$$p_{jt} + \left[(\Omega_t \odot \Delta_t^{s\top})^{-1}s_t\right]_j = x_{jt}\gamma_1 + \gamma_2 z_{jt} + \omega_{jt}. \tag{6.62}$$

Here z_{jt} is a cost shifter excluded from demand, and γ_1 and γ_2 are cost coefficients, unrelated to Euler's constant γ_E. Under either assumption the left side is data, so OLS under $\mathbb{E}[\omega_{jt} \mid x_{jt}, z_{jt}] = 0$ estimates the cost parameters. The conduct assumption determines how large the markup is, and so how much of the price variation across products is attributed to cost. Comparing the two specifications is the logic of the conduct test in Section 6.6.

Remark 6.38 (Existence of a price equilibrium). Bresnahan (1987, footnote 6) observes that a price equilibrium always exists in quality models of this kind, while it can fail in location models. With uniform tastes, consider product j as its own price falls. Its interval of buyers widens, and at some price the next product $j+1$ is dominated out of the market. Demand for j stays continuous at that price, because the interval of $j+1$ shrinks continuously to zero. The slope of demand changes from $-\kappa\big(\frac{1}{\delta_{j+1}-\delta_j} + \frac{1}{\delta_j-\delta_{j-1}}\big)$ to $-\kappa\big(\frac{1}{\delta_{j+2}-\delta_j} + \frac{1}{\delta_j-\delta_{j-1}}\big)$. The second is smaller in absolute value, because $\delta_{j+2} - \delta_j > \delta_{j+1} - \delta_j$. So demand is flatter below the kink than above it, and the derivative $\frac{\partial q_j}{\partial p_j}$ falls as p_j rises. Demand is concave in own price across the kink, and the same holds where the lower neighbor drops out. Profit $(p_j - mc_j)q_j$ is then concave in p_j on the range of prices at which j sells with a positive markup, and it is zero beyond that range. Profit is therefore quasi-concave, and standard fixed-point arguments give an equilibrium. In the Hotelling model with linear costs, demand jumps when a firm captures the rival's location, and existence can fail (Section 6.4.2). Caplin and Nalebuff (1991, Theorem 2) cover general taste densities with single-product firms. Utility must be linear in the taste parameter, as in (6.38) with type v_i. The density of v_i must be ρ-concave with $\rho = -\frac{1}{2}$, the case $n = 1$ of their assumption A2. This means that $\frac{1}{\sqrt{f}}$ is convex, a condition that every log-concave density meets (Section 6.1.3 and Chapter 4).

Example 6.39 (A worked example)**.** Three products and an outside good face exponential tastes with $\lambda = 1$. Observed prices are $p = (1.0, 1.5, 2.5)$ and observed shares are $s = (0.20, 0.15, 0.10)$, so $s_0 = 0.55$. Table 6.2 reports every step, computed to more digits than shown.

The first step inverts the shares. Cumulative shares are $S = (0.45, 0.25, 0.10)$. By (6.60), the cutoffs are $\bar{v}_1 = -\ln 0.55 = 0.598$, $\bar{v}_2 = -\ln 0.75 = 0.288$ and $\bar{v}_3 = -\ln 0.90 = 0.105$. They decrease, as Proposition 6.31 guarantees, so all three products are on the frontier. The recursion (6.49) gives

$$\begin{aligned} \delta_1 &= 1.0 \times 0.598 = 0.598, \\ \delta_2 &= 0.598 + 0.5 \times 0.288 = 0.742, \\ \delta_3 &= 0.742 + 1.0 \times 0.105 = 0.847. \end{aligned}$$

Recomputing the shares at these qualities with (6.44) returns the observed shares exactly. Simulating two million consumers returns them up to simulation error.

The second step computes substitution. The densities at the cutoffs are $f(\bar{v}_j) = 1 - S_j = (0.55, 0.75, 0.90)$. Formula (6.54) gives $g_1 = \frac{0.55 \times 0.598}{1.0} = 0.329$, $g_2 = \frac{0.75 \times 0.288}{0.5} = 0.432$ and $g_3 = \frac{0.90 \times 0.105}{1.0} = 0.095$. These fill the Jacobian through Proposition 6.35. Product 2 has the most elastic demand, $\varepsilon_2 = 5.26$. It sits between two neighbors, and its lower neighbor is only 0.5 away in price. Product 3, at the top, has a single neighbor and the least elastic demand, $\varepsilon_3 = 2.37$. The outside good responds only to p_1.

The third step backs out markups and marginal costs under three ownership structures, holding the observed prices and shares fixed. Under (a) single-product firms, $m_j = \frac{s_j}{g_j + g_{j+1}}$, which gives markups of 0.263, 0.285 and 1.055. Under (b) joint ownership of products 1 and 2,

the boundary between them, where $g_2 = 0.432$ is large, is internalized. The implied markups of 1 and 2 roughly triple to 0.794 and 0.936. The markup of product 3 is unchanged at 1.055, since its own first-order condition does not change. Under (c) a single owner of all three products, the implied markups are 1.369, 1.948 and 3.002. They exceed the prices, so the implied marginal costs are negative. The observed prices are too low to be monopoly prices under this demand system, and conduct (c) is rejected by the requirement that costs be nonnegative. Finally, joint ownership of products 1 and 3 alone reproduces the numbers of case (a) to every digit, as Corollary 6.36 predicts.

Table 6.2: Worked example of the vertical model with exponential tastes

Panel A. Inversion

Product j	p_j	s_j	S_j	$\bar{v}_j$	$f(\bar{v}_j)$	δ_j	g_j
1	1.0	0.20	0.45	0.598	0.55	0.598	0.329
2	1.5	0.15	0.25	0.288	0.75	0.742	0.432
3	2.5	0.10	0.10	0.105	0.90	0.847	0.095

Panel B. Share derivatives $\frac{\partial s_j}{\partial p_k}$ and elasticities ε_{jk}

	Derivative with respect to			Elasticity with respect to		
	p_1	p_2	p_3	p_1	p_2	p_3
Product 1	−0.760	0.432	0	−3.802	3.236	0
Product 2	0.432	−0.526	0.095	2.877	−5.263	1.580
Product 3	0	0.095	−0.095	0	1.422	−2.371
Outside good	0.329	0	0	0.598	0	0

Panel C. Implied markups m_j and marginal costs mc_j at the observed prices

	Markup m_j			Marginal cost mc_j		
Ownership	1	2	3	1	2	3
(a) Single-product firms	0.263	0.285	1.055	0.737	1.215	1.445
(b) Products 1 and 2 joint	0.794	0.936	1.055	0.206	0.564	1.445
(c) One firm owns all	1.369	1.948	3.002	−0.369	−0.448	−0.502

Notes: Tastes are exponential with $\lambda = 1$ and the outside share is $s_0 = 0.55$. In Panel A, $S_j = \sum_{k \geq j} s_k$, $\bar{v}_j = -\ln(1 - S_j)$, $f(\bar{v}_j) = 1 - S_j$, δ_j follows (6.49), and g_j follows (6.54). In Panel B, rows are shares and columns are prices, and $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$. In Panel C, $m = -(\Omega \odot \Delta^{s\top})^{-1}s$ and $mc = p - m$. Joint ownership of products 1 and 3 gives the numbers of row (a).

6.5.7 Extensions

The basic model extends in several directions that the rest of the chapter uses.

Remark 6.40 (An outside alternative with quality). The outside good need not sit at the origin. In the market for new cars, a consumer who buys no new car keeps or buys a used car. Bresnahan (1987, eq. 2) gives this alternative a quality δ_u and a price p_u, so the outside option is the point (p_u, δ_u) of the (p, δ) plane. Every result of this section goes through with $(p_0, \delta_0) = (p_u, \delta_u)$. The lowest cutoff becomes $\bar{v}_1 = \frac{\delta_1 - \delta_u}{p_1 - p_u}$, and in Bresnahan's form the demand for the lowest-quality new car is

$$q_1 = \kappa\left[\frac{p_2 - p_1}{\delta_2 - \delta_1} - \frac{p_1 - p_u}{\delta_1 - \delta_u}\right]$$

(Bresnahan, 1987, eq. 9). In Bresnahan's words, "it is exactly as if there were some other 'product' below the lowest-quality product" (Bresnahan, 1987, p. 463).

Remark 6.41 (Quality measured with error). Suppose consumers know each product's quality but the econometrician observes only a noisy proxy, $\delta_j = \delta(x_j) + \eta_j$ with η_j unobserved. Each consumer still substitutes only between price neighbors. The demand predicted by the econometrician, averaged over η, depends on several neighbors, because the frontier itself is uncertain. Measurement error in quality thus spreads substitution across more products, a step toward random coefficients models. Section 6.6 uses this device as a robustness check.

Remark 6.42 (Income heterogeneity). In the specification $u_{ij} = \delta_j(y_i - p_j)$ of Gabszewicz and Thisse (1979), the type is income. Section 6.4.5 shows that the cutoff between $j-1$ and j is the income $\frac{\delta_j p_j - \delta_{j-1} p_{j-1}}{\delta_j - \delta_{j-1}}$. With an income distribution in place of F, shares, the inversion and the derivatives follow the same steps, with higher incomes buying higher qualities.

Remark 6.43 (A building block for the pure characteristics model). Let $u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j$ with random coefficients β_i on the characteristics and α_i on price. Conditional on β_i, this is a vertical model in the price sensitivity α_i, with qualities $x_j\beta_i + \xi_j$. Shares are therefore a mixture of vertical shares (6.44) over the distribution of β_i (Berry and Pakes, 2007, eq. 18). The general cutoffs (6.43) are essential here, because the frontier changes with β_i. Section 6.8.3 develops the computation.

Remark 6.44 (Natural oligopolies). When firms choose qualities before prices, vertical differentiation limits the number of firms that can survive. A duopoly example of Tirole (1988, sec. 7.5.1), which follows Gabszewicz and Thisse (1979) and Shaked and Sutton (1982), shows the mechanism. Utility is $v\delta_j - p_j$, with v uniform on $[\underline{v}, \bar{v}]$ and $\bar{v} = \underline{v} + 1$. Both firms have unit cost c, qualities satisfy $\delta_1 < \delta_2$, and $h = \delta_2 - \delta_1$. Suppose qualities are high enough that every consumer buys. The type indifferent between the two products is $v^* = \frac{p_2 - p_1}{h}$, so $q_1 = v^* - \underline{v}$ and $q_2 = \bar{v} - v^*$. The first-order conditions for maximizing $(p_1 - c)q_1$ and $(p_2 - c)q_2$ are

$$p_1 = \frac{p_2 + c - \underline{v}h}{2}, \qquad p_2 = \frac{p_1 + c + \bar{v}h}{2}.$$

Substituting the second condition into the first and solving gives

$$p_1 - c = \frac{(\bar{v} - 2\underline{v})h}{3}, \qquad p_2 - c = \frac{(2\bar{v} - \underline{v})h}{3},$$

with quantities $q_1 = \frac{\bar{v} - 2\underline{v}}{3}$ and $q_2 = \frac{2\bar{v} - \underline{v}}{3}$. Profits are

$$\pi_1 = \frac{(\bar{v} - 2\underline{v})^2 h}{9}, \qquad \pi_2 = \frac{(2\bar{v} - \underline{v})^2 h}{9}.$$

Both profits rise with the quality gap h. If qualities are chosen at no cost from a fixed interval before prices are set, the two firms therefore locate at its two ends. The low-quality firm sells a positive quantity only if $\bar{v} > 2\underline{v}$. When $\bar{v} \le 2\underline{v}$, consumers are too similar, and price competition drives the low-quality firm from the market even though entry is free. Shaked and Sutton (1983) generalize this force into a *finiteness result*. Suppose that every consumer would buy the highest quality if all qualities sold at unit cost. Then only a bounded number of firms can have positive market shares, however large the market becomes. The condition requires that unit costs not rise too quickly with quality. It is more likely to hold when the cost of quality falls mainly on research and development or other fixed costs. Tirole contrasts the result with the Salop model, in which the number of firms grows without bound as fixed costs fall.

6.6 Case study: the 1955 automobile price war

The vertical model entered empirical industrial organization through a study of conduct. Bresnahan (1987) asks whether the American automobile boom of 1955 was a price war. The paper embeds the vertical model of Section 6.5 in an oligopoly model with multi-product firms. It solves the model under two conduct hypotheses, collusion and Bertrand-Nash competition, and estimates each version by maximum likelihood for the model years 1954, 1955 and 1956. Non-nested tests then ask which hypothesis the data favor in each year. No cost data enter. Conduct is identified from the fine structure of the cross-section of products. What matters is which products are close neighbors in quality, and whether a close neighbor belongs to the same firm or to a rival.

The section follows the order of a full case study. We state the question and the facts (Sections 6.6.1 and 6.6.2), describe the data (Section 6.6.3), and set out the model (Section 6.6.4). We then prove the equilibrium properties on which the test rests. Markups rise whenever a pair of neighbors starts to cooperate, collusive markups have a closed form, and Bertrand markups of close rivals vanish. Estimation, the non-nested test, the estimates, the counterfactual and the robustness checks follow (Sections 6.6.5 to 6.6.9). The section closes with identification, critiques and the contribution of the paper (Sections 6.6.10 to 6.6.12).

6.6.1 The question and why it matters

In the 1955 model year, American passenger car production was about 45 percent higher than in the two surrounding years, while quality-adjusted prices were lower (Bresnahan, 1987, p. 457). Aggregate demand models fit that year poorly. Chow (1960a, pp. 168–169), a leading study of automobile demand, reports that "the year 1955 is an exception" to the rule of small residuals. Its 1955 residual is "twice as large as the standard error" (quoted in Bresnahan, 1987, footnote 1). Paul Samuelson stated the puzzle more sharply. He "would flunk any econometrics paper that claimed to provide an explanation of 1955 auto sales."[7]

Higher output at a lower price is the signature of a supply shift. A pure demand shock moves the market along an upward-sloping supply relation and raises price, so it cannot produce a price trough in a boom on its own. Bresnahan therefore looks for a supply shock, and he proposes one of a specific form. His hypothesis is a one-year breakdown of tacit collusion among the automakers. Under this hypothesis firms priced to maximize joint profits in the 1954 and 1956 model years and competed in prices in the 1955 model year. The 1955 boom was then, in part, a price war.

The paper matters for three reasons. First, it is the first structural test of conduct in a differentiated-products industry, and it works without any data on costs. Berry et al. (1995, p. 844) call it "perhaps the first attempt at simultaneously modeling and estimating the demand and oligopoly pricing sides of the market." Conduct is encoded in a cooperation matrix Ω, the same object that merger simulation changes when two firms combine (Chapter 11). Second, it shows that conduct can change over time within one industry. This links it to the empirical study of collusion (Chapter 13), where Porter (1983a) documents switches between collusive and non-collusive periods in a railroad cartel from time-series data. Bresnahan instead uses the cross-section of products within each year.

Third, a price war in a boom year speaks to theories of collusion over the business cycle (Chapter 12). In Rotemberg and Saloner (1986), collusion is hardest to sustain when current

[7] Bresnahan reports the classroom remark and attributes the anecdote to Robert E. Hall (Bresnahan, 1987, footnote 2).

demand is high relative to future demand, so collusive prices fall in booms. They read Bresnahan's results as support for their theory, because 1955 was a boom year.[8] In Green and Porter (1984), by contrast, price wars follow unexpectedly low demand. The 1955 episode fits the first theory better. Bresnahan does not test either theory. His contribution is to show that the conduct of 1955 differed from that of the neighboring years. He later judged that such evidence had not separated the theories, and he doubted that further studies of the same kind would. Rotemberg and Saloner combine the regime switches that Porter (1983a) reports with the pattern of conduct that Bresnahan (1987) finds. Bresnahan (1989, p. 1025) sees "little in these investigations that differentiates among the various theories." The timing of changes in conduct is harder to estimate than its average level. A study of what starts and ends price wars has as many observations as there are price wars, far fewer than the number of periods.

6.6.2 Setting and aggregate facts

The American industry of the mid-1950s consisted of three large firms, General Motors (GM), Ford and Chrysler, and a fringe of smaller producers that included American Motors (AMC). Firms sell several models each. The time unit is the *model year*: the row labelled 1955 in the tables covers the fourth quarter of 1954 through the third quarter of 1955. Bresnahan treats the model year as a short run in a precise sense. Within it, firms set prices and quantities, but their product lines are predetermined. With fixed costs of product development, products are imperfect substitutes in equilibrium. Even the "competitive" model therefore has market power. The label refers to noncooperative conduct. Even competing firms are not price takers (Bresnahan, 1987, p. 458).

Table 6.3: Aggregate indicators of the automobile market, model years 1953–1957

	1953	1954	1955	1956	1957
Automobile market (Bresnahan's Table I)					
(1) Production, millions of units	6.13	5.51	7.94	5.80	6.12
(2) Real price: CPI for new cars relative to the CPI	1.01	0.99	0.95	0.97	0.98
(3) Quality-adjusted price (Cagan), percent change	NA	NA	−2.5	6.3	6.1
(4) Real sales, billions of 1957 dollars	14.5	13.9	18.4	15.7	16.2
(5) Quantity index, (4) divided by (2), 1957 = 100	86.8	84.9	117.2	97.9	100.0
Outside the automobile market (Bresnahan's Table II)					
(6) Per capita disposable personal income	1623	1609	1659	1717	1732
(7) Three-month Treasury bill rate, percent	1.9	0.9	1.7	2.6	3.2
(8) Non-auto durables spending, billions of 1957 dollars	14.5	14.5	16.1	17.1	17.0
(9) Accounting profits of the automakers	2.58	2.25	3.91	2.21	2.38

Notes: Reproduced from Bresnahan (1987, Tables I and II, p. 459). Rows are model years. Nominal values are deflated with the GNP deflator. Row (3) is the percentage change in Cagan's (1971) quality-adjusted price index, which uses only physically unchanged models. Row (4) is auto output in constant dollars from the National Income and Product Accounts. The source's note for row (6) reads "billions of 1957 dollars", which cannot apply to a per capita figure. The values are 1957 dollars per person. Row (9) is the profit of the five largest automobile companies. The note that should give its units is not printed in the source.

Table 6.3 shows why 1955 is anomalous. Production jumped to 7.94 million cars. This is 44 percent above 1954, 37 percent above 1956, and 40.4 percent above the average of the two years.

[8] The 1984 NBER working-paper version of Rotemberg and Saloner (1986) discusses Bresnahan's study in its section on evidence.

Bresnahan's round figure of 45 percent is close to the comparison with 1954. At the same time the real price of new cars hit its trough of 0.95. Quality adjustment does not change the picture. The quality-adjusted index of Cagan (1971) fell by 2.5 percent in 1955 and rose by 6.3 percent in 1956. Bresnahan notes that the hedonic index of Griliches (1964) behaves similarly.

Row (4) adds a second fact. Real sales in value terms rose by 32 percent between 1954 and 1955, much less than the 44 percent rise in units. The implicit quantity index of row (5) rose by more than real sales. Bresnahan reads this as a one-year shift of buyers toward smaller, lower-value cars, and he points to production by price group in *Ward's Automotive Yearbook* (his footnote 3). The shift matters later, because the price war hypothesis predicts that competition intensifies most in the small-car segment.

Rows (6) to (8) show that demand factors explain part of the boom. Per capita income rose by 3.1 percent in 1955. The Treasury bill rate of 1.7 percent was below its 1956 and 1957 levels. Spending on other durables rose by 11 percent in 1955, but it did not fall in 1956, while automobile output collapsed. Bresnahan concludes that some of the 1955 increase was due to demand, but that a full demand-side explanation would "need to be fairly fancy" (Bresnahan, 1987, p. 460).

Row (9) invites a wrong inference. Accounting profits jumped from 2.25 to 3.91 in 1955, which seems to suggest less competition. Automobile production, however, has large fixed costs for plant and product development. These are joint costs of production over many years, and accounting practice spreads them smoothly over time. High-volume years therefore look profitable in the accounting sense whatever happens to economic margins. There is no stable time-series relation between accounting profits and price-cost margins. This is why Bresnahan estimates margins from a structural model. His conclusion makes the general point that accounting-based measures of market power are unsuitable for studies of single industries (Bresnahan, 1987, p. 479).

Bresnahan calls the window of 1954 to 1956 "not entirely arbitrary".[9] It starts after the end of wartime controls, ends before foreign competition became consequential in his account, and contains no long strike. Each of the three years is estimated separately, and no restriction links the parameters across years.

6.6.3 Data and the quantity aggregation problem

The unit of observation is a physically distinct car model in a model year. Since demand elasticities in the model are driven by quality differences between products, the definition of a product is central. Model names are not useful for this purpose, because naming conventions vary across firms and over time.[10] Bresnahan treats two models as distinct in three cases. They are of different makes, they have different engines, frames or body types, or they differ in weight or length by more than one percent. Pontiac and Chevrolet are different makes in this sense, although GM produces both. Only hardtop and four-door sedan bodies enter, with

[9] Korean War price and quantity controls were lifted in February and March 1953. Bresnahan dates the start of foreign competition "of any consequence" to Volkswagen's entry in 1957. No labor-based work stoppage lasted more than ten days within the period (Bresnahan, 1987, p. 472, footnote 13). Volkswagen's own company history records that the Dutch businessman Ben Pon brought two Volkswagen cars to New York in 1949. It also records that Volkswagen of America was established in 1955 to organize dealers and provide parts and service (Volkswagen of America, 2026). Bresnahan's 1957 date therefore marks the point at which imports became a consequential competitor. It is later than the first sales of Volkswagen cars in the United States.

[10] Independent manufacturers sometimes doubled the number of model names offered for sale with only trivial changes in the set of physical products. Bresnahan notes that this was usually a warning sign of impending exit (Bresnahan, 1987, footnote 8).

two-door sedans standing in for models without a four-door version. The result is about 80 to 85 models per year, against 140 to 150 at the finest possible disaggregation (pp. 468 and 480).

Prices are list prices in mid-April of the model year, the "PA" prices of Ohta and Griliches (1976). Options are excluded, except heaters where the information is available, and power steering and brakes are included only when standard. No correction for dealer discounts is made, because the discount was constant across models before 1959. List prices appear in tables in the three trade journals *Ward's*, *Automotive News* and *Automotive Industries*, and in the Company Pages of *Ward's*. The *Ward's* and *Automotive News* tables failed to match on about two percent of all prices. In every such case the other two sources gave a three-way match (Bresnahan, 1987, p. 480).

The physical characteristics are those of the hedonic study of Ohta and Griliches (1976). They are length (bumper to bumper, in thousands of inches), curb weight (in thousands of pounds), advertised maximum brake horsepower (in hundreds), the number of cylinders, and a hardtop dummy. We collect them in the row vector x_j of Section 6.1. Quantities are model-year production. They come from *Automotive News*, *Ward's* and Heasley (1977), with gaps filled from monthly production and the dates of model changeover. Production ties each number to a physical product, but it does not correspond exactly to a market. Fleet sales and end-of-year bargains, in particular, cannot be treated adequately.

Production is often reported more coarsely than the product definition. In the 1954 data, for example, Chrysler reports production for the V-8 DeSoto, but both the Firedome and the Fireflite were sold with the V-8 engine. The solution is to aggregate predicted quantities to the level of the data. Let observed quantities be indexed by $m = 1, \dots, N_q$ and let $\mathcal{I}_m$ be the set of models whose production is reported jointly as q_m, with $k_m = |\mathcal{I}_m|$ models in it. The residual for observation m is

$$q_m - \sum_{j \in \mathcal{I}_m} q_j^*, \tag{6.63}$$

where q_j^* is the model's prediction for model j. If each model's quantity error has variance σ_q^2 and errors are independent across models, the aggregated error has variance $k_m \sigma_q^2$. Coarser aggregation thus produces heteroskedasticity of a known form, which the likelihood of Section 6.6.5 handles by weighting.

6.6.4 The model

We write Bresnahan's model in the notation of this chapter. His quality x is our δ, and his physical characteristics z are our x. His taste density δ is our κ, and his upper endpoint $V_{\max}$ is our $\bar{v}$. His used-car quality and price (γ, E) are our $(\delta_{\mathrm{u}}, p_{\mathrm{u}})$. His marginal-cost scale μ is our ψ, and his cooperation matrix H is our Ω. His number of models n is our J.

Assumption 6.45 (Bresnahan's environment)**.**

(i) *Unit demand.* Each consumer buys one new car or none. A consumer who buys no new car obtains a used car, the outside option.

(ii) *Utility.* A consumer with taste for quality v and income y obtains

$$\begin{aligned} u(\delta_j, y, v) &= v\,\delta_j + y - p_j \quad \text{from new car } j, \\ u(\delta_{\mathrm{u}}, y, v) &= v\,\delta_{\mathrm{u}} + y - p_{\mathrm{u}} \quad \text{from the used car.} \end{aligned} \tag{6.64}$$

(iii) *Tastes.* The taste v is uniformly distributed on $[0, \bar{v}]$ with density κ. The number of potential buyers is $M = \kappa\bar{v}$.

(iv) *Costs.* Model j costs $C(\delta_j, q_j) = FC(\delta_j) + mc(\delta_j)\, q_j$ with $mc(\delta) = \psi e^{\delta}$ and $\psi > 0$. The fixed cost $FC(\delta_j)$ is sunk at the pricing stage.

(v) *Used-car price.* $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$.

(vi) *Product set.* Qualities are fixed and ordered, $\delta_{\mathrm{u}} < \delta_1 < \cdots < \delta_J$, and the last quality step costs less than the highest taste for quality, $\frac{mc(\delta_J) - mc(\delta_{J-1})}{\delta_J - \delta_{J-1}} < \bar{v}$.

Parts (i) to (iii) are the vertical model of Assumption 6.24, except that the price sensitivity has support $[\frac{1}{\bar{v}}, \infty)$ and the outside option is a used car, as we show below. Part (v) is a restriction that Bresnahan imposes in estimation, because the used-car price and quality were hard to tell apart in the data (p. 468). Part (vi) says that the consumer with the highest valuation of quality values the last quality step at more than its cost. By convexity of mc, $\bar{v} > mc'(\delta_J)$ is a sufficient condition. Part (vi) guarantees that every product sells when prices equal marginal costs.

Demand

A consumer of type v buys the product with the lowest "total price" $p_j - v\delta_j$, since income enters utility additively. Consider two products h and i with $\delta_i > \delta_h$. The consumer is indifferent when

$$p_i - v\,\delta_i = p_h - v\,\delta_h.$$

Solving for v gives the cutoff type

$$v_{hi} = \frac{p_i - p_h}{\delta_i - \delta_h}, \tag{6.65}$$

and every type above v_{hi} strictly prefers the higher-quality product i. With products ordered by quality and all of them on the frontier, product j is bought by the types in $[v_{j-1,j}, v_{j,j+1}]$. The used car enters as a product 0 with quality δ_{u} and price p_{u}. Comparing the two utilities in (6.64) gives the cutoff $v_{01} = \frac{p_1 - p_{\mathrm{u}}}{\delta_1 - \delta_{\mathrm{u}}}$, which has exactly the form of (6.65). At the top, the type $\bar{v}$ buys the best car. Multiplying the length of each interval by the density κ gives Bresnahan's demand system (his eqs. 9–11):

$$\begin{aligned} q_1 &= \kappa\left[\frac{p_2 - p_1}{\delta_2 - \delta_1} - \frac{p_1 - p_{\mathrm{u}}}{\delta_1 - \delta_{\mathrm{u}}}\right], \\ q_j &= \kappa\left[\frac{p_{j+1} - p_j}{\delta_{j+1} - \delta_j} - \frac{p_j - p_{j-1}}{\delta_j - \delta_{j-1}}\right], \qquad 1 < j < J, \\ q_J &= \kappa\left[\bar{v} - \frac{p_J - p_{J-1}}{\delta_J - \delta_{J-1}}\right]. \end{aligned} \tag{6.66}$$

Demand is linear in prices. Bresnahan chose the uniform distribution for exactly this reason (Bresnahan, 1987, p. 460), and he credits the demand system to Prescott and Visscher (1977).

Equation (6.66) is the vertical model of Section 6.5 in another parametrization. Dividing utility (6.64) by $v > 0$ gives $\delta_j - \frac{p_j}{v} + \frac{y}{v}$. The last term is common to all options and drops out, so the consumer has price sensitivity $\nu = \frac{1}{v}$. The cutoff (6.65) is then the reciprocal $v_{j-1,j} = \frac{1}{\bar{\nu}_j}$ of the cutoff of Section 6.5.2. Example 6.30 derives the implied distribution $F(\nu) = 1 - \frac{1}{\bar{v}\nu}$ of the price sensitivity and shows that Proposition 6.29 then reproduces the interior and top equations of (6.66). The first equation is the used-car extension of Remark 6.40. Besides the support of the price sensitivity, two differences from Section 6.5 remain. The outside option has

a quality δ_u and a price p_u instead of the normalization $\delta_0 = p_0 = 0$. The scale of quality is not a free normalization here, because quality also enters marginal cost, as Section 6.6.10 explains.

Let $h_j = \delta_j - \delta_{j-1}$ be the quality gap below product j, with $h_1 = \delta_1 - \delta_u$. Differentiating (6.66) gives constant derivatives:

$$\frac{\partial q_j}{\partial p_j} = -\kappa\left(\frac{1}{h_j} + \frac{1}{h_{j+1}}\right) (j < J), \qquad \frac{\partial q_J}{\partial p_J} = -\frac{\kappa}{h_J}, \qquad \frac{\partial q_{j+1}}{\partial p_j} = \frac{\partial q_j}{\partial p_{j+1}} = \frac{\kappa}{h_{j+1}}, \tag{6.67}$$

and all other cross derivatives are zero. These are the derivatives of Proposition 6.35 multiplied by the market size. In the notation of (6.54), uniform tastes give $Mg_j = \frac{\kappa}{h_j}$, as computed at the end of Section 6.5.5. The number g_j of the general model is thus inversely proportional to the quality gap h_j. As in Chapter 4, we write Δ for the $J \times J$ matrix of quantity derivatives, $\Delta_{jk} = \frac{\partial q_j}{\partial p_k}$. It is symmetric and tridiagonal, and it equals M times the share Jacobian Δ^s of Section 6.5.5.

The quality gap measures closeness. The diversion ratio from product j to its upper neighbor is

$$D_{j,j+1} = \frac{\frac{\partial q_{j+1}}{\partial p_j}}{-\frac{\partial q_j}{\partial p_j}} = \frac{\frac{1}{h_{j+1}}}{\frac{1}{h_j} + \frac{1}{h_{j+1}}} = \frac{h_j}{h_j + h_{j+1}}.$$

Diversion goes mostly to the closer neighbor. As $h_{j+1} \to 0$, the own and cross derivatives both diverge and their ratio tends to one in absolute value, so the two products become perfect substitutes (Bresnahan, 1987, p. 462). Demand is continuous in prices even where a product's interval shrinks to zero, and a price equilibrium exists (Remark 6.38).

Costs and conduct

The cost function $C(\delta, q) = FC(\delta) + mc(\delta)q$ has a fixed cost and a constant marginal cost at each quality. Marginal cost must increase with quality. Otherwise the best product is also the cheapest to make, and only it would be produced. Bresnahan also wants mc convex. Consumers trade money for quality at a constant marginal rate, so convex costs mean decreasing returns to spending on quality, which rules out degenerate equilibria (his footnote 7). Convexity has a sharp implication in this model. Define the chord slopes

$$\chi_j = \frac{mc(\delta_j) - mc(\delta_{j-1})}{\delta_j - \delta_{j-1}}, \quad j = 1, \ldots, J, \qquad mc(\delta_0) \equiv mc(\delta_u) = p_u, \qquad \chi_{J+1} \equiv \bar{v}. \tag{6.68}$$

At marginal-cost prices, the cutoff between $j-1$ and j equals χ_j. Strict convexity makes the chord slopes increase, $\chi_1 < \chi_2 < \cdots < \chi_J$, and Assumption 6.45(vi) gives $\chi_J < \bar{v}$. Every product therefore sells at marginal-cost prices, with quantity

$$q_j(mc) = \kappa\,(\chi_{j+1} - \chi_j) > 0, \qquad j = 1, \ldots, J. \tag{6.69}$$

The exponential $mc(\delta) = \psi e^{\delta}$ is the simplest increasing and convex form with one parameter. It follows the log-linear hedonic price equations of Ohta and Griliches (1976).

Each model earns $\pi_j = (p_j - mc_j)q_j - FC(\delta_j)$, where $mc_j = mc(\delta_j)$. Bresnahan considers two conduct hypotheses. Under *collusion* (C), all firms set prices to maximize the sum of all profits, as a single monopolist would. Under *Bertrand-Nash competition* (B), each firm sets the prices of its own models to maximize its own profit, taking rivals' prices as given. Bresnahan's

tables call the second hypothesis "Nash-Competition" or "Bertrand". Because demand links only neighbors, conduct enters through the relation between each model and its two neighbors.

Consider first a model whose neighbors do not cooperate with it. Its owner sets the derivative of π_j with respect to p_j to zero (his eq. 15):

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} = 0 \quad \Longleftrightarrow \quad p_j - mc_j = \frac{q_j}{-\frac{\partial q_j}{\partial p_j}}. \tag{6.70}$$

The markup equals quantity divided by the absolute slope of the model's own demand curve. If instead j and $j+1$ cooperate, because one firm makes both or because firms collude, the price of j also accounts for the profit of $j+1$ (his eq. 16):

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + (p_{j+1} - mc_{j+1})\frac{\partial q_{j+1}}{\partial p_j} = 0. \tag{6.71}$$

The extra term is the effect of j's price on its neighbor's profit. It is large when the two products are close, since $\frac{\partial q_{j+1}}{\partial p_j} = \frac{\kappa}{h_{j+1}}$. This is why changing the conduct hypothesis has large effects where products are closely spaced.

The *cooperation matrix* Ω records which products cooperate (his eq. 17):

$$\Omega_{jk} = \begin{cases} 1 & \text{if products } j \text{ and } k \text{ cooperate,} \\ 0 & \text{otherwise.} \end{cases} \tag{6.72}$$

It is symmetric with ones on the diagonal. Under Bertrand it is the ownership matrix of Section 6.5.6. Under collusion every entry is one. In Bresnahan's three-product example, GM makes products 1 and 2 and Chrysler makes product 3 (his eqs. 18–19):

$$\Omega^{\mathrm{B}} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \Omega^{\mathrm{C}} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}. \tag{6.73}$$

With this notation the first-order condition for every model takes one form (his eq. 20):

$$0 = q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + \Omega_{j,j+1}(p_{j+1} - mc_{j+1})\frac{\partial q_{j+1}}{\partial p_j} + \Omega_{j,j-1}(p_{j-1} - mc_{j-1})\frac{\partial q_{j-1}}{\partial p_j}, \tag{6.74}$$

where terms that refer to products outside $1, \dots, J$ are absent. The used car has an exogenous price and no first-order condition. Solving the demand system (6.66) together with the J conditions (6.74) gives the equilibrium (his eq. 21)

$$p^* = p^*(\delta, \Omega, \delta_{\mathrm{u}}, \bar{v}, \kappa, \psi), \qquad q^* = q^*(\delta, \Omega, \delta_{\mathrm{u}}, \bar{v}, \kappa, \psi). \tag{6.75}$$

Because demand is linear, profits are quadratic in prices and the first-order conditions are linear.

The equilibrium as a linear system

The linear structure lets us prove the properties on which Bresnahan's test rests. Write $m_j = p_j - mc_j$ for the markup of model j and $m = (m_1, \dots, m_J)^\top$. We substitute $p_j = mc_j + m_j$ into (6.66). Each quantity splits into its value at marginal-cost prices and a term in markups,

$$q_j = \kappa\left[\frac{(mc_{j+1} - mc_j) + (m_{j+1} - m_j)}{h_{j+1}} - \frac{(mc_j - mc_{j-1}) + (m_j - m_{j-1})}{h_j}\right],$$

where $m_0 = 0$ because $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$. For $j = J$ the first term is replaced by $\kappa\bar{v}$. Using (6.68) and (6.67), this is

$$q = q(mc) + \Delta\, m.$$

The first-order conditions (6.74) read $q_j + \sum_k \Omega_{jk}\Delta_{kj} m_k = 0$, or $q + (\Omega \odot \Delta^{\top})m = 0$ in the notation of Section 6.5.6. Since Δ is symmetric, substituting $q = q(mc) + \Delta m$ gives

$$A(\Omega)\, m = q(mc), \qquad A(\Omega) = -\big(\Delta + \Omega \odot \Delta\big). \tag{6.76}$$

The entries of $A(\Omega)$ are

$$A_{jj} = 2\kappa\Big(\frac{1}{h_j} + \frac{1}{h_{j+1}}\Big)\ (j < J), \qquad A_{JJ} = \frac{2\kappa}{h_J}, \qquad A_{j,j+1} = A_{j+1,j} = -\big(1 + \Omega_{j,j+1}\big)\frac{\kappa}{h_{j+1}}, \tag{6.77}$$

and all other entries are zero. The diagonal does not depend on Ω because $\Omega_{jj} = 1$. Only the neighbor entries $\Omega_{j,j+1}$ matter. The row sums are

$$\begin{aligned} \textstyle\sum_k A_{1k} &= \frac{2\kappa}{h_1} + \big(1 - \Omega_{12}\big)\frac{\kappa}{h_2} > 0, \\ \textstyle\sum_k A_{jk} &= \big(1 - \Omega_{j-1,j}\big)\frac{\kappa}{h_j} + \big(1 - \Omega_{j,j+1}\big)\frac{\kappa}{h_{j+1}} \geq 0, \qquad 1 < j < J, \\ \textstyle\sum_k A_{Jk} &= \big(1 - \Omega_{J-1,J}\big)\frac{\kappa}{h_J} \geq 0. \end{aligned} \tag{6.78}$$

The first row is strictly positive because the lowest new car competes with the used car, whose price nobody in the industry controls. These properties make $A(\Omega)$ a nonsingular M-matrix. We state the facts we need and prove them for completeness, since Appendix B does not cover M-matrices.

Lemma 6.46 (M-matrices)**.** *Let A be an $n \times n$ matrix with the following three properties.*

(i) $A_{jj} > 0$ *for all j, and* $A_{jk} \leq 0$ *for $j \neq k$.*

(ii) A is irreducible. For all $j \neq k$ there is a chain $j = j_0, j_1, \dots, j_r = k$ with $A_{j_{s-1}j_s} \neq 0$ for $s = 1, \dots, r$.

(iii) Every row sum is nonnegative, and at least one row sum is strictly positive.

Then the following hold.

(a) A is nonsingular, and every entry of A^{-1} is strictly positive.

(b) If A' also has properties (i) to (iii), $A' \leq A$ entrywise and $A' \neq A$, then every entry of $A'^{-1} - A^{-1}$ is strictly positive.

Matrices with these properties are nonsingular M-matrices (Berman and Plemmons, 1994, ch. 6).

Proof. (a) Let $\Lambda = \mathrm{diag}(A_{11}, \dots, A_{nn})$ and $T = \Lambda^{-1}(\Lambda - A)$. Then $T \geq 0$, T has a zero diagonal, and $A = \Lambda(I - T)$. The row sums of T are

$$\sum_k T_{jk} = 1 - \frac{\sum_k A_{jk}}{A_{jj}} \leq 1,$$

with strict inequality in the rows with a positive row sum of A. Let $\mathbf{1}$ be the vector of ones and $r^{(t)} = T^t\mathbf{1}$. Then $r^{(1)} \leq \mathbf{1}$. Since $T \geq 0$,

$$r^{(t+1)} = T^t r^{(1)} \leq T^t\mathbf{1} = r^{(t)},$$

so each entry of $r^{(t)}$ is nonincreasing in t and at most one. Suppose $r_k^{(t)} < 1$ and $T_{jk} > 0$. Then

$$r_j^{(t+1)} = \sum_l T_{jl} r_l^{(t)} \le \sum_l T_{jl} - T_{jk}\left(1 - r_k^{(t)}\right) < \sum_l T_{jl} \le 1.$$

The set of rows with $r_j^{(t)} < 1$ is therefore nonempty at $t = 1$, never shrinks, and grows to include every row that points to one of its members. By irreducibility every row reaches a strict row through a chain of length at most $n-1$, so $r_j^{(n)} < 1$ for all j. For a nonnegative matrix the largest row sum is the matrix norm $\|T^n\|_\infty$, hence $\|T^n\|_\infty < 1$. The Neumann series then converges, $(I-T)^{-1} = \sum_{t\ge 0} T^t$, and $A^{-1} = \left(\sum_{t\ge 0} T^t\right)\Lambda^{-1}$. The diagonal entries of A^{-1} are at least $\frac{1}{A_{jj}} > 0$. For $j \neq k$, a chain of length r from j to k gives $(T^r)_{jk} > 0$, so $(A^{-1})_{jk} > 0$.

(b) Direct multiplication verifies the identity

$$A'^{-1} - A^{-1} = A'^{-1}\left(A - A'\right)A^{-1}.$$

By part (a) both inverses have strictly positive entries, and $A - A' \ge 0$ has at least one positive entry. Each entry of the product is a sum of nonnegative terms, at least one of which is positive. □

Proposition 6.47 (Cooperation raises every markup)**.** *Let Assumption 6.45 hold and let Ω be any symmetric matrix with entries in $\{0,1\}$ with unit diagonal. Then (6.76) has a unique solution $m(\Omega)$, and every markup is strictly positive. If Ω' is obtained from Ω by switching some $\Omega_{i,i+1} = \Omega_{i+1,i}$ from 0 to 1, then $m_k(\Omega') > m_k(\Omega)$ for every $k = 1, \dots, J$. In particular $0 < m(\Omega) \le m(\Omega^{\mathrm{C}})$ for every Ω, where Ω^{C} is the matrix of ones.*

Proof. By (6.77) and (6.78), $A(\Omega)$ has a positive diagonal and nonpositive off-diagonal entries, nonnegative row sums, and a strictly positive first row sum. It is irreducible because every super- and sub-diagonal entry is nonzero, so any two indices are linked by a chain of neighbors. By Lemma 6.46(a), $A(\Omega)^{-1}$ exists and has strictly positive entries. Since $q(mc) > 0$ by (6.69), the solution $m(\Omega) = A(\Omega)^{-1} q(mc)$ is unique and strictly positive. Switching $\Omega_{i,i+1}$ from 0 to 1 lowers $A_{i,i+1}$ and $A_{i+1,i}$ by $\frac{\kappa}{h_{i+1}}$ and leaves the other entries unchanged. Hence $A(\Omega') \le A(\Omega)$ with $A(\Omega') \neq A(\Omega)$, and $A(\Omega')$ also satisfies the conditions of the lemma. By Lemma 6.46(b),

$$m(\Omega') - m(\Omega) = \left[A(\Omega')^{-1} - A(\Omega)^{-1}\right] q(mc)$$

is a matrix with strictly positive entries times a strictly positive vector, so every entry is positive. The last claim follows by switching the zero neighbor entries of Ω to one, one pair at a time. □

Proposition 6.47 proves the claim that Bresnahan states as "easy to show": changing any $\Omega_{i,i+1}$ from zero to one raises $p_k - mc_k$ for all k (Bresnahan, 1987, p. 465). Cooperation between one pair raises the markups of that pair directly. Prices are *strategic complements* here: each model's best-response price rises with its neighbors' prices. The neighbors of the pair therefore raise their prices in response, and the effect travels along the whole quality ladder. One caveat applies. The proposition concerns the solution of the linear system. That solution is an equilibrium of the pricing game when every model sells a positive quantity, which we assume from now on, as Bresnahan does.

