag{15.16}$$

with kernel $\mathcal{K}_f$ and bandwidth h_f. The distribution function, quantiles, and any functional of F follow from the pseudo-values or from $\hat{f}$. The estimator involves no optimization and no equilibrium computation.

Heterogeneous auctions. In applications the objects differ and the number of bidders varies. GPV, Section 3.3, extend the estimator jointly over (b, z, n). Define

$$G(b, z, n) = G(b \mid z, n) f_{Zn}(z, n), \qquad g(b, z, n) = g(b \mid z, n) f_{Zn}(z, n).$$

The density f_{Zn} cancels in the ratio, so (15.9) becomes (GPV, eq. (12))

$$V_{it} = B_{it} + \frac{1}{n_t - 1} \psi(B_{it}, Z_t, n_t), \qquad \psi(b, z, n) \equiv \frac{G(b, z, n)}{g(b, z, n)}. \tag{15.17}$$

The ratio ψ is a local symbol of this subsection, unrelated to the virtual valuation ψ of (14.48). The numerator and denominator are estimated by (GPV, eqs. (13)–(14))

$$\hat{G}(b, z, n) = \frac{1}{Th_G^d} \sum_{t=1}^{T} \frac{1}{n_t} \sum_{i=1}^{n_t} \mathbf{1}(B_{it} \le b)\, \mathcal{K}_G\Big(\frac{z - Z_t}{h_G}, \frac{n - n_t}{h_{Gn}}\Big), \tag{15.18}$$

$$\hat{g}(b, z, n) = \frac{1}{Th_g^{d+1}} \sum_{t=1}^{T} \frac{1}{n_t} \sum_{i=1}^{n_t} \mathcal{K}_g\Big(\frac{b - B_{it}}{h_g}, \frac{z - Z_t}{h_g}, \frac{n - n_t}{h_{gn}}\Big). \tag{15.19}$$

The factor $\frac{1}{n_t}$ averages the bids within an auction, because $\mathbb{E}\big[\frac{1}{n_t}\sum_i \mathbf{1}(B_{it} \le b) \mid Z_t, n_t\big] = G(b \mid Z_t, n_t)$. The kernels are products of kernels in each argument. The discrete variable n receives its own bandwidths h_{Gn} and h_{gn}, which vanish as T grows, so that asymptotically only auctions with $n_t = n$ contribute (Bierens, 1987). With discrete covariates one estimates cell by cell, and d counts only the continuous covariates (Guerre et al., 2000, footnote 12).

Estimated boundaries and trimming. The support of bids now varies with (z, n) and is unknown. Even if $\underline{v}(\cdot)$ and $\bar{v}(\cdot)$ were known, $\bar{b}(z, n) = \beta(\bar{v}(z); z, n)$ would depend on F. GPV partition $\mathbb{R}^d$ into hypercubes of side h_∂ and estimate (GPV, eqs. (16)–(17))

$$\hat{\bar{b}}(z, n) = \max\{B_{it} : Z_t \text{ in the hypercube containing } z,\ n_t = n\},$$
$$\hat{\underline{b}}(z) = \min\{B_{it} : Z_t \text{ in the hypercube containing } z\}.$$

The lower estimate pools all n, because $\underline{b}(z, n) = \underline{v}(z)$ does not depend on n. Let $\hat{S}_n = \{(b, z) : z \in [\underline{z}, \bar{z}],\ b \in [\hat{\underline{b}}(z), \hat{\bar{b}}(z, n)]\}$ be the estimated support, and let $S(h)$ denote the support of the rescaled kernel, a hypercube of side h centered at the origin. The pseudo-value is $\hat{V}_{it} = B_{it} + \frac{1}{n_t - 1}\hat{\psi}(B_{it}, Z_t, n_t)$ with (GPV, eqs. (18)–(19))

$$\hat{\psi}(b, z, n) = \begin{cases} \dfrac{\hat{G}(b, z, n)}{\hat{g}(b, z, n)} & \text{if } (b, z) + S(2h_G) \subset \hat{S}_n \text{ and } (b, z) + S(2h_g) \subset \hat{S}_n, \\ +\infty & \text{otherwise.} \end{cases} \tag{15.20}$$

Observations closer to the estimated boundary than a multiple of the bandwidth are trimmed. Without covariates, the factor 2 can be replaced by 1, which returns (15.15) (Guerre et al., 2000, footnote 20).

Second step with covariates. The conditional density of values is the ratio $\hat{f}(v \mid z) = \frac{\hat{f}(v,z)}{\hat{f}(z)}$, where (GPV, eqs. (20)–(21))

$$\hat{f}(v,z) = \frac{1}{T h_f^{d+1}} \sum_{t=1}^{T} \frac{1}{n_t} \sum_{i=1}^{n_t} \mathcal{K}_f\Big(\frac{v - \hat{V}_{it}}{h_f}, \frac{z - Z_t}{h_f}\Big), \tag{15.21}$$

$$\hat{f}(z) = \frac{1}{T h_Z^{d}} \sum_{t=1}^{T} \mathcal{K}_Z\Big(\frac{z - Z_t}{h_Z}\Big).$$

The second step pools auctions with different n. This presumes that values and the number of bidders are independent given Z_t, so that $f(v \mid z, n) = f(v \mid z)$. GPV adopt this restriction and note that its failure calls for an explicit model of entry (Guerre et al., 2000, footnote 14). Section 15.8 develops such models.

Assumption 15.25 (Kernels and bandwidths, GPV Assumptions A3–A4)**.** (i) The kernels $\mathcal{K}_G$, $\mathcal{K}_g$, $\mathcal{K}_f$ and $\mathcal{K}_Z$ are symmetric with bounded hypercube supports, integrate to one, and have two continuous bounded derivatives in their continuous arguments. Their orders are $R+1$, $R+1$, R and $R+1$, so that their moments of lower order vanish. (ii) The discrete bandwidths h_{Gn} and h_{gn} vanish as $T \to \infty$. (iii) For positive constants $c_G, c_g, c_f, c_Z, c_\partial$,

$$h_G = c_G\Big(\frac{\log T}{T}\Big)^{\frac{1}{2R+d+2}}, \qquad h_g = c_g\Big(\frac{\log T}{T}\Big)^{\frac{1}{2R+d+3}},$$
$$h_f = c_f\Big(\frac{\log T}{T}\Big)^{\frac{1}{2R+d+3}}, \qquad h_Z = c_Z\Big(\frac{\log T}{T}\Big)^{\frac{1}{2R+d+2}},$$

and, when $d > 0$, $h_\partial = c_\partial\big(\frac{\log T}{T}\big)^{\frac{1}{d+1}}$.

The bandwidths for G, g and $f(z)$ are the uniformly optimal choices for functions with $R+1$ derivatives. A function of d arguments with $R+1$ derivatives calls for the exponent $\frac{1}{2(R+1)+d} = \frac{1}{2R+d+2}$. The bid density has $d+1$ arguments, which gives $\frac{1}{2R+d+3}$. The factor $\log T$ appears because the results concern uniform convergence. The choice of h_f is unusual. If values were observed, the optimal exponent for $f(\cdot,\cdot)$ would be $\frac{1}{2R+d+1}$, and h_f would shrink faster. The prescribed h_f is larger, so the second step *oversmooths*. Section 15.4.5 explains why this is the only rate that attains the optimal convergence rate.

Bandwidths in practice. GPV's Monte Carlo uses $R = 1$ and $d = 0$, so both h_g and h_f are of order $T^{-\frac{1}{5}}$ up to the logarithm. They use the triweight kernel

$$\mathcal{K}(u) = \frac{35}{32}\big(1 - u^2\big)^3 \mathbf{1}(|u| \le 1)$$

for both steps, with $h_g = 1.06\,\hat{\sigma}_b (nT)^{-\frac{1}{5}}$ and $h_f = 1.06\,\hat{\sigma}_v (nT_T)^{-\frac{1}{5}}$ (Guerre et al., 2000, p. 532). Here $\hat{\sigma}_b$ and $\hat{\sigma}_v$ are the standard deviations of the bids and of the pseudo-values that survive trimming, which GPV call the trimmed pseudo private values. T_T is the number of auctions left after trimming. The factor 1.06 is the Gaussian rule of thumb (Härdle, 1991).

Later work multiplies the rule by 2.978 when it uses the triweight kernel (Li et al., 2002; Campo et al., 2003; Krasnokutskaya, 2011). The factor converts a bandwidth that is optimal for the Gaussian kernel into the equivalent bandwidth for the triweight kernel. We verify it. For a second-order kernel, the bandwidth that minimizes the asymptotic mean integrated squared error is proportional to the kernel constant $\delta_{\mathcal{K}} = \left(\frac{\int \mathcal{K}^2}{(\int u^2\mathcal{K})^2}\right)^{\frac{1}{5}}$. The factor of proportionality does not depend on the kernel (Härdle, 1991). For the Gaussian kernel, $\int \mathcal{K}^2 = \frac{1}{2\sqrt{\pi}}$ and $\int u^2\mathcal{K} = 1$, so $\delta = (2\sqrt{\pi})^{-\frac{1}{5}} \approx 0.7764$. For the triweight kernel,

$$\int_{-1}^{1} \mathcal{K}^2 = \left(\frac{35}{32}\right)^2 \int_{-1}^{1} (1-u^2)^6 du = \frac{350}{429}, \qquad \int_{-1}^{1} u^2\mathcal{K} = \frac{35}{32} \int_{-1}^{1} u^2(1-u^2)^3 du = \frac{1}{9},$$

so $\delta = \left(\frac{350}{429} \cdot 81\right)^{\frac{1}{5}} \approx 2.3122$. The ratio is $\frac{2.3122}{0.7764} \approx 2.978$. GPV's choice, without the factor, is narrower than the Gaussian-equivalent bandwidth. It trims fewer bids and smooths less. Table 15.6 compares the two choices.

The algorithm. For a sample of first-price auctions with all bids recorded, the estimator proceeds as follows.

1. Group auctions by the number of bidders, and by covariate cells if covariates are discrete. Choose kernels and bandwidths, for example by the rule of thumb above.
2. For each bid, compute $\hat{G}(B_{it})$ and $\hat{g}(B_{it})$ from (15.13)–(15.14), or from (15.18)–(15.19) with continuous covariates.
3. Trim the bids within one bandwidth of the estimated boundaries, and compute the pseudo-values of the remaining bids from (15.15) or (15.20).
4. Evaluate $\hat{\xi}(b) = b + \frac{\hat{G}(b)}{(n-1)\hat{g}(b)}$ on a grid and check that it is increasing, as (C2) requires.
5. Estimate the value density by (15.16) or (15.21), and compute the functionals of interest. Examples are value quantiles, the winner's informational rent $\frac{V-B}{V}$, the optimal reserve price from $\hat{F}$ (Corollary 14.47), and expected revenue under other formats, such as $\mathbb{E}[V^{(n-1:n)}]$ for a second-price auction.