The collusive solution has a closed form that clarifies what collusion does in this model.

Proposition 6.48 (Collusive prices)**.** *Let Assumption 6.45 hold. The solution of (6.76) with $\Omega = \Omega^{\mathrm{C}}$ is*

$$m_j^{\mathrm{C}} = \frac{1}{2}\Big[\bar{v}\,(\delta_j - \delta_{\mathrm{u}}) - \big(mc_j - mc(\delta_{\mathrm{u}})\big)\Big], \qquad j = 1, \dots, J. \tag{6.79}$$

The collusive cutoffs are $v^{\mathrm{C}}_{j-1,j} = \frac{1}{2}(\bar{v} + \chi_j)$, every model sells, and $q_j^{\mathrm{C}} = \frac{1}{2} q_j(mc)$ for every j.

Proof. Joint profit, net of fixed costs, is $\Pi = \sum_j m_j q_j = \kappa \sum_{j=1}^{J} m_j\,(v_{j,j+1} - v_{j-1,j})$ with $v_{J,J+1} \equiv \bar{v}$. We rewrite it by summation by parts. With $m_0 \equiv 0$,

$$\begin{aligned}
\sum_{j=1}^{J} m_j\,(v_{j,j+1} - v_{j-1,j}) &= m_J \bar{v} + \sum_{j=1}^{J-1} m_j v_{j,j+1} - \sum_{j=1}^{J} m_j v_{j-1,j} \\
&= m_J \bar{v} + \sum_{j=2}^{J} m_{j-1} v_{j-1,j} - \sum_{j=1}^{J} m_j v_{j-1,j} \\
&= \sum_{j=1}^{J} (m_j - m_{j-1})\,(\bar{v} - v_{j-1,j}),
\end{aligned}$$

where the last step uses $m_J = \sum_{j=1}^{J}(m_j - m_{j-1})$. Let $d_j = m_j - m_{j-1}$ denote the markup increment. Because $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$, each cutoff depends only on its own increment, $v_{j-1,j} = \chi_j + \frac{d_j}{h_j}$. Therefore

$$\Pi = \kappa \sum_{j=1}^{J} d_j \Big(\bar{v} - \chi_j - \frac{d_j}{h_j}\Big).$$

The map from m to $(d_1, \dots, d_J)$ is linear and invertible, and Π is a sum of strictly concave quadratics, one for each increment. The first-order condition for d_j is $\bar{v} - \chi_j - \frac{2d_j}{h_j} = 0$, so

$$d_j = \frac{1}{2}\big(\bar{v}\, h_j - (mc_j - mc_{j-1})\big).$$

Summing over j gives (6.79), because the gaps sum to $\delta_j - \delta_{\mathrm{u}}$ and the cost differences telescope. These first-order conditions are equivalent to (6.74) with Ω^{C}, since both are the stationarity conditions of Π. Substituting d_j into the cutoff gives $v^{\mathrm{C}}_{j-1,j} = \frac{1}{2}(\bar{v} + \chi_j)$. These cutoffs increase in j and lie below $\bar{v}$ because $\chi_1 < \cdots < \chi_J < \bar{v}$, so every model sells. Finally, $q_j^{\mathrm{C}} = \kappa(v^{\mathrm{C}}_{j,j+1} - v^{\mathrm{C}}_{j-1,j}) = \frac{\kappa}{2}(\chi_{j+1} - \chi_j) = \frac{1}{2} q_j(mc)$, with $v^{\mathrm{C}}_{J,J+1} = \bar{v} = \chi_{J+1}$. □

Equation (6.79) formalizes half of Bresnahan's intuition. Under collusion, the markup of model j depends on its own quality and on the used car, but not on where the other models sit or who owns them. A model with a close neighbor keeps a large markup. The cartel acts like a monopolist facing linear demand, and it sells half the marginal-cost quantity of every model. The next remark shows that a region of the quality ladder owned by one firm behaves the same way even under Bertrand competition.

Remark 6.49 (A region owned by one firm). Suppose one firm owns the consecutive top models $k, k+1, \dots, J$, and let the conduct be Bertrand. Then the equilibrium price increments $p_j - p_{j-1}$ for $j = k+1, \dots, J$ equal their collusive values. Hence $q_j^{\mathrm{B}} = q_j^{\mathrm{C}}$ for $j = k+1, \dots, J$, and the

markup gap $m_j^{\mathrm{C}} - m_j^{\mathrm{B}}$ is the same for all $j \geq k$. To see this, apply the summation by parts of the proof above to the firm's own profit:

$$\sum_{j=k}^{J} m_j \left(v_{j,j+1} - v_{j-1,j}\right) = m_k \left(\bar{v} - v_{k-1,k}\right) + \sum_{j=k+1}^{J} d_j \left(\bar{v} - v_{j-1,j}\right).$$

The firm chooses $(m_k, d_{k+1}, \ldots, d_J)$, a relabelling of its own prices. For $j > k$ the cutoff $v_{j-1,j}$ depends only on d_j, so the first-order condition for d_j is the collusive one. Only the level m_k responds to competition from model $k-1$, which another firm owns.

The last result concerns close neighbors, the configuration that gives the test its power.

Proposition 6.50 (Close neighbors)**.** *Let Assumption 6.45 hold. Fix all qualities except δ_{i+1} for some $1 \leq i < J$, and let $h = h_{i+1} = \delta_{i+1} - \delta_i \downarrow 0$. Suppose the solution of (6.76) is an interior equilibrium along the sequence. There is a constant C, independent of h, such that:*

(a) If models i and $i+1$ do not cooperate ($\Omega_{i,i+1} = 0$), then $0 < m_i \leq Ch$ and $0 < m_{i+1} \leq Ch$.

(b) If they cooperate ($\Omega_{i,i+1} = 1$), then $|m_i - m_{i+1}| \leq Ch$, and both markups are bounded below by a positive constant independent of h.

Proof. We first bound markups and quantities. By Propositions 6.47 and 6.48,

$$0 < m_k \leq m_k^{\mathrm{C}} \leq \frac{1}{2}\bar{v}\left(\delta_J - \delta_{\mathrm{u}}\right) \equiv B$$

for every k, where the second inequality uses $mc_k > mc(\delta_{\mathrm{u}})$, and δ_J is the largest quality along the sequence. Equilibrium quantities satisfy $0 < q_k \leq \kappa\bar{v}$. For small h we also have $h_{i+2} = \delta_{i+2} - \delta_i - h \geq \frac{1}{2}(\delta_{i+2} - \delta_i)$ when $i + 2 \leq J$.

(a) With $\Omega_{i,i+1} = 0$, condition (6.74) for model i reads

$$\kappa\Big(\frac{1}{h_i} + \frac{1}{h}\Big)m_i = q_i + \Omega_{i-1,i}\frac{\kappa}{h_i}m_{i-1} \leq \kappa\bar{v} + \frac{\kappa B}{h_i},$$

where the cooperation term is absent if $i = 1$. The left side is at least $\frac{\kappa}{h}m_i$, so $m_i \leq h\left(\bar{v} + \frac{B}{h_i}\right)$. If $i + 1 < J$, the condition for model $i+1$ gives in the same way

$$\kappa\Big(\frac{1}{h} + \frac{1}{h_{i+2}}\Big)m_{i+1} = q_{i+1} + \Omega_{i+1,i+2}\frac{\kappa}{h_{i+2}}m_{i+2} \leq \kappa\bar{v} + \frac{\kappa B}{h_{i+2}},$$

so $m_{i+1} \leq h\left(\bar{v} + \frac{B}{h_{i+2}}\right)$. If $i + 1 = J$, the condition is $\frac{\kappa}{h}m_J = q_J \leq \kappa\bar{v}$, so $m_J \leq h\bar{v}$.

(b) With $\Omega_{i,i+1} = 1$, condition (6.74) for model i can be written as

$$\frac{\kappa}{h}\left(m_{i+1} - m_i\right) = -q_i + \frac{\kappa}{h_i}m_i - \Omega_{i-1,i}\frac{\kappa}{h_i}m_{i-1}.$$

The right side is bounded by $\kappa\bar{v} + \frac{2\kappa B}{h_i}$ in absolute value, so $|m_{i+1} - m_i| \leq h\left(\bar{v} + \frac{2B}{h_i}\right)$. For the lower bound, let $\Omega^{(i)}$ be the identity matrix with $\Omega^{(i)}_{i,i+1} = \Omega^{(i)}_{i+1,i} = 1$. By Proposition 6.47, $m(\Omega) \geq m(\Omega^{(i)})$, so it suffices to bound $m(\Omega^{(i)})$. Under $\Omega^{(i)}$, add the conditions for models i and $i+1$. The terms in $\frac{1}{h}$ cancel, and

$$q_i + q_{i+1} = \frac{\kappa}{h_i}m_i + \frac{\kappa}{h_{i+2}}m_{i+1},$$

where the last term is absent if $i+1 = J$. The left side is the demand for the pair, $\kappa(v_{i+1,i+2} - v_{i-1,i})$. Because all markups are positive,

$$v_{i-1,i} = \chi_i + \frac{m_i - m_{i-1}}{h_i} \le \chi_i + \frac{m_i}{h_i}, \qquad v_{i+1,i+2} = \chi_{i+2} + \frac{m_{i+2} - m_{i+1}}{h_{i+2}} \ge \chi_{i+2} - \frac{m_{i+1}}{h_{i+2}},$$

with $v_{J,J+1} = \bar{v} = \chi_{J+1}$ in the top case. Combining the last three displays gives

$$2\left(\frac{m_i}{h_i} + \frac{m_{i+1}}{h_{i+2}}\right) \ge \chi_{i+2} - \chi_i,$$

where again the term in h_{i+2} is absent in the top case. As $h \to 0$, χ_{i+2} tends to the chord slope of mc between δ_i and δ_{i+2} (or to $\bar{v}$ in the top case). By strict convexity this limit exceeds χ_i, the chord slope between δ_{i-1} and δ_i. The weighted sum of m_i and m_{i+1} is therefore bounded below by a positive constant. Since the two markups differ by at most Ch, each of them is bounded below by a positive constant for small h. □

Proposition 6.50 is the formal core of the test. Two nearly identical cars sold by rival firms are priced almost at marginal cost under Bertrand competition, whatever the rest of the market looks like. If the same two cars cooperate, they behave like a single product whose demand is the pair's combined interval and whose demand slope is set by the outer gaps h_i and h_{i+2}. Their markups stay positive and converge to each other. The proof also shows that part (b) holds under the weakest form of cooperation, a single cooperating pair. Full collusion only raises the markups further. Figure 6.6 traces the three cases in a numerical example.

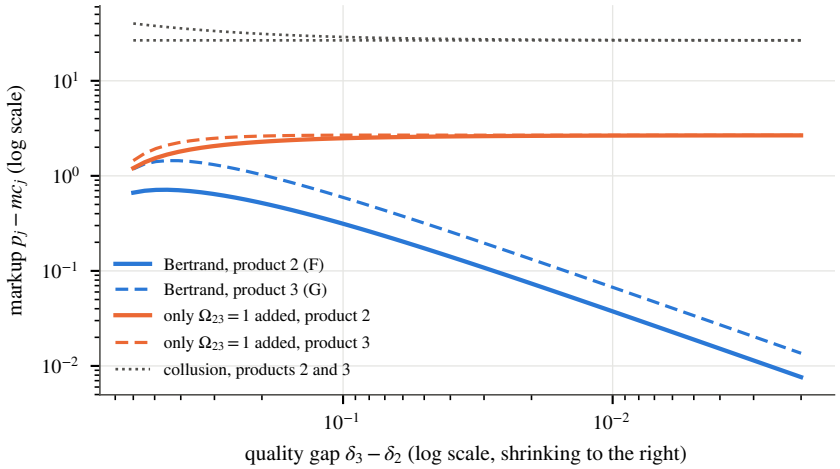

Figure 6.6: Markups of products 2 and 3 as their quality gap shrinks, in the seven-product design of Figure 6.7. Under Bertrand competition between their owners (blue) both markups fall in proportion to the gap, as in Proposition 6.50(a). If the Bertrand ownership matrix is changed only by letting products 2 and 3 cooperate, $\Omega_{23} = 1$ (orange), the markups converge to a common positive value near 2.67, as in part (b). Under full collusion (gray) they converge to about 26.7, the value given by Equation (6.79). Both axes are logarithmic. Computed with `bresnahan_fig2_sim.py`.

The intuition and Bresnahan's Figure 2

Bresnahan states the intuition in two sentences (Bresnahan, 1987, p. 458). If firms compete in prices, price is near marginal cost for the products that have a close substitute sold by a

competitor. If firms collude, the markup on one firm's product hardly depends on whether its close substitutes are sold by competitors or by the firm itself. Propositions 6.48 and 6.50 make both sentences precise. Bresnahan adds a general point. Conduct hypotheses differ in the comparative statics of price and quantity with respect to demand elasticities. So conduct can be discerned even when marginal costs are unobserved, the same logic as the rotation argument of Chapter 3.

His Figure 2 illustrates the point with seven products in quality space and two firms, labelled G and F. We recreate its design by solving the model. Products 2 and 3 are almost identical and belong to different firms. Products 5, 6 and 7, at the top, all belong to G. Figure 6.7 plots marginal cost and equilibrium prices against quality under both conduct hypotheses, and Figure 6.8 shows the original.[11]

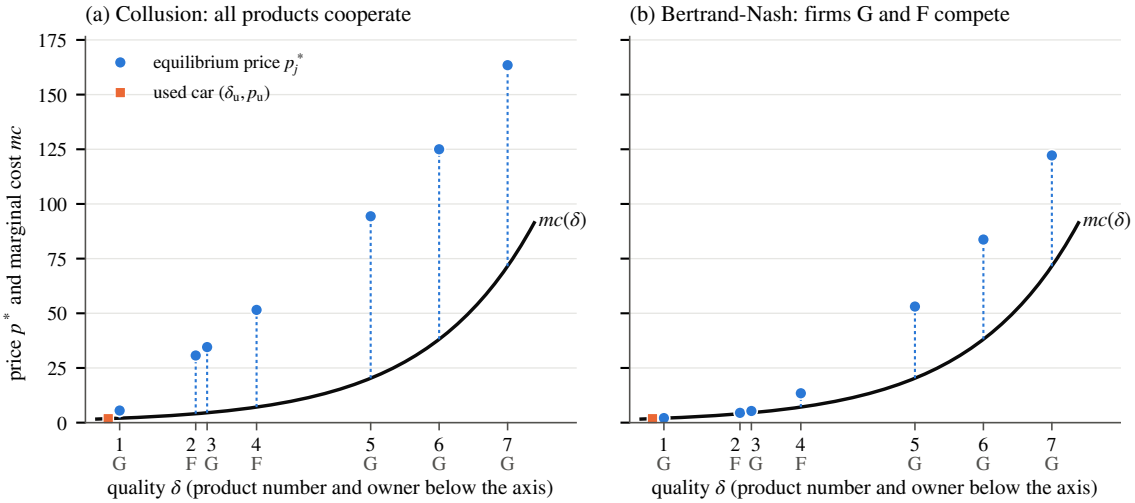

Figure 6.7: Model-generated recreation of the design of Bresnahan (1987), Figure 2. Seven products with qualities $\delta = (1, 2, 2.15, 2.8, 4.3, 5.2, 6.1)$ and owners G, F, G, F, G, G, G. Tastes are uniform with $\kappa = 1$ and $\bar{v} = 48.3$. Marginal cost is $mc(\delta) = e^{0.7\delta}$, which is Bresnahan's ψe^{δ} after a rescaling of quality units. The used car has $\delta_u = 0.85$ and $p_u = mc(\delta_u)$. Dots are equilibrium prices, and dotted segments are markups. Panel (a) solves (6.76) with $\Omega = \Omega^C$ and panel (b) with the ownership matrix. Computed with `bresnahan_fig2_sim.py`. The recreation copies the ownership labels of the original figure. Its markups need not match the original, which Bresnahan drew as a sketch.

The recreation shows three patterns. First, products 2 and 3 have markups of 26.65 and 30.05 under collusion and of only 0.43 and 0.83 under Bertrand competition, so they sit on the cost curve in panel (b). Their rivalry is fierce because they are close substitutes owned by different firms. Second, products 5, 6 and 7 keep between 44 and 55 percent of their collusive markups under Bertrand competition. They are distant from rivals and owned by one firm. By Remark 6.49, the price increments $p_6 - p_5$ and $p_7 - p_6$ and the quantities of products 6 and 7 are identical in the two panels. All three markups fall by the same amount, 41.28. Product 5 sells more under Bertrand competition (7.61 against 5.50), because its lower cutoff falls when

[11] The text of Bresnahan (1987, p. 466) describes the example differently from the figure. It says that "Firm One sells products 2, 4, and 5" and that "Firm Two sells product 3". The prices of products 1 and 6 are held fixed, because a third firm sells them. The figure labels the owners of products 1 to 7 as G, F, G, F, G, G, G. Our recreation follows the figure. The economics is the same under both descriptions, because products 2 and 3 are close neighbors owned by different firms.

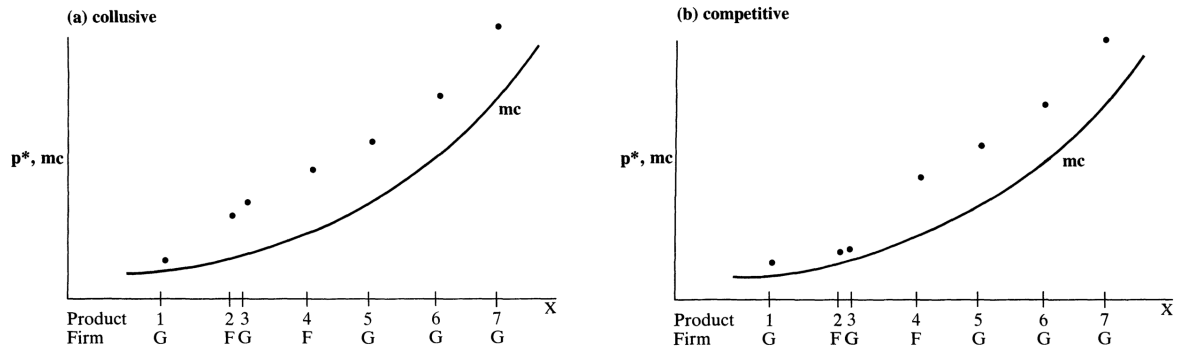

Figure 6.8: Bresnahan's original illustration. Panel (a) shows collusive prices and panel (b) competitive prices, with the marginal cost curve and the owner of each product below the quality axis. Source: Bresnahan (1987), Figure 2.

product 4 competes. Third, product 4, owned by F and wedged between two G products at moderate distances, keeps 14 percent of its collusive markup. Most of its Bertrand markup comes from the large markup of its upper neighbor, product 5, because prices are strategic complements.

The recreation departs from Bresnahan's sketch in one visible respect. In his panel (b), products 4 to 7 keep nearly all of their collusive markups. He writes that "Products 4 and 5 change much less when the solution concept changes" (Bresnahan, 1987, p. 467). In the solved model, product 4 keeps only 14 percent of its markup and products 5 to 7 keep about half. Product 4 faces rival neighbors on both sides. Products 6 and 7 lose the same dollar amount of markup as product 5, the lowest member of the top block (Remark 6.49). Bresnahan's figure is a sketch, and the robust contrast is the collapse of the markups of products 2 and 3.

The figure shows where the data can discriminate between the hypotheses. Regions of the quality ladder crowded with products of different firms look very different under the two hypotheses. Regions with few firms change much less, because market power is substantial even under competition. Bresnahan likens the large-car end of the mid-1950s market, where GM produced most cars, to the region around products 4 and 5 of his example. He likens the smaller-car segments to the region around products 1 and 2. There Ford, Chrysler, GM and, to a lesser extent, AMC and the fringe were all present (Bresnahan, 1987, p. 467). Bresnahan therefore expects the method to have statistical power in this industry. He also notes that the method would be less revealing if every producer had a full product line (Bresnahan, 1987, p. 467). Remark 6.53 makes this precise.

An earlier study supports this reading of the figure. Bresnahan (1989, pp. 1021–1022) summarizes Bresnahan (1981a), which fits the same vertical demand system to cross-sections of the 1977 and 1978 model years. Its demand equation is the interior equation of (6.66) (eq. 7 of the survey). Quality is a hedonic function of length, weight, horsepower and other characteristics (eq. 8). The supply side is (6.74) under Bertrand conduct. Same-owner dummies on the two neighbors of each model play the role of $\Omega_{j,j+1}$ and $\Omega_{j,j-1}$ (eq. 6″). The study reports two related findings. The large price-cost margins appear on the larger vehicles, and the larger vehicles are much farther apart in quality space. Products 5 to 7 of Figure 6.7 show the same pattern. They have no close rival, and they keep about half of their collusive markups under Bertrand competition, while products 2 and 3 keep almost nothing. Bresnahan adds that the finding confirms the view of industry observers based on accounting profits (footnote 13 of the survey).

6.6.5 Econometric specification and estimation

Quality as an index of characteristics. Quality is not observed. Bresnahan proxies it with a function of the physical characteristics (his eq. 22):

$$\delta(x_j) = \sqrt{\beta_0 + x_j\beta}, \tag{6.80}$$

where β_0 and the vector β are parameters. The interpretation comes from the hedonic model of Rosen (1974), developed in Section 6.9. Consumers have preferences over characteristics, and firms produce bundles of characteristics at costs that depend on them. The index is read as the expansion path of efficient, cost-minimizing bundles. Each quality level is produced with the cheapest combination of characteristics that delivers it. For this reason β mixes information about tastes and technology, and its interpretation is "clouded" (Bresnahan, 1987, p. 467). The square-root form is an arbitrary choice.

Computing the model's predictions. The parameters are $\theta = (\beta_0, \beta, \psi, \delta_{\mathrm{u}}, \bar{v}, \kappa)$, and the conduct hypothesis fixes Ω. For each trial value of θ the predictions are computed in three steps.

1. Compute every model's quality δ_j from (6.80).
2. Rank the models by quality, which determines who neighbors whom.
3. Solve the demand system (6.66) and the first-order conditions (6.74) jointly for the predicted prices $p_j^*(\theta, \Omega)$ and quantities $q_j^*(\theta, \Omega)$, which amounts to the linear system (6.76).

The predictions depend only on parameters and on the exogenous characteristics. The used-car parameters are tied together by Assumption 6.45(v), because the demand for the lowest-quality model (6.66) is overparameterized in $(\delta_{\mathrm{u}}, p_{\mathrm{u}})$. Bresnahan imposed $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$ after initial experimentation showed the two were not easily distinguishable (p. 468).

Errors and likelihood. Observed prices and quantities equal the predictions plus additive, independent normal errors. Price errors have variance σ_p^2. The error on aggregated quantity m has variance $k_m\sigma_q^2$, from Section 6.6.3, and price and quantity errors are independent. The likelihood is (his eq. 24)

$$L(\theta, \sigma_p^2, \sigma_q^2) = \prod_{j=1}^{N_p} \frac{1}{\sqrt{2\pi\sigma_p^2}} \exp\Big[-\frac{(p_j - p_j^*)^2}{2\sigma_p^2}\Big] \prod_{m=1}^{N_q} \frac{1}{\sqrt{2\pi k_m\sigma_q^2}} \exp\Big[-\frac{\big(q_m - \sum_{j\in\mathcal{I}_m} q_j^*\big)^2}{2k_m\sigma_q^2}\Big], \tag{6.81}$$

where N_p and N_q are the numbers of price and quantity observations and the predictions depend on (θ, Ω). The variances can be concentrated out. The log-likelihood is

$$\ln L = -\frac{N_p}{2}\ln(2\pi\sigma_p^2) - \frac{1}{2\sigma_p^2}\sum_j (p_j - p_j^*)^2 - \frac{1}{2}\sum_m \ln(2\pi k_m\sigma_q^2) - \frac{1}{2\sigma_q^2}\sum_m \frac{(q_m - \sum_{j\in\mathcal{I}_m} q_j^*)^2}{k_m}.$$

Setting the derivative with respect to σ_p^2 to zero gives $-\frac{N_p}{2\sigma_p^2} + \frac{1}{2\sigma_p^4}\sum_j (p_j - p_j^*)^2 = 0$, and similarly for σ_q^2. Hence

$$\hat{\sigma}_p^2(\theta) = \frac{1}{N_p}\sum_{j=1}^{N_p}(p_j - p_j^*)^2, \qquad \hat{\sigma}_q^2(\theta) = \frac{1}{N_q}\sum_{m=1}^{N_q}\frac{\big(q_m - \sum_{j\in\mathcal{I}_m} q_j^*\big)^2}{k_m}.$$

Substituting back gives the concentrated log-likelihood

$$\ell^{c}(\theta) = -\frac{N_p}{2}\ln\hat{\sigma}_p^2(\theta) - \frac{N_q}{2}\ln\hat{\sigma}_q^2(\theta) - \frac{1}{2}\sum_m \ln k_m - \frac{N_p + N_q}{2}\big(1 + \ln 2\pi\big). \tag{6.82}$$

Maximum likelihood therefore chooses θ to minimize $N_p \ln\hat{\sigma}_p^2(\theta) + N_q \ln\hat{\sigma}_q^2(\theta)$. Equivalently, it minimizes the product $(\hat{\sigma}_p^2)^{N_p}(\hat{\sigma}_q^2)^{N_q}$ of the mean squared price error and the weighted mean squared quantity error. It is a form of nonlinear least squares for a system of two equations. All estimation was done by numerical maximization.

Remark 6.51 (A reduced-form error structure). The errors in (6.81) are appended to the equilibrium predictions. They are not structural demand or cost shocks. Bresnahan calls this "fully a reduced-form error structure" (p. 469). It avoids the usual endogeneity problem, because price never appears as a regressor and the predictions depend only on exogenous characteristics. The cost of this choice is that the errors have no economic interpretation. A cost shock to one model would move its neighbors' prices through the first-order conditions, which additive independent errors cannot capture. Berry et al. (1995, p. 843) note that Bresnahan "allows prices to be correlated with a linear disturbance in an equilibrium pricing equation". They add that he "does not explicitly model the correlation between prices and unobserved characteristics." Modelling an unobserved product characteristic ξ_j and inverting market shares is the response of Berry (1994) and Berry et al. (1995) (Chapters 7 and 8).

An irregular likelihood. The likelihood is not continuous in the parameters. Predicted prices are continuous, but predicted quantities jump at values of β where two models, or a model and the used car, tie in quality. At such points the ranking changes, and so does the set of neighbors. A discontinuous function cannot be concave, and the standard regularity conditions for nonlinear regression fail. Bresnahan argues that ties are unlikely at the true parameter value, so that limiting inference should go through (his footnote 9). He also reports that no local maxima caused trouble and that the points of discontinuity were typically local minima, since they imply extreme predicted quantities (footnote 10). Asymptotic normality of the estimators and of the test statistics remains unproven, as Appendix B acknowledges.

Two further specifications. Two more models serve as alternatives in the tests. The first is the log-linear hedonic model of Cowling and Cubbin (1971), estimated on the British car market. Predicted prices and quantities follow a recursive structure (his eqs. 25–26):

$$p_j^{*} = \exp\big(a_0 + x_j a\big), \qquad q_j^{*} = \exp\big(l_0 + l_1(p_j - p_j^{*})\big), \tag{6.83}$$

where we write a_0, a, l_0 and l_1 for Bresnahan's α_0, α_j, λ_0 and λ_1. The price equation adds GM and Ford dummies, following authors who use firm dummies as a proxy for market power. The model has the same error and aggregation structure as the oligopoly models. Rosen (1974) interprets a hedonic price function as the equilibrium of a perfectly competitive, continuously differentiated market. The hedonic model, "or something like it", should hold if list prices were set in some nonmaximizing way (p. 470). It differs radically from the oligopoly models. The second alternative, called "Products", is the opposite. It follows the oligopoly model exactly but treats every model as if a separate firm made it, so $\Omega = I$. Neither is an appealing story of the industry. Both are useful as tests, because an oligopoly model that survives against them is more credible.

6.6.6 Testing non-nested conduct hypotheses

Collusion and Bertrand competition are non-nested hypotheses. They impose different matrices Ω, and no restriction on the parameters turns one model into the other. The hedonic model is a different family altogether. A classical likelihood ratio test, which compares a model with a restricted version of itself, does not apply. Bresnahan uses the non-nested test of Cox (1961) in the regression form of Pesaran and Deaton (1978) (Bresnahan, 1987, p. 470).

The Cox statistic. Let H_0 and H_1 be two parametric models for the same data, with maximized log-likelihoods L_0 and L_1. The *Cox statistic* for testing H_0 against H_1 is the observed log-likelihood ratio minus an estimate of its expectation under H_0,

$$T_0 = (L_0 - L_1) - \hat{\mathbb{E}}_0\big[L_0 - L_1\big]. \tag{6.84}$$

The expectation is evaluated at the estimate of θ_0. It replaces the parameters of H_1 by their *pseudo-true values*, the probability limit of the H_1 estimator when the data come from H_0. Under H_0 the standardized statistic is asymptotically standard normal. A significantly negative T_0 means that H_1 fits better than it should if H_0 were true, which is evidence against H_0 in the direction of H_1. A significantly positive T_0 means that H_1 fits worse than H_0 predicts. The test is two-tailed, so this also rejects H_0, whose likelihood is "too large" relative to H_1. The test is not symmetric. Testing H_1 against H_0 is a different test, so both models can be rejected, or neither. The next proposition gives the statistic for regression models.

Proposition 6.52 (Cox statistic for non-nested regressions)**.** *Let $y \in \mathbb{R}^N$, $H_0 : y = f_0(\theta_0) + u$ and $H_1 : y = f_1(\theta_1) + w$, with $u \sim N(0, \sigma_0^2 I_N)$ under H_0, smooth mean functions, and parameter vectors of fixed dimension. Let s_0^2 and s_1^2 be the maximum likelihood residual variances under the two models. Fit H_1 to the fitted values of H_0: let $\hat{\theta}_{10}$ minimize $\|f_0(\hat{\theta}_0) - f_1(\theta_1)\|^2$, let $\hat{d} = f_0(\hat{\theta}_0) - f_1(\hat{\theta}_{10})$, and define*

$$\phi^2 = \frac{1}{N}\|\hat{d}\|^2, \qquad s_{10}^2 = s_0^2 + \phi^2, \qquad \tilde{\phi} = \frac{1}{N}\hat{d}^\top M_0 \hat{d},$$

where $M_0 = I_N - F_0(F_0^\top F_0)^{-1}F_0^\top$ and $F_0 = \frac{\partial f_0(\hat{\theta}_0)}{\partial \theta_0^\top}$. Then

$$T_0 = \frac{N}{2}\ln\frac{s_1^2}{s_{10}^2}.$$

If H_0 is true, H_1 does not contain the true mean function, and standard regularity conditions hold, then

$$\frac{T_0}{\sqrt{V_0}} \xrightarrow{d} N(0,1), \qquad V_0 = \frac{N\tilde{\phi}\, s_0^2}{s_{10}^4}.$$

Proof sketch. The concentrated log-likelihood of a normal regression is $-\frac{N}{2}\ln s^2$ plus a constant common to both models. Hence

$$L_0 - L_1 = \frac{N}{2}\ln\frac{s_1^2}{s_0^2}.$$

Under H_0, s_1^2 converges to $\sigma_0^2 + \phi_*^2$, where ϕ_*^2 is the limit of ϕ^2, the part of the H_0 mean that H_1 cannot fit. The estimated expectation of $L_0 - L_1$ is therefore $\frac{N}{2}\ln\frac{s_{10}^2}{s_0^2}$, and subtracting it gives T_0.

For the distribution we expand to first order around the true θ_0 and the pseudo-true value θ_{10}^*. Write $f_0 = f_0(\theta_0)$ and $d = f_0 - f_1(\theta_{10}^*)$. Let F_1 be the gradient of f_1 at θ_{10}^*, define M_1 from F_1 as M_0 is defined from F_0, and let $P_k = I_N - M_k$ be the projection onto the columns of F_k. The first-order condition defining θ_{10}^* is $F_1^\top d = 0$, so $M_1 d = d$. Four steps follow.

1. Fitting H_1 to $y = f_0 + u$ leaves residuals $M_1(d + u)$ to first order. Hence $N s_1^2 \approx \|d\|^2 + 2d^\top u + u^\top M_1 u$.
2. Fitting H_0 leaves residuals $M_0 u$, so $N s_0^2 \approx u^\top M_0 u$.
3. The fitted values of H_0 are $f_0 + P_0 u$ to first order. Fitting H_1 to them, as in step 1, gives $N\phi^2 \approx \|d\|^2 + 2d^\top P_0 u + u^\top P_0 M_1 P_0 u$.
4. Subtracting, $N(s_1^2 - s_{10}^2) \approx 2d^\top M_0 u + R$, where R collects quadratic forms in u on spaces of fixed dimension and is bounded in probability. The term $d^\top M_0 u$ is of order $\sqrt{N}$ because $\|d\|^2$ grows like N.

Since $\ln \frac{s_1^2}{s_{10}^2} \approx \frac{s_1^2 - s_{10}^2}{s_{10}^2}$, the statistic satisfies

$$T_0 \approx \frac{d^\top M_0 u}{\sigma_0^2 + \phi_*^2}, \qquad \operatorname{Var}_0\!\left(d^\top M_0 u\right) = \sigma_0^2\, d^\top M_0 d.$$

The leading term is normal with mean zero and variance $\frac{\sigma_0^2\, d^\top M_0 d}{(\sigma_0^2 + \phi_*^2)^2}$. Its plug-in estimate is V_0, since $N\tilde{\phi}$ estimates $d^\top M_0 d$. Pesaran (1974) and Pesaran and Deaton (1978) give the regularity conditions and the multivariate version. □

The proof explains the two auxiliary regressions in Bresnahan's Appendix B. The first fits H_1 to the fitted values of H_0, which he calls the "phony-data regression". Its residual variance ϕ^2 measures how far H_1 is from H_0. The second regresses the phony-data residuals on the derivatives of H_0's predictions. Its residual variance $\tilde{\phi}$ removes the part of the distance that a small change in θ_0 could absorb. The intuition of the test is simple: H_0 is rejected if H_1 explains a significant part of H_0's residuals (Bresnahan, 1987, p. 471).

Bresnahan's formulas. Bresnahan's models have two equations with independent errors, and the quantity equation is weighted by $\frac{1}{k_m}$. The concentrated log-likelihood (6.82) has the same weights under every model, so the terms in k_m cancel from all likelihood ratios. The contributions of the two equations add. Let s_{jp}^2 and s_{jq}^2 be the estimated price and quantity error variances under H_j, for $j = 0, 1$ (his eqs. B.1–B.2). The phony-data regression fits H_1 to the predictions of H_0 and yields variances ϕ_p^2 and ϕ_q^2. Then (his eqs. B.3–B.5)[12]

$$s_{10p}^2 = s_{0p}^2 + \phi_p^2, \qquad s_{10q}^2 = s_{0q}^2 + \phi_q^2, \qquad T_0 = \frac{N_p}{2} \ln \frac{s_{1p}^2}{s_{10p}^2} + \frac{N_q}{2} \ln \frac{s_{1q}^2}{s_{10q}^2}. \tag{6.85}$$

The second regression takes the residuals of the phony-data regression and regresses them linearly on the derivatives of the H_0 predictions with respect to the H_0 parameters. Its residual variances are $\tilde{\phi}_p$ and $\tilde{\phi}_q$, which Bresnahan writes as ϕp and ϕq. They are variances in their own right. They are not the square roots of ϕ_p^2 and ϕ_q^2. The asymptotic variance of T_0 is (his eq. B.6)

$$V_0(T_0) = N_p \tilde{\phi}_p \frac{s_{0p}^2}{s_{10p}^4} + N_q \tilde{\phi}_q \frac{s_{0q}^2}{s_{10q}^4}, \tag{6.86}$$

[12] Equation (B.4) is printed as $s_{10q}^2 \equiv s_{0p}^2 + \phi_q^2$. The subscript $0p$ is a misprint for $0q$, by analogy with (B.3) and with Proposition 6.52.

and the test statistic is $\frac{T_0}{\sqrt{V_0(T_0)}}$.[13] Each term of (6.85) and (6.86) is the single-equation formula of Proposition 6.52. Bresnahan's footnote 11 notes that the Pesaran-Deaton formulas were altered slightly to account for the aggregation of quantities.

Table 6.4: Cox test statistics for each maintained hypothesis against each alternative, 1954–1956

	Alternative hypothesis H_1			
Maintained hypothesis H_0	Collusion	Nash-Competition	"Products"	Hedonic
(a) 1954				
Collusion	·	0.8951	0.9464	−1.934
Nash-Competition	−2.325*	·	−0.8878	−2.819*
"Products"	−3.978*	3.029*	·	−1.604
Hedonic	−12.37*	−10.94*	−13.02*	·
(b) 1955				
Collusion	·	−10.36*	−9.884*	−13.36*
Nash-Competition	−1.594	·	1.260	0.6341
"Products"	−0.7598	−4.379*	·	−1.527
Hedonic	−3.353*	−8.221*	−5.950*	·
(c) 1956				
Collusion	·	1.227	0.8263	1.629
Nash-Competition	−2.426*	·	−4.586*	0.8314
"Products"	−3.153*	0.9951	·	4.731*
Hedonic	−5.437*	−9.671*	−11.58*	·

Notes: Reproduced from Bresnahan (1987, Table III, p. 471). Each entry is the standardized Cox statistic $\frac{T_0}{\sqrt{V_0}}$ for testing the row model against the column model, asymptotically standard normal under the row model. A dot marks the diagonal. Asterisks are ours and mark rejection at the 5 percent level in a two-tailed test, $\left|\frac{T_0}{\sqrt{V_0}}\right| > 1.96$. Negative values indicate that the alternative fits better than the maintained model predicts. "Products" treats every model as a separate firm ($\Omega = I$). The hedonic model is (6.83).

Results. Table 6.4 reproduces the test results. In 1954 the hedonic model is rejected against every other model. "Products" is rejected against both oligopoly models but not against the hedonic model. Nash-Competition is rejected against Collusion (−2.325) and against the hedonic model (−2.819). Collusion is the only model that escapes rejection against every alternative. Its statistic against the hedonic model, −1.934, is close to the 5 percent cutoff of 1.96 but below it in absolute value. The 1956 results resemble those of 1954. Collusion is not rejected against any alternative, and every other model is rejected at least once. Nash-Competition, for example, is rejected against Collusion (−2.426) and against "Products" (−4.586).

The 1955 results are reversed. Collusion is rejected against all three alternatives, with statistics of −10.36, −9.884 and −13.36. Nash-Competition is rejected against none. The other models are rejected as in the surrounding years. "Products" is rejected against Nash-Competition, and the hedonic model against everything. Some rejections have positive signs, as for "Products" against Nash-Competition in 1954 (3.029) and against the hedonic model in 1956 (4.731). These reject because the likelihood of "Products" is too large relative to the alternative, a possibility Bresnahan's footnote 12 points out for the two-tailed test.

[13] Appendix B prints the statistic as the ratio of T_0 to $V(T_0)$, without a square root. The text (p. 470) divides the deviation of the likelihood ratio from its mean "by its standard deviation". Proposition 6.52 confirms that the square root is required for an asymptotically standard normal statistic. We read the printed ratio as shorthand.

Table 6.5: Parameter estimates under the maintained conduct hypotheses, 1954–1956

Parameter	1954 (Collusion)	1955 (Bertrand)	1956 (Collusion)
Quality index $\delta(x) = \sqrt{\beta_0 + x\beta}$			
Constant β_0	47.91	48.28	50.87
	(32.8)	(43.2)	(29.4)
Weight (thousands of lb)	0.3805	0.5946	0.5694
	(0.332)	(0.145)	(0.374)
Length (thousands of in.)	0.1819	0.1461	0.1507
	(0.128)	(0.059)	(0.146)
Horsepower (hundreds)	2.665	3.350	3.248
	(0.692)	(0.535)	(0.620)
Cylinders	−0.7387	−0.9375	−0.9639
	(0.205)	(0.115)	(0.186)
Hardtop dummy	0.9445	0.4531	0.4311
	(0.379)	(0.312)	(0.401)
Demand and supply			
Marginal cost scale ψ	0.1753	0.1747	0.1880
	(0.024)	(0.020)	(0.035)
Used-car quality δ_{u}	4.593	3.911	4.441
	(1.49)	(2.08)	(1.46)
Upper endpoint $\bar{v}$	1.92×10^7	2.41×10^7	2.83×10^7
	(8.44×10^6)	(9.21×10^6)	(7.98×10^6)
Taste density κ	0.4108	0.4024	0.4075
	(0.138)	(0.184)	(0.159)

Notes: Reproduced from Bresnahan (1987, Table IV, p. 472). Asymptotic standard errors in parentheses. Each column uses the conduct hypothesis not rejected in Table 6.4. The mapping to Bresnahan's symbols is: ψ is his μ, δ_{u} is his γ, $\bar{v}$ is his $V_{\max}$, and κ is his δ. The paper does not report the numbers of price and quantity observations.