15.4.5 Rates of convergence and inference

How fast can any estimator recover $f(\cdot \mid z)$ from bids? GPV answer with the minimax theory of Ibragimov and Has'minskii (1981). We state the criterion, the result, and a sketch of the proof. Let C be a compact subset, with nonempty interior, of the interior of the support of $f_0(v, z)$. For a candidate rate $r_T \to \infty$, consider (GPV, eq. (10))

$$\inf_{\hat{f}} \sup_{f \in U_\epsilon(f_0)} \mathbb{P}_f\Big(r_T \sup_{(v,z)\in C} \big|\hat{f}(v \mid z) - f(v \mid z)\big| > \kappa\Big), \tag{15.22}$$

where the infimum runs over all estimators based on bids. Here $\mathbb{P}_f$ is the law of the observables when values have density f. The neighborhood $U_\epsilon(f_0)$ contains the densities that satisfy Assumption 15.18, lie within ϵ of f_0 in sup norm, and have derivatives up to order R bounded by a constant M. Taking the supremum over a neighborhood rules out estimators that do well at one density only. If r_T grows too fast, (15.22) stays bounded away from zero for every estimator. The optimal uniform rate is the fastest r_T for which some estimator drives (15.22) to zero for large κ.

Theorem 15.26 (Guerre et al., 2000, Theorems 2 and 3)**.** *Let Assumption 15.17 and Assumption 15.18 hold.*

(i) (Lower bound.) There is $\kappa > 0$ such that, with $r_T = (\frac{T}{\log T})^{\frac{R}{2R+d+3}}$,

$$\lim_{\epsilon \to 0} \liminf_{T \to \infty} \inf_{\hat{f}} \sup_{f \in U_\epsilon(f_0)} \mathbb{P}_f \Big(r_T \sup_{(v,z) \in C} \big| \hat{f}(v \mid z) - f(v \mid z) \big| > \kappa \Big) > 0.$$

(ii) (Attainment.) If, in addition, Assumption 15.25 holds, the two-step estimator satisfies, for every closed inner subset C of the support,

$$\sup_{(v,z) \in C} \big| \hat{f}(v \mid z) - f(v \mid z) \big| = O\left(\left(\frac{\log T}{T} \right)^{\frac{R}{2R+d+3}} \right) \quad \text{almost surely.}$$

Hence $(\frac{T}{\log T})^{\frac{R}{2R+d+3}}$ is the optimal uniform rate for estimating $f(\cdot \mid \cdot)$ from bids, and the two-step estimator attains it.

If values were observed, the optimal uniform rate would be $(\frac{T}{\log T})^{\frac{R}{2R+d+1}}$ (Stone, 1982). Not observing values costs two units in the denominator of the exponent. The proof of part (i) adapts the argument of Khas'minskii (1979) and relies on Theorem 15.19 and Proposition 15.24. We do not reproduce it.

Where the loss comes from. Differentiating (15.10) with respect to v gives (GPV, eq. (11))

$$f(v \mid z, n) = \frac{g\big(\xi^{-1}(v; z, n) \mid z, n\big)}{\xi'\big(\xi^{-1}(v; z, n); z, n\big)}. \tag{15.23}$$

Recovering f requires the derivative ξ', and by (15.9) this requires the derivative g'. The bid density has $R + 1$ derivatives in $d + 1$ arguments. By Stone (1982), the optimal uniform rate for the first derivative of such a function is $(\frac{T}{\log T})^{\frac{(R+1)-1}{2(R+1)+(d+1)}} = (\frac{T}{\log T})^{\frac{R}{2R+d+3}}$. Estimating g' is the hardest part of the problem, and its rate is the rate for f. Table 15.5 compares the exponents.

Table 15.5: Exponents of the optimal uniform convergence rates $(\frac{T}{\log T})^a$

R	d	Values observed $a = \frac{R}{2R+d+1}$	Bids only $a = \frac{R}{2R+d+3}$	Pseudo-values, inner sets $a = \frac{R+1}{2R+d+3}$
1	0	$\frac{1}{3}$	$\frac{1}{5}$	$\frac{2}{5}$
2	0	$\frac{2}{5}$	$\frac{2}{7}$	$\frac{3}{7}$
1	1	$\frac{1}{4}$	$\frac{1}{6}$	$\frac{1}{3}$
2	1	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{3}{8}$
1	2	$\frac{1}{5}$	$\frac{1}{7}$	$\frac{2}{7}$

Notes. R is the number of bounded derivatives of the value density and d the number of continuous covariates. The column "Values observed" gives the rate of Stone (1982), and the column "Bids only" gives the rate of Theorem 15.26. The last column gives the rate of $\sup |\hat{V}_{it} - V_{it}|$ over bids away from the boundary (GPV, Proposition 3(ii)). Our computation from these formulas.

Sketch of the proof of part (ii). The argument shows why the second step must oversmooth. Write $\varepsilon_T = \frac{\log T}{T}$. Two preliminary results are needed. The boundary estimators converge at the rate

$\varepsilon_T^{\frac{1}{d+1}}$ (GPV, Proposition 2). The untrimmed pseudo-values satisfy $\sup|\hat{V}_{it} - V_{it}| = O(\varepsilon_T^{\frac{R}{2R+d+3}})$, and on bids away from the boundary $\sup|\hat{V}_{it} - V_{it}| = O(\varepsilon_T^{\frac{R+1}{2R+d+3}})$ almost surely (GPV, Proposition 3). The faster inner rate reflects the extra derivative of g in Proposition 15.24.

Because $\hat{f}(z)$ converges at the faster rate $\varepsilon_T^{\frac{R+1}{2R+d+2}}$ and $f(z)$ is bounded away from zero, it suffices to study $\hat{f}(v,z)$. Let $\tilde{f}(v,z)$ be the infeasible estimator (15.21) computed with the true values V_{it} in place of $\hat{V}_{it}$ (GPV, eq. (22)). We decompose

$$\hat{f}(v,z) - f(v,z) = \big[\hat{f}(v,z) - \tilde{f}(v,z)\big] + \big[\tilde{f}(v,z) - f(v,z)\big].$$

The second bracket is the error of an ordinary kernel estimator. Its bias is $O(h_f^R)$, since $\mathcal{K}_f$ has order R and f has R derivatives. Its stochastic part is $O\big((\frac{\log T}{T h_f^{d+1}})^{\frac{1}{2}}\big)$ uniformly. With $h_f \propto \varepsilon_T^{\frac{1}{2R+d+3}}$, these are

$$h_f^R \propto \varepsilon_T^{\frac{R}{2R+d+3}}, \qquad \left(\frac{\varepsilon_T}{h_f^{d+1}}\right)^{\frac{1}{2}} \propto \varepsilon_T^{\frac{1}{2}\left(1-\frac{d+1}{2R+d+3}\right)} = \varepsilon_T^{\frac{R+1}{2R+d+3}}.$$

The bias dominates, and the second bracket is $O(\varepsilon_T^{\frac{R}{2R+d+3}})$.

For the first bracket, points (v,z) in C use only observations whose true values lie in a slightly larger inner set, once T is large. A second-order Taylor expansion of $\mathcal{K}_f$ in its first argument gives (GPV, eq. (23))

$$\big|\hat{f}(v,z) - \tilde{f}(v,z)\big| \le \frac{\sup|\hat{V}_{it} - V_{it}|}{h_f} A_T + \frac{\sup|\hat{V}_{it} - V_{it}|^2}{2h_f^3} B_T,$$

where the suprema run over inner observations. The terms A_T and B_T are averages of the type $\frac{1}{T h_f^{d+1}} \sum_t |\partial_1 \mathcal{K}_f(\cdot)|$ and $\frac{1}{T h_f^d} \sum_t \sup_v |\partial_1^2 \mathcal{K}_f(\cdot)|$. Like kernel estimators, they stay bounded almost surely. Using the inner rate of Proposition 3, the first term is of order

$$\frac{\varepsilon_T^{\frac{R+1}{2R+d+3}}}{\varepsilon_T^{\frac{1}{2R+d+3}}} = \varepsilon_T^{\frac{R}{2R+d+3}},$$

and the second is of order $\varepsilon_T^{\frac{2(R+1)-3}{2R+d+3}} = \varepsilon_T^{\frac{2R-1}{2R+d+3}}$. Since $R \ge 1$ implies $2R - 1 \ge R$, the second term is no larger than the first. Both brackets are therefore $O(\varepsilon_T^{\frac{R}{2R+d+3}})$, which proves part (ii).

The bookkeeping explains the choice of h_f. The first-step error enters as $\frac{\sup|\hat{V}-V|}{h_f}$, which falls as h_f grows. The smoothing bias h_f^R rises with h_f. Equating $\varepsilon_T^{\frac{R+1}{2R+d+3}} h_f^{-1}$ with h_f^R gives $h_f^{R+1} = \varepsilon_T^{\frac{R+1}{2R+d+3}}$, that is $h_f \propto \varepsilon_T^{\frac{1}{2R+d+3}}$. Given the optimal first-step bandwidths, this is the only rate for h_f that attains the optimal rate (Guerre et al., 2000, p. 546). The usual choice $h_f \propto \varepsilon_T^{\frac{1}{2R+d+1}}$ would undersmooth relative to the first-step noise and give a slower rate.

Inference. Theorem 15.26 gives rates of convergence. It says nothing about limiting distributions, and GPV do not establish asymptotic normality of $\hat{f}$. They note that the second-order term of the expansion can be close to the first when R is small, so normal approximations based

on the leading term may be inaccurate (Guerre et al., 2000, p. 546). They suggest instead an exponential inequality of the form (GPV, eq. (24))

$$\mathbb{P}\left(\left(\frac{T}{\log T}\right)^{\frac{R}{2R+d+3}} \sup_{(v,z)\in C} \left|\hat{f}(v \mid z) - f(v \mid z)\right| > e^*(\tau)\right) \leq P^*(\tau),$$

which would deliver conservative uniform bands $\hat{f} \pm e^*(\tau)(\frac{\log T}{T})^{\frac{R}{2R+d+3}}$ with coverage at least $1 - P^*(\tau)$. The same inequality bounds the expected sup-norm loss and could guide the choice of the bandwidth constants. GPV leave the derivation of e^* and P^* to future work.

Practice has moved in two directions (Athey and Haile, 2007, Section 3.2.1). First, many questions concern functionals of F, such as quantiles, expected revenue or the optimal reserve price. Haile et al. (2003) show that the pseudo-values and fixed quantiles of their empirical distribution are asymptotically normal. Second, applied work uses the bootstrap. Outside the IPV model, bids are correlated within an auction. One therefore resamples whole auctions with replacement within each value of n and recomputes both steps in each bootstrap sample. Subsampling is an alternative (Haile et al., 2003).

15.4.6 A Monte Carlo illustration

GPV's design. GPV illustrate the estimator with a small Monte Carlo study (Guerre et al., 2000, Section 2.4). Each replication has $T = 200$ auctions with $n = 5$ bidders, so 1,000 bids, which they describe as a realistic sample size. Values are lognormal with parameters zero and one, truncated to $[0.055, 2.5]$. GPV say that the truncation leaves out "20% approximately" of the original lognormal distribution (p. 532). Our calculation gives 18.2 percent, almost all of it above 2.5. The truncation makes the support compact as Assumption 15.18 requires. Bids are computed from (15.7) by numerical integration. The estimator uses $R = 1$, triweight kernels in both steps, and the rule-of-thumb bandwidths described in Section 15.4.4. There are 1,000 replications.