Bresnahan stresses that the test results and the output expansion are independent evidence. Each year is estimated separately, and no cross-year restriction, for example on the location of the demand curve, forces the competitive model to be chosen in the high-quantity year. The coincidence of the reversal with the boom is therefore informative (Bresnahan, 1987, p. 472). The results are also robust to the two added specifications, which are rejected throughout. The hedonic model is the cleanest of these rejections, since its likelihood is regular and the caveat on asymptotic normality does not apply to it.

6.6.7 Estimates

Table 6.5 reports the estimates under the specification that survives the tests in each year: Collusion for 1954 and 1956 and Bertrand for 1955. The three columns are close. The marginal-cost scale is 0.1753, 0.1747 and 0.1880. The taste density is 0.4108, 0.4024 and 0.4075. The quality-index coefficients are close in size and sign across years. The estimated primitives barely move, so the change in conduct alone captures the distinct features of 1955.

Table 6.6 tells the opposite story. When one conduct hypothesis is imposed in all three years, the parameters must explain 1955 by themselves, and they behave erratically. Under the collusive specification the 1955 column departs from its neighbors. The marginal-cost scale ψ is an order of magnitude larger, 1.344 against 0.1753 and 0.1880. The taste density κ is an order of magnitude smaller, 0.0575 against about 0.41. The upper endpoint $\bar{v}$ jumps to 1.46×10^8,

Table 6.6: Parameter estimates when one conduct hypothesis is imposed in every year

	(i) Collusive specification			(ii) Bertrand specification		
Parameter	1954	1955	1956	1954	1955	1956
Constant β_0	47.91	−23.37	50.87	31.64	48.28	33.23
	(32.8)	(24.5)	(29.4)	(29.9)	(43.2)	(17.8)
Weight	0.3805	0.0103	0.5694	0.9311	0.5946	6.23×10^{-3}
	(0.332)	(5.43×10^{-2})	(0.374)	(0.210)	(0.145)	(8.73×10^{-4})
Length	0.1819	-2.88×10^{-3}	0.1507	0.1474	0.1461	0.1605
	(0.128)	(0.102)	(0.146)	(0.038)	(0.059)	(0.149)
Horsepower	2.665	0.1165	3.248	4.962	3.350	2.972×10^{-2}
	(0.692)	(0.106)	(0.620)	(0.676)	(0.535)	(1.47×10^{-2})
Cylinders	−0.7387	−1.309	−0.9639	−0.8846	−0.9375	−0.9078

Hardtop	0.9445	1.468	0.4311	−0.2474	0.4531	0.5282
	(0.379)	(1.08)	(0.401)	(0.464)	(0.312)	(0.249)
ψ	0.1753	1.344	0.1880	0.2518	0.1747	0.2902
	(0.024)	(0.151)	(0.035)	(0.074)	(0.312)[a]	(0.249)[a]
δ_u	4.593	1.604	4.441	6.352	3.911	1.204
	(1.49)	(4.83)	(1.46)	(3.54)	(2.08)	(3.19)
$\bar{v}$	1.92×10^7	1.46×10^8	2.83×10^7	9.81×10^5	2.41×10^7	1.03×10^6
	(8.44×10^6)	(6.74×10^6)	(7.98×10^6)	(8.78×10^6)	(9.21×10^6)	(8.90×10^6)
κ	0.4108	5.75×10^{-2}	0.4075	5.04	0.4024	7.334
	(0.138)	(8.28×10^{-2})	(0.159)	(1.21)	(0.184)	(2.46)

Notes: Reproduced from Bresnahan (1987, Tables V(i) and V(ii), pp. 473–474). Asymptotic standard errors in parentheses. Symbols as in Table 6.5. [a] Printed as in the source. These two standard errors duplicate the hardtop standard errors directly above them, (0.312) and (0.249). Table IV reports (0.020) for the same 1955 estimate of ψ, so the printed values are probably typesetting errors. The paper also reports Table V(iii) for the hedonic model and Table V(iv) for "Products".

and length receives a negative coefficient. The parameters must absorb the low prices and high output that collusive pricing cannot generate with stable primitives.

The Bertrand specification is "similarly chaotic" (Bresnahan, 1987, p. 473). Now 1954 and 1956 are the odd years. The 1954 column has the only negative hardtop coefficient estimated in any year under any specification. In 1956 the weight and horsepower coefficients collapse toward zero, to 6.23×10^{-3} and 2.972×10^{-2}. Relative to the surrounding years, tastes in 1955 are spread "at one tenth the density over ten times the range" (p. 475). The comparison is with the Bertrand estimates for 1954 and 1956, where κ is 5.04 and 7.334 and $\bar{v}$ is near 10^6. The 1955 values, 0.4024 and 2.41×10^7, are those of Table 6.5, since both tables estimate 1955 under Bertrand. Bresnahan sums up the comparison in one sentence: "It is change of behavioral assumption, not change of parameter values, that provides a reasonable empirical explanation of 1955" (p. 475).

The lesson is general. A misspecified conduct assumption does not disappear. It is absorbed into the estimated primitives, which then become unstable across periods and implausible in level. Stability of demand and cost parameters across periods is therefore informative about conduct. Table 6.5 is built from the two panels of Table 6.6, and only the combination left unrejected by the tests produces a consistent picture.

The magnitudes in Table 6.5 have sensible readings (Bresnahan, 1987, p. 475). The quality-index coefficients have the signs and sizes one expects from hedonic regressions. The negative cylinders coefficient is familiar from that literature too. Econometrically, horsepower and cylinders are highly collinear. Economically, the cylinders variable captures the fall in the cost

of horsepower after the introduction of the V-8 engine.

The demand parameters describe very diverse tastes for quality. The eight million buyers of 1955 had tastes v between 4.24×10^6 and 2.4×10^7. In Bresnahan's words, the distribution was "20 million wide and 0.4 deep", and 20 million times 0.4 gives the eight million buyers. Bresnahan cautions that this may be an artifact of the constant density. The same numbers imply a potential market of $\kappa\bar{v} = 0.4024 \times 2.41 \times 10^7 \approx 9.7$ million in 1955, of whom about 1.7 million (those with v below 4.24×10^6) chose the used car. The used-car quality δ_u is around 4 in each year, while the lowest new-car quality is around 9. New and used cars are thus not close substitutes. The parameter ψ only converts quality units into money in the marginal-cost function.

Two further readings concern 1956. The 1955 purchases do not seem to have depressed 1956 demand. Both κ and $\bar{v}$ are slightly larger in 1956 than in 1955, and the 1954 and 1956 demand parameters are very similar. The used-car quality rises from 3.911 in 1955 to 4.441 in 1956 (it was 4.593 in 1954), which Bresnahan reads as considerable competition from the used-car market in 1956. For comparison, the hedonic model's quantity equation gives price coefficients l_1 of −3.742 (0.640), −1.312 (0.787) and −3.322 (0.715) in 1954, 1955 and 1956 (Table V(iii)). The 1955 coefficient is the smallest in absolute value and the least precise.

6.6.8 Counterfactual, fit and residuals

Collusion in 1955 as a counterfactual. The estimates allow a simple decomposition of the 1955 expansion into demand and conduct. Bresnahan computes the equilibrium with the 1955 parameters, which were estimated under Bertrand, but with the collusive solution. The counterfactual prices are about one-half of one percent above the average of 1954 and 1956. Predicted 1955 unit sales are 7.1 million, 25.5 percent above the 1954 and 1956 average, instead of the actual 40.4 percent. The change in conduct thus accounts for about 0.8 million cars, the difference between 7.9 and 7.1 million. Bresnahan compares this with the largest residual in the demand system of Chow (1960a), +0.6 million units, which falls in 1955. The two magnitudes are comparable. A supply-side change of the size implied by the price war is thus of the same order as the part of 1955 that demand models could not explain.

Fit. Panel (a) of Table 6.7 gives part of the intuition behind the tests. The reversal between Collusion and Bertrand appears as a reversal in R^2. In the price equation the unrejected model fits better in every year: 0.94 against 0.91 in 1954, 0.96 against 0.92 in 1955, and 0.96 against 0.93 in 1956. In the quantity equation it fits better in 1955 (0.64 against 0.58) and equally well in 1954 (0.62 each).[14] The hedonic model fits quantities better in every year, with R^2_q of 0.71 to 0.73, yet the oligopoly model left unrejected in each year is not rejected against it. Bresnahan concludes that the price equation provides most of the power of the tests. His footnote 14 gives two reasons to read these R^2 values with care. The oligopoly models have no constant in the quantity equation, by (6.66). In the price equation, marginal cost explains much of the cross-sectional variance, so the price R^2 would be high even if little of the markup were explained.

Residuals by firm. Panel (b) compares the average residuals of each of the Big Three with those of all other firms. Since "all other firms" for Ford and Chrysler includes GM, the clearest

[14] Bresnahan writes that "in each year, the model not rejected explains more variance in both equations" (p. 477). In 1956, however, Table VI gives a quantity R^2 of 0.61 for Collusion and 0.62 for Bertrand, so the statement holds strictly only for the price equation.

Table 6.7: Fit of the four models and residuals of the Big Three, 1954–1956

(a) R^2 of the price (p) and quantity (q) equations (Table VI)

	1954		1955		1956	
Model	p	q	p	q	p	q
Collusion	0.94	0.62	0.92	0.58	0.96	0.61
Bertrand	0.91	0.62	0.96	0.64	0.93	0.62
"Products"	0.90	0.62	0.88	0.59	0.92	0.61
Hedonic	0.89	0.71	0.88	0.73	0.88	0.71

(b) Average residual of each firm minus the average of all other firms (Table VII)

	1954 (Collusion)		1955 (Bertrand)		1956 (Collusion)	
Firm	Price	Quantity	Price	Quantity	Price	Quantity
GM	20.92	−99.6	28.80	−82.86	21.48	−68.73
Ford	−12.33	60.2	−6.28	22.97	−11.02	19.06
Chrysler	−13.16	96.89	−9.33	64.47	−17.19	11.94

Notes: Panel (a) reproduces Bresnahan (1987, Table VI, p. 476). Because of the heteroskedasticity, the quantity R^2 is defined as a fraction of explained variance, $R^2_q = \frac{s^2_q - \hat{\sigma}^2_q}{s^2_q}$. Here s^2_q is the second raw moment of the quantity data, computed under the same heteroskedastic variance structure as the models. Panel (b) reproduces Table VII (p. 477), computed from the unrejected specification in each year. Price residuals are in dollars and quantity residuals in cars. "All other firms" includes the other two firms of the Big Three.

message concerns GM. Its average price residual is 20.92, 28.80 and 21.48 dollars, and its average quantity residual is −99.6, −82.86 and −68.73 cars. Bresnahan summarizes these as overpredicting GM prices by about $30, out of the $1,500 price of a typical car. He also describes them as underpredicting GM sales by about 100 units, out of typical sales near 60,000.[15] The errors are small, but they suggest that GM had a cost or quality advantage. Bresnahan therefore estimated two broader specifications for each oligopoly model. One adds a GM dummy to the quality index. The other gives GM its own marginal-cost scale. Neither GM parameter is significant in any unrejected specification, and no Cox test result is reversed. Either parameter does make the GM residuals much closer to zero.

6.6.9 Robustness

Besides the GM extensions, Bresnahan reports two generalizations aimed at the most obvious weaknesses of the model.

Quality measured with error. The tests depend on which products are neighbors. Small errors in the imputed qualities could change the ranking of products, and with it the pattern of same-firm and rival neighbors. Robert Masson raised this concern (footnote 15). Following Bresnahan (1981a), the quality index is rewritten as observed with error,

$$\delta(x_j) = \sqrt{\beta_0 + x_j\beta} + \zeta_j, \tag{6.87}$$

[15]The paper does not define the sign of a residual. Bresnahan's wording matches residuals defined as predicted minus observed values. Under the more common convention, observed minus predicted, the same numbers would mean that the models underpredict GM prices and overpredict GM sales. The magnitudes are unaffected. Note also that the printed price residuals, $21 to $29, are somewhat below the $30 of the text.

where we write ζ_j for Bresnahan's ε_x.[16] Since quality is unobserved, ζ_j must be integrated out of the likelihood. This changes the substitution pattern. With $\mathrm{Var}(\zeta_j) = 0$, each product is a substitute for exactly two others. As the variance grows, the probability of demand-side interaction with less similar products rises, which "smears" the demand equations and reduces the importance of very similar products. Bresnahan does not know how to construct Cox tests for this specification. Its likelihoods, however, still favor Bertrand in 1955 and Collusion in the other years.

Durability. The model treats cars as a flow good, a "glaring shortcoming" for a durable (Bresnahan, 1987, p. 478). Bresnahan adds the stock of similar used cars to both equations:

$$p_j = p_j^*(\theta, \Omega) + \lambda_S \mathcal{S}_j + e_j^p, \qquad q_j = q_j^*(\theta, \Omega) + \theta_S \mathcal{S}_j + e_j^q, \tag{6.88}$$

where we write λ_S and θ_S for his λ and θ, and e_j^p and e_j^q for his error terms. Here $\mathcal{S}_j$ is the stock of used cars "like" model j, meaning within ten percent of its weight, with used cars depreciating at 15 percent per year. The construction is ad hoc. Both coefficients differ significantly from zero, but the Cox test results of Table 6.4 are unaltered. The rerun covers only the collusive and Bertrand specifications (footnote 16).

Bresnahan draws two conclusions from these checks. The highly structured oligopoly models do not tell all of the story the data have to tell, as the significant durability terms show. The conclusions about conduct nonetheless appear robust.

6.6.10 Identification

Bresnahan observes no costs, no instruments in the modern sense, and no variation in ownership. The data for each year are a single cross-section of about 80 to 85 models. We now state what pins down each object.

Demand and cost are identified within a conduct hypothesis by functional form and by the cross-section of prices and quantities. Prices equal marginal cost plus a markup. Marginal cost is a smooth function $\psi e^{\delta(x)}$ of characteristics, while markups depend on quantities and on the gaps between neighbors. The cross-sectional variation of prices with characteristics therefore separates the cost curve from the markups, given the functional forms. Quantities pin down the density κ, which scales all demand derivatives in (6.67).

The scale of quality is fixed by the cost function. In the pure vertical model, quality is identified only up to the scale of tastes, as Proposition 6.33 shows. Here, multiplying all qualities by c and dividing all tastes by c leaves choices unchanged, but it changes ψe^{δ} to $\psi e^{c\delta}$. The exponential cost function and the square-root index thus fix the units of quality. This is identification by functional form, and it is one reason the specification matters.

Conduct is identified by how markups vary across products with the distance to the nearest neighbor and with the owner of that neighbor. By Propositions 6.48 and 6.50, the two hypotheses make sharply different predictions for products with close neighbors owned by rivals. Within a year, the cross-section supplies many such configurations. This plays the role that rotations of demand play in the homogeneous-goods conduct literature (Chapter 3). There, conduct is identified by changes in the slope of demand that leave costs unchanged. Here, the gaps between neighbors are the slopes, and they vary across products within a market. The next remark states exactly which features of ownership matter.

[16] The printed formula on p. 478 reads $\sqrt{\beta_0 + \varepsilon_j \beta_j Z_j} + \varepsilon_x$. The first ε_j is a misprint for the summation sign.

Remark 6.53 (When can the data tell conduct apart?). By (6.77), the matrix $A(\Omega)$ depends on Ω only through the neighbor entries $\Omega_{j,j+1}$. Two conduct hypotheses that agree on every neighbor pair imply identical equilibrium prices and quantities, and no data can distinguish them. Collusion and Bertrand differ exactly at the neighbor pairs owned by different firms. Suppose each of F firms sold one contiguous block of the quality ladder. The two hypotheses would then differ at only $F - 1$ pairs, and Remark 6.49 shows that the top block would keep its collusive price increments under both. Interleaved product lines, as in the small-car segment of the 1950s, create many pairs where the hypotheses differ. In the design of Figure 6.7, the hypotheses differ at the four pairs from $(1, 2)$ to $(4, 5)$ and agree at $(5, 6)$ and $(6, 7)$.

Three further points complete the argument. First, the conduct hypotheses are discrete, and each is estimated separately. The test compares the fit of two fully specified reduced forms (6.75). No continuous conduct parameter is estimated. Second, the hedonic and "Products" alternatives check that the oligopoly models are not chosen merely because the alternatives are poor. Third, no restriction links the years, so the selection of Bertrand in 1955 is not forced by the output spike. The same feature means that each year's identification rests on its own cross-section and functional forms.

6.6.11 Limitations and critiques

Restrictive substitution. Quality is one-dimensional, so each product substitutes only with its two neighbors. This is exactly what gives the test its power, and it is also the most criticized feature of the model. Berry et al. (1995, p. 852) note that cross-price elasticities in the vertical model are determined by market shares and the rank order of prices alone, not by characteristics such as size or power. Their example is a ranking with a \$24,998 family station wagon, a \$24,999 sports car and a \$25,000 station wagon. The vertical model guarantees that the two wagons are not substitutes for each other, while the sports car substitutes for both. Feenstra and Levinsohn (1995) allow multidimensional differentiation while keeping the rest of Bresnahan's framework. Bresnahan's own error-in-quality extension softens the restriction in the same direction.

Functional forms. The uniform taste distribution, the square-root quality index and the exponential cost function are all arbitrary. They identify the scale of quality and shape the markups. Bresnahan concedes that the wide, shallow taste distribution may be an artifact of the constant density.

Unobserved quality and exogenous characteristics. The errors are added to the reduced form, so there is no unobserved product characteristic that consumers see and the econometrician does not (Remark 6.51). Characteristics are treated as exogenous, a defect that Berry (1994, p. 245) notes his own approach shares with Bresnahan's and with nearly all studies of differentiated products. Product lines are predetermined, so the model says nothing about how conduct might affect product choice.

Likelihood-based testing. The non-nested tests require a fully specified likelihood, including the distribution of the errors and a complete supply model. Nevo (2001, p. 335) cites this as a reason to prefer other comparisons of conduct. The likelihood is also irregular, and the asymptotic distribution of the test statistics is unproven. Only the rejection of the hedonic model is statistically clean.

Data and dynamics. Prices are list prices, and quantities are production rather than sales, which misses fleet sales and end-of-year bargains. The model is static, while cars are durable and buyers can time purchases. The durability check of Section 6.6.9 is ad hoc, and its terms are

significant. The study covers three years chosen because one of them is anomalous. Finally, the power of the test depends on crowded regions with interleaved owners, so the method does not transfer to industries where each firm owns a contiguous segment.

6.6.12 Contribution

Bresnahan's paper set the template for testing conduct with differentiated products. It specifies demand and cost explicitly, solves for equilibrium under each conduct hypothesis, and asks which equilibrium fits the data. Conduct enters as a discrete hypothesis about which products cooperate, encoded in the matrix Ω. This representation is the one that merger simulation uses when it changes ownership (Chapter 11), and it is the object later conduct tests compare.

The paper also showed that the fine structure of a cross-section carries information about conduct, even without cost data. Markups of close rivals collapse under competition, while prices within a region owned by one firm move together and keep their differences. Its finding that conduct changed for one year made the temporary breakdown of collusion an empirical object. And its comparison of Tables 6.5 and 6.6 teaches a lesson that applies far beyond automobiles: imposing the wrong conduct leaves unstable and implausible primitives behind.

Later work kept the logic and replaced the parts that critics found weakest. Berry (1994) and Berry et al. (1995) added unobserved product characteristics and richer substitution patterns, with instruments for price (Chapters 7 and 8). Nevo (2001) compared the margins implied by alternative conduct hypotheses with observed margins. Gasmi et al. (1992) applied non-nested tests to conduct in a soft-drink market, and Vuong (1989) developed the model-selection tests that much of this literature uses (Appendix A). Berry and Haile (2014) formalize when alternative oligopoly models can be distinguished with market-level data, building on the early intuitions of Bresnahan (1981a, 1982).

6.7 The idiosyncratic shock: tastes for products versus tastes for characteristics

Bresnahan's test draws its power from a demand system without an idiosyncratic shock. Each car competes only with its neighbors on the quality ladder, and the Bertrand markups of close rivals vanish (Proposition 6.50). The logit-type models of Chapters 7 and 8 make the opposite modeling choice. This section compares the two classes directly, and the next two sections study estimators for models without the shock.

Every random utility model in this chapter can be written in the form

$$u_{ij} = \delta_j + \mu_{ij} + \epsilon_{ij}, \tag{6.89}$$

where δ_j is the mean utility of product j. The consumer-specific deviation μ_{ij} comes from interactions between consumer tastes and product characteristics. The idiosyncratic shock ϵ_{ij} is independent across products and consumers. The logit, the nested logit and the random coefficients logit of Chapters 7 and 8 contain the shock. The Hotelling, ideal-point and vertical models of Section 6.4 do not. This section asks what the shock does to the economics of a model. The short answer is that with ϵ_{ij} the product space can never be exhausted. Each new product arrives with a fresh draw of ϵ_{ij} for every consumer. These draws guarantee the product a positive market share and some market power, whatever its characteristics. Ackerberg et al. (2007, p. 34) question the economic content of the shock. They write that the ϵ_{ij} "are added to the model largely for computational convenience" and "do not seem to match

any omitted causal demand determinant." They add that the shocks give every conceivable product a strictly positive expected share. Every product then has a positive cross-price effect with every other product, so that "competition is never completely local." We make these statements precise, following Berry and Pakes (2007), and then describe what the shock buys in estimation.[17]

6.7.1 Two specifications of the consumer-specific term

Berry and Pakes (2007) start from a general indirect utility $u_{ij} = U(X_j, V_i; \theta)$ (their eq. 1). Here X_j is the vector of characteristics of product j, price included, V_i is a vector of consumer tastes and θ is a parameter vector. They split $X_j = (x_j, \xi_j)$ into characteristics the econometrician observes and an unobserved characteristic ξ_j that consumers and firms see. They split $V_i = (z_i, \nu_i)$ into attributes z_i that a micro data set might record and unobserved tastes ν_i. Empirical models then impose additive separability (their eq. 3),

$$u_{ij} = f(X_j, z_i; \theta) + \mu_{ij}, \tag{6.90}$$

and an assumption on the distribution of μ_{ij} given (X_j, z_i). Both classes of models discussed below let μ_{ij} contain linear interactions $\sum_k \nu_{ik} X_{jk}$, so each consumer has her own marginal utility for each characteristic. The two classes differ in one respect only.

Definition 6.54 (Tastes for products and pure characteristics)**.** A random utility model has *tastes for products* if

$$\mu_{ij}^{tp} = \sum_{k=1}^{K} \nu_{ik} X_{jk} + \epsilon_{ij}, \tag{6.91}$$

where, conditional on (X_j, z_i) and on all $\mu_{ij'}$ with $j' \neq j$, the term ϵ_{ij} has support on the whole real line. A random utility model is a *pure characteristics model* if

$$\mu_{ij}^{pc} = \sum_{k=1}^{K} \nu_{ik} X_{jk}. \tag{6.92}$$

The random coefficients logit of Berry et al. (1995) and random coefficient probit models belong to the first class (eq. 4 of Berry and Pakes, 2007). The ideal-point model belongs to the second, because expanding the squared distance gives a pure characteristics model with a quadratic term in mean utility (Proposition 6.23). The vertical model is the special case of (6.92) in which price is the only characteristic with a random coefficient.

The label "tastes for products" comes from the reading of ϵ_{ij} in Remark 6.12, which Berry and Pakes (2007) attribute to Caplin and Nalebuff (1991). Let $d_{jm} = \mathbf{1}\{j = m\}$ be a set of product dummies and let η_{im} be consumer i's taste for "being product m", drawn independently across products and consumers. Then

$$\epsilon_{ij} = \sum_{m=1}^{J} d_{jm}\, \eta_{im}, \tag{6.93}$$

and (6.91) becomes a pure characteristics model on a space of dimension $K + J$. Every product carries its own characteristic, and every consumer has an independent taste for it. Adding

[17] As stated in Section 6.1.2, citations of Berry and Pakes (2007) use the pages, footnotes, equations and tables of the author manuscript of July 2, 2007.

a product adds a dimension to the characteristic space. Berry and Pakes (2007, p. 6) trace two implications of models with tastes for products to this feature. First, there is a limit on substitution between products, and so a lower bound on markups. Second, each consumer's utility grows without bound as products are added, whatever the characteristics of the new products or of the consumer. Neither implication holds in a pure characteristics model. Both hold in the logit with the qualifications of Section 6.7.2. The markup floor holds for every set of products, while unbounded utility requires that entrants not become too unattractive. Neither implication follows from the full support of ϵ_{ij} alone. With normal shocks and no outside good, markups are positive for every number of products but tend to zero (Proposition 6.57). We now examine both claims in the simplest member of each class.

6.7.2 The logit benchmark

Consider the logit model with an outside good. Utility is $u_{ij} = V_j + \epsilon_{ij}$ with $V_j = \delta_j - \alpha p_j$ and $\alpha > 0$, and $u_{i0} = \epsilon_{i0}$. The shocks are independent standard Gumbel. By Proposition 6.11, the market share of product j is

$$s_j = \frac{e^{V_j}}{1 + \sum_{k=1}^{J} e^{V_k}}. \tag{6.94}$$

By Proposition 6.13, expected maximum utility is $\ln(1 + \sum_k e^{V_k}) + \gamma_E$. Dividing by the marginal utility of money α converts utility into dollars (Small and Rosen, 1981). Expected consumer surplus is then the logit surplus (6.23),

$$CS = \frac{1}{\alpha} \ln\Big(1 + \sum_{k=1}^{J} e^{V_k}\Big) + C, \tag{6.95}$$

where the constant C does not depend on the choice set.

Proposition 6.55 (The logit never exhausts the product space)**.** *In the logit model with an outside good the following hold.*

(i) Every product has a positive share, $s_j > 0$, for every finite vector V.

(ii) If product j is sold by a single-product firm with constant marginal cost c_j that sets its price to maximize profit given rivals' prices, then its markup is

$$p_j - c_j = \frac{1}{\alpha(1 - s_j)} > \frac{1}{\alpha}. \tag{6.96}$$

(iii) Holding the prices of existing products fixed, adding product $J+1$ raises expected consumer surplus by

$$\Delta CS = \frac{1}{\alpha} \ln\left(1 + \frac{e^{V_{J+1}}}{1 + \sum_{k \le J} e^{V_k}}\right) > 0. \tag{6.97}$$

In particular, an exact clone of product 1 raises surplus by $\frac{1}{\alpha}\ln(1 + s_1)$, where s_1 is product 1's share before the clone enters.

(iv) If the J products have a common value V, then $CS = \frac{1}{\alpha}\ln(1 + Je^V) + C$ and

$$\lim_{J \to \infty} \Big[CS - \frac{1}{\alpha} \ln J \Big] = \frac{V}{\alpha} + C. \tag{6.98}$$

Expected surplus grows without bound, at the rate $\frac{1}{\alpha}\ln J$.

Proof. Part (i) holds because the numerator of (6.94) is positive and the denominator is finite.

For part (ii), let $\mathcal{D} = 1 + \sum_k e^{V_k}$. Differentiating (6.94) with respect to V_j gives

$$\frac{\partial s_j}{\partial V_j} = \frac{e^{V_j}\mathcal{D} - e^{V_j}e^{V_j}}{\mathcal{D}^2} = s_j - s_j^2 = s_j(1 - s_j).$$

Since $\frac{\partial V_j}{\partial p_j} = -\alpha$, the chain rule gives $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$. The firm's profit is $(p_j - c_j)Ms_j$, with M the market size. The first-order condition is

$$M\left[s_j + (p_j - c_j)\frac{\partial s_j}{\partial p_j}\right] = M\left[s_j - (p_j - c_j)\,\alpha s_j(1 - s_j)\right] = 0.$$

Dividing by $M\alpha s_j(1-s_j) > 0$ gives (6.96). The logit profit function is quasi-concave in own price, so the first-order condition characterizes the best response (Chapter 7). Because $0 < s_j < 1$, the factor $\frac{1}{1-s_j}$ exceeds one and the markup exceeds $\frac{1}{\alpha}$.

For part (iii), write $\mathcal{D}_J = 1 + \sum_{k\le J} e^{V_k}$. By (6.95),

$$\Delta CS = \frac{1}{\alpha}\left[\ln(\mathcal{D}_J + e^{V_{J+1}}) - \ln \mathcal{D}_J\right] = \frac{1}{\alpha}\ln\left(\frac{\mathcal{D}_J + e^{V_{J+1}}}{\mathcal{D}_J}\right) = \frac{1}{\alpha}\ln\left(1 + \frac{e^{V_{J+1}}}{\mathcal{D}_J}\right),$$

which is positive because the argument of the logarithm exceeds one. For a clone of product 1, $V_{J+1} = V_1$ and $\frac{e^{V_1}}{\mathcal{D}_J} = s_1$.

For part (iv), $\ln(1 + Je^V) = \ln J + \ln(e^V + \frac{1}{J})$, and the second term converges to V. Substituting into the expression for CS gives (6.98). □

The mechanism behind (iii) and (iv) is the extreme value algebra of Lemma 6.9. If J products have the same V, each consumer's maximum utility is the maximum of J independent Gumbel draws shifted by V. Its mean is $V + \ln J + \gamma_E$. Every added product hands every consumer one more lottery ticket. The ticket has positive expected value even when the product is physically identical to one already on sale.

Unbounded growth needs a condition on the entrants. For general values, expected maximum utility $\ln(1 + \sum_{k\le J} e^{V_k}) + \gamma_E$ grows without bound if and only if $\sum_k e^{V_k}$ diverges. This holds for clones and whenever the V_k are bounded below. It fails when entrants become unattractive fast enough. With $V_j = -j^2$, the sum converges to 0.386, so expected maximum utility converges to $\gamma_E + \ln 1.386 \approx 0.904$. Every product still has a positive share and every shock has full support. Each entrant adds a positive gain, but the gains have a finite sum.

Parts (iii) and (iv) hold prices fixed. Equilibrium pricing does not change the conclusion for clones. With J identical single-product firms, (6.96) gives a symmetric markup $\frac{1}{\alpha(1-s)}$, and $s \to 0$ as J grows. The equilibrium price therefore converges to $c + \frac{1}{\alpha}$, so V stays bounded and surplus still grows like $\frac{1}{\alpha}\ln J$. Figure 6.9 computes this case.

Anderson et al. (1992) make the same point about markups in a model without an outside good, where the scale of the shock plays the role of a transport cost.

Proposition 6.56 (Symmetric logit oligopoly)**.** *Let $N \ge 2$ single-product firms with marginal cost c sell products with utility $u_{ij} = \delta - p_j + \sigma_\epsilon \epsilon_{ij}$, where $\sigma_\epsilon > 0$ and ϵ_{ij} is independent standard Gumbel, and let there be no outside good. The unique symmetric Bertrand-Nash equilibrium has markup*

$$p^* - c = \frac{\sigma_\epsilon N}{N - 1}. \tag{6.99}$$

The markup decreases in N and converges to $\sigma_\epsilon > 0$ as $N \to \infty$. It converges to zero as $\sigma_\epsilon \to 0$.

Proof. By Proposition 6.11 with scale σ_ϵ, the share of firm j is

$$s_j = \frac{\exp\left(\frac{\delta - p_j}{\sigma_\epsilon}\right)}{\sum_{k=1}^{N} \exp\left(\frac{\delta - p_k}{\sigma_\epsilon}\right)} = \frac{\exp\left(-\frac{p_j}{\sigma_\epsilon}\right)}{\sum_{k=1}^{N} \exp\left(-\frac{p_k}{\sigma_\epsilon}\right)},$$

since δ is common to all products and cancels. The algebra in the proof of Proposition 6.55, with α replaced by $\frac{1}{\sigma_\epsilon}$, gives $\frac{\partial s_j}{\partial p_j} = -\frac{1}{\sigma_\epsilon} s_j(1 - s_j)$. The first-order condition $s_j + (p_j - c)\frac{\partial s_j}{\partial p_j} = 0$ becomes

$$p_j - c = \frac{\sigma_\epsilon}{1 - s_j}.$$

At any symmetric price vector every share equals $\frac{1}{N}$, so the condition pins down a single symmetric price,

$$p^* - c = \frac{\sigma_\epsilon}{1 - \frac{1}{N}} = \frac{\sigma_\epsilon N}{N - 1}.$$

The limits follow directly from this expression. □

The parameter σ_ϵ measures the dispersion of tastes for products. Compare the Salop circle of Section 6.4, where the symmetric markup is $\frac{\tau}{N}$ and vanishes as firms crowd a fixed space. In the logit each entrant brings its own dimension, so entry never crowds the space and the markup stays above σ_ϵ.

The new dimension alone does not keep the markup up. The floor also depends on the upper tail of the Gumbel distribution, as the normal case shows.

Proposition 6.57 (Symmetric oligopoly with normal tastes for products)**.** *Keep the setting of Proposition 6.56, but let utility be $u_{ij} = \delta - p_j + \sigma_\epsilon Z_{ij}$, where the Z_{ij} are independent standard normal. Let $m_N = \mathbb{E}[\max_{j \le N} Z_{ij}]$. The unique symmetric Bertrand-Nash equilibrium has markup*

$$p^* - c = \frac{\sigma_\epsilon}{m_N} \ge \frac{\sigma_\epsilon}{\sqrt{2 \ln N}}. \tag{6.100}$$

The markup is positive for every $N \ge 2$ and converges to zero as $N \to \infty$.

Proof. Let ϕ and Φ be the standard normal density and CDF. Suppose the $N - 1$ rivals charge $\bar{p}$. Firm j wins a consumer when every rival's shock lies below $Z_{ij} + \frac{\bar{p} - p_j}{\sigma_\epsilon}$, so its share is

$$s_j(p_j) = \int \phi(z)\, \Phi\!\left(z + \frac{\bar{p} - p_j}{\sigma_\epsilon}\right)^{N-1} \mathrm{d}z.$$

At $p_j = \bar{p}$ the share is $\frac{1}{N}$ and

$$\frac{\partial s_j}{\partial p_j} = -\frac{N - 1}{\sigma_\epsilon} \int \phi(z)^2\, \Phi(z)^{N-2}\, \mathrm{d}z.$$

The first-order condition $s_j + (p_j - c)\frac{\partial s_j}{\partial p_j} = 0$ then gives the single symmetric candidate $p^* - c = \frac{\sigma_\epsilon}{N(N-1)\int \phi^2 \Phi^{N-2}\, \mathrm{d}z}$. The maximum of N standard normals has density $N\phi\,\Phi^{N-1}$. Since $z\phi(z) = -\phi'(z)$, integration by parts gives

$$m_N = \int z\, N \phi(z)\, \Phi(z)^{N-1}\, \mathrm{d}z = N(N-1) \int \phi(z)^2\, \Phi(z)^{N-2}\, \mathrm{d}z,$$

with boundary terms that vanish because ϕ vanishes at both ends. This proves the equality in (6.100).

The candidate is an equilibrium. The share s_j is the probability that the shock vector lies in the set where $\sigma_\epsilon z_j - p_j \geq \sigma_\epsilon z_k - \bar{p}$ for every $k \neq j$. This set is convex in (z, p_j) jointly, and the normal density is log-concave. By Prékopa's theorem (Theorem B.158), s_j is log-concave in p_j. Log profit $\ln(p_j - c) + \ln s_j(p_j)$ is then strictly concave for $p_j > c$, so the first-order condition gives the best response.

For the bound, take $t > 0$. Jensen's inequality and $\mathbb{E}[e^{tZ_{ij}}] = e^{\frac{t^2}{2}}$ give

$$e^{t m_N} \leq \mathbb{E}\Big[e^{t \max_j Z_{ij}}\Big] \leq \sum_{j=1}^{N} \mathbb{E}\big[e^{tZ_{ij}}\big] = N e^{\frac{t^2}{2}}.$$

Hence $m_N \leq \frac{\ln N}{t} + \frac{t}{2}$, and $t = \sqrt{2 \ln N}$ gives $m_N \leq \sqrt{2 \ln N}$. The maximum is never below Z_{i1}, which has mean zero, and it exceeds Z_{i1} with positive probability, so $m_N > 0$. For the limit, fix $a > 0$. The maximum exceeds a with probability $1 - \Phi(a)^N$ and is at least Z_{i1} otherwise, so $m_N \geq a\big(1 - \Phi(a)^N\big) - \mathbb{E}|Z_{i1}|$. The right side tends to $a - \mathbb{E}|Z_{i1}|$ as $N \to \infty$. Since a is arbitrary, $m_N \to \infty$ and the markup tends to zero. □

The decline is slow. The markup is $1.77\sigma_\epsilon$ with two firms, $0.40\sigma_\epsilon$ with one hundred and $0.21\sigma_\epsilon$ with one million. It still has no positive floor. The difference from the logit lies in the upper tail. The Gumbel tail is exponential, and the gap between a consumer's best and second-best draws does not shrink as N grows. Normal tails are thinner, so the best draws bunch together and each consumer's top products become close substitutes.

6.7.3 The pure characteristics benchmark

Now take the vertical model of Section 6.5, $u_{ij} = \delta_j - \nu_i p_j$ with $\nu_i > 0$. Let the active products be ordered so that $0 = p_0 < p_1 < \cdots < p_J$, with qualities $0 = \delta_0 < \delta_1 < \cdots < \delta_J$ and decreasing cutoffs (Proposition 6.27). Write $u_j(\nu) = \delta_j - \nu p_j$ for the utility that a consumer of type ν obtains from product j.

Proposition 6.58 (Bounded gains from new products)**.** *Hold the prices of existing products fixed. A new product k enters with price p_k strictly between the prices of two adjacent active products, $p_j < p_k < p_{j+1}$ for some $0 \leq j < J$, and quality δ_k. Define the* chord

$$\bar{\delta}(p_k) = \delta_j + (p_k - p_j)\frac{\delta_{j+1} - \delta_j}{p_{j+1} - p_j}. \tag{6.101}$$

(i) For every type $\nu > 0$, the utility gain from the new product satisfies

$$\max\Big\{u_k(\nu), \max_{m \leq J} u_m(\nu)\Big\} - \max_{m \leq J} u_m(\nu) \;\leq\; \max\{0,\; \delta_k - \bar{\delta}(p_k)\}. \tag{6.102}$$

(ii) If $\delta_k \leq \bar{\delta}(p_k)$, no consumer gains and the new product has zero market share.

(iii) Suppose the existing products lie on a frontier $\delta = \phi(p)$, where ϕ is concave and twice differentiable with $|\phi''| \leq B$, and the new product also lies on it. Then every consumer's gain is at most $\frac{B}{8}(p_{j+1} - p_j)^2$.

Proof. For (i), write p_k as a convex combination of its neighbors' prices,

$$p_k = \lambda p_j + (1-\lambda)p_{j+1}, \qquad \lambda = \frac{p_{j+1}-p_k}{p_{j+1}-p_j} \in (0,1).$$

Then $1-\lambda = \frac{p_k-p_j}{p_{j+1}-p_j}$, so $\lambda\delta_j + (1-\lambda)\delta_{j+1} = \bar{\delta}(p_k)$. A maximum is at least as large as any weighted average, so

$$\max_{m\le J} u_m(\nu) \ge \max\{u_j(\nu), u_{j+1}(\nu)\} \ge \lambda u_j(\nu) + (1-\lambda)u_{j+1}(\nu) = \bar{\delta}(p_k) - \nu p_k.$$

Subtracting this bound from $u_k(\nu) = \delta_k - \nu p_k$ gives $u_k(\nu) - \max_{m\le J} u_m(\nu) \le \delta_k - \bar{\delta}(p_k)$. The gain on the left of (6.102) equals $\max\{0, u_k(\nu) - \max_{m\le J} u_m(\nu)\}$, which yields the bound.

For (ii), if $\delta_k \le \bar{\delta}(p_k)$, part (i) shows that no type strictly prefers k to the best existing product. Ties occur only for a set of types of probability zero, so the share of k is zero.

For (iii), let $e(p) = \phi(p) - \bar{\delta}(p)$ on $[p_j, p_{j+1}]$, where $\bar{\delta}(p)$ is the chord. The function e vanishes at both endpoints, is nonnegative by concavity of ϕ, and satisfies $e'' = \phi''$. Let p^* maximize e on the interval. If p^* is an endpoint, $e \equiv 0$ and there is nothing to prove. Otherwise $e'(p^*) = 0$ and a second-order Taylor expansion around p^* gives, for some ζ between p^* and p_j,

$$0 = e(p_j) = e(p^*) + \tfrac{1}{2}e''(\zeta)(p_j - p^*)^2, \quad \text{so} \quad e(p^*) \le \tfrac{B}{2}(p^* - p_j)^2.$$

The same argument at p_{j+1} gives $e(p^*) \le \frac{B}{2}(p_{j+1} - p^*)^2$. The smaller of the two distances is at most $\frac{1}{2}(p_{j+1} - p_j)$, so $e(p^*) \le \frac{B}{8}(p_{j+1} - p_j)^2$. Part (i) with $\delta_k = \phi(p_k)$ completes the proof. □

Part (iii) is the standard error bound for linear interpolation. It says that once a concave frontier is densely filled, a new product placed on it adds a gain of the order of the square of the price gap. A product below the chord adds nothing at all. The same logic applies to the general pure characteristics model, with the chord replaced by the convex hull of the existing products.

Corollary 6.59 (The convex hull bound)**.** *In the pure characteristics model $u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j$, write $u_{ij} = w_i \cdot z_j$ with $z_j = (x_j, p_j, \xi_j)$ and $w_i = (\beta_i, -\alpha_i, 1)$, and set $z_0 = 0$ for the outside good. Let $\bar{z}$ be any point of the convex hull of $\{z_0, z_1, \dots, z_J\}$. Then the utility gain of consumer i from a new product z_k is at most* $\max\{0, w_i \cdot (z_k - \bar{z})\} \le \|w_i\|\,\|z_k - \bar{z}\|$.