GPV report the results in two figures, without tables. Their Figure 1 plots the true equilibrium strategy with the mean and the 5th and 95th percentiles of the 1,000 estimates $\hat{\xi}(b)$, evaluated at 500 points on $[\beta(0.055), \beta(2.5)]$. Their Figure 2 does the same for the density on $[0.055, 2.5]$. Inside the region delimited by the trimming, the true curves lie within the pointwise 90 percent bands and the mean estimates match them closely (Guerre et al., 2000, p. 533). Each replication took less than a minute in FORTRAN. GPV estimate that a parametric nonlinear least squares estimator would take about 1,000 times longer, because it requires the numerical integration of (15.7) at every trial parameter (Guerre et al., 2000, p. 532).

Our replication. We replicate the design exactly, including the bandwidth rules with the factor 1.06 and 1,000 replications. The script `figures/ch15/src/gpv_montecarlo.py` computes the true bid function by integrating (15.7) on a grid of 200,001 points, with seed 15401. Figure 15.8 reports the results in the format of GPV's Figures 1 and 2. As in their footnote 9, the dotted lines mark the average trimming bounds $B_{\min} + h_g$ and $B_{\max} - h_g$ in panel (a). In panel (b) they mark the average of $\hat{\xi}(B_{\min} + h_g) + h_f$ and $\hat{\xi}(B_{\max} - h_g) - h_f$, which removes the remaining boundary effects of the second step.

The replication reproduces GPV's qualitative findings. Inside the dotted lines the mean estimates are close to the truth, and the true curves lie inside the bands at every grid point. On the trimmed bid range, the mean of $\hat{\xi}$ is never more than 0.013 away from ξ. On the inner value region, the mean of $\hat{f}$ is never more than 0.022 away from f (Table 15.6). The average

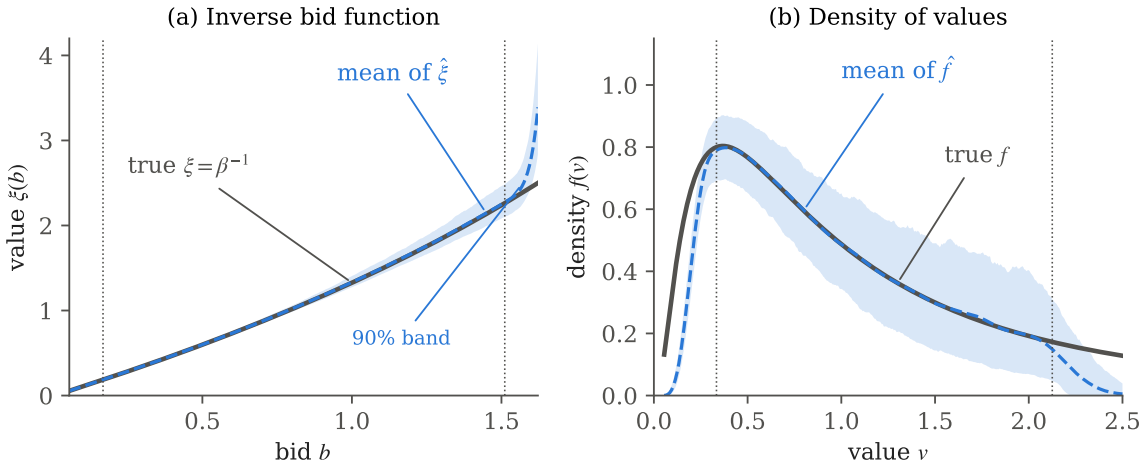


Figure 15.8: Replication of the Monte Carlo design of Guerre et al. (2000, Section 2.4): $T = 200$ auctions, $n = 5$ bidders, values lognormal$(0, 1)$ truncated to $[0.055, 2.5]$, triweight kernels, $h_g = 1.06\,\hat{\sigma}_b(nT)^{-\frac{1}{5}}$, $h_f = 1.06\,\hat{\sigma}_v(nT_T)^{-\frac{1}{5}}$, 1,000 replications. Panel (a): true inverse bid function, mean of $\hat{\xi}(b)$ (dashed) and pointwise 90 percent band of the estimates. Panel (b): true value density, mean of $\hat{f}(v)$ and 90 percent band. Dotted lines mark the average trimming bounds. Our simulation (seed 15401), following the design of Guerre et al. (2000, Section 2.4).

trimming bounds on bids are 0.168 and 1.511, and the inner value region is $[0.334, 2.125]$. Both are close to the lines drawn in GPV's figures. Outside these regions the estimates deteriorate as Section 15.4.4 predicts. Near the top of the bid support the mean of $\hat{\xi}$ bends sharply upward. Near both ends of the value support the mean of $\hat{f}$ falls below the truth.

Figure 15.9 shows the mechanism in one sample. At the largest bid, $\hat{g}$ is 0.54 times the true density, close to the factor $\frac{1}{2}$ derived in Section 15.4.4. The untrimmed estimate $\hat{\xi}$ climbs to about 3.2 at the top of the bid support, against a true maximum value of 2.5. Trimming removes 43 of the 1,000 bids at the top. Among the bids that survive trimming, the mean absolute error of the pseudo-values is 0.016.

Panel A of Table 15.6 compares GPV's bandwidths with the Gaussian-equivalent bandwidths. The wider bandwidths cut the sup-norm errors by a factor of about four. They do so at a price: 36 percent of the bids are trimmed, and the inner value region shrinks to $[0.781, 1.508]$. The tails of F, which matter for reserve prices and for the top of the bid distribution, are then not estimated at all. The trade-off between precision in the middle and coverage of the support is a practical feature of every application of the method.

Panel B illustrates Theorem 15.26. On fixed inner sets, the error of $\hat{f}$ falls more slowly with T than the error of the infeasible estimator that uses true values. The ratio of the two errors rises from 1.9 at $T = 100$ to 3.1 at $T = 1{,}600$. The fitted slope for $\hat{f}$ is -0.17, close to the exponent $-\frac{1}{5}$ that the theorem gives for $R = 1$ and $d = 0$. The slope for $\tilde{f}$ is -0.34. The inverse bid function requires g without its derivative, and its error falls at the faster slope of -0.37. The design has a very smooth density, so these slopes illustrate the theory. They are no test of it. The whole experiment takes a few minutes on a laptop, which makes the computational case for the indirect approach plain.

Table 15.6: Monte Carlo results for the GPV estimator

Panel A. GPV design, $T = 200$, $n = 5$, 1,000 replications		
Bandwidth constant	1.06 (GPV)	2.978×1.06
Mean h_g	0.107	0.320
Mean h_f	0.147	0.334
Share of bids trimmed	0.088	0.363
Mean trimming bounds on bids	[0.168, 1.511]	[0.380, 1.299]
Inner value region	[0.334, 2.125]	[0.781, 1.508]
Max. |mean of $\hat{\xi} - \xi$| on trimmed bids	0.013	0.003
Max. |mean of $\hat{f} - f$| on inner values	0.022	0.006
Mean sup-norm error of $\hat{\xi}$ on trimmed bids	0.161	0.043
Mean sup-norm error of $\hat{f}$ on inner values	0.238	0.055
Seconds per replication (Python)	0.028	0.076

Panel B. Mean sup-norm errors on fixed inner sets, GPV bandwidths, 200 replications				
T	$\hat{\xi}$, bids in [0.25, 1.35]	$\hat{f}$, values in [0.4, 1.8]	$\tilde{f}$ (true values)	Ratio $\frac{\hat{f}}{\tilde{f}}$
100	0.149	0.243	0.128	1.89
200	0.113	0.227	0.102	2.21
400	0.087	0.203	0.080	2.54
800	0.067	0.176	0.064	2.73
1,600	0.053	0.152	0.049	3.07
Log-log slope in T	−0.37	−0.17	−0.34	

Notes. Our simulation, script `figures/ch15/src/gpv_montecarlo.py`, seeds 15401 (panel A) and 15402 (panel B). Values lognormal(0, 1) truncated to $[0.055, 2.5]$, $n = 5$, triweight kernels. In panel A the two columns use the same draws. The inner value region is the average of $[\hat{\xi}(B_{\min} + h_g) + h_f,\ \hat{\xi}(B_{\max} - h_g) - h_f]$, so the error rows of the two columns refer to different regions. In panel B, $\tilde{f}$ is the infeasible kernel estimator computed from the true values with the same kernel and rule-of-thumb bandwidth. Slopes are least-squares fits of the log error on $\log T$. Timings are from one run on a laptop and vary across runs.

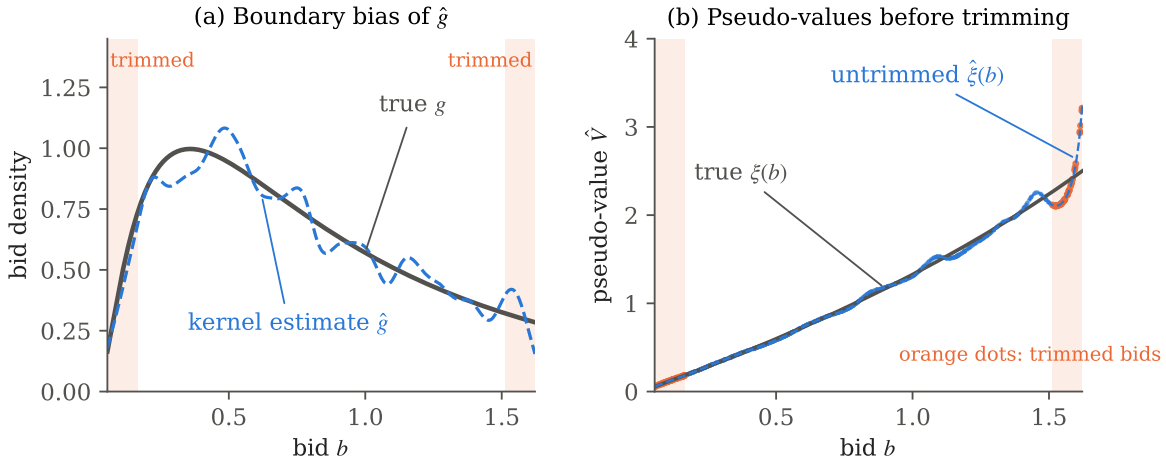

Figure 15.9: Boundary effects in one simulated sample from the design of Figure 15.8 ($h_g = 0.108$). Panel (a): true bid density and the triweight kernel estimate. Shaded areas lie within one bandwidth of the smallest and largest bids. At the largest bid the estimate equals 0.54 times the true density. Panel (b): pseudo-values $B_{it} + \frac{\hat{G}(B_{it})}{(n-1)\hat{g}(B_{it})}$ before trimming (dots), the estimated inverse bid function on a grid (dashed) and the true ξ (solid). Near the top, the underestimated density inflates the markdown, and the estimated inverse bid function rises well above $\bar{v} = 2.5$. Our simulation (seed 15403).

15.4.7 Binding reserve prices and unknown numbers of potential bidders

In practice sellers often announce a reserve price high enough to screen out some bidders. GPV, Section 4, extend their results to this case. A binding reserve price creates a new unknown. Let N denote the number of *potential bidders*, who draw values and decide whether to bid. Let n^* denote the number of *actual bidders*, who submit a bid of at least r. The econometrician observes n^* but typically not N. Following GPV, bidders do not observe which rivals participate when they bid.

The inverse bid function with a reserve. Fix one auction with reserve price $r \in (\underline{v}, \bar{v})$. Bidders with values below r do not bid, and bidders with values $v \geq r$ bid $\beta(v)$ from (14.29), with $\beta(r) = r$. Let G^* denote the distribution of an actual bid, with density g^* on $[r, \bar{b}]$. Then

$$G^*(b) = \mathbb{P}\big(\beta(V) \leq b \,\big|\, V \geq r\big) = \frac{F\big(\beta^{-1}(b)\big) - F(r)}{1 - F(r)}.$$

We derive the analog of (15.9) from the bidder's problem. A bid $b \geq r$ beats a given rival if that rival's value is below r, which has probability $F(r)$, or if the rival bids but bids less than b, which has probability $(1 - F(r))G^*(b)$. Rivals are independent, so the win probability is

$$H(b) = \Big[F(r) + \big(1 - F(r)\big)G^*(b)\Big]^{N-1}.$$

The bidder maximizes $(v - b)H(b)$. The first-order condition is

$$(v - b)(N - 1)\Big[F(r) + \big(1 - F(r)\big)G^*(b)\Big]^{N-2}\big(1 - F(r)\big)g^*(b) = \Big[F(r) + \big(1 - F(r)\big)G^*(b)\Big]^{N-1}.$$

Dividing by $(N-1)[F(r)+(1-F(r))G^*(b)]^{N-2}(1-F(r))g^*(b)$ and adding b gives

$$v = b + \frac{F(r) + \big(1-F(r)\big)G^*(b)}{(N-1)\big(1-F(r)\big)g^*(b)}.$$

Splitting the fraction yields GPV's equation (25):

$$v = \xi\big(b; G^*, N, F(r)\big) \equiv b + \frac{1}{N-1}\Big(\frac{G^*(b)}{g^*(b)} + \frac{F(r)}{1-F(r)}\,\frac{1}{g^*(b)}\Big). \tag{15.24}$$

The second term in the parentheses reflects the potential bidders who do not bid. Ignoring it understates the markdown, especially near r, where G^* is small. Unlike (15.9), equation (15.24) involves two unknowns, N and $F(r)$.

Why the bid density is unbounded at the reserve. By (15.8) with N bidders, $\beta'(v) = (N-1)\frac{f(v)}{F(v)}\big(v-\beta(v)\big)$. At $v=r$ the markdown $v-\beta(v)$ vanishes while $F(r)>0$, so $\beta'(r)=0$. Let $\Delta(v)=v-\beta(v)$. Then $\Delta(r)=0$ and $\Delta'(r)=1-\beta'(r)=1$, so $\Delta(v)=(v-r)(1+o(1))$. Substituting,

$$\beta'(v) = (N-1)\frac{f(r)}{F(r)}(v-r)\big(1+o(1)\big), \qquad \beta(v)-r = \frac{(N-1)f(r)}{2F(r)}(v-r)^2\big(1+o(1)\big).$$

The bid function is flat and quadratic near the reserve. Many values just above r map into a short interval of bids, and the density $g^*(b) = \frac{f(v)}{\beta'(v)(1-F(r))}$ behaves like $(b-r)^{-\frac{1}{2}}$ as $b \downarrow r$ (Guerre et al., 2000, p. 549).

Theorem 15.27 (Guerre et al., 2000, Theorem 4)**.** *Let $G^* \in \mathcal{P}$ have support $[r,\bar b]$, and let $\mathcal{Q}$ be a discrete distribution on $\{0,1,2,\dots\}$. Consider a first-price SIPV auction with reserve price $r \in (\underline v, \bar v)$. There exist $F \in \mathcal{P}$ and $N \ge 2$ that generate G^* as the distribution of actual bids and $\mathcal{Q}$ as the distribution of the number of actual bidders if and only if the following hold.*

(C1) $\mathcal{Q}$ is binomial with parameters $(N, 1-F(r))$, where $0<F(r)<1$.

(C2) Conditional on n^*, actual bids are i.i.d. with distribution G^*, and $g^*(b)\to+\infty$ as $b\downarrow r$.

(C3) The function $\xi(\cdot; G^*, N, F(r))$ in (15.24) is strictly increasing on $[r,\bar b]$, and its inverse is differentiable on $[r,\bar v] \equiv [\xi(r), \xi(\bar b)]$.

If (C1)–(C3) hold, N and $F(r)$ are unique, and F is unique on $[r,\bar v]$, with

$$F(v) = F(r) + \big(1-F(r)\big)G^*\big(\xi^{-1}(v; G^*, N, F(r))\big).$$

Moreover, $\xi(\cdot; G^*, N, F(r))$ is the inverse of the equilibrium strategy on $[r,\bar b]$.

Sketch of proof. Necessity of (C1) holds because each potential bidder bids independently with probability $1-F(r)$. For (C2), consider k actual bidders. Exchangeability and independence give

$$\mathbb{P}\big(B_1^* \le b_1, \dots, B_k^* \le b_k \,\big|\, n^* = k\big) = \frac{\binom{N}{k}F(r)^{N-k}\prod_{j=1}^k \mathbb{P}(r \le B_j \le b_j)}{\binom{N}{k}F(r)^{N-k}\big(1-F(r)\big)^k} = \prod_{j=1}^k \frac{F\big(\beta^{-1}(b_j)\big)-F(r)}{1-F(r)}.$$

The unbounded density follows from $\beta'(r)=0$, as shown above. Necessity of (C3) follows as in Theorem 15.19, because (15.24) is the first-order condition. For sufficiency, (C1) identifies N and $F(r)$, as in Proposition 15.13(iii): the mean and variance of n^* are $N(1-F(r))$ and $NF(r)(1-F(r))$.

The rest of the argument repeats the proof of Theorem 15.19 with the truncated distributions G^* and $\frac{F-F(r)}{1-F(r)}$. The condition $g^* \to \infty$ plays the role of (15.11): it gives $\lim_{b \downarrow r} \xi(b) = r$, so that the candidate strategy satisfies $\beta(r) = r$. Below r, any absolutely continuous extension of F rationalizes the data. GPV, Appendix A.1, give the details. □

The theorem parallels Theorem 15.19. The data identify the number of potential bidders and the probability of not bidding. The value distribution is identified only above the reserve price. Below r the data contain no information about F beyond the mass $F(r)$.

Estimation. GPV, Section 4.2, assume that $N \geq 2$ is constant across auctions. The reserve price is a smooth deterministic function $r(Z_t)$ of the characteristics, bounded away from both ends of the value support (their Assumption A5). Both N and the function $r(\cdot)$ may be unknown to the analyst. The estimator has four parts.

- The number of potential bidders is estimated by $\hat{N} = \max_t n_t^*$. By (C1), $\hat{N} = N$ almost surely once T is large.
- Let $\Phi(z) = F(r(z) \mid z)$. Because $\mathbb{E}[n_t^* \mid Z_t] = N(1 - \Phi(Z_t))$, a Nadaraya-Watson regression (Nadaraya, 1964; Watson, 1964) gives

$$\hat{\Phi}(z) = 1 - \frac{1}{\hat{N}} \frac{\sum_t n_t^* \mathcal{K}_Z\left(\frac{z - Z_t}{h_Z}\right)}{\sum_t \mathcal{K}_Z\left(\frac{z - Z_t}{h_Z}\right)},$$

  which always lies in $[0, 1]$.
- The unbounded density of bids at r would slow down kernel estimation. GPV transform bids into $B^\dagger = (B^* - r)^{\frac{1}{2}}$. The transformed bids have distribution $G^\dagger(b^\dagger) = G^*(r + (b^\dagger)^2)$ and bounded density $g^\dagger(b^\dagger) = 2b^\dagger g^*(r + (b^\dagger)^2)$, which tends to a positive constant as $b^\dagger \downarrow 0$. Since $\frac{G^*}{g^*} = \frac{2b^\dagger G^\dagger}{g^\dagger}$ and $\frac{1}{g^*} = \frac{2b^\dagger}{g^\dagger}$, equation (15.24) becomes (GPV, eq. (27), in conditional form)

$$V_{it} = r(Z_t) + (B_{it}^\dagger)^2 + \frac{2B_{it}^\dagger}{N - 1}\left(\frac{G^\dagger(B_{it}^\dagger \mid Z_t)}{g^\dagger(B_{it}^\dagger \mid Z_t)} + \frac{\Phi(Z_t)}{1 - \Phi(Z_t)} \frac{1}{g^\dagger(B_{it}^\dagger \mid Z_t)}\right). \tag{15.25}$$

- The transformed bids are independent of n_t^* given Z_t by (C2), so $G^\dagger$ and $g^\dagger$ are estimated by (15.18)–(15.19) with n_t^* in place of n_t and without the discrete argument. Pseudo-values follow from (15.25) with trimming. The truncated density $f^*(v \mid z) = \frac{f(v|z)}{1-\Phi(z)}$ is estimated as in (15.21), and $\hat{f}(v \mid z) = (1 - \hat{\Phi}(z))\hat{f}^*(v \mid z)$.

Under these assumptions, $\hat{f}(\cdot \mid \cdot)$ is uniformly consistent with the optimal rate $(\frac{T}{\log T})^{\frac{R}{2R+d+3}}$ on closed inner subsets of $\{(v, z) : v \in [r(z), \bar{v}(z)]\}$ (GPV, Theorem 5). The transformation is what preserves the rate: the transformed density satisfies the smoothness properties of Proposition 15.24 (GPV, Proposition 4). If the reserve price varies randomly given Z_t, for example across sellers, the estimator remains consistent at the slower rate $(\frac{T}{\log T})^{\frac{R}{2R+d+4}}$ (Guerre et al., 2000, footnote 24).