Proof. Write $\bar{z} = \sum_m \lambda_m z_m$ with $\lambda_m \ge 0$ and $\sum_m \lambda_m = 1$. Then $\max_m u_{im} \ge \sum_m \lambda_m u_{im} = w_i \cdot \bar{z}$. The gain is $\max\{0, w_i \cdot z_k - \max_m u_{im}\} \le \max\{0, w_i \cdot (z_k - \bar{z})\}$. The Cauchy-Schwarz inequality gives the second bound. □

The corollary formalizes a statement of Berry and Pakes (2007, p. 7). In the pure characteristics model, they write, the gain from a new product is "limited by a smooth (usually linear) function of the distance in characteristic space" to the existing products. A product inside the hull of existing products adds nothing. As the space fills, every new product lies close to the hull and the gains vanish. Berry and Pakes (2007, footnote 8) report that the decline is exponential in the cases they worked out. They add that the argument holds the environment fixed, ruling out new technologies and changes in complementary goods.

Markups behave in the same way. Proposition 6.50 shows that, with uniform tastes, the Bertrand markups of two neighboring products owned by different firms go to zero as their qualities converge. Crowding the product space therefore drives a pure characteristics market

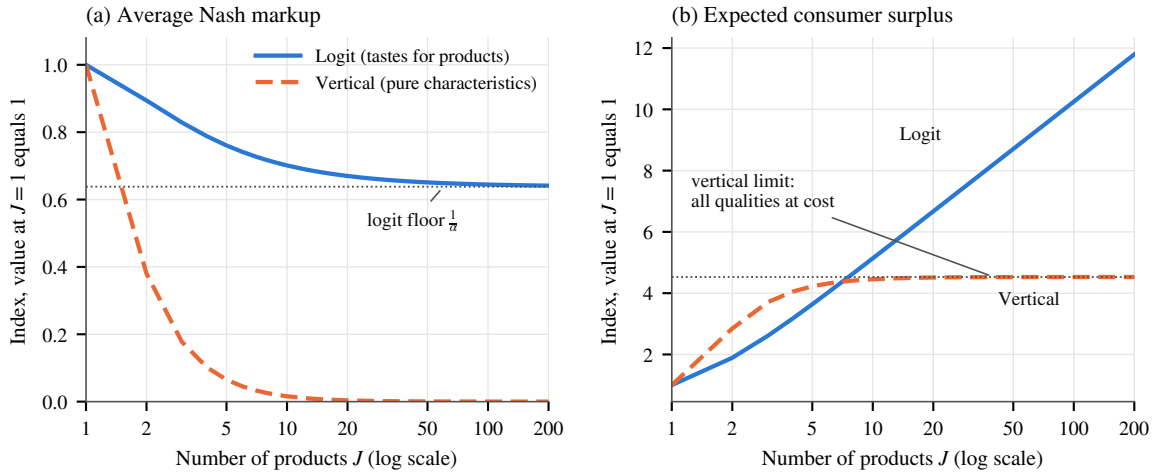

Figure 6.9: Average Nash markup and expected consumer surplus as products are added, in a logit model with identical products and in a vertical model whose products fill a fixed quality interval. Each product has its own owner. The logit has $u_{ij} = 2 - p_j + \epsilon_{ij}$, outside good $u_{i0} = \epsilon_{i0}$ and marginal cost 1. The vertical model uses Bresnahan's form (Section 6.6), with utility $v\delta_j - p_j$ and v uniform on $[0, 1]$. Its qualities sit at the midpoints of J equal bins of $[1, 3]$, marginal cost is $0.05\,e^{\delta}$, and the outside good has $\delta_0 = p_0 = 0$. Each series is divided by its value at $J = 1$ because the units of the two models are not comparable. The figure is qualitative. Computed with `figures/ch06/src/clones.py`.

toward the competitive outcome. The private incentive to add a further product disappears with the markup.

Figure 6.9 computes both models as single-product firms are added. In the logit, the markup falls from 1.567 at $J = 1$ to 1.005 at $J = 200$ and approaches the floor $\frac{1}{\alpha} = 1$. Surplus rises from 0.449 to 5.298 and keeps rising linearly in $\ln J$. In the vertical model, the sales-weighted markup falls from 0.815 at $J = 1$ to 0.013 at $J = 10$ and to 0.00003 at $J = 200$. Surplus converges to 0.752, the surplus when every quality in $[1, 3]$ is sold at marginal cost.

6.7.4 Why the distinction matters

The first implication concerns new goods and price indexes. Retrospective measurement of the gains from new products goes back to Trajtenberg (1989), who used a nested logit to value innovations in computed tomography scanners. Such measurement is also part of constructing ideal price indexes. Berry and Pakes (2007) note that, according to the Boskin Commission (Boskin et al., 1996), failing to measure these gains is the major source of bias in the Consumer Price Index. A model with tastes for products credits every new variety with a surplus gain through (6.97), however close it is to existing goods.

Hausman (1997, p. 230) puts the objection directly. The independence of irrelevant alternatives, he writes, "typically leads to a vast overestimate of the consumer's surplus from a new good." The logit fails to "incorporate sufficiently the similarities to existing goods." Logit and constant elasticity of substitution demand are positive at every finite price, so the reservation price at which a new good's demand would vanish is infinite. Petrin (2002) quantifies the role of the shock for the minivan. His average compensating variation for minivan buyers is \$13,652 with an OLS logit and \$7,414 with an instrumented logit (1982–84 dollars, his Table 8). It falls to \$3,171 with random coefficients and to \$1,247 when micro moments are

added. The part attributed to the logit error falls from \$95,121 to \$396 across the same columns. Chapter 10 treats these studies in full.

The second implication concerns market structure. In the logit, markups stay above $\frac{1}{\alpha}$ however many products crowd the market, so there is always a further incentive to develop products. Berry and Pakes (2007, p. 7) conclude that with tastes for products market outcomes do not approach competition as the number of products grows. The conclusion depends on the distribution of the shock. With normal shocks and no outside good, markups are positive for every finite number of products but tend to zero, slowly (Proposition 6.57). A researcher studying a market with hundreds of products, or the welfare effect of entry, imposes these properties by choosing the model.

6.7.5 What the idiosyncratic shock buys

Models with tastes for products have three practical advantages (Berry and Pakes, 2007, pp. 7–8). Their choice probabilities are integrals with simple limits of integration, because conditional on the random coefficients the logit integral is in closed form (McFadden, 1981). Their purchase probabilities are positive at every parameter value and, under regularity conditions, have smooth derivatives. Their market shares can be inverted to recover the unobserved characteristics ξ_j as a linear function of parameters and data. Instrumental variables can then handle the correlation between price and ξ_j (Berry et al., 1995).

Pure characteristics models lose each advantage. The set of tastes for which a product is chosen is a polyhedron whose shape changes with every parameter value. Feenstra and Levinsohn (1995) computed these acceptance regions directly, a calculation that becomes complicated with several characteristics. Shares are zero whenever a product is dominated, so the share function has flat regions, and simulated shares have kinks where a product enters or leaves the frontier (Section 6.8.3). The inversion requires new arguments, which Section 6.8 develops.

6.7.6 Nesting the two models: the modified BLP model

A natural idea is to nest the two classes and let the data choose. Berry and Pakes (2007, eqs. 7–8) introduce a scale parameter $\sigma_\epsilon \geq 0$,

$$u_{ij} = f_{ij}(\theta) + \sum_{k=1}^{K} \nu_{ik} X_{jk} + \sigma_\epsilon \epsilon_{ij}, \tag{6.103}$$

with ϵ_{ij} independent standard Gumbel. The model with tastes for products is the case $\sigma_\epsilon = 1$, and the pure characteristics model is the case $\sigma_\epsilon = 0$. For $\sigma_\epsilon > 0$ define $\mu_\epsilon = \frac{1}{\sigma_\epsilon}$ and multiply all utilities by μ_ϵ. This leaves choices unchanged. If $F(\nu)$ is the distribution of $\nu = (\nu_1, \ldots, \nu_K)$, the logit formula gives (their eq. 9)

$$P_{ij}(\theta, \mu_\epsilon) = \int \frac{\exp\left(\mu_\epsilon \left[f_{ij}(\theta) + \sum_k \nu_k X_{jk} \right]\right)}{\sum_q \exp\left(\mu_\epsilon \left[f_{iq}(\theta) + \sum_k \nu_k X_{qk} \right]\right)} \, \mathrm{d}F(\nu). \tag{6.104}$$

We call (6.104) the *modified BLP model*. Formula (6.104) needs $\mu_\epsilon < \infty$, so no value of μ_ϵ reproduces the pure characteristics model exactly. It is reached only as a limit.

Proposition 6.60 (Pure characteristics as a limit)**.** *Let* $U_{ij}(\nu) = f_{ij}(\theta) + \sum_k \nu_k X_{jk}$ *and let*

$$P_{ij}^{pc}(\theta) = \int \mathbf{1}\{U_{ij}(\nu) > U_{iq}(\nu) \text{ for all } q \neq j\}\, \mathrm{d}F(\nu)$$

be the pure characteristics choice probability. Suppose ties have probability zero, that is, F *assigns probability zero to the set of* ν *with* $U_{ij}(\nu) = U_{iq}(\nu)$ *for some* $q \neq j$*. Then* $P_{ij}(\theta, \mu_\epsilon) \to P_{ij}^{pc}(\theta)$ *as* $\mu_\epsilon \to \infty$*.*

Proof. Fix ν outside the tie set and let m be the unique maximizer of $U_{iq}(\nu)$ over q. Divide the numerator and denominator of the integrand by the numerator to obtain

$$\frac{1}{1 + \sum_{q \neq j} \exp\big(\mu_\epsilon [U_{iq}(\nu) - U_{ij}(\nu)]\big)}.$$

If $j = m$, every exponent is negative and each exponential converges to zero, so the integrand converges to one. If $j \neq m$, the exponent for $q = m$ is positive and that exponential diverges, so the integrand converges to zero. The integrand therefore converges to $\mathbf{1}\{j = m\}$ for F-almost every ν. It lies in $[0, 1]$, and the constant one is integrable against the probability measure F. The dominated convergence theorem gives the result. □

Berry and Pakes (2007, footnote 9) add that a covering argument makes the convergence uniform in θ. One might hope that estimating μ_ϵ along with the other parameters would deliver a large estimate whenever the pure characteristics model generated the data. Berry and Pakes (2007, p. 9) give four reasons to doubt it.

1. Consistency proofs assume that the true parameter lies in a compact set. One would therefore have to prove consistency for $\sigma_\epsilon = \frac{1}{\mu_\epsilon}$ on an interval that contains zero. The predicted shares are undefined at $\sigma_\epsilon = 0$. The objective is then not a continuous function on a compact parameter set that contains the truth, and the uniform convergence that standard proofs require fails at that boundary.
2. A good approximation needs a small σ_ϵ, that is, a large μ_ϵ. For large μ_ϵ the computer cannot evaluate the exponentials in (6.104).
3. If σ_ϵ is known to be zero, an estimator that imposes it should estimate the other parameters more precisely. With market-level data this efficiency gain can matter.
4. To learn whether these problems matter in a given application, one needs an estimator that does not rely on the approximation (6.104).

A test of $\sigma_\epsilon = 0$ faces a further, standard difficulty. The null hypothesis lies on the boundary of the parameter space, where likelihood-ratio and Wald statistics have nonstandard limiting distributions.

Remark 6.61 (The two models as bounds). Real products differ in more than one unobserved characteristic. A pure characteristics model with as many unobserved characteristics as products contains the model with tastes for products as a special case, by (6.93). The pure characteristics model with a single unobserved characteristic and the model with tastes for products are therefore opposite extremes. Berry and Pakes (2007, p. 12) suggest that the two might bound the effects of unobserved product heterogeneity. Models with several unobserved characteristics are hard to estimate from market data, although panel data on repeated choices of the same consumers can identify them (Goettler and Shachar, 2001).

6.8 Case study: estimating the pure characteristics model

Berry and Pakes (2007) turn the pure characteristics model, long used in theory, into an estimable model for market data. Their paper has no field data. It develops the econometric machinery and then uses Monte Carlo experiments to compare the pure characteristics model with models that have tastes for products. We follow the order of a case study, with the simulated designs in the place of a data set.

6.8.1 The question

The paper asks three questions. Can the pure characteristics model be estimated from market-level data on prices, quantities and characteristics? How much computation does that take? When do models with tastes for products, possibly with an estimated scale μ_ϵ, reproduce the implications of the pure characteristics model for elasticities and for welfare? The questions matter because welfare analysis of new products extrapolates beyond observed prices. As Section 6.7 showed, the two classes of models extrapolate very differently.

6.8.2 Model and normalizations

Utility of consumer i from product $j = 0, 1, \ldots, J$ is (their eq. 10)

$$u_{ij} = x_j\beta_i - \alpha_i p_j + \lambda_i \xi_j, \tag{6.105}$$

with $\beta_{ik} = \beta_k + \nu_{ik}$, $\alpha_i = \alpha + \nu_{ip} > 0$ and $\lambda_i > 0$. Here β_k is the mean marginal utility of characteristic k and ν_{ik} is consumer i's deviation from it. Two assumptions are built into (6.105).

Assumption 6.62 (Berry and Pakes, A1 and A2)**.** (A1) There is a single unobserved product characteristic, so $X_j = (x_j, \xi_j) \in \mathbb{R}^K \times \mathbb{R}$. (A2) The unobserved characteristic is vertical: every consumer prefers more of it.

Utility is identified only up to a consumer-specific increasing affine transformation (Proposition 6.4). Berry and Pakes use both degrees of freedom. They subtract u_{i0} from every utility, so the outside option has utility zero and every characteristic is measured relative to the outside option. They then divide by λ_i, so the coefficient on ξ equals one for every consumer. After relabeling the rescaled coefficients, the model is (their eq. 11)

$$u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j, \qquad u_{i0} = 0. \tag{6.106}$$

This is the model of Berry et al. (1995) without the shock ϵ_{ij}. Units remain free. Multiplying every ξ_j, β_i and α_i by the same positive constant changes no choice (their footnote 12). Berry and Pakes set the mean of α_i to one, so utility and ξ are measured in units of the mean price coefficient.

Two interpretive points follow from the normalizations. First, ξ_j measures the unobserved quality of product j relative to that of the outside option (their footnote 11). A rise in average ξ over time may therefore reflect better products or a worse outside option, which matters for price indexes (Pakes et al., 1993). Second, ξ_j often stands for the combined effect of many minor characteristics (their footnote 4). If consumers differ in their relative tastes for several unobserved characteristics, (6.106) is misspecified.

6.8.3 Computing market shares

The vertical building block. Start with the vertical model $u_{ij} = \delta_j - \alpha_i p_j$, where $\delta_j = x_j\beta + \xi_j$ is quality (their eqs. 12–13). It is the model of Section 6.5 with the price coefficient α_i in the role of the price sensitivity v_i. Order the goods by increasing price. Section 6.5.2 showed that consumer i buys j if and only if $\underline{\nu}_j(\delta, p) < \alpha_i < \bar{\nu}_j(\delta, p)$, with the general cutoffs (6.43) (their eqs. 14–16). If F is the distribution of α_i, the share of product j is (6.44) (their eq. 17). We write it as $s_j(x, p, \xi; \theta, F)$ to show its dependence on the data and on the unknown parameters θ. Any parameter vector that puts a product below the quality-price frontier predicts a zero share for it. A model with tastes for products never predicts a zero share.

Extension to K dimensions. In (6.106) the coefficients on x vary across consumers. Conditional on $\beta_i = \beta$, however, the model is again vertical in α_i, with qualities $\delta_j(\beta) = x_j\beta + \xi_j$ that depend on the draw. Compute the cutoffs $\bar{\nu}_j(\beta)$ and $\underline{\nu}_j(\beta)$ from (6.43) with $\delta_j(\beta)$ in place of δ_j, and integrate over β (their eq. 18):

$$s_j(x, p, \xi; \theta, F, G) = \int \left[F(\bar{\nu}_j(\beta) \mid \beta) - F(\underline{\nu}_j(\beta) \mid \beta)\right] \mathbf{1}\{\bar{\nu}_j(\beta) > \underline{\nu}_j(\beta)\} \, \mathrm{d}G(\beta). \tag{6.107}$$

Here $F(\cdot \mid \beta)$ is the distribution of α_i given $\beta_i = \beta$ and G is the distribution of β_i. The pure characteristics share function is a mixture of vertical-model share functions. The conditioning argument avoids computing the region of (β, α) space in which a consumer chooses j, the route taken by Feenstra and Levinsohn (1995). The integral over β has no closed form, so it is simulated (Pakes, 1986). With ns draws $\beta_1, \ldots, \beta_{ns}$ from G and their empirical distribution G_{ns} (their eqs. 19–20),

$$s_j(x, p, \xi; \theta, F, G_{ns}) = \frac{1}{ns} \sum_{r=1}^{ns} \left[F(\bar{\nu}_j(\beta_r) \mid \beta_r) - F(\underline{\nu}_j(\beta_r) \mid \beta_r)\right] \mathbf{1}\{\bar{\nu}_j(\beta_r) > \underline{\nu}_j(\beta_r)\}. \tag{6.108}$$

Berry and Pakes note that if F has a density that is differentiable in the parameters, the simulated share function is continuously differentiable in the parameters. This holds only away from frontier changes. When a product enters or leaves the frontier of some draw β_r, the cutoffs of that draw switch formulas and the simulated share can have a kink. For example, let one draw give the products prices 1 and 2 and qualities $1 + t$ and 2, where t moves with the parameters, and let α_i be exponential with mean one. The conditional share of product 1 for this draw, which is the simulated share when $ns = 1$, is $\max\{e^{-(1-t)} - e^{-(1+t)}, 0\}$. Its derivative at $t = 0$ is 0 from the left and $\frac{2}{e}$ from the right, although F is smooth. The switching type $\alpha_i = 1$ has probability zero, so a condition that rules out ties does not remove the kink. The simulated share (6.108) is therefore continuous and piecewise continuously differentiable, with kinks where some draw changes its frontier. Suppose that at a given parameter value the draws whose frontier changes there have probability zero under G. Independent draws from G then avoid such changes with probability one, so the simulated share is differentiable at that value almost surely. As the example shows, this does not make it continuously differentiable everywhere. The same condition makes the exact share (6.107) differentiable at that value if the conditional shares are *Lipschitz* in the parameters with a constant C that does not depend on β. This means that a move of the parameters from θ to θ' changes each conditional share by at most $C\|\theta - \theta'\|$. The appendix states the definition right after Definition B.126. Every difference quotient of a conditional share is then bounded by C, and dominated convergence allows differentiation under the integral. The simulation adds error to the computed shares, as in Berry et al. (1995).

The comparison with the random coefficients logit is instructive. There the first step integrates out ϵ_{ij} analytically conditional on β_i, which yields the logit formula. Here the first step integrates out α_i analytically conditional on β_i, which yields the vertical formula. Both models simulate the remaining integral. A practical version of (6.108) proceeds as follows (their footnote 15).

1. Draw $\beta_1, \dots, \beta_{ns}$ from G once, and keep the draws fixed across parameter values so that the objective function is continuous in the parameters. Berry and Pakes (2007, p. 13) describe the resulting objective as smooth. It is differentiable except at the frontier changes described above.
2. For each draw r, compute $\delta_j(\beta_r) = x_j\beta_r + \xi_j$ for $j = 1, \dots, J$, with $\delta_0 = p_0 = 0$.
3. Sort the products by price and drop those that are dominated for this draw, using the frontier algorithm that follows Proposition 6.26. The survivors have decreasing adjacent cutoffs.
4. For each survivor compute $F(\bar{v}_j \mid \beta_r) - F(\bar{v}_{j+1} \mid \beta_r)$ with cutoffs between adjacent survivors. Assign zero to the dropped products.
5. Average the conditional shares over the ns draws.

In the Monte Carlo design of Section 6.8.8, $\ln \alpha_i = \sigma_p \nu_{ip}$ with ν_{ip} standard normal and independent of β_i. Step 4 then uses $F(a \mid \beta) = \Phi\big(\frac{\ln a}{\sigma_p}\big)$ for $a > 0$, with Φ the standard normal distribution function.

6.8.4 Existence and uniqueness of the inverse*

Estimation follows the three steps of Berry et al. (1995). For each parameter vector one recovers the unobserved characteristics from the observed shares, computes them with an algorithm, and then chooses the parameters that best satisfy moment conditions on ξ. The first step requires that the share equations have exactly one solution.

Fix (x, p, θ, F, G) and write $\sigma_j(\xi_0, \xi)$, $j = 0, 1, \dots, J$, for the share of good j as a function of the unobserved characteristics of all goods, the outside good included. Let s^o be the observed share vector, assumed to lie in the interior of the unit simplex, so that every share is strictly between zero and one. With the normalization $\xi_0 = 0$, we seek $\xi \in \mathbb{R}^J$ such that (their eq. 21)

$$\sigma(0, \xi) = s^o. \tag{6.109}$$

For good $j \geq 1$ define the *element-by-element inverse* $r_j(\xi_{-j})$ as the value of ξ_j that matches good j's share when the other inside goods are held at ξ_{-j} (their eq. 23):

$$\sigma_j\big(0, r_j(\xi_{-j}), \xi_{-j}\big) = s^o_j. \tag{6.110}$$

Stack the inverses into $r(\xi) = (r_1(\xi_{-1}), \dots, r_J(\xi_{-J}))$, a map from $\mathbb{R}^J$ to $\mathbb{R}^J$. A vector ξ solves (6.109) if and only if it is a fixed point (their eq. 24)

$$\xi = r(\xi). \tag{6.111}$$

Indeed, a fixed point matches every inside share, and the outside share then matches because shares sum to one.

Theorem 6.63 (Berry and Pakes 2007, Theorem 1)**.** *Suppose the share function σ has the following properties.*[18]

(1) Monotonicity. *Each σ_j, $j = 0, \dots, J$, is continuous, nondecreasing in its own ξ_j and nonincreasing in every other component. It is strictly increasing in ξ_j at any point where $0 < \sigma_j < 1$. For fixed values of the other components, $\sigma_j \to 0$ as $\xi_j \to -\infty$ and $\sigma_j \to 1$ as $\xi_j \to \infty$.*

(2) Linearity of utility in ξ. *Raising ξ for every good, the outside good included, by the same amount changes no share: $\sigma(\xi_0 + c, \xi + c\mathbf{1}) = \sigma(\xi_0, \xi)$ for every $c \in \mathbb{R}$.*

(3) Substitutes with some other good. *Let (ξ_0, ξ) give interior shares. Let $(\tilde{\xi}_0, \tilde{\xi}) \geq (\xi_0, \xi)$ componentwise, with equality exactly on a nonempty proper subset I of $\{0, 1, \dots, J\}$. Then $\sigma_j(\tilde{\xi}_0, \tilde{\xi}) < \sigma_j(\xi_0, \xi)$ for at least one $j \in I$.*

Then for every s^o in the interior of the unit simplex, (6.109) has exactly one solution $\xi \in \mathbb{R}^J$. Moreover, r is a weak contraction in the sup norm: $\|r(\xi') - r(\xi)\|_\infty \leq \|\xi' - \xi\|_\infty$.

Condition (3) says that when the unobserved characteristics of some goods rise, at least one good whose characteristic did not rise loses share strictly. The proof has five steps. Steps 3 and 4 follow Berry and Pakes (2007, eqs. 27–31). They attribute existence to the argument in Berry (1994). Step 5 gives a self-contained existence argument. Throughout we write the arguments of σ_j in the order (outside good, own, other inside goods) when it helps.

Proof. Step 1: r is well defined and continuous. Fix j and ξ_{-j}, and let $g(a) = \sigma_j(0, a, \xi_{-j})$. By condition (1), g is continuous with limits 0 and 1. Since $0 < s_j^o < 1$, the intermediate value theorem gives a solution of $g(a) = s_j^o$. Two solutions $a < a'$ would make g constant at the interior value s_j^o on $[a, a']$, which strict monotonicity rules out. For continuity of r_j, take $h > 0$. Strict monotonicity gives $g(r_j + h) > s_j^o > g(r_j - h)$. By continuity of σ_j in ξ_{-j}, both strict inequalities survive small changes in ξ_{-j}, which keeps the solution within h of r_j.

Step 2: r is monotone. Let $\xi \leq \xi'$ and suppose $r_j(\xi'_{-j}) < r_j(\xi_{-j})$ for some j. Raising the rivals from ξ_{-j} to ξ'_{-j} weakly lowers j's share, so

$$s_j^o = \sigma_j\big(0, r_j(\xi'_{-j}), \xi'_{-j}\big) \leq \sigma_j\big(0, r_j(\xi_{-j}), \xi'_{-j}\big) \leq \sigma_j\big(0, r_j(\xi_{-j}), \xi_{-j}\big) = s_j^o.$$

The first inequality uses own monotonicity. Both inequalities hold with equality, so $\sigma_j(0, \cdot, \xi'_{-j})$ is constant at s_j^o on an interval, which contradicts strict monotonicity. Hence $r(\xi) \leq r(\xi')$.

Step 3: r is a weak contraction. Take $\xi, \xi' \in \mathbb{R}^J$ with $d = \|\xi - \xi'\|_\infty$, and write $r_j = r_j(\xi_{-j})$ and $r'_j = r_j(\xi'_{-j})$. By the definition of r_j and linearity with $c = d$,

$$\sigma_j\big(d, r_j + d, \xi_{-j} + d\big) = \sigma_j\big(0, r_j, \xi_{-j}\big) = s_j^o. \tag{6.112}$$

Now $\xi'_{-j} \leq \xi_{-j} + d$ and $0 < d$. Lowering the rivals' characteristics from $(d, \xi_{-j} + d)$ to $(0, \xi'_{-j})$ weakly raises j's share, so

$$\sigma_j\big(0, r_j + d, \xi'_{-j}\big) \geq s_j^o. \tag{6.113}$$

Suppose $r'_j > r_j + d$. Then own monotonicity and (6.113) give

$$s_j^o = \sigma_j\big(0, r'_j, \xi'_{-j}\big) \geq \sigma_j\big(0, r_j + d, \xi'_{-j}\big) \geq s_j^o,$$

[18] Berry and Pakes (2007) state monotonicity in weak form and the substitutes condition as the pair of inequalities in their eqs. 25–26. We add strict monotonicity in own ξ on the interior, which makes the element-by-element inverse single valued. We also state the substitutes condition in the form that the proof uses. Berry et al. (2013) generalize conditions of this type under the name "connected substitutes".

so $\sigma_j(0, \cdot, \xi'_{-j})$ would be constant at s_j^o on $[r_j + d, r'_j]$. This contradicts strict monotonicity, so $r'_j \le r_j + d$. The same argument with $c = -d$ gives $r'_j \ge r_j - d$. Hence $|r'_j - r_j| \le d$ for every j, which is the weak contraction property.

Step 4: uniqueness. Suppose $\xi \ne \xi'$ both solve (6.109). Exchanging their names if necessary, $\bar{c} = \max_k(\xi_k - \xi'_k) > 0$. Let $I = \{k : \xi_k - \xi'_k = \bar{c}\}$, a nonempty set of inside goods. Define $\tilde{\xi} = \xi' + \bar{c}\mathbf{1}$ and $\tilde{\xi}_0 = \bar{c}$. By linearity,

$$\sigma(\tilde{\xi}_0, \tilde{\xi}) = \sigma(0, \xi') = s^o.$$

Compare $(\tilde{\xi}_0, \tilde{\xi})$ with $(0, \xi)$. For each inside good, $\tilde{\xi}_k - \xi_k = \bar{c} - (\xi_k - \xi'_k) \ge 0$, with equality exactly for $k \in I$. For the outside good, $\tilde{\xi}_0 - 0 = \bar{c} > 0$. So $(\tilde{\xi}_0, \tilde{\xi}) \ge (0, \xi)$ with equality exactly on I, a nonempty proper subset of $\{0, \dots, J\}$. Shares at $(0, \xi)$ equal s^o and are interior. Condition (3) then yields a good $j \in I$ with $\sigma_j(\tilde{\xi}_0, \tilde{\xi}) < \sigma_j(0, \xi) = s_j^o$. But $\sigma_j(\tilde{\xi}_0, \tilde{\xi}) = s_j^o$, a contradiction.

Step 5: existence. We first find a vector $\xi^{(0)}$ with $r(\xi^{(0)}) \ge \xi^{(0)}$. By linearity, $\sigma(0, a\mathbf{1}) = \sigma(-a, \mathbf{0})$. As $a \to -\infty$, the outside good's own characteristic $-a$ goes to infinity, so by condition (1) its share goes to one and every inside share goes to zero. Choose a with $\sigma_j(0, a\mathbf{1}) < s_j^o$ for all $j \ge 1$. At own value a and rivals at a, good j falls short of its target, so own monotonicity gives $r_j(a\mathbf{1}_{-j}) > a$. Set $\xi^{(0)} = a\mathbf{1}$ and iterate $\xi^{(n+1)} = r(\xi^{(n)})$. By Step 2 and induction, the sequence is nondecreasing.

Next, the sequence is bounded. Because it is nondecreasing, it can be unbounded only if some component diverges to infinity. Since $\xi_j^{(n)} \le r_j(\xi_{-j}^{(n)})$ and σ_j increases in own ξ_j, every inside share satisfies $\sigma_j(0, \xi^{(n)}) \le s_j^o$. Shares sum to one, so $\sigma_0(0, \xi^{(n)}) \ge s_0^o > 0$. Suppose component $\xi_k^{(n)}$ diverged. Because the other components are at least $\xi_{-k}^{(0)}$ and σ_0 is nonincreasing in inside characteristics,

$$\sigma_0\big(0, \xi^{(n)}\big) \le \sigma_0\big(0, \xi_k^{(n)}, \xi_{-k}^{(0)}\big) \le 1 - \sigma_k\big(0, \xi_k^{(n)}, \xi_{-k}^{(0)}\big) \to 0,$$

by the limit in condition (1). This contradicts $\sigma_0 \ge s_0^o$. A bounded nondecreasing sequence converges, say to ξ^*. By continuity of r, $\xi^* = \lim r(\xi^{(n)}) = r(\xi^*)$, so ξ^* solves (6.109). □

Remark 6.64 (The conditions in the pure characteristics model). Berry and Pakes (2007, Comment 1) observe that the conditions hold for any finite θ as long as $F(\cdot \mid \beta)$ has a positive density. The distribution G need not have a density, so the simulated G_{ns} of (6.108) is allowed. Linearity holds by construction in (6.106), and their Comment 2 notes that any model that is linear in ξ alone would share the result. Condition (3) can be checked draw by draw. Conditional on β, the undominated goods form a chain ordered by price, and each good on the chain competes with its neighbors. The outside good is always on the chain. If the chain contains goods both inside and outside I, some adjacent pair has one member in each. Raising the characteristic of the member outside I strictly lowers the conditional share of its neighbor in I, because F has a positive density. Interior aggregate shares ensure that such draws have positive probability.

Steps 3 to 5 are constructive. The iteration in Step 5 is the element-by-element inverse started from a low point. It converges monotonically, but the argument gives no rate. The weak contraction property gives no rate either, because its modulus may equal one. Berry and Pakes (2007) report that they could not prove a modulus below one. This is the main computational difference from the logit-based contraction of Berry et al. (1995), which converges at a geometric rate.

6.8.5 Computing the inverse*

Berry and Pakes offer three methods, because each fails in some of their experiments.

The modified BLP contraction. Apply the BLP contraction of Chapter 8 to the modified BLP model (6.104) with a large fixed μ_ϵ. Since the logit part of (6.104) depends on mean utility only through $\mu_\epsilon \delta$, the iteration on mean utilities reads

$$\delta^{(h+1)} = \delta^{(h)} + \frac{1}{\mu_\epsilon}\big[\ln s^o - \ln s(\delta^{(h)}; \mu_\epsilon)\big]. \tag{6.114}$$

The method is fast. It is inaccurate when μ_ϵ cannot be set high enough, and numerical overflow limits how high it can go.

The element-by-element inverse. Start from a candidate vector. For each product j, hold the other products at their current values and solve the one-dimensional monotone equation (6.110) for ξ_j. Update all products and repeat until predicted shares match observed shares. By Theorem 6.63 each pass is a weak contraction. In practice the method sometimes makes large gains in the first iterations and then nearly stops. If predicted shares are then positive, Newton steps can finish the job.

The homotopy. A homotopy deforms a problem with a known solution into the problem of interest. Berry and Pakes use the fixed-point homotopy (their eq. 32)

$$h(\xi, t, \xi_0) = (1-t)(\xi - \xi_0) + t\big(\xi - r(\xi)\big), \qquad t \in [0,1], \tag{6.115}$$

where ξ_0 is a starting guess, for example the output of another method. Let $\xi(t)$ solve $h(\xi, t, \xi_0) = 0$. At $t = 0$ the solution is ξ_0, and at $t = 1$ it is the fixed point (6.111). Rearranging $h = 0$ gives (their eq. 33)

$$\xi(t) = (1-t)\,\xi_0 + t\,r\big(\xi(t)\big). \tag{6.116}$$

Proposition 6.65 (Convergence of the homotopy)**.** *Under the conditions of Theorem 6.63, let ξ^* be the unique solution of (6.109).*

(i) For each $t \in [0,1)$, the map $\Phi_t(\xi) = (1-t)\xi_0 + t\,r(\xi)$ is a contraction with modulus at most t. Hence $\xi(t)$ exists, is unique, and is the limit of the recursion $\xi \mapsto (1-t)\xi_0 + t\,r(\xi)$ (their eq. 34) from any starting point.

(ii) $\|\xi(t) - \xi^*\|_\infty \le \|\xi_0 - \xi^*\|_\infty$ for every $t \in [0,1)$, and $\xi(t) \to \xi^*$ as $t \to 1$.

Proof. For (i), $\|\Phi_t(\xi) - \Phi_t(\xi')\|_\infty = t\|r(\xi) - r(\xi')\|_\infty \le t\|\xi - \xi'\|_\infty$ by the weak contraction property. The contraction mapping theorem (Appendix B) gives the rest.

For (ii), subtract $\xi^* = (1-t)\xi^* + t\,r(\xi^*)$ from (6.116):

$$\xi(t) - \xi^* = (1-t)(\xi_0 - \xi^*) + t\big[r(\xi(t)) - r(\xi^*)\big].$$

Taking norms and using the weak contraction property,

$$\|\xi(t) - \xi^*\|_\infty \le (1-t)\|\xi_0 - \xi^*\|_\infty + t\|\xi(t) - \xi^*\|_\infty.$$

Collecting terms and dividing by $1 - t > 0$ gives the bound. The path is therefore bounded. Take any sequence $t_n \to 1$ along which $\xi(t_n)$ converges, say to $\hat{\xi}$. Passing to the limit in (6.116) and using continuity of r gives $\hat{\xi} = r(\hat{\xi})$. By uniqueness $\hat{\xi} = \xi^*$. Every convergent subsequence has the same limit, so $\xi(t) \to \xi^*$. □

The modulus t explains the practical behavior. Each tenfold reduction in the error of the recursion takes about $\frac{\ln 10}{-\ln t}$ iterations. That is about 229 iterations at $t = 0.99$, 459 at $t = 0.995$ and 1,150 at $t = 0.998$. Berry and Pakes start at $t = 0.99$ and move t toward one slowly, solving for each new $\xi(t)$ by Newton's method when the recursion becomes slow. They find that the homotopy gets much closer to the solution than the element-by-element inverse before it slows down.

What the paper calls the "homotopy" method is an integrated routine that combines the three methods.

1. Run the modified BLP contraction (6.114) with a high μ_ϵ, lowering μ_ϵ if numerical errors arise.
2. If needed, switch to the element-by-element inverse, with periodic Newton steps when possible.
3. If that does not converge quickly, use the homotopy recursion. For small problems, push t to one or very near it. For large problems, use only a few values such as $t = 0.99$, 0.995 and 0.998.

6.8.6 Simulation error and limit theory*

Berry et al. (2004b) derive limit theorems as the number of products J grows, for models with and without tastes for products. The two classes behave very differently, and the difference has computational consequences.

In the plain logit no simulation is needed, but observed shares contain sampling error from a finite sample of consumers. The inversion is analytic (their eqs. 35–36),

$$\xi_j = \ln s_j - \ln s_0 - x_j\beta, \qquad \frac{\partial \xi_j}{\partial s_j} = \frac{1}{s_j}. \tag{6.117}$$

With many products most shares are small, so the recovered ξ_j are very sensitive to any error in s_j. Berry et al. (2004b) show that simulation error causes the same problem in the random coefficients logit. A back-of-the-envelope calculation shows the orders of magnitude. If s_j is estimated from n independent draws, its variance is about $\frac{s_j(1-s_j)}{n}$. The delta method then gives

$$\operatorname{Var}(\ln \hat{s}_j) \approx \frac{1}{s_j^2} \cdot \frac{s_j(1-s_j)}{n} = \frac{1-s_j}{n s_j}.$$

With s_j of order $\frac{1}{J}$, the standard deviation of the error in ξ_j is of order $\sqrt{\frac{J}{n}}$. It grows with the number of products unless n grows faster than J.

The pure characteristics model behaves in the opposite way. As products crowd the space, competition becomes local and fierce, so $\frac{\partial s_j}{\partial \xi_j}$ is large and the inverse map is insensitive to share errors. The vertical model makes this concrete. By Proposition 6.31, $\delta_j = \sum_{m \le j}(p_m - p_{m-1})F^{-1}(S_m)$, where $S_m = \sum_{k \ge m} s_k$ is a cumulative share. A cumulative share estimated from n draws has variance at most $\frac{1}{4n}$, whatever J. The weights $\frac{p_m - p_{m-1}}{f(F^{-1}(S_m))}$ translate errors in S_m into errors in δ_j. Their sum is bounded when prices lie in a bounded interval and the density f is bounded away from zero there. The error in each δ_j is then of order $\frac{1}{\sqrt{n}}$, independent of J.

The formal results preserve this ranking, with higher required rates than the heuristic suggests. Berry et al. (2004b) derive conditions for asymptotic normality of the parameter

estimates. The number of simulation draws must grow at rate J in the vertical model and at rate J^2 in logit-type models. Berry and Pakes (2007, p. 23) report the Monte Carlo results of that paper. About fifty draws suffice for the limit distribution to describe the vertical model with up to two hundred products. The logit with one hundred products requires over two thousand draws.

Two forces therefore pull in opposite directions (Berry and Pakes, 2007, pp. 23–24). The required number of draws grows like J^2 with tastes for products and like J without them, which favors the pure characteristics model. The BLP contraction converges geometrically, while no rate is known for the pure characteristics inverse, which favors the model with tastes for products. Which force dominates depends on the number of products and on how often the inverse must be computed, which grows with the number of parameters.

6.8.7 Estimator, instruments and identification

Write mean quality as $\delta_j = x_j\beta + \xi_j$ and split the parameters into the linear parameters $\theta_1 = \beta$ and the nonlinear parameters θ_2 that govern the distribution of $(\beta_i - \beta, \alpha_i)$. For each θ_2, Theorem 6.63 delivers a unique $\delta(\theta_2)$ that matches the observed shares, computed by the methods of Section 6.8.5. The structural error is $\xi_j(\theta) = \delta_j(\theta_2) - x_j\beta$. With instruments z_j satisfying $\mathbb{E}[\xi_j z_j] = 0$, the GMM estimator solves

$$\hat{\theta} = \arg\min_{\theta} \; \xi(\theta)^\top Z \, W \, Z^\top \xi(\theta), \tag{6.118}$$

where Z stacks the instruments and W is a weighting matrix. The linear parameters can be concentrated out by instrumental variables regression of $\delta(\theta_2)$ on x, exactly as in Chapter 8.

Equilibrium prices respond to ξ, so price is in general correlated with it, and the instruments must exclude it. The small Monte Carlo design uses five instruments. They are a constant, x, x^2, the market mean of x and the distance from each product to its nearest neighbor in x. These functions of the characteristics of rival products shift each product's competitive environment, and so its price and share, without entering its own utility. The distance to the nearest neighbor suits the pure characteristics model, where substitution is local. An approximation to optimal instruments had little effect (their footnote 17). The large design uses a constant and x, each interacted with market dummies. Berry and Pakes attribute their success to the requirement that one utility model fit three markets whose product sets differ sharply.

6.8.8 The Monte Carlo designs

Data are drawn from the model (their eqs. 37–39)

$$u_{ij} = \delta_j + \sigma_x \nu_{ix} x_j - \alpha_i p_j, \qquad \ln \alpha_i = \sigma_p \nu_{ip}, \qquad \delta_j = \beta_0 + \beta_x x_j + \xi_j, \tag{6.119}$$

with (ν_{ix}, ν_{ip}) independent standard normal. The true values are $\sigma_x = 1$, $\sigma_p = 1$, $\beta_0 = 2$ and $\beta_x = 1$. The price coefficient is lognormal with $\mathbb{E}[\ln \alpha_i] = 0$. This fixes the median of α_i at one. Its mean is $e^{\frac{\sigma_p^2}{2}} \approx 1.65$ at the true $\sigma_p = 1$. The design therefore normalizes the median of the price coefficient, while their text describes a normalization of the mean (Berry and Pakes, 2007, p. 11).

The characteristic x equals twice a firm-specific uniform $(0, 1)$ draw plus one half of a uniform $(0, 1)$ draw common to all firms in the market, which correlates characteristics within a market. Its variance is $\frac{4}{12} + \frac{1}{4} \cdot \frac{1}{12} = \frac{17}{48} \approx 0.354$. In the base design ξ_j is uniform on $(-\frac{1}{2}, \frac{1}{2})$,

with variance $\frac{1}{12} \approx 0.083$. A second design uses ξ_j uniform on $(-1.5, 1.5)$, with variance 0.75, which exceeds the variance of x. Price is a convex function of quality, $p_j = \frac{e^{\delta_j}}{20}$. Equivalently, $\delta_j = \ln(20 p_j)$ is strictly concave in price. In the vertical case this makes the cutoffs strictly decreasing, so every product sells (Proposition 6.26). Since price depends on δ_j and hence on ξ_j, price is endogenous by construction. Observed shares come from the choices of 5,000 simulated consumers at the true parameters. Prices come from this formula, and no pricing game is solved, so the design does not need a price equilibrium to exist. Dividing utility by α_i puts it in the linear form of assumption A1 of Caplin and Nalebuff (1991), with type vector $(\frac{1}{\alpha_i}, \frac{\sigma_x \nu_{ix}}{\alpha_i})$. In the vertical case, $\sigma_x = 0$, the type $\frac{1}{\alpha_i}$ is lognormal with log-variance $\sigma_p^2 = 1$. It therefore satisfies their assumption A2, which for a one-dimensional lognormal type holds exactly when the log-variance is at most 2 (Section 6.1.3). For the two-dimensional design, A2 would have to be checked for the joint density of this type vector.