Figure 15.10 applies the procedure to simulated data. With $N = 5$ and $r = 0.6$, the expected number of actual bidders is $5(1 - 0.370) = 3.15$. In the sample, $\hat{N} = 5$ and $\hat{F}(r) = 1 - \frac{3.254}{5} = 0.349$. Among bids that survive trimming, the mean absolute error of the pseudo-values is 0.025 with the full formula and 0.151 for the naive formula without the term in $F(r)$. For values within 0.3

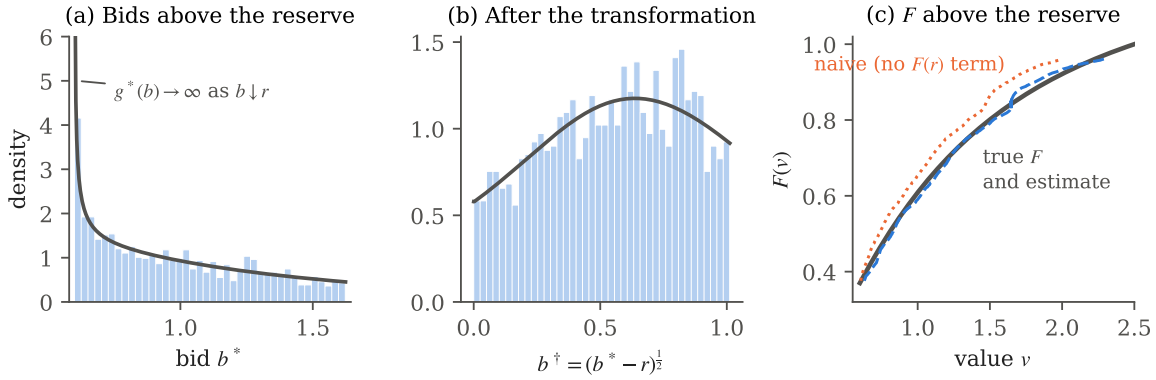

Figure 15.10: A binding reserve price. $T = 500$ auctions with $N = 5$ potential bidders, values lognormal$(0, 1)$ truncated to $[0.055, 2.5]$, reserve price $r = 0.6$ with $F(r) = 0.370$. Panel (a): histogram of the 1,627 actual bids and the true density g^*, which diverges at r. Panel (b): the transformed bids $(b^* - r)^{\frac{1}{2}}$ have a bounded density. Panel (c): true F above r (solid), the estimate based on (15.25) with $\hat{N} = 5$ and $\hat{F}(r) = 0.349$ (dashed), and a naive estimate that drops the term in $F(r)$ (dotted). Our simulation (seed 15404).

of the reserve, the naive pseudo-values are too low by 0.078 on average. The missing term is the markdown that comes from competing against potential bidders who stay out.

Affiliated values and observed participation. Athey and Haile (2007, Section 6.3.1) extend these results to affiliated private values when bidders do not know the set of actual bidders. With all bids, bidder identities and the reserve price, the joint distribution of the actual bidders' values above r is identified (their Theorem 6.4). Each marginal F_i is identified above r when the set of potential bidders is observed (their Theorem 6.5). Section 15.8.2 states these results and the inversion behind them. Exogenous variation in reserve prices would trace out more of F, as GPV note. Estimators that combine auctions with different reserve prices to recover F below the observed reserves had not been developed when Athey and Haile wrote their survey (Athey and Haile, 2007, Section 6.3.1). Section 15.7 discusses the opposite case, in which the reserve price carries information about the object.

15.4.8 Incomplete bid data and Dutch auctions

Many data sets record only the winning bid. In a Dutch auction the clock stops at the first bid, so only the transaction price exists. The Dutch auction is strategically equivalent to the first-price auction (Proposition 14.4). In other settings the auctioneer records only the winner. With independent private values, the winning bid suffices.

Proposition 15.28 (Athey and Haile, 2002, Theorem 6(i), and Athey and Haile, 2007, Theorem 3.2 and Corollary 3.1)**.** *In a first-price or Dutch auction with independent private values, suppose the transaction price and the number of bidders are observed. If bidders are asymmetric, suppose also that the set of bidders and the identity of the winner are observed. Then the value distribution of every bidder is identified.*

Proof. Symmetric bidders. Let $G_{(n:n)}$ denote the distribution of the winning bid $B^{(n:n)}$, with density $g_{(n:n)}$. Bids are i.i.d. with distribution G, so $G_{(n:n)}(b) = G(b)^n$ and

$$G(b) = G_{(n:n)}(b)^{\frac{1}{n}}. \tag{15.26}$$

Hence the winning bid identifies the distribution of a single bid, and Theorem 15.19 applies. To write the inverse bid function directly in terms of the winning bid, differentiate: $g_{(n:n)}(b) = nG(b)^{n-1}g(b)$. Then

$$\frac{G_{(n:n)}(b)}{g_{(n:n)}(b)} = \frac{G(b)^n}{nG(b)^{n-1}g(b)} = \frac{G(b)}{ng(b)} = \frac{n-1}{n}\cdot\frac{G(b)}{(n-1)g(b)},$$

which is equation (3.7) of Athey and Haile (2007). Substituting into (15.9),

$$\xi(b) = b + \frac{n}{n-1}\,\frac{G_{(n:n)}(b)}{g_{(n:n)}(b)}. \tag{15.27}$$

This observation is due to Guerre et al. (1995).

Asymmetric bidders. Let G_i denote the distribution of bidder i's bid, and let $G_i^w(b) = \mathbb{P}(B_i \le b,\ B_i \ge B_j \text{ for all } j)$ be the probability that i wins with a bid of at most b. It is observable when the winner's identity is recorded. By independence,

$$G_i^w(b) = \int_{\underline{b}}^{b} \prod_{j\neq i} G_j(s)\, dG_i(s).$$

Summing over bidders, $\sum_j G_j^w(s) = \mathbb{P}(\max_j B_j \le s) = \prod_j G_j(s)$, the distribution of the winning bid. Therefore

$$\frac{dG_i^w(s)}{\sum_j G_j^w(s)} = \frac{\prod_{j\neq i} G_j(s)\, dG_i(s)}{\prod_j G_j(s)} = \frac{dG_i(s)}{G_i(s)} = d\ln G_i(s).$$

Integrating from b to $\bar{b}$ and using $G_i(\bar{b}) = 1$ gives

$$G_i(b) = \exp\Big\{-\int_b^{\bar{b}} \Big(\sum_{j=1}^{n} G_j^w(s)\Big)^{-1} dG_i^w(s)\Big\}. \tag{15.28}$$

This is the competing-risks formula of Berman (1963), adapted to auctions by Athey and Haile (2002). The right side is observable, so each G_i is identified. The marginals G_j determine the distribution of each bidder's highest rival bid, $G_{M_i} = \prod_{j\neq i} G_j$. The asymmetric first-order condition (14.77), rearranged as $v_i = b + \big[\sum_{j\neq i} \frac{g_j(b)}{G_j(b)}\big]^{-1}$, then gives each inverse bid function and each F_i. □

The formula in Athey and Haile (2007, eq. (3.8)) is printed with the integral running from $-\infty$ to b and without the minus sign. The derivation above gives the form (15.28). Brendstrup and Paarsch (2003) propose estimating (15.28) by replacing G_i^w with its empirical counterpart and dG_i^w with a kernel estimate (Athey and Haile, 2007, Section 3.3.1). Athey and Haile add that survival-analysis estimators such as the Kaplan-Meier or Nelson-Aalen estimators could be adapted.

Estimation with symmetric bidders. With T winning bids B_t^w, one estimates $G_{(n:n)}$ by the empirical distribution and $g_{(n:n)}$ by a kernel estimator. Equation (15.27) then gives the estimated winner's value $\hat{V}_t^{(n:n)} = \hat{\xi}(B_t^w)$, after trimming as in (15.15). The winners' values have distribution F^n, so $\hat{F}(v) = \big[\frac{1}{T}\sum_t \mathbf{1}(\hat{V}_t^{(n:n)} \le v)\big]^{\frac{1}{n}}$.

The cost of observing only the winner. The data contain one bid per auction instead of n, and the inversion through the n-th root loses precision in the lower tail. To see how much,

ignore first-step error and suppose the winners' values were observed. Let $H = F^n$ and let $\hat{H}$ be the empirical distribution of the T winners' values, with variance $\frac{H(1-H)}{T}$. Since $\frac{dF}{dH} = \frac{1}{n}H^{\frac{1}{n}-1} = \frac{1}{n}F^{1-n}$, the delta method gives

$$\operatorname{Var}\left(\hat{F}(v)\right) \approx \frac{1}{n^2}F^{2-2n}\,\frac{F^n(1-F^n)}{T} = \frac{F^{2-n}(1-F^n)}{n^2T}.$$

With all nT values observed, the variance of the empirical distribution is $\frac{F(1-F)}{nT}$. The ratio of the two variances is

$$\frac{F^{2-n}(1-F^n)}{n^2T}\cdot\frac{nT}{F(1-F)} = \frac{1-F^n}{nF^{n-1}(1-F)} = \frac{1+F+\cdots+F^{n-1}}{nF^{n-1}}.$$

It equals one at the top of the support and grows without bound as $F \to 0$. With $n = 5$ at the median of F, the ratio is $\frac{1.9375}{0.3125} = 6.2$. This is our calculation. The winning bid identifies F, but low values are rarely revealed by winners, so the lower tail is estimated poorly.

An unknown number of bidders. In some Dutch auctions only the transaction price is recorded, and the number of bidders is unknown. Then F is not identified nonparametrically (Athey and Haile, 2007, Section 3.3.1). For any candidate n', the distribution $G_{(n:n)}^{\frac{1}{n'}}$ is a valid bid distribution, and n' bidders bidding i.i.d. from it generate the same winning-bid distribution. Each n' for which the implied inverse bid function is increasing yields a different F. Laffont et al. (1995) instead estimate n within a parametric model (Section 15.3).

Covariates and testability. Athey and Haile (2002, Theorem 6) extend the result in three directions. If $V_i = g_i(A_i, W_0)$ with W_0 observed by bidders and the econometrician and $A_1, \ldots, A_n$ independent given W_0, then each $F_i(\cdot \mid w_0)$ is identified, because part (i) applies for each fixed w_0. If $V_i = g_0(W_0) + A_i$ with the A_i mutually independent and independent of W_0, then each F_{A_i} and g_0 are identified up to location. Finally, the models are testable. With symmetric bidders, observing more than one bid per auction, or exogenous variation in n, gives two estimates of G from (15.26) that must agree. With asymmetric bidders, observing the second-highest bid or exogenous variation in n plays the same role (Athey and Haile, 2002, Theorem 6(iv)–(v)).

15.4.9 Specification testing in first-price auctions

Theorem 15.19 lists the restrictions that the SIPV model places on bids. Athey and Haile (2007, Section 5.1) characterize the restrictions in the broader affiliated private values (APV) model of Section 15.5. Write $\xi_i(b; \mathcal{N}) = b + \frac{G_{M_i|B_i}(b|b;\mathcal{N})}{g_{M_i|B_i}(b|b;\mathcal{N})}$ for bidder i's inverse bid function when the set of bidders is $\mathcal{N}$. Here M_i is the highest rival bid and $G_{M_i|B_i}$ its distribution conditional on i's bid, as in (15.32). Let $[\underline{b}_i, \bar{b}_i]$ be the support of B_i.

Theorem 15.29 (Athey and Haile, 2007, Theorem 5.2)**.** *Consider the APV first-price auction with a fixed set of bidders $\mathcal{N}$. Assume the joint density of values is continuously differentiable, and that either (i) values are mutually independent or (ii) bidders are symmetric. A joint distribution of bids $\mathbf{G}$ is rationalized by equilibrium bidding if and only if:*

(a) The bids $(B_1, \ldots, B_n)$ are affiliated. They are independent in case (i) and exchangeable in case (ii).

(b) Each $\xi_i(\cdot; \mathcal{N})$ is differentiable and strictly increasing on the support of B_i.