The paper uses two sample designs. The small design has 20 markets, each with a number of products drawn with equal probability from $\{2, \ldots, 10\}$, and 100 simulated data sets. The large design is patterned on the evolution of processor speed in personal computers from 1995 to 1997 (Pakes, 2003). It has three markets, or years, with 75, 100 and 125 products. The characteristic x is uniform between the year's minimum and maximum megahertz, divided by ten. The ranges are 25 to 133 in year 1, 25 to 200 in year 2 and 33 to 240 in year 3. The unobserved characteristic equals the year's megahertz range times $(2u_j - 1)$, with u_j uniform on $[0, 1]$, so that it scales with x. Prices fall over time (their eq. 40),

$$\ln p_j = (t - 1) \ln 0.7 + 1.1 \ln \delta_j, \tag{6.120}$$

so the price of a given bundle falls about 30 percent a year, and price remains convex in quality. Equation (6.120) requires $\delta_j = 2 + x_j + \xi_j > 0$, and the description does not guarantee it. If the range is in megahertz, ξ_j is uniform on $(-108, 108)$ in year 1, and $\delta_j \leq 0$ with probability 0.45 in year 1 and 0.46 in years 2 and 3. If the range is in the units of x, these probabilities are 0.09 in year 1 and 0.14 in years 2 and 3. Berry and Pakes do not report whether they rescaled, truncated or redrew such products. The large design therefore cannot be reproduced exactly from its description. Some shares are very small, smaller than in typical data sets. The large design uses one data set and asymptotic standard errors. Its homotopy starts from the output of the modified BLP contraction with fixed μ_ϵ and iterates 25 times on (their eq. 41)

$$\delta' = 0.05\, \delta + 0.95\, r(\delta). \tag{6.121}$$

Recursion (6.121) anchors on the current δ instead of a fixed starting point, so it is a damped element-by-element inverse. Its fixed points are those of r.

6.8.9 Results

Computing mean utilities. Table 6.8 reproduces Table 1 of Berry and Pakes (2007). It takes one simulated market with five products and computes δ by different methods. The homotopy with the same 5,000 draws that generated the data recovers the true δ exactly. With 500 draws it still fits the shares to machine precision, but the δ's differ from the truth by 0.15 to 0.23. Their order is preserved. The modified BLP contraction with $\mu_\epsilon = 1$, which is the original BLP contraction in these units, takes one-fiftieth of the homotopy's time but bears little relation to the truth. With $\mu_\epsilon = 10$ one value is out of order: $\delta_5 = 4.06$ falls below $\delta_4 = 4.10$. With $\mu_\epsilon = 50$ the order is right and the errors are 1 to 2 percent, but the time rises to 58 percent of the full

Table 6.8: Computing δ by different methods: one market with five products

	True	Homotopy		Modified BLP contraction, fixed μ_ϵ			
Draws (ns)	5,000	5,000	500	5,000	5,000	5,000	500
μ_ϵ				1	10	50	50
δ_1	2.99	2.99	3.14	3.08	3.02	3.04	3.25
δ_2	3.21	3.21	3.36	2.09	3.19	3.26	3.51
δ_3	3.56	3.56	3.71	3.13	3.60	3.62	3.94
δ_4	4.04	4.04	4.27	4.13	4.10	4.10	4.61
δ_5	4.10	4.10	4.32	2.68	4.06	4.16	4.65
Relative time		1	0.15	0.02	0.12	0.58	0.03

Source: Berry and Pakes (2007), Table 1. Data come from model (6.119). The "True" column uses the 5,000 consumer draws that generated the shares. Relative time is computing time relative to the homotopy with 5,000 draws.

homotopy's. With 500 draws and $\mu_\epsilon = 50$ the errors grow to between 0.26 and 0.57, larger than the homotopy's errors with the same draws.

Parameter estimates with few products. Table 6.9 combines Tables 2 and 3 of the paper. With a small variance of ξ, the modified BLP contraction with μ_ϵ fixed at 30 does about as well as the homotopy. The means of σ_x are 1.04 and 1.03 and those of β_0 are 2.06 and 2.00. With the larger variance of ξ, Berry and Pakes needed $\mu_\epsilon = 50$ for comparable performance, and computational problems prevented pushing μ_ϵ much higher. All methods then overestimate σ_x (1.24 and 1.26) and β_0 (2.34 and 2.33). In the first experiment $\mu_\epsilon = 30$ worked a little better than $\mu_\epsilon = 50$, perhaps because of approximation errors in computing exponentials of large numbers (their footnote 18).

The numbers in parentheses need care. For Table 2, the paper's text describes them as standard deviations of the estimates across the 100 samples. The precision of each reported mean is then about one tenth of the number shown. On that reading, the overestimate of σ_x in the high-variance design, about 0.25, is many times the standard error of the mean. It reflects finite-sample bias, which Monte Carlo noise cannot explain. Berry and Pakes conclude that the asymptotic approximation understates the variance of the estimator at these sample sizes. They also note that every method does worse when the unobservable has more variance, so more data are needed for a given precision.

Estimating μ_ϵ avoids the need to choose it, but at a cost. With the base variance the estimates move away from the truth ($\sigma_x = 1.14$, $\beta_0 = 2.19$). With the large variance they are poor ($\sigma_x = 1.64$, $\beta_0 = 2.79$). The estimates of μ_ϵ have means of 34.08 and 15.50 and much smaller medians of 17.81 and 4.67. Their distribution is therefore skewed, and in the high-variance design the typical estimate gives the logit error a large role. Imposing the traditional logit scale normalization, in place of the normalization on the price coefficient, made convergence without numerical errors much less likely (their footnote 19).

Substitution patterns with few products. Parameter estimates are rarely the object of interest. Table 6.10 reproduces Table 4 of the paper. It reports derivatives of the share of the cheapest product in one market of the high-variance design with respect to the prices of products 1 to 5. Each derivative is computed for every Monte Carlo parameter estimate and then averaged, which approximates averaging over the sampling distribution of the estimator. The last two columns form a *hybrid*. They use the parameters estimated by the modified BLP model with estimated μ_ϵ but compute derivatives from either the pure characteristics functional form or

Source: Berry and Pakes (2007), Tables 2 and 3. Entries are means across 100 simulated data sets of 20 markets with 2 to 10 products each. The paper's text describes the numbers in parentheses in Table 2 as standard deviations of the estimates across samples. The standard error of each mean is then about one tenth of the number shown. The note to Table 3 calls them estimated standard deviations of the mean estimates. Columns (5) and (6) use 500 simulation draws. In some runs of columns (5) and (6), μ_ϵ rose until numerical errors occurred and was then fixed at 50 (once at 25). The homotopy took about ten times as long as the modified BLP estimates.

the modified BLP form with $\mu_\epsilon = 50$.

The homotopy with the pure characteristics functional form reproduces the true pattern far better than either modified BLP estimate with its own functional form. Even with μ_ϵ fixed at 50, the modified BLP model misses the fourth entry badly, predicting 0.0278 where the truth is zero. Product 4 is not a neighbor of product 1, and only a pure characteristics model can produce an exact zero. The surprise is the hybrid. The parameters from the modified BLP model with estimated μ_ϵ, combined with the pure characteristics functional form, give -0.5241, 0.1629, 0.1461, 0.0001 and 0.0212. Berry and Pakes draw two lessons (their p. 31). Good parameter estimates need not produce good predictions when the model's functional form is used to compute them. Even if one estimates with the modified BLP contraction, one may not want to use (6.104) to compute implications.

Parameter estimates and elasticities with many products. Table 6.11 combines Tables 5 and 6 of the paper. The differences across methods are much larger than with few products. The modified BLP model with estimated scale does worst. Its estimate $\mu_\epsilon = 0.934$ gives the logit error a large role, and to match the small shares the constant is driven to $\beta_0 = -6.455$, with a standard error of 66.864. With μ_ϵ fixed (at 10, halved where numerical problems arose), $\beta_0 = 1.354$ is still too low. The homotopy is close to the truth, with $\beta_0 = 1.956$. The reason is the small shares of this design. A pure characteristics model generates small shares when products have similar characteristics. A model with tastes for products can generate them only through very low mean utilities. Twenty-five iterations of (6.121) raise the mean of the computed δ's substantially relative to the modified BLP output.

Panel B shows the implications. All methods capture the general pattern of substitution, although the modified BLP model is more diffuse. Only the homotopy captures the level of

Source: Berry and Pakes (2007), Tables 5 and 6. One simulated data set with three markets of 75, 100 and 125 products. Asymptotic standard errors in parentheses. The fixed scale was set to 10 and halved for parameter values and markets that caused numerical problems, in a few cases down to 2.5. Elasticities in Panel B are computed from a discrete 1 percent price change. The last column of Panel B takes the σ estimates of the modified BLP model with estimated scale. It recomputes δ with the homotopy contraction and β from the new δ, and it uses the pure characteristics functional form.

the elasticities. The products with very small shares have excellent substitutes in the pure characteristics model. For the fourth product, with a share of 0.0038 percent, a 1 percent price increase wipes out all sales, an elasticity of −100. The modified BLP model with estimated scale predicts −3.7 for the same product, and the model with fixed scale predicts −14.8. Such a product would survive only if a multi-product firm sold it, so that some markup could be sustained (their footnote 21). The hybrid column again comes close to the truth. Berry and Pakes read this as evidence that BLP-type estimates can locate the relative importance of the characteristics even when the data say little about how local substitution is. Holding the σ's fixed and taking μ_ϵ to infinity is then a cheap robustness check.

Welfare. Table 6.12 reports the average gain per person, in dollars, from moving from the year-1 choice set to the year-3 choice set. Between the two years the number of products rises, quality improves and prices fall, so many consumers leave the outside good and the true gain is large. All methods do well. The homotopy is within 0.5 percent of the truth (265.3 against 266.1). The modified BLP model with estimated scale is within 3 percent (259.0). Berry and Pakes explain the result through share fitting. The contraction fits observed shares exactly, so the extra surplus that the logit errors would add is offset by lower mean utilities. This roughly cancels the welfare bias of the model with tastes for products.

Table 6.12: Average welfare gain per person from the year-1 to the year-3 choice set

Method	Gain ($)
True	266.1
Homotopy	265.3
Modified BLP, $\mu_\epsilon = 10$	270.0
Modified BLP, μ_ϵ estimated	259.0
Modified BLP, μ_ϵ estimated, final homotopy contraction	272.1

6.8.10 Robustness and interpretation

The robustness evidence lies in the comparison of designs. With few products and a small unobservable variance, every method recovers parameters and elasticities reasonably well. With a larger unobservable variance, all methods lose precision and the modified BLP model with estimated scale degrades most. With many products and small shares, only the pure characteristics computation recovers the level of the elasticities. Two results recur. The functional form used to compute implications matters at least as much as the parameter estimates. Welfare changes between two observed choice sets are robust in this design because both models fit the observed shares exactly.

We read the welfare result as specific to its setting. Both choice sets are observed and both models are fit to them. The logit's mechanical credit for variety is then absorbed into lower mean utilities. A counterfactual that adds or removes products without observed shares to discipline the mean utilities would not have this protection. That is where Proposition 6.55 predicts the largest differences.

Berry and Pakes (2007, pp. 36–37) conclude with practical advice. The easiest approach uses the existing BLP method with their normalization on the price coefficient in place of the usual normalization on the scale of the logit error. It worked in their experiments when the number

of products was not large and the relative variance of ξ was not high. Fixing μ_ϵ at a large value imposes the pure characteristics restriction and gains efficiency by estimating one parameter fewer. One cannot know in advance how large a value suffices, however, and numerical errors limit how large it can be. The homotopy is the most accurate method and the slowest. A practical compromise is to estimate by BLP methods and then compute the implications with the pure characteristics share function. At a minimum this provides a robustness check.

6.8.11 Limitations, critiques and contribution

The model allows a single unobserved characteristic, and that characteristic is vertical (Assumption 6.62). If consumers differ in their tastes for several unobserved characteristics, the model is misspecified. Market data seem to offer little scope for estimating richer structures (Remark 6.61). The Monte Carlo evidence is limited: two designs, one data set in the large design, and prices that are exact functions of mean utility with no cost shocks. The inverse has no known convergence rate, and the computational burden grows quickly with the number of products. Pure characteristics models also assume that consumers compare all products. With hundreds of close substitutes this produces very large elasticities, a point that Bajari and Benkard (2005) confront directly in Section 6.9.5. Song (2007) applies the pure characteristics model to the market for computer processors and compares its welfare measures with those of a random coefficients logit.

The paper made the theoretical class of pure characteristics models usable with market data. It showed how to compute shares by conditioning on all but one random coefficient, and it proved that shares can be inverted under weak conditions. The proof became a template for later invertibility results (Berry et al., 2013). It provided algorithms with known properties and documented their trade-offs. It also showed that the choice of functional form for computing elasticities and welfare can matter more than the estimation method. Above all, it framed the question of what the idiosyncratic shock assumes about the world and how much the answers to applied questions depend on it.

6.9 The hedonic approach

The hedonic approach also drops the idiosyncratic shock, but it starts from prices. Each product is a bundle of characteristics, and the market prices bundles. The relationship between price and characteristics reveals, at each chosen bundle, the buyer's marginal willingness to pay. We first develop the classical model of Rosen (1974) and the identification problems raised against it. We then study Bajari and Benkard (2005), who adapt the approach to oligopolistic markets with an unobserved characteristic and a finite number of products.[19]

6.9.1 Rosen's hedonic model

Consumers. Products are described by a vector of characteristics $z = (z_1, \ldots, z_K)$, and a continuum of product types is available. In this subsection we follow Rosen and write

[19] Numbers are taken from the January 2004 working-paper version of Bajari and Benkard (2005), NBER Working Paper 10278. All the numbers we cite for it refer to that version. These are its pages, footnotes, equations (1, 6–18, 21–22 and 29–34), assumptions A1 to A9, Theorems 1 to 8, Appendices A and B, tables and figures. The article in the *Journal of Political Economy* reports a revised application based on bounds, with different tables and figures. The Gibbs-sampler estimates of Section 6.9.5, including the taste correlations, elasticities and demand curves, appear only in the working paper. The working paper's title page lists the authors as Benkard and Bajari.

characteristics as z, not as x. The market assigns a price $p(z)$ to each bundle. We call $p(\cdot)$ the *hedonic price function*. Consumers take it as given. A consumer with income y and taste parameter a buys one unit of one product and spends the rest on a numeraire c:

$$\max_{c,z} \; U(c, z; a) \quad \text{subject to} \quad c + p(z) = y. \tag{6.122}$$

Substituting the budget constraint and differentiating with respect to z_k gives the first-order condition

$$\frac{\partial p(z)}{\partial z_k} = \frac{U_{z_k}(y - p(z), z; a)}{U_c(y - p(z), z; a)}, \qquad k = 1, \dots, K. \tag{6.123}$$

At the chosen bundle, the *implicit price* of each characteristic equals the consumer's marginal rate of substitution between that characteristic and money.

Rosen describes preferences through the *bid function* $\theta(z; u, y, a)$, the amount the consumer would pay for bundle z and still reach utility u. It is defined by

$$U\big(y - \theta(z; u, y, a), z; a\big) = u. \tag{6.124}$$

In this section θ denotes Rosen's bid function. It is unrelated to the parameter vector θ of Section 6.2. Implicit differentiation gives $\theta_{z_k} = \frac{U_{z_k}}{U_c} > 0$ and $\theta_u = -\frac{1}{U_c} < 0$. A higher bid curve corresponds to lower utility. The consumer reaches the highest utility u^* whose bid curve still touches the price function. At the optimum z^*,

$$\theta(z^*; u^*, y, a) = p(z^*), \qquad \theta_{z_k}(z^*; u^*, y, a) = p_{z_k}(z^*), \qquad \theta(z; u^*, y, a) \le p(z) \text{ for all } z. \tag{6.125}$$

The bid curve is tangent to the price function from below.

Producers. A firm with technology parameter b can produce bundle z at unit cost $C(z; b)$ under constant returns. Its *offer function* $\phi(z; \pi, b) = C(z; b) + \pi$ is the price at which it would supply z and earn profit π per unit. The firm chooses the bundle that maximizes $p(z) - C(z; b)$. At the optimum, with maximal profit π^*, $\phi(z; \pi^*, b) \ge p(z)$ for every z, with equality at the chosen bundle. The offer curve is tangent to the price function from above. With general returns to scale the offer function also embeds the optimal output, but the tangency is the same (Rosen, 1974).

Equilibrium. The price function clears the market for every bundle: the distribution of bundles demanded equals the distribution supplied. In equilibrium $p(z)$ is an envelope of the bid functions of all consumers, which touch it from below. It is also an envelope of the offer functions of all firms, which touch it from above. Figure 6.10 draws the geometry. The gradient of the price function at a traded bundle equals both the marginal willingness to pay of its buyer and the marginal cost of its seller. The price function is an equilibrium locus. It is neither a demand curve nor a supply curve.

Rosen's two-step procedure. The model suggests two steps. First, regress the prices of products in a market on their characteristics with a flexible functional form. This yields an estimate $\hat{p}(z)$ and implicit prices $\hat{p}_{z_k}(z_j)$ at each traded bundle. Second, treat the implicit prices as observed marginal prices. Estimate the marginal bid functions $\hat{p}_{z_k}(z_j) = F^k(z_j, Y_{1j})$, which depend on characteristics and buyer attributes Y_{1j}. Estimate them jointly with the marginal offer functions $\hat{p}_{z_k}(z_j) = G^k(z_j, Y_{2j})$, which depend on seller attributes Y_{2j}.

The identification critique. The second step runs into two problems, which a one-characteristic example makes transparent. Let the price function be quadratic,

$$p(z) = \pi_0 + \pi_1 z + \tfrac{1}{2}\pi_2 z^2, \qquad \pi_2 > 0,$$

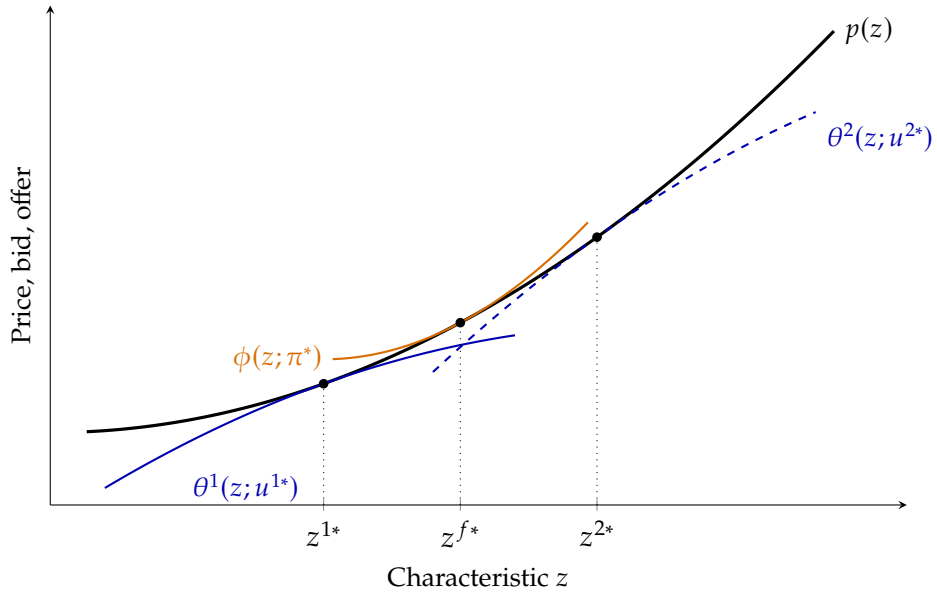

Figure 6.10: The hedonic price function $p(z)$. Consumer 1 and consumer 2 choose z^{1*} and z^{2*}, where their bid curves θ^1 and θ^2 (concave) touch $p(z)$ from below. A firm chooses z^{f*}, where its offer curve ϕ touches $p(z)$ from above. At each traded bundle the slope of $p(z)$ equals the buyer's marginal willingness to pay and the seller's marginal cost.

so the implicit price is $p_z(z) = \pi_1 + \pi_2 z$. The coefficients π_0, π_1, π_2 are unrelated to the profit π of the offer function. Let consumer i's marginal bid be linear,

$$\theta_z(z) = b_0 - b_1 z + b_2 Y_i + \eta_i, \qquad b_1 > 0,$$

where Y_i is an observed attribute and η_i an unobserved taste. The first-order condition $p_z(z_i) = \theta_z(z_i)$ gives

$$\pi_1 + \pi_2 z_i = b_0 - b_1 z_i + b_2 Y_i + \eta_i \quad \Longrightarrow \quad z_i = \frac{b_0 - \pi_1 + b_2 Y_i + \eta_i}{\pi_2 + b_1}. \tag{6.126}$$

The first problem was raised by Brown and Rosen (1982). In one market the constructed implicit price $\pi_1 + \pi_2 z_i$ is an exact linear function of z_i. Regressing it on z_i and Y_i fits perfectly with coefficients $(\pi_1, \pi_2, 0)$. The second step merely reproduces the first-step price function and reveals nothing about the slope $-b_1$ of the marginal bid curve. Identification requires restrictions that the data cannot supply in a single market, such as different functional forms for the price function and the marginal bid function.

The second problem was stressed by Epple (1987) and Bartik (1987). By (6.126), the chosen quantity z_i rises with the unobserved taste η_i. Consumers who value the characteristic more buy more of it, and along a nonlinear price function they also pay a higher implicit price. The regressor z_i is correlated with the error of the marginal bid equation. The consumer's own attributes are poor instruments, because they enter the bid function or may correlate with unobserved tastes. A valid instrument must shift the price function that the consumer faces without shifting tastes. Variation in (π_1, π_2) across separate markets with the same distribution of tastes does this. In market m the first-order condition reads $\pi_{1m} + \pi_{2m} z_i = b_0 - b_1 z_i + b_2 Y_i + \eta_i$, and market indicators identify b_1 through their effect on z_i.

Ekeland et al. (2004) show that the linear-quadratic structure behind the critique is special. Equilibrium price functions are generically nonlinear, and with additive separability

assumptions this nonlinearity can identify preferences from a single market with one observed characteristic. Rosen's framework also connects to earlier sections. Bresnahan's quality index $\delta(x) = \sqrt{\beta_0 + \sum_k x_k \beta_k}$ is read as a hedonic expansion path of cost-minimizing characteristics, and his non-nested tests include a hedonic alternative (Section 6.6).

6.9.2 Bajari and Benkard: the model and the price function

Motivation. Bajari and Benkard (2005, pp. 1–5) give two reasons why hedonic models are rarely used in industrial organization. First, Rosen assumes perfect competition and a continuum of products. Yet oligopoly is often the object of study, and oligopolistic markets rarely contain more than a few hundred products. Under imperfect competition a hedonic price function need not exist, and where it exists it is unlikely to be additively separable. Second, Rosen assumes that every characteristic is observed. In their data on personal computers, 357 of the 695 products are dominated. For each of them, another product is better in every observed characteristic and cheaper. No hedonic model with full observability can rationalize positive demand for such products. Discrete choice models avoid the problem through the shock ϵ_{ij}. Bajari and Benkard instead add one characteristic that consumers see and the econometrician does not.

They contrast their model with BLP-type models along the lines of Section 6.7. An i.i.d. shock makes the characteristic space infinite dimensional. Together with the distributional assumptions, it typically produces demand curves of hyperbolic shape that approach both axes. The hedonic model restricts demand only to slope downward, so the two models can differ sharply when demand is predicted at prices outside the data.

The model. A product j is a vector (x_j, ξ_j), with $x_j \in \mathbb{R}^K$ observed by consumers and econometrician and a scalar ξ_j observed by consumers only. Markets are indexed by $t \in \mathcal{T}$ and prices by p_{jt}. Consumer i has utility $u_i(x_j, \xi_j, c)$ over the product and a composite good $c \geq 0$ with price one. With income y_i, the consumer solves (their eq. 1)

$$\max_{(j,c)} \; u_i(x_j, \xi_j, c) \quad \text{subject to} \quad p_{jt} + c \leq y_i. \tag{6.127}$$

Assumption 6.66 (Bajari and Benkard, A1 to A3)**.** For every consumer and market: (A1) u_i is continuously differentiable and strictly increasing in c, with $\frac{\partial u_i}{\partial c} \geq \underline{m} > 0$ for $c \in (0, y_i]$. (A2) u_i is Lipschitz continuous in (x_j, ξ_j) with constant L. (A3) u_i is strictly increasing in ξ_j.

We state the bounds $\underline{m}$ and L as common to all consumers, which the Lipschitz property of the price function requires. Assumption A3 is the strongest. It rules out satiation in the unobserved characteristic.

Theorem 6.67 (Bajari and Benkard, Theorem 1)**.** *Under Assumption 6.66, for any two products j and j' with positive demand in market t:*

(i) If $x_j = x_{j'}$ and $\xi_j = \xi_{j'}$, then $p_{jt} = p_{j't}$.

(ii) If $x_j = x_{j'}$ and $\xi_j > \xi_{j'}$, then $p_{jt} > p_{j't}$.

(iii) $|p_{jt} - p_{j't}| \leq \bar{L}\big(\|x_j - x_{j'}\| + |\xi_j - \xi_{j'}|\big)$ with $\bar{L} = \frac{L}{\underline{m}}$.

Proof. Each part shows that a violation would leave one of the two products with no buyers.

(i) Suppose $p_{jt} > p_{j't}$. A consumer who can afford j gets the same product characteristics from j' with more of the composite good. By A1 she strictly prefers j', so j has no demand.

(ii) Suppose $p_{jt} \le p_{j't}$. For a consumer who can afford j', A1 and then A3 give

$$u_i(x_j, \xi_j, y_i - p_{jt}) \ge u_i(x_j, \xi_j, y_i - p_{j't}) > u_i(x_j, \xi_{j'}, y_i - p_{j't}),$$

so j' has no demand.

(iii) Let $d = \|x_j - x_{j'}\| + |\xi_j - \xi_{j'}|$ and suppose $p_{jt} - p_{j't} > \bar{L}d$. Take a consumer who can afford j, so $y_i \ge p_{jt}$. Split the utility difference into a change in c and a change in characteristics:

$$\begin{aligned} u_i(x_{j'}, \xi_{j'}, y_i - p_{j't}) - u_i(x_j, \xi_j, y_i - p_{jt}) &= \left[u_i(x_{j'}, \xi_{j'}, y_i - p_{j't}) - u_i(x_{j'}, \xi_{j'}, y_i - p_{jt})\right] \\ &\quad + \left[u_i(x_{j'}, \xi_{j'}, y_i - p_{jt}) - u_i(x_j, \xi_j, y_i - p_{jt})\right] \\ &\ge \underline{m}\,(p_{jt} - p_{j't}) - Ld. \end{aligned}$$

The first bracket uses the mean value theorem and A1, and the second uses A2. The last expression exceeds $\underline{m}\bar{L}d - Ld = 0$. Every potential buyer of j strictly prefers j', so j has no demand. Exchanging the roles of j and j' covers the other sign. □

The theorem uses only consumer optimization and the fact that consumers take prices as given. It places no restriction on the supply side, so it holds under oligopoly and in static or dynamic equilibria. Its conclusions justify writing prices in market t as an equilibrium *price function* $p_t(x, \xi)$ with $p_{jt} = p_t(x_j, \xi_j)$. Bajari and Benkard stress what the function is not (their pp. 7–8). It is an equilibrium object that changes whenever any primitive changes: a new product, a cost shock, a change in ownership. It does not predict the price of a product that is not on the market. It is specific to each market. Even simple oligopoly models imply that it is nonlinear and not additively separable in ξ, because markups depend on all characteristics. They therefore keep the general form.

6.9.3 The first stage: the unobserved characteristic as a price quantile

The first stage recovers ξ_j from prices. The unobserved characteristic has no natural units and is identified only up to an increasing transformation. Bajari and Benkard normalize it to be uniform on $[0, 1]$, which amounts to measuring it by its own distribution function. Two further assumptions are needed.

Assumption 6.68 (Bajari and Benkard, A4 and A5)**.** (A4) ξ is independent of x. (A5) For every market t and every x, $p_t(x, \cdot)$ is strictly increasing, with $\frac{\partial p_t(x,\xi)}{\partial \xi} > \underline{\kappa}$ for all (x, ξ) and some $\underline{\kappa} > 0$.

A4 strengthens the mean independence common in the literature. Because ξ enters the price function nonseparably, the model can still generate patterns that look like heteroskedasticity. Bajari and Benkard note that the monotonicity in A5 follows from consumer preferences through Theorem 6.67(ii). Let $F_{p_t|x=x_0}$ denote the distribution of prices in market t among products with observed characteristics x_0.

Theorem 6.69 (Bajari and Benkard, Theorem 2)**.** *Suppose prices are observed without error and A4 and A5 hold. Then for each market t the price function p_t is identified within the class of price functions that are strictly increasing in ξ. The unobserved characteristics are also identified:*

$$\xi_j = F_{p_t|x=x_j}(p_{jt}), \qquad p_t(x_0, e_0) = F^{-1}_{p_t|x=x_0}(e_0). \tag{6.128}$$

Proof. The argument is a chain of equalities.

$$\begin{aligned} F_{p_t|x=x_j}(p_{jt}) &= \mathbb{P}\big(p_t(x,\xi) \le p_{jt} \mid x = x_j\big) && \text{(definition)} \\ &= \mathbb{P}\big(\xi \le p_t^{-1}(x_j, p_{jt}) \mid x = x_j\big) && (p_t(x_j,\cdot) \text{ strictly increasing}) \\ &= \mathbb{P}\big(\xi \le p_t^{-1}(x_j, p_{jt})\big) && \text{(A4)} \\ &= p_t^{-1}(x_j, p_{jt}) && (\xi \text{ uniform on } [0,1]) \\ &= \xi_j && (p_{jt} = p_t(x_j, \xi_j)). \end{aligned}$$

Here $p_t^{-1}(x,\cdot)$ is the inverse of $p_t(x,\cdot)$. The same chain with $(x_0, p_t(x_0, e_0))$ in place of (x_j, p_{jt}) gives $F_{p_t|x=x_0}(p_t(x_0,e_0)) = e_0$. Inverting this identity gives the second equation in (6.128). Both objects are functions of the observable distribution of prices given characteristics, which proves identification. □

The unobserved characteristic is the rank of a product's price among products with the same observed characteristics. A computer priced at the 90th percentile among computers with identical observed specifications has $\xi = 0.9$. Identification uses a single cross-section, so ξ_j and its distribution may change over time. The first part of the argument follows Matzkin (2003). If prices are measured with error, identification requires each product to be observed in many markets, so that averaging removes the error (their Appendix A, Theorem 6). The estimator replaces the conditional distribution with a nonparametric estimate (their eq. 18):

$$\hat{\xi}_{jt} = \hat{F}_{p_t|x=x_j}(p_{jt}). \tag{6.129}$$

Kernel estimators, which weight products by the closeness of their characteristics to x_j, can be used. So can series estimators, which fit a regression on a growing set of known functions of the characteristics (Sections A.11.1 and A.11.3). In the application a local linear kernel estimator (Fan and Gijbels, 1996) worked best.

Bajari and Benkard offer three alternatives to independence. Under *options packages* (their Theorem 3), products are grouped into models, such as a particular line of desktop computers, and an options package x is chosen within a model. All products of a model share the same ξ (their A6), and a baseline package $\bar{x}$ is available for every model (their A7). Normalizing ξ given $x = \bar{x}$ to be uniform, ξ_j is the price quantile of the baseline version of j's model. The approach is a nonparametric analog of fixed effects. It works in one cross-section even with measurement error, and it is testable because many products share the same ξ.

Under a *rich set of price functions* (their Theorem 4), some market has prices that depend on ξ alone (their A8). Packaged goods whose flavors all sell at the same price are an example. Prices weakly increase in x and strictly increase in ξ in every market (their A9). With full support and products observed in many markets, these conditions identify the ranking of the ξ_j. Finally, nonseparable nonparametric instrumental variables methods for triangular systems (Imbens and Newey, 2009) could replace independence. They require instruments that determine the endogenous observed characteristics yet are independent of ξ, and such instruments are hard to find in product markets.

6.9.4 The second stage: preferences

With ξ recovered, Bajari and Benkard treat it as an observed characteristic. If demand were observed for every price function, the results of Mas-Colell (1977) would recover preferences. Data are rarely that rich, and often each consumer is observed once. Two cases arise.

Continuous choice set. Suppose utility is linear in the logarithms of the characteristics and in the composite good (their eq. 6):

$$u_{ij} = \beta_{i1} \ln x_{1j} + \cdots + \beta_{iK} \ln x_{Kj} + \beta_{i\xi} \ln \xi_j + c, \qquad c = y_i - p_t(x_j, \xi_j). \tag{6.130}$$

If the choice set is a continuum and the choice is interior, the consumer chooses (x, ξ) on the price surface to maximize (6.130). Differentiating with respect to x_k and ξ gives (their eqs. 7–8)

$$\frac{\beta_{ik}}{x_{kj}} = \frac{\partial p_t(x_j, \xi_j)}{\partial x_k}, \quad k = 1, \ldots, K, \qquad \frac{\beta_{i\xi}}{\xi_j} = \frac{\partial p_t(x_j, \xi_j)}{\partial \xi}.$$

Solving for the tastes gives (their eqs. 9–10)

$$\beta_{ik} = x_{kj} \frac{\partial p_t(x_j, \xi_j)}{\partial x_k}, \qquad \beta_{i\xi} = \xi_j \frac{\partial p_t(x_j, \xi_j)}{\partial \xi}. \tag{6.131}$$

A single observed choice therefore identifies a consumer's entire taste vector, given the price function and ξ_j. Each taste is the implicit price of the characteristic times the chosen quantity, which is the consumer's willingness to pay, in dollars, for a unit increase in the logarithm of the characteristic. Pooling consumers' choices traces out the population distribution of tastes nonparametrically. The precision of these estimates depends only on the first-stage sample.

More generally, write $u_i(x, c) = u(x, y_i - p(x); \beta_i)$ with $\beta_i \in \mathbb{R}^B$ (their eq. 11). The first-order conditions $\frac{\partial}{\partial x_k} u(x, y_i - p(x); \beta_i) = 0$ define the optimal choice $x(\beta)$. Implicit differentiation gives $x'(\beta) = -[D_{xx}\bar{u}]^{-1} D_{x\beta}\bar{u}$, where $\bar{u}(x; \beta) = u(x, y_i - p(x); \beta)$ (their eqs. 12–14). Their Theorem 5 states that β_i is locally identified when $x'(\beta)$ is locally positive or negative definite, by the inverse function theorem. With as many taste parameters as characteristics ($B = K$) and $x'(\beta)$ definite everywhere on an open convex set, the map $x(\cdot)$ is one-to-one and tastes are globally identified (Gale and Nikaidô, 1965). One choice identifies at most K random coefficients.

Discrete choice set. With finitely many products, utility maximization yields inequalities. If consumer i chooses product j, then (their eq. 15)

$$u(x_j, \xi_j, y_i - p_{jt}; \beta_i) \geq u(x_k, \xi_k, y_i - p_{kt}; \beta_i) \quad \text{for all } k \neq j, \tag{6.132}$$

so β_i lies in the *revealed preference set* $A_{ij} = \{\beta : (6.132) \text{ holds}\}$ (their eq. 16). The set typically contains more than one point, so individual tastes are not identified. It can still be small when the choice set is rich. Their Appendix B makes this precise when every characteristic is observed. Utility $u(x_j, p_j; \beta_i)$ does not depend on income, and there is no outside option. The characteristics lie in an open, bounded and convex set $\mathcal{X}$, and the tastes lie in an open, bounded and convex set $\mathcal{B}$ (their Assumption 1). When the whole of $\mathcal{X}$ is available, the Jacobian $x'(\beta)$ is positive or negative definite for every taste vector (their Assumption 2). As in the continuous case above, this makes the continuum choice map $x(\cdot)$ one-to-one. Products are drawn at random from $\mathcal{X}$. Their Theorem 8 states that, with probability one, a consumer's revealed preference set shrinks to her taste vector as the number of products grows.

Their rate argument concerns only an average. Each set depends only on the product chosen, and the sets for the J products partition $\mathcal{B}$. Their average Lebesgue measure, or volume, is therefore $\frac{m(\mathcal{B})}{J}$. An outside option would add one more set and leave the rate unchanged. A small average volume does not make every set small, and their Theorem 8 needs their Assumption 2 for that conclusion. Suppose two characteristics take values on a square grid with spacing h in $[1, 2]^2$, with price $p(x) = \frac{x_1^2 + x_2^2}{2}$ and utility $\beta_1 x_1 + \beta_2 x_2 - p(x)$. Let tastes be

uniform on $[1,3]^2$. With the whole square available, the choice is $x_k = \min\{\beta_k, 2\}$. Every consumer with both tastes above 2 then chooses the corner $(2,2)$, so their Assumption 2 fails. On the grid, the corner product is chosen exactly when β_1 and β_2 both exceed $2 - \frac{h}{2}$. Its set has area $(1 + \frac{h}{2})^2$, which tends to 1, and it holds a share $\frac{(1+\frac{h}{2})^2}{4}$ of consumers, which tends to $\frac{1}{4}$. The average area $\frac{4}{J}$ still tends to zero. With tastes uniform on $[1,2]^2$ instead, the choice map is $x(\beta) = \beta$, and every set has sides of length at most h.

Consumers who buy nothing are treated as buying a bundle with zero characteristics at zero price (their eq. 17):

$$u(0, 0, y_i; \beta_i) \geq u(x_k, \xi_k, y_i - p_{kt}; \beta_i) \quad \text{for all } k.$$

These conditions are only inequalities, so the tastes of non-purchasers are not point identified even with a continuous product space.

The sets A_{ij} deliver bounds on the population distribution of tastes. Let $\mathcal{B}(\bar{\beta}) = \{\beta : \beta \leq \bar{\beta}\}$. The share of consumers whose whole set A_{ij} lies in $\mathcal{B}(\bar{\beta})$ is a lower bound for the taste distribution function at $\bar{\beta}$. The share whose set meets $\mathcal{B}(\bar{\beta})$ is an upper bound. When utility is quasi-linear, as in (6.130), income cancels from (6.132). All buyers of product j then share one set A_j, and product-level quantities suffice for estimation.

A Bayesian point estimate and the Gibbs sampler. For a point estimate, Bajari and Benkard turn the inequalities into a likelihood. Consumer i with tastes β_i chooses j with likelihood (their eq. 21)

$$L(j \mid x, y_i, \beta_i) = \mathbf{1}\big\{u(x_j, y_i - p_j; \beta_i) \geq u(x_k, y_i - p_k; \beta_i) \text{ for all } k \neq j\big\}, \tag{6.133}$$

where x_j now includes ξ_j. With a uniform prior on a box $\mathcal{B}$ that contains every A_{ij}, the posterior $\pi(\beta_i \mid j) \propto \mathbf{1}\{\beta_i \in \mathcal{B}\}\, L(j \mid x, y_i, \beta_i)$ is uniform on A_{ij} (their eq. 22).

Sampling from a uniform distribution on a set defined by many inequalities is easy coordinate by coordinate. In model (6.130), choice of j requires, for every $k \neq j$ (their eq. 29),

$$\sum_l \beta_{il} \ln x_{lj} + y_i - p_j \geq \sum_l \beta_{il} \ln x_{lk} + y_i - p_k.$$

Collecting the terms in β_{i1} gives

$$\beta_{i1} (\ln x_{1j} - \ln x_{1k}) \geq \sum_{l \neq 1} \beta_{il} (\ln x_{lk} - \ln x_{lj}) + (p_j - p_k).$$

Define the ratio

$$R_k(\beta_{i,-1}) = \frac{\sum_{l \neq 1} \beta_{il} (\ln x_{lk} - \ln x_{lj}) + (p_j - p_k)}{\ln x_{1j} - \ln x_{1k}}. \tag{6.134}$$

If $x_{1j} > x_{1k}$, the denominator is positive and the inequality reads $\beta_{i1} \geq R_k$. If $x_{1j} < x_{1k}$, dividing by a negative number flips it to $\beta_{i1} \leq R_k$. If $x_{1j} = x_{1k}$, the inequality does not involve β_{i1}. Given the other coordinates, β_{i1} is therefore uniform on $[\beta_{1,\min}, \beta_{1,\max}]$ with (their eqs. 32–33)[20]

$$\beta_{1,\min} = \max\Big\{\underline{b}_1, \max_{k: x_{1j} > x_{1k}} R_k(\beta_{i,-1})\Big\}, \qquad \beta_{1,\max} = \min\Big\{\bar{b}_1, \min_{k: x_{1j} < x_{1k}} R_k(\beta_{i,-1})\Big\}, \tag{6.135}$$

where $[\underline{b}_1, \bar{b}_1]$ is the range of the first coordinate in the prior box. The other coordinates are handled in the same way. The sampler proceeds as follows.

[20] The working paper prints the price term in eqs. 30–33 as $(y_i - p_j) - (y_i - p_k)$, which has the opposite sign. The expression here follows from their eq. 29.

1. Start from a point $\beta_i^{(0)}$ in A_{ij}. Bajari and Benkard use the tastes implied by the continuous-case formulas (6.131) and search nearby when that point violates an inequality.
2. Given $\beta_i^{(s)}$, draw $\beta_{i1}^{(s+1)}$ from the uniform distribution on $[\beta_{1,\min}, \beta_{1,\max}]$ computed at the current values of the other coordinates.
3. Draw each remaining coordinate $l = 2, \ldots, K$ in the same way, conditioning on the most recent values of the others.
4. Repeat, discarding an initial set of draws.

Each inequality is linear in β_i, so A_{ij} is an intersection of half-spaces. It is therefore convex, hence connected, and standard sufficient conditions for convergence of the sampler hold (their footnote 8). The distribution function of tastes is estimated by the frequency of draws below each point (their eq. 34),

$$\hat{F}(\bar{\beta}_1, \ldots, \bar{\beta}_K) = \frac{1}{S} \sum_{s=1}^{S} \mathbf{1}\{\beta_1^{(s)} \le \bar{\beta}_1, \ldots, \beta_K^{(s)} \le \bar{\beta}_K\}, \tag{6.136}$$

with draws pooled across consumers. The uniform prior selects one distribution among the many consistent with the data. The sampler extends to repeated choices, which add inequalities, and to estimation error in ξ, by drawing ξ from its sampling distribution before each run.

When independence fails. If ξ is locally positively correlated with some observed characteristic, the first stage attributes part of the price effect of ξ to that characteristic. Its implicit price is biased upward and the implicit price of ξ downward. Through (6.131) the estimated tastes inherit the same biases. Because a product is a bundle of both characteristics, the biases partly offset in the demand for products. Bajari and Benkard report that they cancel exactly with linear utility and a linear price function.

6.9.5 Application: personal computers, December 1999

Data. The data come from the PC Data Retail Hardware Monthly Report. They contain quantities, average prices and characteristics of desktop computers for 29 months. The analysis concentrates on December 1999, with 695 models, a cross-section in which traditional demand methods typically struggle. The data reportedly cover about 75 percent of U.S. retail computer sales. Processor dummies are replaced by a CPU benchmark score, which a regression on chip speed interacted with chip dummies explains with an R^2 of 0.999. The score is an index of processor performance taken from the website cpuscorecard.com (their footnote 10). The paper gives it no physical unit. Within a chip family it rises with clock speed, as Panel A of Table 6.14 shows. The final data contain 19 characteristics. The three main continuous characteristics are the benchmark, RAM and hard drive capacity. Following their Table 1, the others are MMX, SCSI, CD-ROM, DVD, a network card, a monitor dummy, monitor size, a zip drive, desktop versus tower, refurbished and no modem. All of them except monitor size are dummies. Five operating-system dummies complete the list, one of which is omitted in the regression. The paper does not define the hardware labels, so we give their standard meanings. MMX is a set of instructions for multimedia work that Intel introduced in 1997. The paper does not say how the MMX dummy was coded. Nearly every desktop processor sold in 1999 supported MMX, yet the dummy has mean 0.64. It therefore cannot simply record support for the instruction set. The SCSI dummy marks a machine with the Small Computer System Interface, a fast

connection for hard drives and other devices. Only about 1 percent of the machines have one. A zip drive reads removable high-capacity disks, and a network card connects the computer to a local network. With all characteristics treated as observed, 357 of the 695 products are dominated. Table 6.13 reproduces selected rows of their Table 1, including an OLS hedonic regression.

Table 6.13: Personal computers, December 1999: summary statistics and a linear hedonic regression

Variable	Mean	S.D.	Min	Max	OLS coefficient
CPU benchmark	1354.5	362.3	516	2544	0.836
RAM (MB)	74.0	35.1	16	256	3.010
Hard drive (MB)	9276.8	4850.3	2100	40000	0.008
MMX	0.64	0.48	0	1	−56.971
SCSI	0.01	0.08	0	1	310.747
CD-ROM	0.67	0.47	0	1	26.478
DVD	0.14	0.35	0	1	32.213
Monitor included	0.31	0.46	0	1	29.625
Monitor size	0.75	3.27	0	15	22.822
Desktop (not tower)	0.17	0.37	0	1	25.611
Refurbished	0.09	0.28	0	1	−144.314
No modem	0.55	0.50	0	1	145.169
Constant					−590.2
R^2					0.79
N					695

Source: Bajari and Benkard (2005), Table 1 (working-paper version). The dependent variable of the OLS regression is price in dollars. Rows not shown are the network card, zip drive and four operating-system dummies (Windows NT 4.0, Windows NT, Windows 98, Windows 95, with Windows 3.1 omitted). The paper reports no standard errors for this regression.

First stage. A nonparametric estimator in 19 dimensions is impractical, so the first stage treats three continuous characteristics nonparametrically: CPU benchmark, RAM and hard drive. The price function is assumed additively separable in the other 16, with coefficients fixed at the OLS values of Table 6.13. Bajari and Benkard argue that many of these are peripherals that can be bought and sold separately, so arbitrage limits nonseparability. The estimator is (6.129) with a local linear kernel and a normal kernel. Bandwidths were chosen by eye, which oversmooths relative to the mean-squared-error optimum. Smooth estimates help because derivatives of the price function supply starting values for the sampler. With a finite product space, only the $\hat{\xi}_j$ are needed for the demand system itself.

The unobserved characteristics are precisely estimated (their Table 2). Asymptotic standard errors average 0.010, have median 0.009, and are below 0.018 for 95 percent of products, with a maximum of 0.104. Bootstrap standard errors, from 1,000 samples drawn with i.i.d. sampling of products, average 0.012, have 95th percentile 0.022 and maximum 0.121. For 508 of the 695 products the bootstrap standard error exceeds the asymptotic one. Two features explain the precision. A quantile is easier to estimate than a density, and the characteristic space is densely filled, so almost every product has close neighbors. The estimated bias was small and barely changed the ranking of the $\hat{\xi}_j$, so it was left out.

Second stage. The demand system uses all 19 observed characteristics and ξ. Utility is quasi-linear, linear in the logarithms of CPU benchmark, hard drive, RAM and ξ, and linear in the other characteristics and in price. The $\hat{\xi}_j$ were rescaled so that budget sets are convex,

and other normalizations changed the results little. After discarding initial draws, the sampler produced 1,000 taste draws per product, a total of 695,000 twenty-dimensional draws. These were reweighted by each product's sales. Including the initial draws, the computation took about an hour on their Sun Ultra 60 workstation.

The estimated willingness-to-pay distributions (their Figures 1–5) look roughly lognormal except for the CPU benchmark. The modal marginal willingness to pay is between \$1 and \$2 per megabyte of RAM and about 1.25 cents per megabyte of hard drive. The data are informative even about the taste for SCSI, a dummy characteristic, because extreme values of one coefficient require extreme values of others to rationalize a choice. Tastes are strongly positively correlated (their Table 3). The correlation between the CPU and SCSI coefficients is 0.694, between RAM and hard drive 0.533, and between CPU and RAM 0.510. The taste for ξ correlates positively with every other taste, from 0.351 with hard drive to 0.477 with RAM. This arises even though ξ was assumed independent of x in the first stage.

Elasticities. Aggregating the taste draws gives demand curves and elasticities for every product. With all 695 products the median own-price elasticity ε_{jj} was about -100. Bajari and Benkard read this as a rejection of perfect information. With 695 products, neighbors are close in price and characteristics, so a fully informed consumer would switch at a tiny price change. Real consumers search and consider only a handful of products. They therefore re-estimated the model with only the 24 products that sold at least 5,000 units, a minimum share of 0.75 percent. These products account for 72 percent of sales. Own-price elasticities then range from -4 to -72, with a median of -11. They caution that the selection retained similar best-selling products, so these elasticities may still be too large in magnitude.

Table 6.14: The five best-selling computers in December 1999 and their estimated price elasticities

Panel A. Characteristics (Table 4)

Model	CPU (benchmark)	RAM	Hard drive	Price (\$)	Sales
HP Pavilion 6535	Intel Celeron 466 MHz (1281)	64 MB	8.4 GB	590	71,199
Compaq Presario 5441	AMD K6-2 475 MHz (1076)	64 MB	8.0 GB	540	54,449
Compaq Presario 5461	AMD K6-2 500 MHz (1115)	64 MB	10.0 GB	727	43,029
E-Machines eTower 433	Celeron 433 MHz (1167)	32 MB	4.3 GB	471	40,399
HP Pavilion 6545C	Celeron 500 MHz (1398)	64 MB	13.0 GB	858	34,198

Panel B. Matrix of price elasticities (Table 5)

	HP6535	Compaq5441	Compaq5461	E-Machines	HP6545C
HP6535	−4.14	0.12	0.00	0.43	0.28
Compaq5441	0.17	−5.95	2.98	0.73	0.55
Compaq5461	0.00	2.80	−8.00	0.85	0.11
E-Machines	0.61	0.69	0.91	−10.65	0.66
HP6545C	0.70	0.86	0.18	1.02	−4.46

Source: Bajari and Benkard (2005), Tables 4 and 5 (working-paper version). Table 4 of the paper prints the processor as "AMD A6-2". Panel A corrects it to the AMD K6-2 chip. Elasticities come from the model estimated on the 24 products selling at least 5,000 units. The paper does not state whether rows or columns index the product whose price changes.

Table 6.14 shows the five best sellers and their elasticity matrix. Two features stand out. The most similar products substitute most, as the two Compaq models do (2.98 and 2.80). Some cross elasticities are exactly zero: the HP6535 and the Compaq5461 do not substitute at all, presumably because other products lie between them in characteristic space. A model with an

i.i.d. shock cannot produce a zero cross elasticity, since every product keeps some buyers who rank it second.

Panel (a) of Figure 6.11 shows the estimated demand curve for the HP6535. It is steep at high prices, flat near the observed price and steep again at low prices. A small group of consumers strongly prefers this model, which explains the steep upper part. Near the observed price many consumers would switch to neighboring products for little compensation, which flattens the curve. At low prices the product already has a large share and few consumers remain to be won. Utility maximization forces the curve to slope down, but nothing else restricts its shape. Bajari and Benkard contrast it with the curves of standard discrete choice models, which approach both axes, and with those of multi-stage budgeting models, which are typically quadratic.

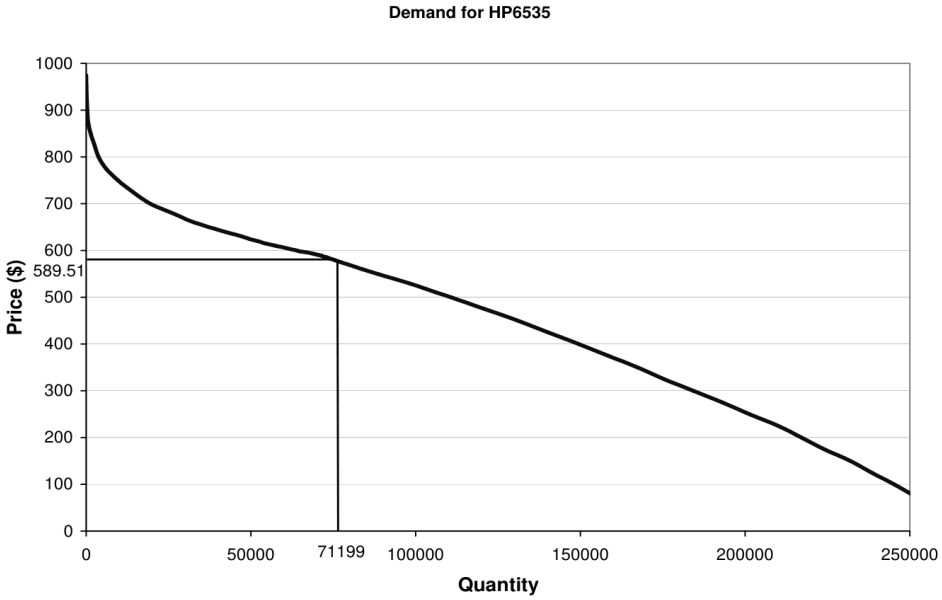
Panel (b) shows estimates from other months of the data. The distribution of the CPU taste shifts up sharply between August 1997 and December 1999. In the intermediate period it has markedly higher variance. Bajari and Benkard speculate that the shift reflects complementarity between computer hardware and the rapidly growing use of the internet (their p. 33). The estimates document the shift, but they do not test this explanation. The evidence suggests that the common assumption of a taste distribution that is constant over time would fail in this industry.

Assessment. The hedonic approach estimates the distribution of a twenty-dimensional taste vector nonparametrically. It allows demand curves of any downward-sloping shape and exact zeros in the matrix of cross elasticities. It identifies the unobserved characteristic from a single cross-section without instruments for price, because price is a function of (x, ξ) and ξ is recovered from the price distribution itself. Its costs are equally clear. The first stage needs many products per market and full independence of ξ from x, stronger than the mean independence that BLP-type estimators impose relative to their instruments. Ackerberg et al. (2007, p. 35) stress that the consistency of the first stage rests on asymptotics in the number of products. Products must eventually "fill up" the characteristic space, so that every product has others with observed characteristics arbitrarily close to its own. They add that experience is still too limited to know what "many" products means here. The unobservable is single and vertical. Consumers are assumed fully informed, which the elasticities with 695 products reject.

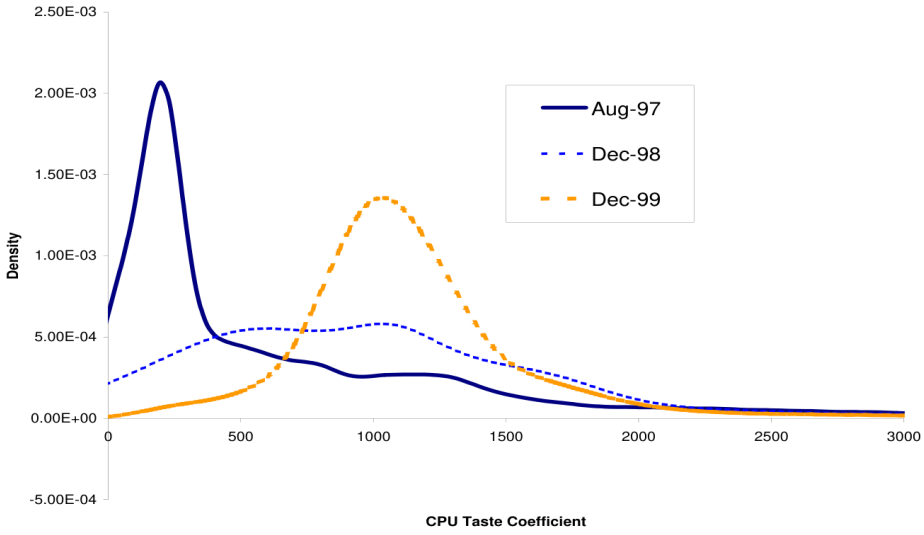
The comparison with Berry and Pakes (2007) is instructive. Both papers drop the idiosyncratic shock and keep one vertical unobservable. Berry and Pakes keep a parametric taste distribution, invert market shares for ξ and use instruments for price, following Berry et al. (1995). Bajari and Benkard recover ξ from prices and use revealed preference to recover a nonparametric taste distribution. In both, many close substitutes produce very large elasticities. This suggests that in models with tastes for products the shock ϵ_{ij} partly stands in for frictions such as limited information and search, which pure characteristics models must then model explicitly. The random coefficients logit of Chapter 8 remains the workhorse, and the models of this section and the last are the natural checks on what its shock assumes.

6.10 Bibliographic notes

Random utility models go back to the law of comparative judgment of Thurstone (1927), the ancestor of the probit. Luce (1959) stated the choice axiom, and Marschak (1960) connected probabilistic choice with utility maximization. McFadden (1974) turned the conditional logit into an econometric model of choice among discrete alternatives, and McFadden (1978)



(a) Estimated demand for the HP Pavilion 6535



(b) Estimated density of the taste for CPU

Figure 6.11: Panel (a) shows the estimated demand curve of the HP Pavilion 6535, with the observed price ($589.51) and quantity (71,199) marked. Panel (b) shows the estimated distribution of the CPU taste coefficient in August 1997, December 1998 and December 1999. Source: Bajari and Benkard (2005), Figures 6 and 7 (working-paper version).

introduced the generalized extreme value family. Williams (1977), Daly and Zachary (1978) and McFadden (1981) developed the social surplus function, and Small and Rosen (1981) derived the corresponding welfare measures. Yellott (1977) characterized the Gumbel distribution through Luce's axiom. McFadden (1984) surveys the econometrics of qualitative response models, including estimation from sampled subsets of alternatives. Hausman and McFadden (1984) develop the specification test of the independence of irrelevant alternatives. Train (2009) is the standard textbook treatment of discrete choice models and their estimation by simulation.

The characteristics approach to consumer demand is due to Lancaster (1966) and Gorman (1980). Address models start with Hotelling (1929) and Salop (1979), and d'Aspremont et al. (1979) corrected Hotelling's analysis of location. Vertical differentiation was developed for oligopoly by Gabszewicz and Thisse (1979) and Shaked and Sutton (1982, 1983), and for monopoly by Mussa and Rosen (1978). Tirole (1988, ch. 7) treats the linear and circular cities and, in a supplementary section, vertical differentiation at textbook level. Bresnahan credits the demand system that he estimates to Prescott and Visscher (1977). Anderson et al. (1992) synthesize discrete choice theory and the theory of product differentiation. Among other results, they derive the logit from a representative consumer (Anderson et al., 1988a) and relate it to address models (Anderson et al., 1989). Caplin and Nalebuff (1991) prove the existence of price equilibrium for a broad class of these models.

Bresnahan (1987) builds on his earlier work on market power in the automobile industry and on the identification of conduct (Bresnahan, 1981a, 1982). His survey (Bresnahan, 1989) places both the 1981 study and the time-series evidence on price wars in the wider literature on market power. The 1987 tests follow the non-nested approach of Cox (1961) and Pesaran and Deaton (1978). Vuong (1989) later proposed the model selection tests that much applied work uses, and Gasmi et al. (1992) applied non-nested tests to collusion in a soft-drink market. Feenstra and Levinsohn (1995) extended the oligopoly model to several dimensions of quality. Nevo (2001) compares the margins implied by alternative conduct hypotheses within a random coefficients demand system, and Berry and Haile (2014) study when market-level data can distinguish oligopoly models. The temporary breakdown of collusion that Bresnahan documents connects his work to the theories of collusion over the business cycle of Rotemberg and Saloner (1986) and Green and Porter (1984) (Chapter 12).

The pure characteristics model is the model of product differentiation that theorists use. Berry and Pakes (2007) made it estimable with market data, and Song (2007) applies it to the market for computer processors. Berry et al. (2004b) derive limit theory for both classes of models as the number of products grows. Ackerberg et al. (2007) survey the econometric tools behind these demand models and question the economic content of the idiosyncratic shock. Berry et al. (2013) generalize the invertibility arguments of Berry (1994) and Berry and Pakes (2007). The hedonic approach starts with Rosen (1974). Its identification problems were raised by Brown and Rosen (1982), Epple (1987) and Bartik (1987), and revisited by Ekeland et al. (2004). Bajari and Benkard (2005) adapt the approach to oligopolistic markets with an unobserved characteristic, and Pakes (2003) uses hedonic regressions to build price indexes for personal computers. The welfare value of new products depends heavily on the idiosyncratic shock. Trajtenberg (1989), Hausman (1997) and Petrin (2002) study it, and Chapter 10 treats their work.

6.11 Exercises

1. (Single crossing and the frontier.)

(a) In the specification $u_{ij} = \delta_j(y_i - p_j)$ of Gabszewicz and Thisse (1979), let $0 < \delta_0 < \delta_1 < \cdots < \delta_J$ and $0 = p_0 < p_1 < \cdots < p_J$, where $j = 0$ is the outside good. Show that $u_{ij} - u_{ik}$ is strictly monotone in income y_i for every $j \neq k$. Derive the income y_j at which a consumer is indifferent between $j-1$ and j.

(b) Suppose $y_1 < y_2 < \cdots < y_J$, and let incomes have a continuous CDF H. Show that consumers with incomes in (y_j, y_{j+1}) buy product j, with $y_{J+1} = \infty$, and write the market shares in terms of H.

(c) Return to Assumption 6.24. Suppose $\bar{v}_j \leq \bar{v}_{j+1}$ for some j. Show that product j sells nothing. Show also that once product j is deleted, the cutoff between $j-1$ and $j+1$ lies between $\bar{v}_j$ and $\bar{v}_{j+1}$.

(d) Prove that for a product on the frontier the general cutoffs (6.43) equal the adjacent cutoffs (6.41). This completes the argument sketched in Remark 6.28.

2. (Market size and recovered qualities.) Consider the exponential vertical model of Example 6.32 with $\lambda = 1$. Hold the observed quantities $q_1, \ldots, q_J$ fixed and vary the market size M, so that $s_j = \frac{q_j}{M}$.

(a) Show that

$$\frac{\partial \delta_j}{\partial M} = -\frac{1}{M} \sum_{m=1}^{j} (p_m - p_{m-1}) \frac{S_m}{1 - S_m},$$

and conclude that every recovered quality falls when M rises.

(b) Show that a larger M also shrinks every quality step $\delta_j - \delta_{j-1}$. What does a market with more nonbuyers reveal about the products?

(c) Recompute the cutoffs, the qualities and the single-product markups of Example 6.39 with the market size doubled, so that $s = (0.10, 0.075, 0.05)$. Compare the proportional change in qualities with the proportional change in markups. Use (6.60) to explain why markups depend much less on M than qualities do when shares are small.

3. (A lognormal taste distribution.) Let $\ln v_i \sim N(0, \sigma^2)$ in the vertical model, as in Remark 6.34.

(a) Show that the median of v_i equals one for every σ. Which normalization of Proposition 6.33 does this impose?

(b) Derive $\frac{\partial \delta_{jt}(\sigma)}{\partial \sigma}$. Show that a higher σ raises the quality step $\delta_{(m)t} - \delta_{(m-1)t}$ if and only if $S_{mt} > \frac{1}{2}$. Interpret the result in terms of where the cutoffs fall in the taste distribution.

(c) Show that for every σ the OLS coefficient $\hat{\beta}(\sigma)$ satisfies the K sample moments $\sum_{j,t} x_{jt}^{\top}\big(\delta_{jt}(\sigma) - x_{jt}\hat{\beta}(\sigma)\big) = 0$ exactly. Conclude that these moments cannot identify σ.

(d) Let z_{jt} be a cost shifter excluded from x_{jt}. Write the GMM objective function that identifies σ, and describe the variation in the data that pins it down. Explain why standard errors should be clustered by market.

4. (Close neighbors in Bresnahan's model.) Two products with qualities $0 < \delta_1 < \delta_2$ are sold to consumers whose taste for quality v is uniform on $[0, \bar{v}]$ with density κ. Utility is $v\delta_j - p_j$, and the outside good has $\delta_0 = p_0 = 0$. Marginal cost is $mc(\delta) = \psi\delta^2$ with $\psi(\delta_1 + \delta_2) < \bar{v}$. Write $h = \delta_2 - \delta_1$.

(a) Write the demand system, and show that both products sell at marginal-cost prices.

(b) Solve the Bertrand equilibrium with separate owners. Show that

$$m_1 = \frac{\delta_1 h(\bar{v} + \psi h)}{3\delta_1 + 4h}, \qquad m_2 = \frac{h(\delta_1 + h)\big(2\bar{v} - \psi(3\delta_1 + 2h)\big)}{3\delta_1 + 4h},$$

and verify that both markups are positive.

(c) Solve the equilibrium under joint ownership, and verify the formula of Proposition 6.48.

(d) Let $h \to 0$ with δ_1 fixed. Show that the Bertrand markups vanish at rate h, with $\frac{m_1}{h} \to \frac{\bar{v}}{3}$. Show that the markups under joint ownership converge to $\frac{1}{2}(\bar{v}\delta_1 - \psi\delta_1^2) > 0$. Relate both results to Proposition 6.50.

5. (Extreme value algebra.)

(a) Let ϵ be standard Gumbel. Show that $e^{-\epsilon}$ is exponential with mean one. The minimum of independent exponential variables with rates r_j is exponential with rate $\sum_j r_j$. Use this fact to give a second proof of Lemma 6.9.

(b) In the logit model of Proposition 6.11 with $\sigma_\epsilon = 1$, show that the consumers who choose j have expected shock $\mathbb{E}[\epsilon_{ij} \mid j \text{ chosen}] = \gamma_E - \ln P_{ij}$. Use (6.22).

(c) Use part (b) to explain why the buyers of a product with a small share have large shocks on average. What does this imply for the welfare loss that the logit attributes to the withdrawal of such a product?

(d) The fourth moment of the standard logistic distribution is $\frac{7\pi^4}{15}$. Verify that its excess kurtosis is 1.2, as stated in Section 6.3.1.

6. (Clones in three models.) Hold all prices fixed.

(a) In the logit with an outside good, show that adding n exact clones of product 1 raises expected consumer surplus by $\frac{1}{\alpha}\ln(1 + n s_1)$, where s_1 is the share of product 1 before entry. What happens as $n \to \infty$?

(b) Place product 1 and its n clones in one nest of a nested logit with nesting parameter σ, and every other product in a nest of its own. Use (6.29) and Theorem 6.18 to show that the gain is

$$\frac{1}{\alpha}\ln\Big(1 + \big[(n+1)^{1-\sigma} - 1\big]s_1\Big).$$

Find its limits as $\sigma \to 0$ and as $\sigma \to 1$.

(c) In the vertical model, show that a new product placed on the chord between two adjacent products adds no surplus. Show that a product whose quality exceeds the chord by $\eta > 0$ raises no consumer's utility by more than η, and find the types who buy it.

(d) Interpret parts (a) to (c) with Propositions 6.55 and 6.58. Which model would you trust to value a new brand of breakfast cereal, and which to value a new airline cabin class?

7. (Characteristics as instruments.)

(a) Explain why sums of rival characteristics are valid instruments for price in (6.1) only under (6.2). Give two economic mechanisms through which firms' choices of characteristics violate this condition.

(b) State a timing and information assumption under which characteristics are valid instruments. Explain why choosing characteristics before prices is not enough.

(c) Suppose the condition holds. Explain why sums of rival characteristics are inefficient instruments. Describe a two-step procedure that approximates the efficient instrument (6.3).

(d) Propose cost-shifter instruments for a differentiated-products market of your choice. Give one reason why they might fail.

8. (Wrong conduct and unstable primitives.) Use Tables 6.5 and 6.6.

(a) Under the collusive specification, list the parameters whose 1955 estimates differ most from their 1954 and 1956 values. Under the Bertrand specification, list the parameters whose 1954 and 1956 estimates differ most from their 1955 values.

(b) Suppose demand and cost primitives are stable across years. Explain why a misspecified conduct assumption should then show up as unstable estimates of the primitives.

(c) Design a test of parameter stability across years based on the maximum likelihood estimator of Section 6.6.5. State the null hypothesis and the test statistic. What would you conclude if stability is rejected under one conduct hypothesis but not under the other?

(d) Give one reason why the primitives might change across years even when conduct does not. Explain how it would affect the interpretation of your test.

Chapter 7

Logit, Nested Logit, and the Berry Inversion

Demand for differentiated products is an input to almost every question in this book. Markups, the price effects of mergers, the value of new goods and the incidence of taxes all depend on how consumers substitute among products. Product-space demand systems, such as the almost ideal demand system of Chapter 5, give every pair of products its own cross-price parameter. With J products they need on the order of J^2 elasticities, which few data sets can pin down. Characteristic-space models avoid this curse of dimensionality. They treat a product as a bundle of characteristics and let each consumer choose the bundle she likes best (Chapter 6). The number of parameters then grows with the number of characteristics, which is far smaller than the number of product pairs.

The logit is the simplest characteristic-space model and the workhorse of applied work. Its tractability rests on one analytic step. Market shares can be inverted in closed form to recover mean utilities, so the unobserved product characteristic enters a linear equation as an error term. Demand can then be estimated by instrumental variables from aggregate data on prices, quantities and characteristics. The estimation is cheap, so researchers run it as a first look at a data set before they try richer models.

The chapter develops two lessons. The first is that the inversion of Berry (1994) makes instrumental variables possible in discrete choice models. Prices must be instrumented, because firms set them knowing the unobserved quality of their products. The second lesson is that the independent taste shock of the logit restricts substitution. Consumers who leave a product spread over the other options in proportion to their market shares, own-price elasticities rise with price, and markups barely vary across products. These restrictions motivate the nested logit in this chapter and the random coefficients model of Chapter 8.

The chapter proceeds from theory to cases. Section 7.1 states the logit model, derives its shares, elasticities and diversion ratios, shows how independence of irrelevant alternatives restricts substitution, and estimates the model from individual choices. Section 7.2 presents the Berry inversion, proves that market shares can be inverted in a broad class of models, and discusses what the inversion requires of the data. Section 7.3 explains why prices are endogenous, which instruments the literature uses and what instrumenting does in practice. Section 7.4 adds Bertrand pricing. It recalls the logit markups, uniqueness and pass-through of Chapter 4, derives best responses, and uses the markups to recover costs and test conduct. Section 7.5 relaxes independence of irrelevant alternatives with generalized extreme value models and the nested logit, and derives nested-logit markups. Section 7.6 measures consumer

welfare with the log-sum formula and states its limits.

Three case studies follow the theory. Section 7.7 reads Berry (1994) in its own terms. Section 7.8 shows how Einav (2007) uses a nested logit without prices to separate seasonal demand for movies from the seasonality of releases. Section 7.9 studies Hendel (1999), who extends discrete choice to buyers of many units of several brands. Section 7.10 closes with the evidence against the restrictions of the logit and sets up the random coefficients model.

The chapter builds on Chapter 6 for random utility, the outside good, the type-I extreme value algebra and the vertical model, and on Chapter 4 for multi-product Bertrand pricing. Its results feed Chapters 8 to 11. Sections A.3 and A.5 collect the instrumental variables and generalized method of moments theory we use, and Appendix C works through longer logit problems.

7.1 The logit model of demand

The logit is the simplest discrete choice model that delivers market demand for many differentiated products from a handful of parameters. This section states its assumptions and derives its shares, elasticities and diversion ratios. It then shows how the independence of the taste shocks restricts substitution. It closes with estimation from individual choices, the setting in which McFadden (1974) introduced the model.

7.1.1 Setup and assumptions

We observe markets $t = 1, \dots, T$. A market is a time period, a geographic area, or both. Market t offers the inside products $j \in \mathcal{J}_t = \{1, \dots, J_t\}$ and an *outside good* $j = 0$, which stands for buying none of the inside products. A measure M_t of consumers, the *market size*, chooses among these $J_t + 1$ options. We interpret M_t as the number of potential buyers. It is rarely observed, so the researcher must choose it, and Section 7.2.5 studies the consequences of that choice. Product j in market t has observed characteristics x_{jt} (a $1 \times K$ row vector), a price p_{jt}, and an *unobserved product characteristic* ξ_{jt}.

Assumption 7.1 (Logit demand)**.**

(i) Each consumer i in market t buys one unit of exactly one option $j \in \{0\} \cup \mathcal{J}_t$, the option that gives her the highest utility.

(ii) Utility is $u_{ijt} = \delta_{jt} + \epsilon_{ijt}$ for $j \in \mathcal{J}_t$ and $u_{i0t} = \epsilon_{i0t}$ for the outside good.

(iii) The *mean utility* is $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, with $\alpha > 0$.

(iv) The shocks ϵ_{ijt} are independent across consumers, options and markets. Each has the type-I extreme value (Gumbel) distribution with CDF $F(\epsilon) = \exp(-e^{-\epsilon})$. The shocks are independent of (x_t, p_t, ξ_t).

(v) Consumers and firms observe ξ_{jt}. The econometrician does not.

Part (iii) contains a quasi-linear utility over income. Let consumer i have income y_i, utility $\alpha(y_i - p_{jt}) + x_{jt}\beta + \xi_{jt} + \epsilon_{ijt}$ from product j, and utility $\alpha y_i + \epsilon_{i0t}$ from the outside good. The term αy_i is common to all options, so it drops out of every comparison, and the model reduces to parts (ii) and (iii). The coefficient α is the marginal utility of income. It converts utils into dollars. Quasi-linearity rules out income effects, a restriction we revisit in Section 7.1.4. Part

(i) rules out the purchase of several units or several products, which Hendel (1999) relaxes (Section 7.9).

The unobserved characteristic ξ_{jt} collects everything about product j that consumers value and the econometrician does not measure. Berry (1994, p. 243) mentions style, perceived quality, durability, status and service at the point of sale. The term plays three roles. It is the demand shock of the model, the analogue of the error in a homogeneous-goods demand curve. It lets the model fit the observed shares exactly, as Section 7.2 shows. Finally, firms observe ξ_{jt} when they set prices, so prices respond to it, which makes them endogenous (Section 7.3).

The shock ϵ_{ijt} admits several readings. It may capture characteristics of the consumer or of the product that the econometrician does not observe. It may reflect measurement error or approximation error in the utility function. It may also represent psychological biases or mistakes. McFadden (1984, p. 1412) contrasts factors known to the decision maker but not to the observer with a random element in the decision protocol itself. He notes that choice data cannot ordinarily distinguish the two. The distinction matters for welfare. If ϵ_{ijt} measures taste, the expected maximum utility counts it as a benefit. If it measures mistakes, the same formula counts errors as gains (Section 7.6.3).

We need ϵ_{ijt} for the same reason that a regression needs an error term. Without it, every consumer in a market ranks the products by δ_{jt} alone and buys the product with the highest mean utility. Such a deterministic model predicts that one product takes the whole market, which no data set shows. The shock spreads consumers over all options and makes every predicted share interior.

Two normalizations are needed because choices reveal only the ranking of utilities. Adding a constant to every utility leaves choices unchanged, so we set the mean utility of the outside good to zero. This is the location normalization. Multiplying every utility by a positive number also leaves choices unchanged, so we fix the variance of ϵ_{ijt} at $\frac{\pi^2}{6}$, the variance of the standard Gumbel. This is the scale normalization. The coefficients β and α are therefore measured in units of the scale of the taste shock. Ratios such as $\frac{\beta_k}{\alpha}$, the dollar value of characteristic k, do not depend on the normalization. Chapter 6 develops both normalizations (Proposition 6.4) and the role of the outside good (Section 6.2.2). The outside good does more than fix the location. Without it, demand depends only on differences in prices, so a general increase in inside prices cannot reduce aggregate output (Berry, 1994, p. 247). Berry (1994) cites Morrison and Winston (1986) as an example of a model with this unfortunate feature.

7.1.2 Choice probabilities and market shares

Proposition 7.2 (Logit shares)**.** *Under Assumption 7.1, the probability that a consumer in market t chooses option j, and hence the market share of j, is*

$$s_{jt} = \frac{e^{\delta_{jt}}}{1 + \sum_{k \in \mathcal{J}_t} e^{\delta_{kt}}} \quad (j \in \mathcal{J}_t), \qquad s_{0t} = \frac{1}{1 + \sum_{k \in \mathcal{J}_t} e^{\delta_{kt}}}. \tag{7.1}$$

The proposition restates Proposition 6.11 with $V_{ij} = \delta_{jt}$ for $j \in \mathcal{J}_t$, $V_{i0} = 0$ and $\sigma_\epsilon = 1$. Section 6.3.2 proves it twice, once by integrating over the Gumbel density and once from the max-stability of the Gumbel distribution (Lemma 6.9). We write $\Lambda_t = 1 + \sum_{k \in \mathcal{J}_t} e^{\delta_{kt}}$ for the common denominator, the *inclusive sum*, so that $s_{jt} = \frac{e^{\delta_{jt}}}{\Lambda_t}$ and $s_{0t} = \frac{1}{\Lambda_t}$. The "1" in the inclusive sum is $e^{\delta_{0t}}$ with the outside good's mean utility normalized to zero.

Remark 7.3 (What the extreme value assumption buys). The Gumbel distribution has one main virtue. It yields a closed form for the integral over the maximum of utilities. Its density

resembles a normal density skewed to the right. Choices depend only on differences of shocks, and the difference of two independent Gumbel variables has the logistic distribution, which looks like a normal with fatter tails. Logit and probit models with independent errors therefore fit data in similar ways. The substantive restrictions of the logit come from the independence and additivity of the shocks (Section 7.1.4). The Gumbel form adds tractability and little else.

Remark 7.4 (From probabilities to shares). Proposition 7.2 gives a choice probability. It equals the market share when the market has a continuum of consumers, so that the law of large numbers holds exactly. With M_t distinct consumers choosing independently, the observed share is an average of M_t Bernoulli draws and has variance $\frac{s_{jt}(1-s_{jt})}{M_t}$ (Berry, 1994, footnote 4). Berry (1994) treats the share equation as exact, which amounts to a continuum of consumers. Shares computed from samples of consumers contain sampling error, the subject of Section 7.2.5.

Remark 7.5 (A representative consumer). The same shares solve the problem of a representative consumer who allocates one unit of consumption across the options $j = 0, \dots, J$ to maximize $\sum_j \delta_j q_j - \sum_j q_j \ln q_j$, with $\delta_0 = 0$ (Anderson et al., 1988a, 1992). The entropy term expresses a taste for variety. Chapter 4 develops this foundation and compares the logit with the constant elasticity of substitution system.

7.1.3 Derivatives, elasticities and diversion

Every substitution pattern of the logit follows from the derivatives of (7.1). We drop the market index throughout this subsection.

Proposition 7.6 (Logit share derivatives). *Under Assumption 7.1, for $j, k \in \mathcal{J}$ with $k \neq j$,*

$$\frac{\partial s_j}{\partial \delta_j} = s_j(1 - s_j), \qquad \frac{\partial s_j}{\partial \delta_k} = -s_j s_k, \qquad \frac{\partial s_0}{\partial \delta_k} = -s_0 s_k. \tag{7.2}$$

Since $\frac{\partial \delta_j}{\partial p_j} = -\alpha$, the price derivatives are

$$\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j), \qquad \frac{\partial s_j}{\partial p_k} = \alpha s_j s_k, \qquad \frac{\partial s_0}{\partial p_k} = \alpha s_0 s_k. \tag{7.3}$$

Proof. Write $s_j = \frac{e^{\delta_j}}{\Lambda}$ with $\Lambda = 1 + \sum_l e^{\delta_l}$, and note that $\frac{\partial \Lambda}{\partial \delta_k} = e^{\delta_k}$. The quotient rule gives the own derivative:

$$\frac{\partial s_j}{\partial \delta_j} = \frac{e^{\delta_j}\Lambda - e^{\delta_j}e^{\delta_j}}{\Lambda^2} = \frac{e^{\delta_j}}{\Lambda} - \left(\frac{e^{\delta_j}}{\Lambda}\right)^2 = s_j(1 - s_j).$$

For $k \neq j$ the numerator of s_j does not depend on δ_k, so only the denominator moves:

$$\frac{\partial s_j}{\partial \delta_k} = -\frac{e^{\delta_j}e^{\delta_k}}{\Lambda^2} = -s_j s_k.$$

The same step applied to $s_0 = \frac{1}{\Lambda}$ gives $\frac{\partial s_0}{\partial \delta_k} = -\frac{e^{\delta_k}}{\Lambda^2} = -s_0 s_k$. The price derivatives follow from the chain rule, because p_k enters only δ_k, with coefficient $-\alpha$. □

Elasticities. Multiplying the price derivatives by $\frac{p_k}{s_j}$ gives the elasticities. Following the convention of this book, we report the own-price elasticity as a positive number:

$$\varepsilon_j = -\frac{\partial s_j}{\partial p_j}\frac{p_j}{s_j} = \alpha p_j(1 - s_j), \qquad \varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j} = \alpha p_k s_k, \qquad \varepsilon_{0k} = \frac{\partial s_0}{\partial p_k}\frac{p_k}{s_0} = \alpha p_k s_k. \tag{7.4}$$

Since $q_j = M s_j$ and M does not depend on prices, quantity elasticities equal share elasticities. The cross elasticity ε_{jk} does not depend on j. Arrange the elasticities in a matrix whose rows index the option whose demand responds and whose columns index the product whose price changes. Every off-diagonal entry of column k equals $\alpha p_k s_k$, and so does the entry of the outside good. A rise in p_k therefore raises the demand for every other option, inside or outside, by the same percentage. Some studies report *semi-elasticities*, the percentage change in a share per unit change in a price, $100\,\frac{\partial s_j}{\partial p_k}\frac{1}{s_j}$. In the logit these equal $-100\,\alpha(1-s_j)$ on the diagonal and $100\,\alpha s_k$ off it. Chapter 8 reads a table of semi-elasticities from Berry et al. (1995) in these units.

Diversion ratios. The *diversion ratio* D_{jk} is the fraction of the sales that product j loses after a small increase in its own price that goes to option k. By Proposition 7.6,

$$D_{jk} = -\frac{\frac{\partial s_k}{\partial p_j}}{\frac{\partial s_j}{\partial p_j}} = \frac{\alpha s_j s_k}{\alpha s_j (1 - s_j)} = \frac{s_k}{1 - s_j}, \qquad D_{j0} = \frac{\alpha s_j s_0}{\alpha s_j (1 - s_j)} = \frac{s_0}{1 - s_j}. \tag{7.5}$$

The ratios sum to one over the options other than j, because the shares of those options sum to $1 - s_j$. Consumers who leave j spread over the remaining options in proportion to their shares, whatever the similarity of those options to j. Diversion ratios measure how closely two products compete. They drive the upward pricing pressure of a merger, so (7.5) reappears in Chapter 11.

The category elasticity. Market definition asks how demand for a group of products responds when all of their prices rise together. Raise every inside price by the same amount Δ, so that every mean utility falls by $\alpha\Delta$. Let $E = \sum_{k \in \mathcal{J}} e^{\delta_k}$ denote the inside sum at $\Delta = 0$. The total inside share and its logarithm are

$$1 - s_0(\Delta) = \frac{e^{-\alpha\Delta} E}{1 + e^{-\alpha\Delta} E}, \qquad \ln\big(1 - s_0(\Delta)\big) = -\alpha\Delta + \ln E - \ln\big(1 + e^{-\alpha\Delta} E\big).$$

Differentiate with respect to Δ and evaluate at $\Delta = 0$:

$$\frac{\mathrm{d}\ln(1 - s_0)}{\mathrm{d}\Delta} = -\alpha + \alpha\,\frac{E}{1 + E} = -\alpha + \alpha(1 - s_0) = -\alpha s_0. \tag{7.6}$$

For a proportional increase $p_k \mapsto (1 + \lambda) p_k$ of every inside price, each mean utility moves at the rate $\frac{\partial \delta_k}{\partial \lambda} = -\alpha p_k$. Writing $\ln(1 - s_0) = \ln E - \ln \Lambda$ and differentiating at $\lambda = 0$,

$$\begin{aligned} \frac{\mathrm{d}\ln(1 - s_0)}{\mathrm{d}\lambda} &= \sum_k \frac{e^{\delta_k}}{E}(-\alpha p_k) - \sum_k \frac{e^{\delta_k}}{\Lambda}(-\alpha p_k) = -\alpha \sum_k p_k s_k \Big(\frac{1}{1 - s_0} - 1\Big) \\ &= -\alpha s_0 \sum_k \frac{s_k}{1 - s_0}\, p_k = -\alpha s_0\, \bar{p}, \end{aligned} \tag{7.7}$$

where $\bar{p}$ is the share-weighted average inside price. The category elasticity is proportional to the outside share. When few consumers choose the outside good, the inside products as a group face inelastic demand, even if each of them faces elastic demand. A hypothetical monopolist of all inside products would then raise prices, which is the logic of the hypothetical monopolist test in Chapter 11. Since s_0 depends on the assumed market size, so does the category elasticity (Section 7.2.5).