(c) *The distribution* $\mathbf{G}\left(\xi_1^{-1}(u_1;\mathcal{N}),\ldots,\xi_n^{-1}(u_n;\mathcal{N})\right)$ *is absolutely continuous in* $\boldsymbol{u}$*. Its density is positive and continuously differentiable on the product of the supports of* $\xi_i(B_i;\mathcal{N})$ *and zero elsewhere.*

(d) $\xi_i(\underline{b};\mathcal{N}) = \underline{b}$ *for all* i*.*

(e) $\xi_i(\bar{b}_i;\mathcal{N}) = \xi_j(\bar{b}_j;\mathcal{N})$ *for all* i, j*.*

(f) *The support of* B_i *is convex, compact, and the same for all* i*.*

Without independence or symmetry, conditions of this type remain necessary but are not known to be sufficient. The equilibrium of the asymmetric APV model lacks a full characterization (Athey and Haile, 2007, Theorem 5.1). Sufficiency in Theorem 15.29 uses the argument of Step 4 in the proof of Theorem 15.19. Under independence or symmetry, payoffs satisfy single crossing. Local optimality of each bid together with monotone strategies then implies global optimality. Athey and Haile stress why such a result matters. Without it, nothing guarantees that a bid b is a best response for the value $\xi_i(b)$ that the first-order condition assigns to it. Verifying the conditions is the analog of verifying second-order conditions (Athey and Haile, 2007, Section 5.1). For SIPV, the conditions reduce to (C1)–(C2) of Theorem 15.19.

Each condition suggests a test. We describe the main ones, following Athey and Haile (2007, Sections 5.2–5.5).

Monotonicity of the inverse bid function. Condition (C2), or (b), says that $\hat{\xi}$ should be increasing. GPV propose this as a test of equilibrium bidding and note that it requires estimating ξ under a monotonicity constraint (Guerre et al., 2000, p. 552). No formal test had been developed by the time of the Athey-Haile survey. Standard tests of monotone regression do not apply directly, because the realizations $\xi_i(B_i)$ are themselves estimates. Applications typically find few violations (Hendricks et al., 2003; Haile et al., 2003). Two caveats apply. First, a rejection does not reveal which assumption failed: unobserved heterogeneity, risk aversion, or non-equilibrium play could each cause it. Second, no test of monotonicity is consistent against all violations of the model, since some misspecified models still produce an increasing ξ.

The boundary condition. Condition (e) says that all bidders' inverse bid functions meet at the top of the bid support, since all bidders share the upper bound of values. In the asymmetric IPV model, $G_{M_i}(\bar{b}) = 1$, so $\xi_i(\bar{b}) = \bar{b} + \frac{1}{g_{M_i}(\bar{b})}$, and (e) becomes

$$g_{M_i}(\bar{b}) = g_{M_j}(\bar{b}) \qquad \text{for all } i, j, \tag{15.29}$$

which is equation (5.1) of Athey and Haile (2007). The densities of the highest rival bid must agree at the top. Section 15.5.4 works through an example of Athey and Haile in which the condition fails because the value supports of the two bidders have different upper bounds, which the maintained model excludes.

Multi-sample tests with exogenous variation in n*.* If the number of bidders varies exogenously, the value distribution estimated from n-bidder auctions must equal the one estimated from n'-bidder auctions. Under IPV, the inverse bid functions $\xi(\cdot;G_n,n)$ differ across n, because bidding becomes more aggressive as n rises (Proposition 14.36). The implied value distributions must nevertheless coincide. Testing equality of distributions is standard when the data are observed. Here the values are estimated in a first nonparametric step, which complicates the asymptotic theory. Haile et al. (2003) develop formal tests of this kind. They use them to test private against common values, which Section 15.6 takes up.

Multiple order statistics. In IPV models, any single order statistic of bids identifies F, together with n. When two order statistics are recorded, for example the two highest bids, the two implied estimates of F must agree up to sampling error. This test needs no variation in n (Athey and Haile, 2007, Section 5.4).

Direct tests of independence and exchangeability. Condition (C1) can be tested directly when all bids are observed. Exchangeability can be tested with the bootstrap distance tests of Romano (1988, 1989), which compare a multivariate distribution with its permutations. Equality of the marginal distributions of different bidders can be tested by Kolmogorov-Smirnov statistics. Independence can be tested by comparing the joint distribution of bids with the product of its marginals. GPV suggest the test of Blum et al. (1961), which Campo et al. (2003) later apply to offshore oil bids. With covariates, regression tests of conditional independence and exchangeability are natural. Section 15.10 describes them in the form that Bajari and Ye (2003) use to look for collusion in highway procurement.

Athey and Haile (2002, p. 2123) add a warning. Monotonicity of ξ holds under many natural alternatives to the IPV model, so the test most often used in early work has little power against affiliated or common values. The restrictions that come from comparing different order statistics or different numbers of bidders typically fail under those alternatives. They are the more informative tests.

Assessment. GPV changed the econometrics of auctions. Before them, structural work required closed-form equilibria or simulation, and parametric assumptions carried an unclear part of the identification (Athey and Haile, 2007, Section 3.1). After them, the first-order condition became a measurement device. The ingredients were a constructive identification result with sharp testable restrictions, an estimator that requires only kernel smoothing, and a proof that the estimator is rate-optimal. The same principle extends to affiliated values, asymmetric bidders, procurement with quality, binding reserve prices and dynamic bidding. It also inspired parametric two-step estimators that keep the inversion and add structure in one of the steps (Guerre et al., 2000, footnote 25).

The approach has limits that later sections address. It maintains independent private values and risk neutrality, and it assumes that observed covariates capture all heterogeneity across auctions. Ignoring unobserved heterogeneity flattens the estimated inverse bid function and inflates estimated markups (Section 15.7). The second step pools across n only if participation is exogenous given covariates (Section 15.8). Each additional continuous covariate slows convergence, and the boundary trimming discards the tails of F, which matter for reserve prices. No distribution theory for $\hat{f}$ was available. Bandwidth constants are set by rules of thumb, and data-driven choices had not been explored (Athey and Haile, 2007, Section 3.2.1). Finally, the model needs all bids, or the winning bid with known n. When bidding takes place under richer information structures, bids reveal less, as Sections 15.5 and 15.6 show.

The rest of the chapter relaxes the maintained assumptions one at a time. Section 15.5 replaces independence with affiliation and symmetry with bidder classes, and the inversion runs through the distribution of the highest rival bid conditional on one's own bid. Section 15.6 asks what bids can reveal when values are common. Section 15.7 handles heterogeneity that bidders observe and the econometrician does not. Section 15.8 treats endogenous participation, dynamics and risk aversion. In each case the first step of the GPV estimator survives, and the work lies in finding the right conditioning set for the distribution of rival bids.

15.5 Affiliated and Asymmetric Private Values

The inversion of Section 15.4 rests on two assumptions besides private values. Values are independent across bidders, and bidders are symmetric. Both assumptions often fail. Bidders who appraise the same tract of timber tend to have correlated values. They react to features of the tract that the econometrician does not record. Bidders also differ in systematic ways. A sawmill differs from a logger, a consortium from a single firm, and a contractor next to the site from one far away.

This section shows that the first-order condition can still be inverted when both assumptions fail. The key observable becomes the joint distribution of a bidder's own bid and the highest rival bid. We first treat symmetric affiliated private values (Li et al., 2002). We then ask what the two highest bids alone reveal (Athey and Haile, 2002). Next we study asymmetric affiliated private values and joint bidding for offshore oil leases (Campo et al., 2003). We close with asymmetric independent private values.

15.5.1 Symmetric affiliated private values: Li, Perrigne and Vuong (2002)

Question. Before 2002, structural work on first-price auctions used either the independent private value (IPV) model or the pure common value model. Li et al. (2002), henceforth LPV, ask whether the *affiliated private value* (APV) model can be identified and estimated from bids alone, without a parametric form for the dependence among values. The question matters because affiliation changes equilibrium shading. An analyst who imposes independence on affiliated data misreads bids, and so misreads values and rents.

Model. A single object is sold by first-price sealed bid to $n \geq 2$ risk-neutral bidders. In the affiliated value model of Milgrom and Weber (1982), bidder i's utility is $U(v_i, c)$, where v_i is her private signal and c a common component. The APV model is the case $U(v, c) = v$. Values $\boldsymbol{V} = (V_1, \ldots, V_n)$ have a joint distribution F with density f on $[\underline{v}, \bar{v}]^n$. The density is symmetric (exchangeable) and affiliated in the sense of Definition 14.11. The reserve price does not bind. Let $Y_1 = \max_{j \neq 1} V_j$ be the highest rival value. Write $F_{Y_1|V_1}$ and $f_{Y_1|V_1}$ for its conditional distribution and density given V_1. Affiliation leaves the form of dependence unrestricted. A common component plus independent noise is one example among many.

The symmetric equilibrium in strictly increasing strategies β is the special case of Proposition 14.58 with $v(\alpha, \alpha) = \alpha$. It solves the differential equation

$$\beta'(v) = \big(v - \beta(v)\big) \frac{f_{Y_1|V_1}(v \mid v)}{F_{Y_1|V_1}(v \mid v)}, \qquad \beta(\underline{v}) = \underline{v}, \tag{15.30}$$

which is equation (1) of Li et al. (2002). Its solution is

$$\beta(v) = v - \int_{\underline{v}}^{v} L(\alpha \mid v)\, d\alpha, \qquad L(\alpha \mid v) = \exp\left(- \int_{\alpha}^{v} \frac{f_{Y_1|V_1}(u \mid u)}{F_{Y_1|V_1}(u \mid u)}\, du \right), \tag{15.31}$$

their equation (2). The bid depends on F through the whole conditional law of the highest rival value along the diagonal. A parametric family for F, such as a multivariate lognormal, rarely yields a closed form for β.

From the differential equation to observables. Bids are random with joint distribution $\boldsymbol{G}$, which the econometrician observes when all bids are recorded. Let B_i be bidder i's bid and $M_i = \max_{j \neq i} B_j$

the highest rival bid. Let $G_{M|B}(m \mid b) = \mathbb{P}(M_i \le m \mid B_i = b)$, with density $g_{M|B}(m \mid b)$ in m. Because β is strictly increasing, $M_1 = \beta(Y_1)$ and the event $\{B_1 = b\}$ equals $\{V_1 = \beta^{-1}(b)\}$. Hence

$$G_{M|B}(m \mid b) = \mathbb{P}\big(\beta(Y_1) \le m \mid \beta(V_1) = b\big) = F_{Y_1|V_1}\big(\beta^{-1}(m) \mid \beta^{-1}(b)\big),$$
$$g_{M|B}(m \mid b) = \frac{f_{Y_1|V_1}\big(\beta^{-1}(m) \mid \beta^{-1}(b)\big)}{\beta'\big(\beta^{-1}(m)\big)}.$$

Evaluate both at $m = b = \beta(v)$ and take the ratio:

$$\frac{G_{M|B}(b \mid b)}{g_{M|B}(b \mid b)} = \beta'(v)\,\frac{F_{Y_1|V_1}(v \mid v)}{f_{Y_1|V_1}(v \mid v)} = v - \beta(v),$$

where the second equality is (15.30). Rearranging gives the inverse bid function

$$v = \xi(b; \boldsymbol{G}) \equiv b + \frac{G_{M|B}(b \mid b)}{g_{M|B}(b \mid b)}, \tag{15.32}$$

equation (4) of Li et al. (2002). It is the first-order condition (14.68) written in observables. Conditioning on the value is the same as conditioning on the bid, because the equilibrium is strictly monotone. With independent values $G_{M|B}(b \mid b) = G(b)^{n-1}$, and (15.32) reduces to the inversion (15.9).

Definition 15.30 (Rationalization in the APV model)**.** A joint distribution $\boldsymbol{G}$ of bids is *rationalized* by an APV structure F if $\boldsymbol{G}$ is the equilibrium bid distribution of the first-price auction with values drawn from F. The APV model is identified if no two distinct structures $F \neq \tilde{F}$ lead to the same $\boldsymbol{G}$ (Li et al., 2002, Definition 1).

Proposition 15.31 (Li et al., 2002, Proposition 1)**.** *The symmetric APV model is identified. Let $\boldsymbol{G}$ have support $[\underline{b}, \bar{b}]^n$. It can be rationalized by a symmetric APV model if and only if two conditions hold.*

(i) *$\boldsymbol{G}$ is symmetric and affiliated.*

(ii) *$\xi(\cdot; \boldsymbol{G})$ in (15.32) is strictly increasing on $[\underline{b}, \bar{b}]$.*

The rationalizing distribution is

$$F(v_1, \dots, v_n) = \boldsymbol{G}\big(\xi^{-1}(v_1; \boldsymbol{G}), \dots, \xi^{-1}(v_n; \boldsymbol{G})\big). \tag{15.33}$$

Proof. Identification. Let F and $\tilde{F}$ both generate $\boldsymbol{G}$, with equilibrium strategies β and $\tilde{\beta}$. Both strategies satisfy (15.30), which is equivalent to (15.32). So $\beta^{-1} = \tilde{\beta}^{-1} = \xi(\cdot; \boldsymbol{G})$, and $F(\boldsymbol{v}) = \mathbb{P}\big(\xi(B_i) \le v_i \ \forall i\big) = \tilde{F}(\boldsymbol{v})$.

Necessity. If F rationalizes $\boldsymbol{G}$, then $\boldsymbol{G}(\boldsymbol{b}) = F\big(\beta^{-1}(b_1), \dots, \beta^{-1}(b_n)\big)$. Strictly increasing transformations preserve symmetry and affiliation, which gives (i). Since $\xi = \beta^{-1}$, (ii) holds.

Sufficiency. Let $\boldsymbol{G}$ satisfy (i) and (ii) and define F by (15.33). Then F is a symmetric affiliated distribution on $[\underline{v}, \bar{v}]^n$ with $\underline{v} = \xi(\underline{b})$ and $\bar{v} = \xi(\bar{b})$. Let bidders use $\beta = \xi^{-1}$. Then $\boldsymbol{G} = F \circ \beta^{-1}$ by construction, and the steps above reverse to show that β solves (15.30). For the boundary condition, LPV argue that $\ln G_{M|B}$ diverges at $\underline{b}$. Divergence of the logarithm alone does not force the markdown $\frac{G_{M|B}(b|b)}{g_{M|B}(b|b)}$ to vanish. It does vanish when $G_{M|B}(b \mid b) \to 0$ and $g_{M|B}(b \mid b)$ stays bounded away from zero as $b \downarrow \underline{b}$, and we maintain this regularity. Then $\xi(\underline{b}) = \underline{b}$. Second-order conditions are maintained throughout (Li et al., 2002, footnote 7). □

Three remarks place the result. First, Laffont and Vuong (1996) show that the general affiliated value model is not identified from bids. Any affiliated value model with fixed n is observationally equivalent to some APV model. Restricting attention to APV therefore loses nothing in explaining bids. In this sense the symmetric APV model is the most general model identified from bids alone (Li et al., 2002, p. 175). It does not exclude common values. It only cannot distinguish them (Section 15.6.1). Second, condition (ii) is a testable restriction of equilibrium play, as in Theorem 15.19. Third, condition (i) implies that independence of values can be tested through independence of bids within auctions, for example with the test of Blum et al. (1961).

Estimator. The ratio in (15.32) can be written with joint objects that are easier to estimate. Let $G_{M,B}(m,b) = G_{M|B}(m \mid b)\, g_B(b)$, which is $\frac{\partial}{\partial b}\mathbb{P}(M \le m,\, B \le b)$, and let $g_{M,B}(m,b) = g_{M|B}(m \mid b)\, g_B(b)$ be the joint density of (M,B). Then

$$\frac{G_{M|B}(b \mid b)}{g_{M|B}(b \mid b)} = \frac{G_{M|B}(b \mid b)\, g_B(b)}{g_{M|B}(b \mid b)\, g_B(b)} = \frac{G_{M,B}(b,b)}{g_{M,B}(b,b)},$$

because the marginal density g_B cancels. Fix n and let T_n be the number of n-bidder auctions. With a kernel $\mathcal{K}$ and bandwidths h_G and h_g, the first step computes

$$\hat{G}_{M,B}(b,b) = \frac{1}{nT_n h_G} \sum_{t=1}^{T_n} \sum_{i=1}^{n} \mathbf{1}(M_{it} \le b)\, \mathcal{K}\left(\frac{b - B_{it}}{h_G}\right), \tag{15.34}$$

$$\hat{g}_{M,B}(b,b) = \frac{1}{nT_n h_g^2} \sum_{t=1}^{T_n} \sum_{i=1}^{n} \mathcal{K}\left(\frac{b - M_{it}}{h_g}\right) \mathcal{K}\left(\frac{b - B_{it}}{h_g}\right), \tag{15.35}$$

equations (5)–(6) of Li et al. (2002) and (3.3)–(3.4) of Athey and Haile (2007). Averaging over the n bidders in each auction uses symmetry. The pseudo-values are

$$\hat{V}_{it} = B_{it} + \frac{\hat{G}_{M,B}(B_{it}, B_{it})}{\hat{g}_{M,B}(B_{it}, B_{it})} \quad \text{if } B_{\min} + h_g \le B_{it} \le B_{\max} - h_g, \tag{15.36}$$

and $\hat{V}_{it} = +\infty$ otherwise. Trimming bids within one bandwidth of the boundaries removes the pseudo-values that kernel boundary bias would distort (Li et al., 2002, p. 181).

The second step estimates the n-variate density of values from the auctions that survive trimming,

$$\hat{f}(v_1, \dots, v_n) = \frac{1}{T_n h_f^n} \sum_{t=1}^{T_n} \mathcal{K}_f\left(\frac{v_1 - \hat{V}_{1t}}{h_f}, \dots, \frac{v_n - \hat{V}_{nt}}{h_f}\right), \tag{15.37}$$

with a product kernel $\mathcal{K}_f$. A kernel with compact support gives zero weight to any auction with an infinite pseudo-value, so trimmed auctions drop out. Symmetry is imposed by averaging $\hat{f}$ over the $n!$ permutations of its arguments. The marginal density of values uses all pseudo-values, $\hat{f}_n(v) = \frac{1}{nT_n h_m} \sum_t \sum_i \mathcal{K}\big(\frac{v - \hat{V}_{it}}{h_m}\big)$. Comparing $\hat{f}_n$ across n checks whether the value distribution depends on the number of bidders. If it does not, pseudo-values from different n can be pooled.

Remark 15.32 (Rates). Let f have R continuous bounded derivatives. With $h_G \propto (\frac{\log T_n}{T_n})^{\frac{1}{2R+2n-3}}$, $h_g \propto (\frac{\log T_n}{T_n})^{\frac{1}{2R+2n-2}}$ and $h_f \propto (\frac{\log T_n}{T_n})^{\frac{R+n-2}{(R+n+1)(2R+2n-2)}}$, and if $R > n-2$, $\hat{f}$ is uniformly consistent on

inner compact sets with rate $(\frac{T_n}{\log T_n})^{\frac{R(R+n-2)}{(R+n+1)(2R+2n-2)}}$ (Li et al., 2002, Proposition 2). With observed values the optimal rate would be $(\frac{T_n}{\log T_n})^{\frac{R}{2R+n}}$ (Stone, 1982). For $R=2$ and $n=2$ the exponents are $\frac{2}{15}$ and $\frac{5}{15}$. The marginal density $\hat{f}_n$ converges faster, with exponent $\frac{(R+n-1)(R+n-2)}{(R+n+1)(2R+2n-2)}$ (Li et al., 2002, Proposition 3), which equals $\frac{1}{5}$ for $R=2$ and $n=2$. Optimality of these rates is not established, because the minimax argument of Guerre et al. (2000) does not carry over. The exponents fall with n. This is the curse of dimensionality.

Implementation. Li et al. (2002, pp. 180–181) use the triweight kernel $\mathcal{K}(u)=\frac{35}{32}(1-u^2)^3\mathbf{1}(|u|\le 1)$, a kernel of order two, and product kernels in several dimensions. Kernels of order three would be required in theory for $n=3$. They would produce negative density estimates and pseudo-values below bids, so order two is used throughout. Bandwidths follow the rate in Remark 15.32 with $R=2$. For $n=2$ they set $h_G=c_G(nT)^{-\frac{1}{5}}$ and $h_g=c_g(nT)^{-\frac{1}{6}}$. For $n=3$ the exponents are $-\frac{1}{7}$ and $-\frac{1}{8}$. The constants follow Silverman's rule of thumb, $c=2.978\times 1.06\,\hat{\sigma}_b$, where $\hat{\sigma}_b$ is the standard deviation of bids. The factor 2.978 converts the rule from a Gaussian to a triweight kernel. In the second step $h_f=c_f(2!\,T^*)^{-\frac{1}{15}}$ for $n=2$ and $c_f(3!\,T^*)^{-\frac{1}{16}}$ for $n=3$, with T^* the number of auctions left after trimming. When bids are skewed, the authors suggest working with $\ln(1+b)$ and transforming back (Li et al., 2002, footnote 13).

Monte Carlo design. The design follows the laboratory experiments of Kagel et al. (1987). Each value is a common draw plus noise, $V_i=Q+E_i$, with Q uniform on $[\frac{1}{4},\frac{3}{4}]$ and E_i independent and uniform on $[-\frac{1}{4},\frac{1}{4}]$. Values lie in $[0,1]$. Since $\operatorname{Var}(Q)=\operatorname{Var}(E_i)=\frac{1}{48}$, the correlation between two values is

$$\operatorname{Corr}(V_i,V_j)=\frac{\operatorname{Var}(Q)}{\operatorname{Var}(Q)+\operatorname{Var}(E_i)}=\frac{1}{2}.$$

The sum of two independent uniforms of width $\frac{1}{2}$ has the triangular marginal density $f(v)=4v$ on $[0,\frac{1}{2}]$ and $f(v)=4-4v$ on $[\frac{1}{2},1]$. Its kink at $\frac{1}{2}$ makes it nondifferentiable there.