Example 7.7 (An illustrative logit market)**.** Consider one market with four inside products, $\alpha = 1$, mean utilities $\delta = (1.0, 0.5, 0.1, -0.5)$ and prices $p = (2.0, 2.5, 3.0, 4.0)$. The implied non-price utility $x_j\beta + \xi_j = \delta_j + \alpha p_j$ equals $(3.0, 3.0, 3.1, 3.5)$, so the expensive products are somewhat better. Table 7.1 reports the shares, the elasticity matrix and the diversion ratios, computed by `figures/ch07/src/logit_example.py`. Three features stand out. Own elasticities rise with price, from 1.23 for the cheapest product to 3.66 for the most expensive one. Each column of cross elasticities is constant and equals the outside-good entry, for example $\alpha p_1 s_1 = 2.0 \times 0.384 = 0.768$ in column 1. When any of products 2 to 4 raises its price, the largest share of its lost sales goes to product 1, the largest product. Product 1's own lost sales go mostly to product 2, the next largest. The category elasticities are $\alpha s_0 = 0.141$ per unit of common price increase and $\alpha s_0 \bar{p} = 0.356$ for a proportional increase. The category faces inelastic demand while every product faces elastic demand.

Table 7.1: Shares, price elasticities and diversion ratios in an illustrative logit market

Panel A. Price elasticities ε_{jk}

			Product k whose price changes			
Option j	p_j	s_j	1	2	3	4
1	2.0	0.384	−1.232	0.582	0.468	0.343
2	2.5	0.233	0.768	−1.918	0.468	0.343
3	3.0	0.156	0.768	0.582	−2.532	0.343
4	4.0	0.086	0.768	0.582	0.468	−3.657
0 (outside)		0.141	0.768	0.582	0.468	0.343

Panel B. Diversion ratios D_{jk}

	Option k receiving the diverted sales				
Product j	0	1	2	3	4
1	0.229		0.378	0.253	0.139
2	0.184	0.501		0.204	0.112
3	0.167	0.455	0.276		0.102
4	0.155	0.420	0.255	0.171	

Notes: $\alpha = 1$, $\delta = (1.0, 0.5, 0.1, -0.5)$. Panel A: entry (j, k) is $\frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, so own elasticities appear on the diagonal as negative numbers. Panel B: entry (j, k) is $D_{jk} = \frac{s_k}{1-s_j}$, and each row sums to one. Computed by `figures/ch07/src/logit_example.py`.

7.1.4 Independence of irrelevant alternatives

Definition 7.8 (IIA)**.** A system of choice probabilities $P(j \mid C)$, defined for every choice set C, satisfies *independence of irrelevant alternatives* (IIA) if, for all $j, k \in A \subseteq C$,

$$\frac{P(j \mid C)}{P(k \mid C)} = \frac{P(j \mid A)}{P(k \mid A)}.$$

The ratio must also not depend on the characteristics of the alternatives other than j and k.

Luce (1959) took IIA as an axiom of probabilistic choice. The logit satisfies it, since (7.1) gives

$$\frac{s_j}{s_k} = e^{\delta_j - \delta_k}, \tag{7.8}$$

which involves only j and k. Section 6.3.4 relates the axiom to the Gumbel distribution.

The red bus and the blue bus. Debreu (1960) objected to Luce's axiom with an example of two nearly identical alternatives. The standard version concerns commuting (Train, 2009, Section 3.3.2, p. 46). A commuter chooses between a car and a red bus with equal mean utilities v, so each has probability $\frac{1}{2}$. Now add a blue bus, identical to the red bus except for its color. The logit gives

$$P_{\text{car}} = P_{\text{red}} = P_{\text{blue}} = \frac{e^v}{3e^v} = \frac{1}{3}.$$

IIA requires $\frac{P_{\text{car}}}{P_{\text{red}}} = 1$ to survive the new option, so the blue bus draws riders from the car and from the red bus in equal proportions. Common sense says the blue bus draws riders only from the red bus, giving the probabilities $(\frac{1}{2}, \frac{1}{4}, \frac{1}{4})$. The logit also predicts that painting some buses blue raises the total bus share from $\frac{1}{2}$ to $\frac{2}{3}$. Section 7.5.3 shows how the nested logit repairs the example (Figure 7.6).

Implications for demand. IIA has three consequences for a demand system. The first is substitution in proportion to shares, through (7.5). Suppose the price of a BMW 7-series rises. The logit sends its buyers to a Mazda 323 and to a Lexus LS400 in proportion to their shares, so the small car, which sells more, gains more. Berry et al. (1995, p. 847) make the point with a Yugo and a Mercedes that have the same share. The two cars must then have the same cross-price derivative with respect to any third car. A rise in the BMW price therefore raises the demand for Yugos and for Mercedes equally. Nevo (2000a, p. 523) gives a cereal version. If Cap'n Crunch, a children's cereal, and Grape Nuts, a nutrition cereal, have similar shares, a rise in the price of Lucky Charms, another children's cereal, diverts equally to both.

The second consequence concerns own elasticities. With small shares, $\varepsilon_j = \alpha p_j(1 - s_j) \approx \alpha p_j$, so own elasticities rise almost in proportion to price (Figure 7.1). Expensive products face the most elastic demand. This runs against the intuition that buyers of expensive products are less sensitive to price. Under single-product Bertrand pricing the Lerner index equals $\frac{1}{\varepsilon_j}$, so cheaper products must carry higher percentage markups. Nevo (2000a, p. 522) notes that this requires cheaper brands to have lower marginal costs as a percentage of price, which need not hold.

The third consequence concerns markups. A single-product firm facing logit demand sets the dollar markup $p_j - mc_j = \frac{1}{\alpha(1-s_j)}$ (Section 7.4). Two products with the same share carry the same markup, whatever their characteristics. Berry et al. (1995, p. 847) illustrate with a Jaguar and a Yugo of equal share, which must have the same own-price derivative and hence the same markup.

The source of the restriction. A consumer buys product j either because δ_j is high or because her shock ϵ_{ij} is high. When p_j rises, the consumers who leave j are those whose shock ϵ_{ij} was just large enough to make j their choice. Their shocks for the other products are independent of ϵ_{ij}. Their second choices therefore follow the same distribution as the first choices of the population, which is the vector of market shares (Nevo, 2000a, p. 523). Berry (1994, p. 246) stresses that the restriction comes from the i.i.d. additive error. Whenever tastes vary only through such an error, the mean utilities δ_j determine shares and elasticities. Two products with the same shares then have the same cross elasticity with any third product, whatever the

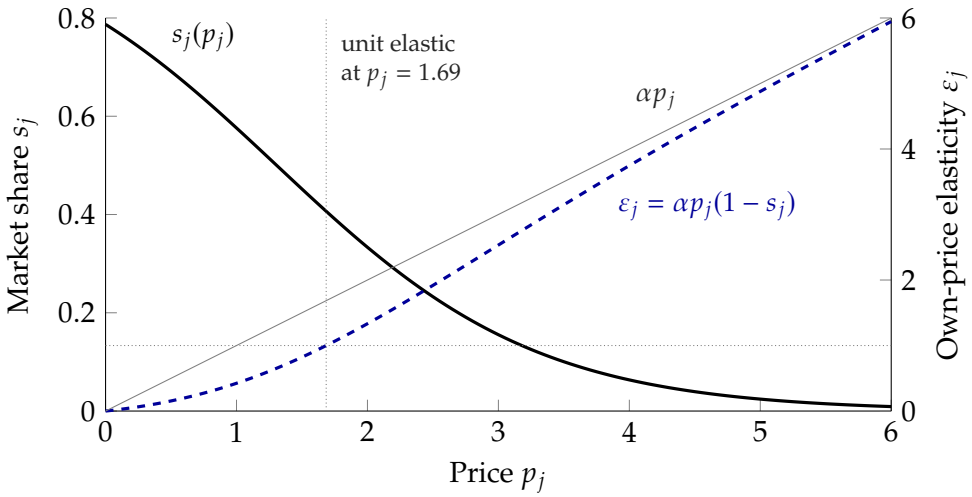


Figure 7.1: Logit demand and its own-price elasticity. The solid curve (left axis) is the share of one product, $s_j = \frac{e^{2-p_j}}{2+e^{2-p_j}}$, holding the other options fixed, with $\alpha = 1$. The dashed curve (right axis) is the own-price elasticity $\alpha p_j(1 - s_j)$, which approaches the line αp_j as the share falls. The dotted horizontal line marks an elasticity of one.

distribution of the error (Remark 7.33 gives the argument). An independent probit has the same problem, which led Hausman and Wise (1978) to allow correlated errors.

The cure is correlation of utility across similar products. The nested logit (Section 7.5) builds the correlation into the shock. Random coefficients (Chapter 8) generate it from heterogeneous tastes for characteristics. Both remedies add heterogeneity across consumers. A different distribution for an independent shock would leave the problem in place. McFadden (1984, pp. 1414–1415) adds a related point. IIA follows from letting the utility of j depend only on the attributes of j. If utilities may depend on the attributes of all alternatives, the logit form can approximate any continuous choice model (Remark 6.15). The restriction lies in the specification of utility, and the logistic function plays no part in it.

Other functional forms for price. The elasticity pattern also reflects the linearity of utility in price. Suppose utility depends on the logarithm of price, $\delta_j = x_j\beta - \alpha \ln p_j + \xi_j$. Then $\frac{\partial \delta_j}{\partial p_j} = -\frac{\alpha}{p_j}$ and

$$\frac{\partial s_j}{\partial p_j} = -\frac{\alpha}{p_j} s_j(1 - s_j), \qquad \varepsilon_j = \alpha(1 - s_j),$$

which is nearly constant across products (Nevo, 2000a, pp. 522–523). Björnerstedt and Verboven (2016) compare a unit-demand nested logit, linear in price, with a constant-expenditure version. In the latter, price enters in logarithms and a buyer spends a constant fraction of income on the chosen product (eq. (3), p. 139). For Swedish analgesics in December 2008, their nested logit models give average brand-level own elasticities of 2.43 under constant expenditure and 8.84 under unit demand (Table 6, p. 147). The difference has large consequences for predicted merger effects (Chapter 11). Asker and Nocke (2021, p. 231) list the paper among the ex-post evaluations of the accuracy of merger simulation. Either way, the functional form decides how own elasticities vary across products before any data are used.

Income effects require leaving the quasi-linear form. With $u_{ij} = \alpha \ln(y_i - p_j) + x_j\beta + \xi_j + \epsilon_{ij}$, income no longer cancels, and the marginal utility of money $\frac{\alpha}{y_i - p_j}$ varies across consumers.

Market shares become averages of logit probabilities over the income distribution of the market. This is a random coefficients model, and its shares must be simulated (Chapter 8).

Remark 7.9 (Adequacy depends on the use). Whether the logit is good enough cannot be judged in isolation. If a question does not hinge on the matrix of cross elasticities, the logit may serve well. Einav (2007) uses a nested logit without prices to separate seasonal swings in the demand for movies from seasonal swings in the number and quality of releases (Section 7.8). The same model would be a poor basis for merger simulation, which depends on the cross elasticities between close substitutes.

7.1.5 Logit with individual data: maximum likelihood

The logit began as a model of individual choice. McFadden (1974) introduced the *conditional logit*, in which choice probabilities depend on attributes of the alternatives, and studied its maximum likelihood estimator. Individual data let us interact product characteristics with consumer attributes, which relaxes IIA across consumer types.

The conditional logit with consumer attributes. Suppose we observe in each market t a sample $\mathcal{I}_t$ of consumers, their attributes D_i (an R-vector), and their choices $y_{ijt} \in \{0,1\}$. Let

$$u_{ijt} = \delta_{jt} + \sum_{k=1}^{K}\sum_{r=1}^{R} x_{jkt}\pi_{kr}D_{ir} + \epsilon_{ijt}, \qquad u_{i0t} = \epsilon_{i0t}, \tag{7.9}$$

with ϵ_{ijt} as in Assumption 7.1. The terms δ_{jt} are *alternative-specific constants*, one for each product and market. They absorb $x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$ in full. The coefficients π_{kr} let consumers with different attributes value characteristics differently. Collect the parameters in $\theta = (\delta, \pi)$. Write the deterministic utility as $V_{ijt} = w_{ijt}\theta$, where the row vector w_{ijt} contains a dummy for the pair (j,t) and the interactions $x_{jkt}D_{ir}$, and set $w_{i0t} = 0$. The choice probabilities and the log-likelihood are

$$P_{ijt}(\theta) = \frac{e^{w_{ijt}\theta}}{\sum_{k=0}^{J_t} e^{w_{ikt}\theta}}, \qquad \ell(\theta) = \sum_{t=1}^{T}\sum_{i\in\mathcal{I}_t}\sum_{j=0}^{J_t} y_{ijt}\ln P_{ijt}(\theta). \tag{7.10}$$

Proposition 7.10 (Global concavity)**.** *The log-likelihood in (7.10) is concave in θ. It is strictly concave if the matrix that stacks the rows w_{ijt}, over all sampled consumers i, all $j \in \mathcal{J}_t$ and all t, has full column rank. A stationary point of ℓ is then its unique global maximum.*

Proof. Fix a consumer i in market t and drop the index t. Since $\sum_j y_{ij} = 1$, her contribution to the log-likelihood is

$$\ell_i(\theta) = \sum_j y_{ij} w_{ij}\theta - \ln\sum_k e^{w_{ik}\theta}.$$

The first term is linear in θ. Differentiating once,

$$\frac{\partial \ell_i}{\partial \theta} = \sum_j y_{ij} w_{ij}^{\top} - \sum_k P_{ik} w_{ik}^{\top} = \sum_j (y_{ij} - P_{ij})\, w_{ij}^{\top}.$$

Let $\bar{w}_i = \sum_k P_{ik} w_{ik}$ be the probability-weighted mean of the rows. The probabilities satisfy $\frac{\partial P_{ik}}{\partial \theta^{\top}} = P_{ik}(w_{ik} - \bar{w}_i)$. Differentiating a second time,

$$\frac{\partial^2 \ell_i}{\partial \theta\, \partial \theta^{\top}} = -\sum_k P_{ik}\, w_{ik}^{\top}(w_{ik} - \bar{w}_i) = -\sum_k P_{ik}\,(w_{ik} - \bar{w}_i)^{\top}(w_{ik} - \bar{w}_i),$$

where the second equality subtracts $\bar{w}_i^\top \sum_k P_{ik}(w_{ik} - \bar{w}_i) = 0$. For any vector v,

$$v^\top \frac{\partial^2 \ell_i}{\partial\theta\,\partial\theta^\top} v = -\sum_k P_{ik}\left[(w_{ik} - \bar{w}_i)v\right]^2 \le 0.$$

The right side is minus the variance of $w_{ik}v$ when k is drawn with probabilities P_{ik}. Summing over consumers shows that the Hessian of ℓ is negative semidefinite at every θ, so ℓ is concave.

For strict concavity, suppose that $v^\top \nabla^2 \ell(\theta) v = 0$. Every P_{ik} is positive, so $(w_{ik} - \bar{w}_i)v = 0$ for all i and k. Then $w_{ik}v$ takes the same value for every option k of consumer i, and that value is $w_{i0}v = 0$. Hence $w_{ijt}v = 0$ for every row of the stacked matrix, and the rank condition gives $v = 0$. A strictly concave function has at most one maximizer, and any stationary point is that maximizer. □

McFadden (1974) established this property, and McFadden (1984, p. 1413) restates it: barring linear dependence of the explanatory variables, any stationary value is a global maximum. Equation (6.16) derives the same Hessian in the notation of Chapter 6. Concavity has practical value. Newton's method with a line search, such as step-halving, converges to the maximum from any starting value. The estimate therefore does not depend on where the search begins. Undamped Newton steps can still overshoot from poor starting values. A maximum can fail to exist when some combination of the regressors predicts the observed choices perfectly, as with separation in a binary logit.

Constants and shares. The first-order condition for the constant δ_{jt} reads

$$\frac{\partial \ell}{\partial \delta_{jt}} = \sum_{i \in \mathcal{I}_t} \left(y_{ijt} - P_{ijt}(\hat{\theta})\right) = 0, \tag{7.11}$$

so the average predicted probability of j equals its sample share $\hat{s}_{jt}$. Without interactions ($\pi = 0$), every consumer in market t has $P_{ijt} = \frac{e^{\delta_{jt}}}{1+\sum_k e^{\delta_{kt}}}$, and (7.11) gives $\hat{\delta}_{jt} = \ln \hat{s}_{jt} - \ln \hat{s}_{0t}$. The maximum likelihood estimates of the constants are the logit inversion of the sample shares, which Section 7.2.2 derives for market data.

Micro data do not remove the need for instruments. The constants absorb ξ_{jt}, so the likelihood in (7.10) has no endogeneity problem. The price coefficient, however, cannot be estimated from it. All consumers in a market face the same price, so p_{jt} is collinear with the dummy for (j, t). The coefficients β and α come from a second step that regresses the estimated constants on characteristics and prices,

$$\hat{\delta}_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt} + (\hat{\delta}_{jt} - \delta_{jt}). \tag{7.12}$$

This step compares products and markets. There p_{jt} is correlated with ξ_{jt} for the reasons given in Section 7.3, so the second step needs instruments, exactly as with market data (Berry, 1994, p. 259). Micro data reveal how tastes differ across consumers within a market, including interactions of price with income. The average response to price still requires exogenous variation in prices. Section 8.8.2 develops the two-step estimator with random coefficients, and Chapter 8 discusses Goldberg (1995) and Berry, Levinsohn, and Pakes (2004a).

Testing IIA. IIA has a testable implication. Let D be a subset of the full choice set C. If the logit is correct, the probability of choosing j given that the choice lies in D is the logit $\frac{e^{V_{ij}}}{\sum_{k\in D} e^{V_{ik}}}$, with the same parameters. We can therefore estimate the model on the consumers who chose an

alternative in D, treating D as their choice set. This gives a consistent but inefficient estimator $\hat{\beta}_D$ of the parameters that choices within D identify. The full-sample estimator $\hat{\beta}_C$ is consistent and efficient. If IIA fails, the two estimators generally converge to different limits. Following the principle of Hausman (1978), the variance of the difference under the null is the difference of the variances, $\hat{V}_D - \hat{V}_C$. The statistic

$$S = (\hat{\beta}_D - \hat{\beta}_C)^\top (\hat{V}_D - \hat{V}_C)^- (\hat{\beta}_D - \hat{\beta}_C), \tag{7.13}$$

where $^-$ denotes a generalized inverse when the difference of the variances is singular. The statistic is asymptotically chi-squared with degrees of freedom equal to the rank of $\hat{V}_D - \hat{V}_C$ (McFadden, 1984, pp. 1417–1418). Hausman and McFadden (1984) develop the test. McFadden cautions that it is an omnibus test, which may reject because of misspecifications other than IIA. He adds that it has little power unless the departures from the logit are substantial.

McFadden (1984, Section 3.11) applies the test to the housing status of 159 single elderly men in the Albany-Schenectady-Troy (New York) metropolitan area, from the 1977 U.S. Annual Housing Survey. The alternatives are to own (73 cases), to rent as a non-head of household (38 cases) and to rent as head (48 cases). Two variables measure prices: the out-of-pocket cost of each alternative (*OPCOST*) and the expected net return on equity in owned units (*RETURN*). Income enters through interactions with dummies for owning (*YOWN*) and for non-headship (*YNH*). Table 7.2 reproduces the logit estimates. Deleting the owner alternative gives $S_{\text{own}} = 22.4$. McFadden compares it with the chi-squared distribution with three degrees of freedom and rejects IIA at the 0.001 level. Deleting the renter-head alternative gives $S_{\text{head}} = 1.7$, which does not reject. He concludes that the logit should be rejected.

A nested logit that groups the two rental options confirms the verdict. Its *inclusive value coefficient* multiplies the logarithm of the summed exponentiated utilities of the two rental options, and the logit sets it to one. In the notation of Section 7.5 it equals $1 - \sigma$. McFadden first tests the logit against this tree with the Lagrange multiplier statistic of his equation (3.59), which needs only the logit estimates (pp. 1427–1428). It is asymptotically chi-squared with one degree of freedom, and its value of 15.73 rejects the logit at the 0.001 level (p. 1431).

Panel B of Table 7.2 reports the full maximum likelihood estimates of the nested logit (Table 3.3). The inclusive value coefficient is 0.179 (standard error 0.109), so $\sigma = 1 - 0.179 = 0.821$. *OPCOST*, *RETURN* and *YNH* keep their logit signs, while *YOWN*, insignificant in both models, turns positive. *OPCOST* and *YNH* remain significant, and *RETURN* is significant at the 10 percent level only. The Wald statistic for the restriction that the coefficient equals one is 56.77, which rejects at the 0.001 level. The likelihood ratio statistic is

$$LR = 2\left[-10.79 - (-15.91)\right] = 10.24,$$

which rejects at the 0.005 level but not at the 0.001 level. The three statistics satisfy $LR < LM < W$. McFadden reads their spread as a warning that first-order asymptotics may be inaccurate in a sample of 159 (p. 1431). Panel D shows what IIA imposes. In the logit, the elasticities of owning and of renting as head with respect to the cost of renting as non-head are both 1.06. The nested logit gives 5.15 for the close substitute and 0.54 for owning.

Sampling alternatives and choice-based samples. IIA also simplifies estimation. Under IIA, the model can be estimated on a random subset of the alternatives (McFadden, 1984, Section 3.6). This helps when the choice set is very large, such as the stock of dwellings in a housing market. When the sample is stratified on the chosen alternative, as in surveys of the buyers of particular products, the weighted estimator of Manski and Lerman (1977) restores consistency in any

Table 7.2: Logit and nested logit models of housing status in McFadden (1984)

Panel A. Logit estimates (Table 3.2)			
Variable	Estimate	Standard error	t-statistic

Nested logit	0.54	−7.48	5.15

Notes: 159 single elderly men, 1977 U.S. Annual Housing Survey, Albany-Schenectady-Troy. Alternatives: own (73), rent as non-head (38), rent as head (48). Costs and returns in thousands of 1977 dollars. Panel B: full maximum likelihood, with the units within each cluster treated as homogeneous. Its t-statistic for the inclusive value coefficient tests a value of zero. Panel C: S is the Hausman-McFadden statistic of (7.13), and LM, W and LR test the logit against the nested logit of Panel B. Panel D: elasticities at sample means. Source: McFadden (1984, Tables 3.2 to 3.4 and pp. 1430–1431).

choice model (McFadden, 1984, Section 4.4). The logit allows a simpler route. Selection rates that depend only on the chosen alternative enter its probabilities as shifts in the alternative-specific constants, so the conditional likelihood of the sample keeps the logit form (McFadden, 1984, eq. 4.15).

McFadden's survey in context. McFadden (1984) organizes the econometrics of discrete choice around the random utility model and maximum likelihood. He compares three families of functional forms, built on the work of Luce (logit), Thurstone (probit) and Tversky (elimination models). In his verdict the multinomial logit "scores well on simplicity and computation, but poorly on flexibility" (p. 1410). The generalized extreme value family of McFadden (1978) keeps closed forms while allowing similarity among alternatives (Sections 3.9 and 3.10), and Section 7.5 uses it. McFadden also finds the logit "relatively robust, as measured by goodness of fit or prediction accuracy, in many cases where the IIA property is theoretically implausible" (p. 1414). That robustness helps explain why the logit remains the first model that applied researchers estimate.

7.2 The Berry inversion

Industrial organization economists rarely observe individual choices. They usually observe prices, characteristics and quantities for many products in many markets. Berry (1994) showed how to estimate discrete choice demand from such data when an unobserved characteristic is correlated with price. This section explains the problem he solved, derives his inversion for the logit, proves that the inversion exists in a general class of models, and discusses the data it requires.

7.2.1 The estimation problem with aggregate data

Suppose we observe, for markets $t = 1, \dots, T$, the shares $s_{jt} = \frac{q_{jt}}{M_t}$, prices p_{jt}, characteristics x_{jt} and cost shifters w_{jt}. The model says that observed shares equal predicted shares,

$$s_{jt} = s_j(x_t, p_t, \xi_t; \theta), \qquad j \in \mathcal{J}_t, \tag{7.14}$$

where x_t, p_t and ξ_t stack the characteristics, prices and unobserved characteristics of all products in market t (Berry, 1994, eq. 10). Prices are correlated with ξ_t. With homogeneous goods, an additive demand error and instruments for price solve this problem. Here the error enters (7.14) nonlinearly, through every product's share, "thus frustrating the application of traditional instrumental variables methods" (Berry, 1994, p. 248). To see why, consider nonlinear least squares on $s_{jt} = s_j(x_t, p_t, 0; \theta) + e_{jt}$. The composite error $e_{jt} = s_j(x_t, p_t, \xi_t; \theta) - s_j(x_t, p_t, 0; \theta)$ is a nonlinear function of ξ_t and of the prices. Its mean given the instruments is generally not zero, even when $\mathbb{E}[\xi_{jt} \mid z_t] = 0$, because the conditional mean of a nonlinear function differs from the function of the conditional mean. No choice of instruments restores a valid moment condition at the true parameters.

Before 1994, applied work took one of three routes. The first worked in product space, with the constant-elasticity system $\ln q_j = a_j + \sum_k \varepsilon_{jk} \ln p_k + e_j$ (Berry, 1994, eq. 1). The error is additive, so instrumental variables apply. But J goods require J^2 elasticities, and the roughly 100 automobiles in Bresnahan (1987) imply almost 10,000 of them (Berry, 1994, p. 244) (Chapter 5). The second estimated discrete choice models while ignoring unobserved characteristics. Prices then absorb the effect of omitted quality. In Trajtenberg's (1989) study of CT scanners, price

sometimes appears to raise demand, an anomaly he attributes to unobserved quality (Berry, 1994, p. 243). The third, used by Bresnahan (1987), replaced unobserved characteristics with measurement error in prices and quantities (Chapter 6).

Berry (1994, Section 7) also explains why three tempting shortcuts fail. The first treats each ξ_j as a fixed effect to be estimated with β and α. Mean utility is $\delta_j = x_j\beta - \alpha p_j + \xi_j$, and any combination of $(\xi_1, \ldots, \xi_J, \beta, \alpha)$ that produces the same δ predicts the same choices. The vector ξ is therefore not identified separately from the coefficients on product-level variables. The logic is that of grouped data: a group mean cannot be estimated together with the coefficients of variables that do not vary within the group. With panel data, product fixed effects absorb only the time-invariant part of ξ_{jt} (Section 7.3.3).

The second shortcut integrates ξ out of the share function while holding prices fixed. Optimal prices respond to ξ, so the distribution of ξ_t conditional on p_t differs from its unconditional distribution Φ. Formally,

$$\mathbb{E}[s_{jt} \mid x_t, p_t] = \int s_j(x_t, p_t, \xi; \theta)\, \mathrm{d}\Phi(\xi \mid x_t, p_t) \neq \int s_j(x_t, p_t, \xi; \theta)\, \mathrm{d}\Phi(\xi),$$

and matching observed shares to the right side gives inconsistent estimates. Berry notes that the price-setting model is inconsistent with any assumption of an exogenous distribution of ξ conditional on x and p (Berry, 1994, p. 256).

The third shortcut solves for the reduced form. Suppose equilibrium is unique, so that prices $p(z, \xi, \omega, \theta)$ and quantities $q(z, \xi, \omega, \theta)$ are functions of the observed data z, the demand and cost unobservables (ξ, ω) and the parameters. Integrating over a distribution $\Phi(\cdot \mid z, \theta_u)$ of the unobservables gives expected prices and quantities,

$$\bar{p}(z, \theta, \theta_u) = \int p(z, \xi, \omega, \theta)\, \Phi\big(\mathrm{d}(\xi, \omega) \mid z, \theta_u\big),$$

$$\bar{q}(z, \theta, \theta_u) = \int q(z, \xi, \omega, \theta)\, \Phi\big(\mathrm{d}(\xi, \omega) \mid z, \theta_u\big),$$

and nonlinear least squares can fit $p = \bar{p} + v$ and $q = \bar{q} + e$ (Berry, 1994, eqs. 34 and 35). Bresnahan (1987) and Berry (1990) took this route. It has two problems. The integrals are over implicitly defined functions, which are costly to evaluate at every trial parameter. More seriously, they require a unique equilibrium for almost all values of the unobservables, and existence at particular values is not enough. Uniqueness is hard to establish in this class of models, although Caplin and Nalebuff (1991) prove it for the logit and the vertical model (Berry, 1994, p. 257). The reduced form has one advantage. It is linear in observed prices and quantities, so it tolerates measurement error in them.

The key idea of Berry (1994) is to write $\delta(s)$ instead of $s(\delta)$. Suppose the distribution of the consumer-specific terms is known, so that shares depend on the data only through the mean utilities, $s_t = s(\delta_t)$. If this system can be inverted at the observed shares, the structural error enters linearly:

$$\delta_{jt}(s_t) = x_{jt}\beta - \alpha p_{jt} + \xi_{jt} \tag{7.15}$$

(Berry, 1994, eq. 12). Standard instrumental variables then apply, with $\delta_{jt}(s_t)$ as the dependent variable and ξ_{jt} as the error. Berry stresses that the transformation of the data is unimportant. Apart from the computation, he writes, the approach "is little different than" regressions that use "some other transformation of the observed data (e.g., logarithms) as a dependent variable" (p. 249). Mean utilities play the role that quantities play in a homogeneous-goods demand regression. Demand estimation then requires neither a parametric distribution for ξ nor a model of how prices are set (p. 249).

7.2.2 The logit inversion

In the logit the inverse has a closed form. Divide the share of product j in (7.1) by the outside share. The inclusive sum cancels:

$$\frac{s_{jt}}{s_{0t}} = \frac{\frac{e^{\delta_{jt}}}{\Lambda_t}}{\frac{1}{\Lambda_t}} = e^{\delta_{jt}}, \qquad \Lambda_t = 1 + \sum_{k \in \mathcal{J}_t} e^{\delta_{kt}}.$$

Taking logarithms gives $\delta_{jt} = \ln s_{jt} - \ln s_{0t}$. Substituting the specification of mean utility yields the estimating equation

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \qquad s_{0t} = 1 - \sum_{j \in \mathcal{J}_t} s_{jt} \tag{7.16}$$

(Berry, 1994, eq. 14). Berry et al. (1995, eqs. 6.4 and 6.5) write the implied demand unobservable as $\xi_{jt} = \ln s_{jt} - \ln s_{0t} - x_{jt}\beta + \alpha p_{jt}$.

Equation (7.16) is a linear regression with a known dependent variable and a structural error. Prices are endogenous, so it is estimated by two-stage least squares or the linear generalized method of moments with instruments for price (Section 7.3). The linear form is the main reason the logit is used so much. Estimation is cheap, so the logit is a natural first look at any data set before richer models are tried. Three features of the equation deserve emphasis.

First, the inversion uses the observed shares, so the model fits them exactly. Every discrepancy between data and model is attributed to ξ_{jt} (Nevo, 2000a, p. 533). Second, the outside share requires the market size M_t, which Section 7.2.5 discusses. Third, each market is one observation of a system of J_t equations. With many independent markets, the errors may be correlated arbitrarily within a market (Berry, 1994, p. 250). With a single market, the demand parameters can still be estimated from many products if the ξ_j are independent across products. Prices are then still correlated across products through the first-order conditions, which raises issues of dependence (footnote 6).

7.2.3 Invertibility in general*

The logit is unusual in having an explicit inverse. For other models, we need to know that the system $s = s(\delta)$ has exactly one solution for every observed share vector. Berry (1994, Appendix) proves this for a broad class of models. Fix a market and drop its index. Let utility be $u_{ij} = \delta_j + \nu_{ij}$ for $j = 0, 1, \ldots, J$, where the vector $\nu_i = (\nu_{i0}, \ldots, \nu_{iJ})$ has a distribution that does not depend on δ. The logit is the case $\nu_{ij} = \epsilon_{ij}$. The random coefficients logit of Chapter 8 is the case $\nu_{ij} = \mu_{ij} + \epsilon_{ij}$. Shares are

$$s_j(\delta_0, \delta_1, \ldots, \delta_J) = \mathbb{P}\big(\delta_j + \nu_{ij} > \delta_k + \nu_{ik} \text{ for all } k \neq j\big), \tag{7.17}$$

viewed as functions of all $J+1$ mean utilities and evaluated at $\delta_0 = 0$. Let $H_j(\delta_j) = \mathbb{P}(\delta_j + \nu_{ij} > \nu_{i0})$ be the share that j would have if only j and the outside good were available.

Proposition 7.11 (Invertibility of market shares)**.** *Suppose that*

(a) The share functions are continuously differentiable in $(\delta_0, \ldots, \delta_J)$*.*

(b) The derivatives satisfy $\frac{\partial s_j}{\partial \delta_j} > 0$ *and* $\frac{\partial s_j}{\partial \delta_k} < 0$ *for every* $k \neq j$*, including* $k = 0$*.*

(c) Each H_j *is continuous and strictly increasing, with limits 0 and 1 as* $\delta_j \to -\infty$ *and* $\delta_j \to \infty$*.*

Let $s^{\text{obs}} = (s_1^{\text{obs}}, \dots, s_J^{\text{obs}})$ *satisfy* $s_j^{\text{obs}} > 0$ *for every* j *and* $s_0^{\text{obs}} = 1 - \sum_j s_j^{\text{obs}} > 0$. *Then exactly one* $\delta \in \mathbb{R}^J$ *satisfies* $s_j(0, \delta) = s_j^{\text{obs}}$ *for* $j = 1, \dots, J$.

A density of ν_i that is strictly positive and continuous on $\mathbb{R}^{J+1}$ is sufficient for the conditions (Berry, 1994, p. 260). Berry, Gandhi, and Haile (2013) give a general version, discussed after the proof.

Proof. We follow Berry (1994, pp. 260–261) and write $s_j(\delta)$ for $s_j(0, \delta)$.

Step 1: the element-by-element inverse. Fix j and the other inside mean utilities δ_{-j}. As δ_j rises from $-\infty$ to ∞, s_j rises strictly by (b), from 0 to 1, because the shocks are finite with probability one. So exactly one value $r_j(\delta_{-j})$ solves

$$s_j\big(\delta_1, \dots, \delta_{j-1}, r_j(\delta_{-j}), \delta_{j+1}, \dots, \delta_J\big) = s_j^{\text{obs}}. \tag{7.18}$$

By the implicit function theorem, r_j is continuously differentiable with

$$\frac{\partial r_j}{\partial \delta_k} = -\frac{\frac{\partial s_j}{\partial \delta_k}}{\frac{\partial s_j}{\partial \delta_j}} > 0, \qquad k \neq j,\ k \geq 1. \tag{7.19}$$

Let $r = (r_1, \dots, r_J)$ and treat r_j as a function of the whole vector δ that ignores δ_j. If $s(\delta) = s^{\text{obs}}$, then each δ_j solves (7.18), so $\delta_j = r_j(\delta)$. Conversely, $\delta = r(\delta)$ implies $s(\delta) = s^{\text{obs}}$. The inverse problem is therefore the fixed-point problem $\delta = r(\delta)$.

Step 2: a lower bound. Adding products can only lower the share of j, since the event that j beats every option is contained in the event that j beats the outside good. Hence $s_j(\delta) \leq H_j(\delta_j)$ for every δ. At $\delta_j = r_j(\delta)$ this gives $s_j^{\text{obs}} \leq H_j(r_j(\delta))$, so

$$r_j(\delta) \geq H_j^{-1}(s_j^{\text{obs}}) \geq \underline{\delta} \equiv \min_k H_k^{-1}(s_k^{\text{obs}}) \quad \text{for every } \delta.$$

Step 3: an upper bound (Berry's lemma). Let $\bar{\delta}_j = H_j^{-1}(1 - s_0^{\text{obs}})$, the mean utility at which j alone would leave the outside good with its observed share. Choose $\bar{\delta} > \max_j \bar{\delta}_j$. We claim that if $\delta_j \geq \bar{\delta}$ for some j, then $r_k(\delta) < \delta_k$ for some k. Indeed, the event that the outside good beats every option is contained in the event that it beats j, so

$$s_0(\delta) \leq 1 - H_j(\delta_j) < 1 - H_j(\bar{\delta}_j) = s_0^{\text{obs}},$$

where the strict inequality uses $\delta_j > \bar{\delta}_j$ and (c). The inside shares at δ therefore sum to more than $\sum_k s_k^{\text{obs}}$, so some product k has $s_k(\delta) > s_k^{\text{obs}}$. Since s_k rises strictly in δ_k, matching s_k^{obs} requires a lower value, that is, $r_k(\delta) < \delta_k$. Note also that $\bar{\delta} > \underline{\delta}$, because $1 - s_0^{\text{obs}} \geq s_j^{\text{obs}}$ implies $\bar{\delta}_j \geq H_j^{-1}(s_j^{\text{obs}})$.

Step 4: existence. Define the truncated map $\bar{r}_j(\delta) = \min\{r_j(\delta), \bar{\delta}\}$. By Steps 1 and 2, $\bar{r}$ is continuous and maps $\mathbb{R}^J$ into the box $B = [\underline{\delta}, \bar{\delta}]^J$. Brouwer's fixed-point theorem applied to $\bar{r}$ on the compact convex set B gives a point $\delta^* \in B$ with $\delta^* = \bar{r}(\delta^*)$. Suppose some component satisfies $\delta_j^* = \bar{\delta}$. By Step 3 there is a k with $r_k(\delta^*) < \delta_k^*$, and then $\bar{r}_k(\delta^*) \leq r_k(\delta^*) < \delta_k^*$, which contradicts $\delta^* = \bar{r}(\delta^*)$. Hence every $\delta_j^* < \bar{\delta}$. Then $\min\{r_j(\delta^*), \bar{\delta}\} = \delta_j^* < \bar{\delta}$ forces $r_j(\delta^*) = \delta_j^*$. So δ^* is a fixed point of r, and $s(\delta^*) = s^{\text{obs}}$.

Step 5: uniqueness. Adding the same constant to all of $(\delta_0, \delta_1, \dots, \delta_J)$ leaves every share unchanged. Differentiating $s_j(\delta_0 + c, \dots, \delta_J + c)$ with respect to c at $c = 0$ gives

$$\sum_{k=0}^{J} \frac{\partial s_j}{\partial \delta_k} = 0 \quad \Longrightarrow \quad \frac{\partial s_j}{\partial \delta_j} + \sum_{k \geq 1,\, k \neq j} \frac{\partial s_j}{\partial \delta_k} = -\frac{\partial s_j}{\partial \delta_0} > 0.$$

Divide by $\frac{\partial s_j}{\partial \delta_j} > 0$ and use (7.19):

$$\sum_{k \geq 1,\, k \neq j} \frac{\partial r_j}{\partial \delta_k} = 1 + \frac{\frac{\partial s_j}{\partial \delta_0}}{\frac{\partial s_j}{\partial \delta_j}} < 1. \tag{7.20}$$

This is the diagonal dominance condition $\sum_{k \geq 1, k \neq j} |\frac{\partial s_j}{\partial \delta_k}| < \frac{\partial s_j}{\partial \delta_j}$ of Berry (1994, eq. A2). Now suppose $\delta \neq \delta'$ are two fixed points of r, and let $\|\cdot\|$ denote the maximum norm. For each j, the mean value theorem applied to r_j on the segment between δ' and δ gives a point $\tilde{\delta}$ on that segment with

$$|\delta_j - \delta'_j| = |r_j(\delta) - r_j(\delta')| = \Big| \sum_{k \neq j} \frac{\partial r_j(\tilde{\delta})}{\partial \delta_k} (\delta_k - \delta'_k) \Big| \leq \Big(\sum_{k \neq j} \frac{\partial r_j(\tilde{\delta})}{\partial \delta_k} \Big) \|\delta - \delta'\| < \|\delta - \delta'\|.$$

Choosing j with $|\delta_j - \delta'_j| = \|\delta - \delta'\|$ yields $\|\delta - \delta'\| < \|\delta - \delta'\|$, a contradiction. The fixed point is unique. □

The logit satisfies the conditions. With a general δ_0, $s_j = \frac{e^{\delta_j}}{e^{\delta_0} + \sum_k e^{\delta_k}}$, so $\frac{\partial s_j}{\partial \delta_0} = -s_j s_0$. By Proposition 7.6,

$$\sum_{k \geq 1} \frac{\partial s_j}{\partial \delta_k} = s_j(1 - s_j) - s_j \sum_{k \geq 1,\, k \neq j} s_k = s_j \Big(1 - \sum_{k \geq 1} s_k \Big) = s_j s_0 = -\frac{\partial s_j}{\partial \delta_0},$$

and the row sum in (7.20) equals $\sum_{k \geq 1, k \neq j} \frac{s_k}{1 - s_j} = 1 - \frac{s_0}{1 - s_j} < 1$. Two-option shares are $H_j(\delta_j) = \frac{e^{\delta_j}}{1 + e^{\delta_j}}$, which satisfy (c).

Remark 7.12 (A diversion reading of uniqueness). In an additive random utility model the matrix $\frac{\partial s}{\partial \delta^\top}$ is symmetric, because it is the Hessian of the expected maximum utility (Theorem 6.7). Hence

$$\frac{\partial r_j}{\partial \delta_k} = -\frac{\frac{\partial s_j}{\partial \delta_k}}{\frac{\partial s_j}{\partial \delta_j}} = -\frac{\frac{\partial s_k}{\partial \delta_j}}{\frac{\partial s_j}{\partial \delta_j}},$$

which is the diversion ratio from j to k after a fall in δ_j. The row sum (7.20) is one minus the diversion ratio from j to the outside good. Uniqueness thus rests on every product losing some of its customers to the outside good. When price enters utility only through δ_j, as in the logit, these are the price diversion ratios of (7.5), and the row sum is $1 - D_{j0}$.