We can derive the equilibrium for $v\le\frac{1}{2}$ by hand. Given $V_1=v\le\frac{1}{2}$, Bayes' rule makes Q uniform on $[\frac{1}{4},v+\frac{1}{4}]$. Given $Q=q$, each rival value is below x with probability $2(x-q)+\frac{1}{2}$, clipped to $[0,1]$. For $x\le v$ the substitution $u=2(x-q)+\frac{1}{2}$ gives

$$F_{Y_1|V_1}(x\mid v)=\frac{1}{v}\int_{\frac{1}{4}}^{x+\frac{1}{4}}\Big(2(x-q)+\frac{1}{2}\Big)^{n-1}dq=\frac{1}{2v}\int_0^{2x}u^{n-1}\,du=\frac{(2x)^n}{2nv}.$$

For x slightly above v the upper limit of q is $v+\frac{1}{4}$, so $F_{Y_1|V_1}(x\mid v)=\frac{(2x)^n-(2x-2v)^n}{2nv}$. Both pieces have derivative $2^{n-1}v^{n-2}$ at $x=v$, and $F_{Y_1|V_1}(v\mid v)=\frac{2^{n-1}v^{n-1}}{n}$. Therefore

$$\frac{f_{Y_1|V_1}(v\mid v)}{F_{Y_1|V_1}(v\mid v)}=\frac{n}{v},\qquad \beta'(v)=\big(v-\beta(v)\big)\frac{n}{v}.$$

The linear function $\beta(v)=\frac{n}{n+1}v$ satisfies this equation and $\beta(0)=0$. This is equation (10) of Li et al. (2002). For $n=2$ the same line $\beta(v)=\frac{2}{3}v$ holds on all of $[0,1]$ (their equation (11)). For $n=3$ the bid is nonlinear above $\frac{1}{2}$ (their equation (12)). A simple design thus produces a complicated equilibrium.

Compare the IPV benchmark with the same triangular marginal. On $[0,\frac{1}{2}]$, $F(v)=2v^2$, and the bid of (14.29) is

$$\beta^{IPV}(v)=v-\frac{\int_0^v(2x^2)^{n-1}dx}{(2v^2)^{n-1}}=v-\frac{v}{2n-1}=\frac{2n-2}{2n-1}\,v.$$

For $n = 2$ this equals the APV bid $\frac{2}{3}v$. For $n = 3$ it is $\frac{4}{5}v$, above the APV bid $\frac{3}{4}v$ (Li et al., 2002, footnote 17). Figure 15.11 shows both strategies on the whole support. Affiliation makes low types bid less aggressively and high types more aggressively. A bidder with a low value expects rivals with low values, so she faces weak competition. A bidder with a high value expects strong competition and shades less.

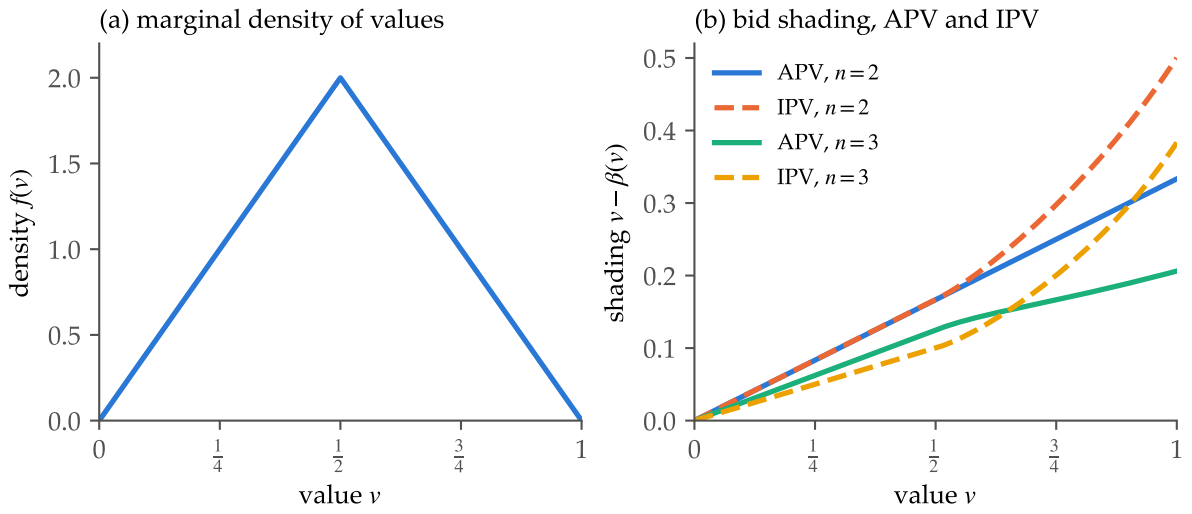

Figure 15.11: The Monte Carlo design of Li et al. (2002). Panel (a): the triangular marginal density of values when $V_i = Q + E_i$ with $Q \sim U[\frac{1}{4}, \frac{3}{4}]$ and $E_i \sim U[-\frac{1}{4}, \frac{1}{4}]$. Panel (b): bid shading $v - \beta(v)$ in the APV equilibrium (solid) and in the IPV equilibrium with the same marginal density (dashed), for $n = 2$ and $n = 3$. The APV bids use equations (10)–(12) of Li et al. (2002), which we checked against a numerical solution of (15.30). Our computation, with no random numbers (script `lpv_design.py`).

Each replication draws 100 auctions with two bidders and 100 auctions with three bidders, which gives 500 bids. The experiment is replicated 1,000 times (Li et al., 2002, p. 179). Each replication takes less than three seconds (Li et al., 2002, p. 182). The average first-step bandwidths (h_G, h_g) are $(0.148, 0.177)$ for $n = 2$ and $(0.076, 0.122)$ for $n = 3$.

Results. The median estimate of the inverse bid function tracks the truth closely and lies slightly above it. The pointwise 90 percent band contains the true function except near the boundaries (their Figures 1–2). The estimated marginal density follows the triangle except near the kink, where kernel smoothing rounds the peak (their Figures 3–5). The winner's *informational rent* in auction t is

$$\mathrm{IR}_t = \frac{v_{wt} - b_{wt}}{v_{wt}}, \tag{15.38}$$

with v_{wt} and b_{wt} the winner's value and bid (Li et al., 2002, eq. (16)). For $n = 2$ the APV bid is $\frac{2}{3}v$ on the whole support, so the true rent is exactly one third. Table 15.7 reports the true mean rent and the distribution across replications of the estimated average rent. The APV estimator slightly overstates the rent, consistent with the slight upward bias in $\hat{\xi}$. Rents fall from $n = 2$ to $n = 3$, a competition effect.

Imposing independence on affiliated data. The authors then apply the IPV estimator of Guerre et al. (2000) to the same simulated bids. The estimated inverse bid function matches the truth for low bids but lies well above it for high bids (their Figures 6–7). The implied value density is too dispersed (their Figures 8–9), and rents are overstated (Table 15.7). The authors report

Table 15.7: Winners' informational rents in the Monte Carlo of Li et al. (2002)

	APV estimator (Table 1)		IPV estimator (Table 2)	
	$n = 2$	$n = 3$	$n = 2$	$n = 3$
True mean IR	33.33	23.47	33.33	23.47
Estimated average IR	36.76	26.96	38.65	29.11
Empirical 5th percentile	32.44	19.32	31.53	19.05
Empirical 95th percentile	41.18	34.69	49.33	44.97

Notes. Percent. The informational rent is (15.38). Each column summarizes 1,000 replications, each with 100 two-bidder and 100 three-bidder auctions. The APV columns use the estimator (15.34)–(15.36). The IPV columns apply the estimator of Guerre et al. (2000) to the same affiliated bids. Source: Li et al. (2002, Tables 1 and 2).

overstatements of 17 and 24 percent for $n = 2$ and $n = 3$ (Li et al., 2002, p. 186). Relative to the true means in the table, the overstatements are 16 and 24 percent (our calculation).

A short calculation shows why. With $n = 2$ the bid is $\frac{2}{3}v$, so the marginal bid distribution is $G(b) = F(\frac{3}{2}b)$ with density $g(b) = \frac{3}{2}f(\frac{3}{2}b)$. The IPV inversion returns

$$\xi^{IPV}(b) = b + \frac{G(b)}{g(b)} = \frac{2}{3}v + \frac{2}{3}\frac{F(v)}{f(v)}, \qquad v = \tfrac{3}{2}b.$$

For $v \le \frac{1}{2}$, $\frac{F(v)}{f(v)} = \frac{2v^2}{4v} = \frac{v}{2}$, so $\xi^{IPV} = v$ and low values are recovered exactly. For $v > \frac{1}{2}$, $\frac{F(v)}{f(v)} = \frac{1-2(1-v)^2}{4(1-v)}$. At $v = \frac{3}{4}$ this is $\frac{7}{8}$, so $\xi^{IPV} = \frac{1}{2} + \frac{7}{12} = \frac{13}{12}$ against a true value of $\frac{3}{4}$. The inversion explodes near the top because the marginal density vanishes there. The IPV model reads the aggressive bidding of high types under affiliation as evidence of high values.

Assessment. The paper extends the indirect approach to dependent values and supplies a usable guide. Its limits are statistical and economic. The density of values is n-variate, so data demands grow quickly with n, and estimation proceeds separately for each n. The estimator conditions on the number of bidders, so it cannot by itself say how affiliation interacts with entry. Under APV, bids can fall as n rises (Pinkse and Tan, 2005). Regressions of bids on n therefore cannot separate private from common values (Section 15.6.2). Finally, correlation in values may come from auction features that bidders observe and the econometrician does not. That alternative is observationally equivalent to affiliation with a fixed n, and Section 15.7 treats it.

15.5.2 What the two highest bids reveal

Many first-price data sets record only the winning bid, or the two highest bids. Procurement agencies keep the second-lowest bid in case the winner defaults. Participants also track the gap between the top two bids, which they call "money left on the table" (Athey and Haile, 2002, p. 2123). Two bids suffice for part of the identification problem. Equation (15.32) involves only the distribution of the highest rival bid given one's own bid. In equilibrium the top two bids come from the bidders with the top two values. Let $I^{(n:n)}$ denote the identity of the winner.

Proposition 15.33 (Athey and Haile, 2002, Lemma 1, Theorem 7 and Corollary 1)**.** *Consider the APV model of the first-price auction, and suppose the two highest bids are observed. If bidders are asymmetric, suppose the identity of the winner is also observed.*

(i) The equilibrium bid functions β_i, $i = 1, \dots, n$, are identified.

(ii) With symmetric bidders, the joint distribution of $(V^{(n:n)}, V^{(n-1:n)})$ is identified.

(iii) With symmetric bidders, the joint distribution F of values is not identified if any lower bid is unobserved.

Proof. (i) Take bidder 1 and a bid b in the support of B_1. Multiply the numerator and denominator of the markdown by the density of B_1 at b. Then translate each event into events about the top two bids:

$$\frac{G_{M_1|B_1}(b \mid b)}{g_{M_1|B_1}(b \mid b)} = \frac{\frac{\partial}{\partial y}\mathbb{P}\left(M_1 \le b,\ B_1 \le y\right)\Big|_{y=b}}{\frac{\partial^2}{\partial x\,\partial y}\mathbb{P}\left(M_1 \le x,\ B_1 \le y\right)\Big|_{x=y=b}} = \frac{\frac{\partial}{\partial x}\mathbb{P}\left(B^{(n:n)} \le x,\ I^{(n:n)} = 1\right)\Big|_{x=b}}{\frac{\partial^2}{\partial x\,\partial y}\mathbb{P}\left(B^{(n-1:n)} \le x,\ B^{(n:n)} \le y,\ I^{(n:n)} = 1\right)\Big|_{x=y=b}}.$$