Three further remarks place the result. First, Berry's argument establishes existence through Brouwer's theorem, which gives no algorithm. Berry et al. (1995, Appendix I) show that the map $\delta \mapsto \delta + \ln s^{\text{obs}} - \ln s(\delta)$ is a contraction for the random coefficients logit, which

both proves invertibility and computes the inverse. Theorem 8.14 develops that route, and Remark 8.17 compares the two proofs. Second, the proposition requires every observed share to be positive. A product with zero observed sales has no finite mean utility, a problem taken up in Section 7.2.5. Third, the proof uses neither the logit form nor any property of the pricing equilibrium. Demand estimation based on the inversion therefore does not rely on a unique equilibrium, in contrast with the reduced-form approach (Berry, 1994, p. 243).

Berry, Gandhi, and Haile (2013) weaken condition (b) to *connected substitutes*. Let $s_j(\delta, p)$ denote the share function (Berry and Haile write σ_j). Goods $0, 1, \ldots, J$ are connected substitutes in δ if two conditions hold. First, each share s_k is nonincreasing in δ_j for every $j \geq 1$ and $k \neq j$. Second, for every nonempty set $\mathcal{K}$ of inside goods there are $k \in \mathcal{K}$ and $l \notin \mathcal{K}$ (possibly $l = 0$) such that s_l is strictly decreasing in δ_k (Berry and Haile, 2014, Definition 1, p. 1759). Under this condition, and an index restriction on how ξ_j enters, there is at most one δ that rationalizes any interior share vector (Berry and Haile, 2014, Lemma 1, p. 1760). The vertical model shows why the weaker condition matters. In it, $\frac{\partial s_j}{\partial \delta_k} = 0$ for products that are not neighbors in price, so condition (b) fails. Yet the chain of neighbors links every inside good to the outside good, the shares are connected substitutes, and the inverse exists in closed form (Proposition 6.31).

7.2.4 Other analytic inversions

A few other models share the logit's explicit inverse. In the nested logit with nesting parameter σ and within-nest share $s_{j|g}$,

$$\ln s_{jt} - \ln s_{0t} = \delta_{jt} + \sigma \ln s_{j|g,t} \tag{7.21}$$

(Berry, 1994, eq. 27). Proposition 7.26 derives it, and (7.69) is the resulting estimating equation. The within-nest share depends on ξ_{jt}, so it is a second endogenous regressor. In the vertical model with $u_{ij} = \delta_j - \nu_i p_j$ and products ordered by price, the inverse is recursive:

$$\delta_j = \delta_{j-1} + (p_j - p_{j-1})\, F^{-1}\Big(\sum_{k \geq j} s_k\Big), \qquad \delta_0 = p_0 = 0,$$

where F is the distribution of the price sensitivity ν_i (Proposition 6.31). Section 7.7 presents Berry's version of this recursion in terms of quality. The principles of differentiation generalized extreme value (GEV) model of Bresnahan et al. (1997) also inverts analytically (Nevo, 2000a, p. 532). For random coefficients there is no closed form, and the inverse must be computed numerically for every value of the nonlinear parameters (Chapter 8).

7.2.5 Data requirements: market size, sampling error and zeros

The inversion turns observed shares into mean utilities. It is therefore only as reliable as the shares, which depend on the definition of the market, on the sampling of consumers and on how zero sales are handled.

Market size. Shares require the number of potential buyers M_t, and the outside share $s_{0t} = 1 - \frac{\sum_j q_{jt}}{M_t}$ depends entirely on it. Berry (1994, p. 247) notes that M_t is either observed as the population of a market or parameterized as a function of market-level data and estimated, as in Berry (1990). Applications choose it in different ways. Berry et al. (1995, p. 869) use the number of U.S. households. Nevo (2001, p. 337) assumes a potential of one serving of cereal per capita per day. Einav (2007) divides weekly box-office revenue by the ticket price and the

U.S. population (Section 7.8). Miller and Weinberg (2017, p. 1774) set market size 50 percent above the maximum observed unit sales in each region.

Example 7.13 (Scaling the market size)**.** Suppose the researcher uses κM_t instead of the true M_t, with $\kappa > 1 - s_{0t}$ so that the outside share stays positive. Quantities are unchanged, so the new shares are

$$\tilde{s}_{jt} = \frac{q_{jt}}{\kappa M_t} = \frac{s_{jt}}{\kappa}, \qquad \tilde{s}_{0t} = 1 - \frac{1 - s_{0t}}{\kappa} = \frac{\kappa - (1 - s_{0t})}{\kappa}.$$

The new dependent variable of (7.16) is

$$\ln \tilde{s}_{jt} - \ln \tilde{s}_{0t} = \ln s_{jt} - \ln \kappa - \ln \left(\kappa - (1 - s_{0t})\right) + \ln \kappa = \ln s_{jt} - \ln \left(\kappa - (1 - s_{0t})\right),$$

so it changes by

$$\left(\ln \tilde{s}_{jt} - \ln \tilde{s}_{0t}\right) - \left(\ln s_{jt} - \ln s_{0t}\right) = -\ln \kappa - \ln \frac{\kappa - (1 - s_{0t})}{\kappa s_{0t}}. \tag{7.22}$$

The first term is a constant, which the intercept absorbs. The second term is common to all products in market t but varies across markets with s_{0t}. Two conclusions follow. With market fixed effects, the estimates of α and of the coefficients on characteristics that vary within markets are unaffected by κ. These estimates use only variation within markets, so they require several products per market whose prices and instruments differ. Without fixed effects, the second term becomes part of the error. For $\kappa > 1$ it rises with s_{0t}, which is high in markets with high prices, so it biases $\hat{\alpha}$ toward zero.

The script `figures/ch07/src/logit_market_size.py` illustrates. It simulates 400 markets with six single-product firms, logit demand with $\alpha = 1$, and Bertrand-Nash prices driven by a cost shifter with a market-level and a product-level component. The true outside share averages 0.273. Two-stage least squares with the cost shifter as instrument gives $\hat{\alpha} = 0.994$ at the true market size and 1.027 with market fixed effects. Doubling the market size ($\kappa = 2$) leaves the fixed-effects estimate at 1.027 and lowers the pooled estimate to 0.651. With $\kappa = 4$ the pooled estimate is 0.599. Even with fixed effects, the implied substitution patterns move. The mean diversion ratio to the outside good rises from 0.311 to 0.679 with $\kappa = 2$ and to 0.844 with $\kappa = 4$, because $D_{j0} = \frac{\tilde{s}_{0t}}{1 - \tilde{s}_{jt}}$ depends directly on the assumed outside share. The mean own elasticity changes less, from 1.91 to 2.05 with $\kappa = 2$.

The example shows what the data can and cannot say about market size. The split of substitution between inside products and the outside good, the category elasticity (7.6) and the welfare measures of Section 7.6 all depend on M_t through s_{0t}. The nested logit with all inside goods in one nest adds a parameter that governs substitution to the outside good. Section 7.5.4 describes how one merger application uses it to limit the influence of the assumed market size.

Sampling error. Shares often come from samples, such as scanner panels, ticket samples or surveys of buyers. Let $\hat{s}_{jt}$ be the share of product j among n_t sampled consumers, so that $\text{Var}(\hat{s}_{jt}) = \frac{s_{jt}(1 - s_{jt})}{n_t}$ (Equation (6.17)). A first-order expansion gives

$$\ln \hat{s}_{jt} - \ln s_{jt} \approx \frac{\hat{s}_{jt} - s_{jt}}{s_{jt}}, \qquad \text{Var}\left(\ln \hat{s}_{jt}\right) \approx \frac{1 - s_{jt}}{n_t s_{jt}}.$$

The inverted mean utility then equals $\delta_{jt} + \eta_{jt}$, where $\eta_{jt} = (\ln \hat{s}_{jt} - \ln s_{jt}) - (\ln \hat{s}_{0t} - \ln s_{0t})$. The extra error has two problems. Its variance is large for products with few sampled buyers

$n_t s_{jt}$. Its mean is not zero. A second-order expansion gives $\mathbb{E}[\ln \hat{s}_{jt}] \approx \ln s_{jt} - \frac{1-s_{jt}}{2n_t s_{jt}}$, a bias that depends on s_{jt} and hence on ξ_{jt} and p_{jt}. The error is then correlated with the instruments, and the estimator is inconsistent for fixed n_t. Consistency requires the number of sampled consumers to grow quickly relative to the number of products, because shares fall as products are added. Berry et al. (1995, p. 859) report that the asymptotic theory for their specification requires the consumer sample to grow on the order of J^3. Their consumer population is the roughly 100 million U.S. households, so the sampling variance is negligible in their application. Berry, Linton, and Pakes (2004b) develop limit theory for these estimators. Berry (1994, p. 259) warns that the nonlinear inversion "may be quite sensitive to measurement error in observed market shares."

Zero shares. In finite samples, products with small true shares often have zero recorded sales. Then $\ln \hat{s}_{jt}$ is undefined, and no finite mean utility rationalizes the observation, since the logit predicts a positive share for every product with finite δ_{jt}. Two common fixes are ad hoc. Dropping the zeros selects on the dependent variable. A product survives when ξ_{jt} is high enough, and expensive products need a higher ξ_{jt} to survive. Among the retained products, ξ_{jt} is then positively correlated with price, which biases $\hat{\alpha}$ toward zero. Adding a small number to every share avoids the logarithm of zero, but the estimates depend on the arbitrary number. Gandhi et al. (2023, pp. 381–383) impose a lower bound on expected sales. It yields upper and lower bounds on the conditional expectation of the inverted mean utility, which remain valid with zeros and, more generally, with sampling error in shares. The bounds become moment inequalities, from which they construct a point estimator of the demand parameters. It is consistent and asymptotically normal when markets have many consumers and an exogenous characteristic picks out observations whose choice probabilities are bounded away from zero (p. 383). The difficulty mirrors a feature of the logit discussed in Section 7.10. Each product brings its own taste shock, so the model gives every product a positive share and cannot accommodate products that nobody buys.

7.3 Price endogeneity and instruments

The Berry inversion turns logit demand into a linear equation. With market shares observed in markets $t = 1, \ldots, T$, Equation (7.16) reads

$$y_{jt} \equiv \ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}. \tag{7.23}$$

The left side is data. The right side contains the observed characteristics x_{jt}, the price p_{jt} and the unobserved product characteristic ξ_{jt}, which now plays the role of a regression error. Equation (7.23) looks like a textbook regression, and it is tempting to estimate it by ordinary least squares (OLS). This section explains why OLS fails, which instruments the literature uses instead, what each instrument assumes, and what instrumenting does in practice. It closes with a Monte Carlo experiment that replicates the one in Berry (1994).

7.3.1 Why prices are endogenous

Prices are chosen by firms, and firms know ξ_{jt}. The unobserved characteristic stands for everything that consumers value and the econometrician does not measure. Examples are the styling and perceived quality of a car, the reputation of a brand, the effect of past advertising, a favorable shelf position, or the quality of after-sales service. Each of these raises demand. A

firm that faces higher demand for its product sets a higher price. So the price and the error in (7.23) move together.

The logit model makes this link explicit. Suppose each firm sells one product, marginal cost mc_{jt} is constant, and firms set prices in a Nash equilibrium. Section 7.4 shows that the equilibrium price is

$$p_{jt} = mc_{jt} + m_{jt}, \qquad m_{jt} = \frac{1}{\alpha(1 - s_{jt})}, \tag{7.24}$$

where m_{jt} is the dollar markup (Proposition 7.16). The markup depends on ξ_{jt} through the share. To see the size of the effect, hold rivals' prices and the marginal cost fixed and raise ξ_j by $\mathrm{d}\xi$ (we drop the market index). The share changes because δ_j rises by $\mathrm{d}\xi$ and falls by $\alpha\,\mathrm{d}m_j$. With the derivatives of Proposition 7.6,

$$\mathrm{d}s_j = s_j(1 - s_j)\,(\mathrm{d}\xi - \alpha\,\mathrm{d}m_j).$$

Differentiating the markup in (7.24) gives $\mathrm{d}m_j = \frac{\mathrm{d}s_j}{\alpha(1-s_j)^2} = \alpha m_j^2\,\mathrm{d}s_j$. Substituting the first expression into the second,

$$\begin{aligned} \mathrm{d}m_j &= \alpha m_j^2 s_j(1 - s_j)\,(\mathrm{d}\xi - \alpha\,\mathrm{d}m_j) \\ &= m_j s_j\,(\mathrm{d}\xi - \alpha\,\mathrm{d}m_j), \end{aligned}$$

where the second line uses $\alpha m_j(1 - s_j) = 1$. Collecting the terms in $\mathrm{d}m_j$,

$$\mathrm{d}m_j\,(1 + \alpha m_j s_j) = m_j s_j\,\mathrm{d}\xi.$$

Since $1 + \alpha m_j s_j = 1 + \frac{s_j}{1-s_j} = \frac{1}{1-s_j}$, we obtain

$$\frac{\partial p_j}{\partial \xi_j} = \frac{\partial m_j}{\partial \xi_j} = m_j s_j(1 - s_j) = \frac{s_j}{\alpha} > 0. \tag{7.25}$$

A product with a higher unobserved quality therefore carries a higher price even when its cost does not depend on quality. If better quality is also more expensive to produce, so that mc_{jt} rises with ξ_{jt}, the cost channel adds to the markup channel. In both cases $\mathrm{Cov}(p_{jt}, \xi_{jt}) > 0$.

Nevo (2001, p. 320) writes the same argument in general form. Any Nash pricing rule gives $p_{jt} = mc_{jt} + f(\xi_{jt}, \dots)$. Decompose the marginal cost and the markup into a product mean and a market-specific deviation,

$$p_{jt} = (mc_j + f_j) + (\Delta mc_{jt} + \Delta f_{jt}). \tag{7.26}$$

Both components of the markup depend on the corresponding components of ξ_{jt}. The mean component is the persistent quality of a brand, and the deviation is a local or temporary demand shock that firms observe and react to. Fixed effects deal with the first (Section 7.3.3). Instruments must deal with the second.

The consequence for OLS is the familiar omitted-variable bias. The next proposition states it for (7.23) and also gives the bias in the taste coefficients, which is less often written down.

Proposition 7.14 (OLS bias in the logit regression)**.** *Let the observations (j, t) be such that sample second moments converge to their population counterparts. Suppose (7.23) holds with $\mathbb{E}[\xi_{jt}] = 0$ and*

$\mathbb{E}[x_{jt}^\top \xi_{jt}] = 0$, *where* x_{jt} *contains a constant. Let* $p_{jt} = x_{jt}\Gamma + \tilde{p}_{jt}$ *be the linear projection of price on* x_{jt}*, with residual* $\tilde{p}_{jt}$ *and* $\mathrm{Var}(\tilde{p}_{jt}) > 0$*. Define*

$$b = \frac{\mathrm{Cov}(p_{jt}, \xi_{jt})}{\mathrm{Var}(\tilde{p}_{jt})}.$$

Then the OLS estimates from the regression of y_{jt} *on* (x_{jt}, p_{jt}) *satisfy*

$$\operatorname{plim} \hat{\alpha}_{OLS} = \alpha - b, \qquad \operatorname{plim} \hat{\beta}_{OLS} = \beta - \Gamma b. \tag{7.27}$$

If $\mathrm{Cov}(p_{jt}, \xi_{jt}) > 0$*, then* $\hat{\alpha}_{OLS}$ *is biased toward zero, and it converges to a negative number (an upward-sloping demand curve) when* $\mathrm{Cov}(p_{jt}, \xi_{jt}) > \alpha \,\mathrm{Var}(\tilde{p}_{jt})$*.*

Proof. OLS converges to the coefficients of the linear projection of y_{jt} on (x_{jt}, p_{jt}). We compute that projection in three steps. First, substitute $p_{jt} = x_{jt}\Gamma + \tilde{p}_{jt}$ into (7.23):

$$y_{jt} = x_{jt}(\beta - \alpha\Gamma) - \alpha\tilde{p}_{jt} + \xi_{jt}.$$

Second, project ξ_{jt} on $(x_{jt}, \tilde{p}_{jt})$. By construction $\mathbb{E}[x_{jt}^\top \tilde{p}_{jt}] = 0$, so the two regressors are orthogonal and each coefficient is a simple regression coefficient. The coefficient on x_{jt} is zero because $\mathbb{E}[x_{jt}^\top \xi_{jt}] = 0$. The coefficient on $\tilde{p}_{jt}$ is

$$\frac{\mathbb{E}[\tilde{p}_{jt}\xi_{jt}]}{\mathbb{E}[\tilde{p}_{jt}^2]} = \frac{\mathbb{E}[p_{jt}\xi_{jt}] - \Gamma^\top \mathbb{E}[x_{jt}^\top \xi_{jt}]}{\mathrm{Var}(\tilde{p}_{jt})} = \frac{\mathrm{Cov}(p_{jt}, \xi_{jt})}{\mathrm{Var}(\tilde{p}_{jt})} = b,$$

where we used $\mathbb{E}[\tilde{p}_{jt}] = 0$ and $\mathbb{E}[\xi_{jt}] = 0$, which hold because x_{jt} contains a constant. Hence the projection of y_{jt} on $(x_{jt}, \tilde{p}_{jt})$ is $x_{jt}(\beta - \alpha\Gamma) + (b - \alpha)\tilde{p}_{jt}$. Third, substitute back $\tilde{p}_{jt} = p_{jt} - x_{jt}\Gamma$:

$$\begin{aligned} x_{jt}(\beta - \alpha\Gamma) + (b - \alpha)(p_{jt} - x_{jt}\Gamma) &= x_{jt}\big(\beta - \alpha\Gamma - (b - \alpha)\Gamma\big) + (b - \alpha)p_{jt} \\ &= x_{jt}(\beta - \Gamma b) - (\alpha - b)p_{jt}. \end{aligned}$$

The coefficient on p_{jt} is $-(\alpha - b)$, so $\operatorname{plim} \hat{\alpha}_{OLS} = \alpha - b$. The coefficient on x_{jt} is $\beta - \Gamma b$. The last two claims follow because $b > 0$ when the covariance is positive, and $\alpha - b < 0$ exactly when $\mathrm{Cov}(p_{jt}, \xi_{jt}) > \alpha \,\mathrm{Var}(\tilde{p}_{jt})$. □

OLS therefore makes demand look too inelastic. It also biases downward the coefficient of any characteristic that raises price ($\Gamma_k > 0$), because it attributes to price part of what the characteristic is worth. Section 7.3.6 confirms both predictions numerically.

The bias has a sharp economic signature. A profit-maximizing firm never prices on the inelastic part of its demand curve, since a small price increase would then raise revenue and lower cost. Formally, Proposition 7.17 below gives $p_j - mc_j = \frac{1}{\alpha(1 - S_f)}$ for a firm with combined share $S_f \geq s_j$. Since $mc_j > 0$,

$$1 > \frac{p_j - mc_j}{p_j} = \frac{1}{\alpha p_j (1 - S_f)} \geq \frac{1}{\alpha p_j (1 - s_j)} = \frac{1}{\varepsilon_j}, \tag{7.28}$$

so the own-price elasticity $\varepsilon_j = \alpha p_j (1 - s_j)$ (Section 7.1.3) exceeds one under any ownership structure. Counting the products with $\hat{\alpha} p_j (1 - s_j) < 1$ is a cheap specification check.

7.3.2 Instruments

The remedy is instrumental variables (IV). Let z_{jt} be a row vector of L instruments. It contains the K exogenous characteristics x_{jt} and $L - K$ excluded variables.

Assumption 7.15 (Instruments for the logit regression)**.**

(i) *Exogeneity.* The instruments satisfy $\mathbb{E}[\xi_{jt} \mid z_t] = 0$, where z_t collects the instruments of all products in market t. The weaker unconditional version is $\mathbb{E}[z_{jt}^\top \xi_{jt}] = 0$.

(ii) *Relevance (rank).* The $L \times (K+1)$ matrix $\mathbb{E}[z_{jt}^\top (x_{jt}, p_{jt})]$ has full column rank $K+1$. In particular, at least one excluded instrument must be correlated with p_{jt} after partialling out x_{jt}.

The conditional version of (i) is the assumption of Berry et al. (1995, eq. 4.1). It implies that any function of z_t is a valid instrument, so the practical question is which functions to use. Prices and quantities are excluded from z_t because the model determines them jointly with ξ. Characteristics and cost shifters are included because the model does not explain them, and that choice drives most of the debate below.

Three families of excluded instruments dominate the literature. We take them in turn and then discuss what fixed effects add.

Cost shifters. A *cost shifter* w_{jt} moves marginal cost and does not enter utility. Examples are input prices (the price of milk for yogurt), wages, exchange rates for imported goods, and taxes on producers. They are the traditional instruments in homogeneous-goods markets, and Berry (1994, p. 249) notes that they "continue to be appropriate" with differentiated products. Their validity rests on the independence of cost and demand shocks.

Cost shifters are scarce in practice. They must vary across products or markets in ways that fixed effects do not absorb, and an input price common to all products is collinear with time effects. Hausman et al. (1994, pp. 161, 164) observe that at the brand level "excluded cost shifting variables . . . may be difficult to find." A characteristic that enters cost but not utility also works. Berry et al. (1995, p. 874) put miles per gallon in cost and miles per dollar in utility, because the cost of building a fuel-efficient car does not depend on the price of gasoline. The ideal instrument, a product-specific cost shifter, is the hardest to find.

Characteristics of other products. Berry (1994, p. 249) pointed out a second source of exogenous price variation. In a model with exogenous characteristics, "the characteristics of other firms $(x_k, k \neq j)$ are also appropriate instruments." They are excluded from the utility of product j, and they are correlated with its price "via the markups in the first-order conditions." Berry calls this "a specific example of the general proposition that, in imperfectly competitive markets, demand-side instruments can be variables that affect markups as well as variables that affect marginal cost." A product that faces close substitutes has a low markup. A product in an empty region of the characteristic space has a high one.

Berry et al. (1995, Section 5.1), BLP hereafter, turned the idea into the *BLP instruments*. Their starting point is the efficient instrument under a conditional moment restriction (Chamberlain, 1987). Take the logit regression with parameters $\theta_1 = (\beta, \alpha)$, and suppose the errors are homoskedastic and uncorrelated across products. The efficient instrument for observation (j, t) is then

$$z_{jt}^* = \mathbb{E}\left[\frac{\partial \xi_{jt}(\theta_1)}{\partial \theta_1} \,\middle|\, z_t \right] = \big(-x_{jt},\ \mathbb{E}[p_{jt} \mid z_t] \big), \tag{7.29}$$

since $\xi_{jt}(\theta_1) = y_{jt} - x_{jt}\beta + \alpha p_{jt}$. The efficient instrument for price is the expected equilibrium price given all exogenous variables. Computing it requires solving the pricing game for many draws of the unobservables, integrating over them, and selecting among equilibria (Berry et al., 1995, p. 860). A series approximation in the characteristics of all J_t products would need a number of terms that grows with J_t. BLP avoid this with an exchangeability argument (Pakes, 1994). An equilibrium does not change when we reorder rival firms, a rival's products, or a firm's other products. The first-order basis functions for characteristic k of product j, owned by firm f, are then

$$x_{jkt}, \qquad z^{\text{own}}_{jkt} = \sum_{r \in \mathcal{J}_f, r \neq j} x_{rkt}, \qquad z^{\text{riv}}_{jkt} = \sum_{r \notin \mathcal{J}_f} x_{rkt}. \tag{7.30}$$

With the constant among the characteristics, the numbers of own and rival products are instruments too. The sums vary because they exclude product j, because firms own different sets of products, and because the product set changes over time. BLP found higher-order terms nearly collinear with the linear ones. They use 15 demand-side instruments (three terms for each of five demand characteristics) and 19 cost-side instruments (Berry et al., 1995, pp. 861–862).

The logit model shows why the sums are relevant. Under multi-product pricing every product of firm f carries the markup $\frac{1}{\alpha(1-S_f)}$ (Proposition 7.17). The firm's combined share $S_f = \frac{\sum_{k \in \mathcal{J}_f} e^{\delta_k}}{1+\sum_k e^{\delta_k}}$ falls when rival products become more attractive and rises when the firm adds products. So z^{riv} shifts the markup down and z^{own} shifts it up, holding the product's own characteristics fixed. In richer models the markup depends on the distance to the nearest competitors, which is why BLP separate own and rival sums.

The exogeneity of characteristics deserves scrutiny. It requires that characteristics be chosen without knowledge of ξ, or independently of it. Berry et al. (1995, p. 854) acknowledge that if a "true" model jointly determines observed and unobserved characteristics, their assumption "will only be correct if that model has very specific properties." A weaker alternative for panel data lets ξ and ω follow a first-order Markov process whose innovations are independent of a model's initial characteristics. BLP judged it "much more demanding of the data" (Berry et al., 1995, p. 855).

Is it enough that characteristics are predetermined, that is, chosen before prices? It is not. Predetermination concerns timing, while exogeneity concerns information. A manufacturer that knows its new model has attractive styling may also give it more horsepower, because horsepower pays more in a car that sells well. Then $\mathbb{E}[\xi_{jt} \mid x_t] \neq 0$ although x_t was fixed long before prices were set. Timing delivers exogeneity only if ξ_{jt} was unpredictable when x_t was chosen, which is the Markov assumption above. Nevo (2001, p. 320) remarks that treating characteristics as predetermined "is as reasonable (or unreasonable)" in his application "as it was in previous work."

Characteristic-based instruments are therefore often called inefficient and probably inconsistent. They are inefficient because the sums in (7.30) are a linear approximation to $\mathbb{E}[p_{jt} \mid z_t]$, which is a nonlinear function of all characteristics. Approximations to the efficient instrument evaluate the model's derivatives at a preliminary estimate, with the unobservables set to their mean of zero. In Monte Carlo studies of the random coefficients logit, Reynaert and Verboven (2014) find that such instruments reduce small-sample bias and are even more effective at improving precision and stability. The characteristic-based instruments are probably inconsistent because characteristics respond to demand. Most researchers recognize both

problems and use these instruments for lack of better ones.

A third problem appears in markets with many products. As the number of products grows, each logit share goes to zero, and the markup $\frac{1}{\alpha(1-s_j)}$ converges to the constant $\frac{1}{\alpha}$. The variation in prices that rival characteristics induce then vanishes, and the instruments become weak. Armstrong (2016) formalizes this point with asymptotics in the number of products per market. He considers single-product firms and logit demand, or random coefficients logit demand without a random coefficient on price. Markups then converge to $\frac{1}{\alpha}$ so fast that estimates based on BLP instruments are inconsistent. Cost shifters escape the problem because they move prices without moving markups. BLP instruments keep their power in other settings, for example with logit demand and a fixed number of asymmetric multi-product firms. Our Monte Carlo extension in Table 7.6 illustrates the point.

Differentiation instruments (Gandhi and Houde, 2019, Section 2.3) refine the BLP idea. Substitution depends on proximity in the characteristic space, so these instruments use the differences $d_{jrk} = x_{rkt} - x_{jkt}$ between product j and each other product r in the market. The *local* version counts rivals within a band, $\sum_r \mathbf{1}\{|d_{jrk}| < \kappa_k\}$, with κ_k a proximity threshold, for example the standard deviation of characteristic k across markets. The *quadratic* version is $\sum_r d_{jrk}^2$. Both share the exogeneity assumption of the BLP sums. Gandhi and Houde (2019, p. 7) take excluded instruments for price as given. They design differentiation instruments to identify the parameters that govern substitution in random coefficients demand (Chapter 8).

Prices in other markets (Hausman instruments). A third family uses panel data in which the same products are sold in many cities. Hausman et al. (1994, p. 164) model the log price of brand j in city n and period τ as

$$\ln p_{jn\tau} = \delta_j \ln c_{j\tau} + \alpha_{jn} + \omega_{jn\tau}. \tag{7.31}$$

Here $c_{j\tau}$ is a cost common to all cities, since the products are sold at a uniform national wholesale price. The term α_{jn} is a city-brand effect for transport costs or local wages, and $\omega_{jn\tau}$ is a local shock such as a promotion. (The symbols δ_j and α_{jn} are used only in this display.) Suppose the local shocks are independent across cities. After brand and city effects, the price of j in other cities then moves with the common cost and is uncorrelated with the local demand shock. With a market t defined as a city-period pair, the *Hausman instrument* is the average price of the same product in the set $\mathcal{N}_{-t}$ of other cities in the same period,

$$\bar{p}_{j,-t} = \frac{1}{|\mathcal{N}_{-t}|} \sum_{t' \in \mathcal{N}_{-t}} p_{jt'}. \tag{7.32}$$

Chapter 5 discusses its first use, and Hausman (1997) applies it to cereal. Nevo (2001, pp. 320–321) uses regional average prices of the brand in all twenty quarters, excluding the city being instrumented. He assumes that, "controlling for brand-specific means and demographics, city-specific valuations are independent across cities."

Hausman instruments fail when demand shocks are correlated across markets. A national advertising campaign raises demand, and hence prices, in every city. Nevo's example is the discovery that fiber reduces the risk of cancer. Promotions coordinated within a region break the assumption for nearby cities. Bresnahan (1997, p. 242) pressed this objection against Hausman's cereal study. With nationwide demand shocks, he argues, the own-price coefficients are "biased upward, toward zero," and the estimator "is like doing ordinary least squares" on a supply and demand system. His appendix derives the asymptotic bias (pp. 246–247). Its sign and size depend on the covariance matrix of the national component of the demand shock (p. 242). Hausman's assumption that this matrix is zero removes the bias. Nevo focuses on

established brands, absorbs aggregate shocks with time dummies, and compares the results with a second instrument set. It consists of proxies for city-level marginal cost: region dummies, city density and supermarket wages. Agreement between instruments with different threats is his main evidence. Hausman instruments also require the same product in many markets, so they are unavailable for national markets like automobiles.

Endogenous characteristics and the long run. Exogenous characteristics are also built into counterfactuals. A merger simulation or a tax analysis usually holds the set of products and their characteristics fixed, which makes it a short-run exercise. In the long run firms reposition their products. Sweeting (2010) finds that firms that buy competing music radio stations differentiate their playlists. Fan (2013) shows that ignoring the adjustment of newspaper characteristics "causes substantial differences in estimated effects of mergers" (Chapter 11). Once characteristics are choices, characteristic-based instruments lose their justification and fixed-characteristic counterfactuals lose their realism. Product-specific cost shifters solve only the first problem. Berry (1994, p. 259) already noted that a full solution requires "a reasonable model of the dynamic process that generates product characteristics."

7.3.3 Product and market fixed effects

Panel data allow a different treatment of the persistent part of ξ. Suppose the same products appear in many markets, and write $\xi_{jt} = \bar{\xi}_j + \Delta\xi_{jt}$. Including a product fixed effect d_j in (7.23) gives

$$y_{jt} = d_j + \lambda_t - \alpha p_{jt} + \Delta\xi_{jt}, \qquad d_j = x_j\beta + \bar{\xi}_j, \tag{7.33}$$

where λ_t is a market or time effect and x_j does not vary across markets. The product effect absorbs the persistent quality $x_j\beta + \bar{\xi}_j$, the main source of correlation between prices and ξ in cross sections. Nevo (2001, p. 322) adds that brand dummies improve the fit when observed characteristics are incomplete, and that the number of parameters grows with J, not J^2.

Fixed effects do not end the endogeneity problem. The remaining error $\Delta\xi_{jt}$ is the market-specific deviation in (7.26), and firms price on it. Identification of α now comes from price variation within a product across markets, which Hausman instruments and local cost shifters supply. BLP instruments do not if characteristics and choice sets are fixed. With brand dummies in the regression, Nevo's characteristic-based instrument matrix "will be essentially singular" (Nevo, 2001, p. 320). Brand dummies can instead serve as instruments, a nonparametric way to use all the information in fixed characteristics.

The taste parameters β are recovered in a second step. Let $\hat{d}$ be the $J \times 1$ vector of estimated product effects, V_d its covariance matrix, and X the $J \times K$ matrix of characteristics. From $d = X\beta + \bar{\xi}$ and the assumption $\mathbb{E}[\bar{\xi} \mid X] = 0$, the minimum-distance estimator of Chamberlain (1982) is

$$\hat{\beta} = (X^\top V_d^{-1} X)^{-1} X^\top V_d^{-1} \hat{d}, \qquad \hat{\bar{\xi}} = \hat{d} - X\hat{\beta} \tag{7.34}$$

(Nevo, 2001, pp. 322–323). Exogeneity of characteristics is still needed, but only for β, so it does not contaminate the price coefficient that drives elasticities and markups (Nevo, 2001, n. 19). The cost is that β rests on only J observations. Market effects λ_t absorb shocks common to all products in a market, which removes one threat to Hausman instruments.

7.3.4 Two-stage least squares, GMM and standard errors

Stack the $N = \sum_t J_t$ observations. Let y be the $N \times 1$ vector of y_{jt}, $X = [x, -p]$ the $N \times (K+1)$ matrix of regressors, $\theta_1 = (\beta^\top, \alpha)^\top$, and Z the $N \times L$ matrix of instruments with $L \geq K+1$. The

structural error is $\xi(\theta_1) = y - X\theta_1$, and the sample moments are

$$\bar{g}(\theta_1) = \frac{1}{N} Z^\top (y - X\theta_1).$$

The generalized method of moments (GMM) estimator with a positive definite $L \times L$ weighting matrix W minimizes $\bar{g}(\theta_1)^\top W \bar{g}(\theta_1)$. The objective is quadratic in θ_1. Its first-order condition is

$$-\frac{2}{N^2} X^\top Z W Z^\top (y - X\hat{\theta}_1) = 0,$$

and solving for $\hat{\theta}_1$ gives

$$\hat{\theta}_1 = (X^\top Z W Z^\top X)^{-1} X^\top Z W Z^\top y. \tag{7.35}$$

With $W = (Z^\top Z)^{-1}$, (7.35) is two-stage least squares (2SLS), $\hat{\theta}_1 = (\hat{X}^\top X)^{-1} \hat{X}^\top y$ with first-stage fitted values $\hat{X} = Z(Z^\top Z)^{-1} Z^\top X$. This weight is efficient when the errors are homoskedastic, which is why Nevo (2001, p. 319) notes that his GMM procedure "simplifies to two-stage least squares" in the logit. The two-step efficient estimator first computes 2SLS residuals $\hat{\xi}$, then sets $W = \hat{S}^{-1}$ with

$$\hat{S} = \frac{1}{N} \sum_{t=1}^{T} \Big(\sum_{j \in \mathcal{J}_t} z_{jt}^\top \hat{\xi}_{jt} \Big) \Big(\sum_{j \in \mathcal{J}_t} z_{jt}^\top \hat{\xi}_{jt} \Big)^\top, \tag{7.36}$$

and re-estimates. With $G = \mathbb{E}[z_{jt}^\top (x_{jt}, -p_{jt})]$ and S the probability limit of $\hat{S}$, the asymptotic variance of (7.35) is the sandwich

$$(G^\top W G)^{-1} G^\top W S W G (G^\top W G)^{-1},$$

which collapses to $(G^\top S^{-1} G)^{-1}$ with the efficient weight (Appendix A).

The summation in (7.36) clusters by market. This allows arbitrary correlation of ξ_{jt} among products in the same market, which Berry (1994, p. 250) emphasizes is permitted when many independent markets are observed. The right cluster depends on the dependence the researcher fears. With product fixed effects or Hausman instruments, the errors of the same product over time are likely correlated, and clustering by product is natural. Berry et al. (1995, p. 862) treat the sum of the moments of a car model over all its years as a single observation, which is clustering by model.

Three diagnostics accompany every IV logit. The first-stage F statistic for the excluded instruments measures their strength. The rule of thumb of Staiger and Stock (1997) flags F below 10 as weak (Stock and Yogo, 2005, p. 101). With one endogenous regressor, $\frac{1}{F}$ is their estimate of the bias of two-stage least squares relative to OLS (Staiger and Stock, 1997, p. 566). Stock and Yogo (2005, Tables 5.1–5.4) tabulate thresholds that depend on the estimator, the numbers of instruments and endogenous regressors, and the tolerated bias or size distortion. With one endogenous regressor, their test statistic is the first-stage F (p. 82). Hansen's J statistic, $N\, \bar{g}(\hat{\theta}_1)^\top \hat{S}^{-1} \bar{g}(\hat{\theta}_1)$, tests the overidentifying restrictions. It is asymptotically χ^2_{L-K-1} under the null that all instruments are valid (Hansen, 1982). Finally, the implied elasticities should exceed one, by (7.28). In very large samples the J test rejects almost any model, a point Nevo (2001, n. 23) makes about his own rejections.

7.3.5 Evidence: what instrumenting does

Two classic applications show the size of the endogeneity bias with field data.

Automobiles. Berry et al. (1995) use data on essentially all car models sold in the United States from 1971 to 1990. A model-year is an observation, which gives 2,217 observations on 997 distinct models. Prices are list prices of the base model in thousands of 1983 dollars, and market size is the number of households (Berry et al., 1995, p. 869). Before estimating their random coefficient model, they estimate the logit regression (7.23) with five characteristics: horsepower divided by weight, a dummy for standard air conditioning, miles per dollar, size, and a constant. Table 7.3 reproduces the OLS and IV columns of their Table III. The IV column uses the instruments of (7.30).

Table 7.3: Logit demand for automobiles: OLS and IV.

	OLS logit	IV logit
Constant	−10.068	−9.273
	(0.253)	(0.493)
Horsepower/weight	−0.121	1.965
	(0.277)	(0.909)
Air conditioning standard	−0.035	1.289
	(0.073)	(0.248)
Miles per dollar	0.263	0.052
	(0.043)	(0.086)
Size	2.341	2.355
	(0.125)	(0.247)
Price	−0.089	−0.216
	(0.004)	(0.123)
Number of inelastic demands	1,494	22
(at ±2 standard errors of the price coefficient)	(1,429–1,617)	(7–101)
R^2	0.387	n.a.
Observations	2,217	2,217

Notes: Source: Berry et al. (1995, Table III, p. 873), columns 1 and 2. Dependent variable $\ln s_{jt} - \ln s_{0t}$. Prices in thousands of 1983 dollars. Standard errors in parentheses. Continuous characteristics enter in levels. Column 3 of the original table, a regression of log price on cost characteristics under marginal cost pricing, is omitted.

Instrumenting changes the estimates in the direction Proposition 7.14 predicts. The price coefficient "more than doubles" in absolute value, from −0.089 to −0.216 (Berry et al., 1995, p. 873). The coefficients on horsepower per weight and air conditioning, negative under OLS, become positive and significant. These are the characteristics most likely to raise price, so their OLS coefficients absorb part of the price effect, as the bias term $-\Gamma b$ predicts. The specification check is decisive. Under OLS, 1,494 of the 2,217 models have inelastic demand, which is "inconsistent with profit maximizing price choices." Imprecision does not explain the count. At two standard errors on either side of the estimate, 1,429 to 1,617 demands remain inelastic (Berry et al., 1995, p. 872). Under IV only 22 demands are inelastic.

Berry et al. (1995, p. 874) read the OLS R^2 of 0.387 as implying that 61 percent of the variance in mean utility is due to unobserved characteristics. The regression supports a narrower statement: 61 percent of the variance of y_{jt} is unexplained by the OLS regressors. Price is correlated with ξ_{jt}, so the OLS residual is not ξ_{jt}. By the proof of Proposition 7.14, the population residual is $\xi_{jt} - b\tilde{p}_{jt}$, whose variance $\operatorname{Var}(\xi_{jt}) - b^2 \operatorname{Var}(\tilde{p}_{jt})$ is below $\operatorname{Var}(\xi_{jt})$ whenever $b \neq 0$. If the characteristics are uncorrelated with ξ_{jt}, as the IV estimator assumes, the ratio $\frac{\operatorname{Var}(\xi_{jt})}{\operatorname{Var}(y_{jt})}$ is therefore at least the population value of $1 - R^2$, which the sample puts at 0.61. Unobserved quality is large in this market.

Ready-to-eat cereal. Nevo (2001) uses scanner data from Information Resources, Inc. (IRI) on

the 25 brands of cereal with the highest national shares. The data cover up to 65 cities over the 20 quarters from 1988 to 1992. A market is a city-quarter, and the sample has 27,862 brand-city-quarter observations. Market size is one serving per capita per day, and price is per serving (Nevo, 2001, pp. 317, 337). Table 7.4 reproduces seven of the ten columns of his Table V.

Table 7.4: Logit demand for cereal: OLS and IV with different instruments.

	OLS		IV				
	(i)	(ii)	(iv)	(v)	(vi)	(ix)	(x)
Price	−4.96	−7.26	−8.17	−17.57	−17.12	−23.37	−23.07
	(0.10)	(0.16)	(0.11)	(0.50)	(0.49)	(0.47)	(1.17)

	(0.002)	(0.002)	(0.002)	(0.002)	(0.002)	(0.002)	(0.002)
Brand dummies	no	yes	no	yes	yes	yes	yes
Demographics	no	no	no	no	no	yes	no
City dummies	no	no	no	no	no	no	yes
Instruments			brand dummies	regional prices	cost proxies	prices, cost	prices, cost
Adjusted R^2 or overid. test	0.54	0.72	436.9	168.5	181.2	85.87	15.06
(95% quantile of χ^2)			(26.30)	(30.14)	(16.92)	(42.56)	(42.56)
First-stage R^2			0.889	0.908	0.908	0.913	0.952
First-stage F			5,119	124	288	144	180

Notes: Source: Nevo (2001, Table V, p. 324). Columns (iii), (vii) and (viii) are omitted. Dependent variable $\ln S_{jt} - \ln S_{0t}$, with 27,862 brand-city-quarter observations. Asymptotically robust standard errors in parentheses. All regressions include time dummies. Columns (i) and (iv) include product characteristics (calories from fat, sugar, fiber, a mushiness dummy and segment dummies) in place of brand dummies. Column (ix) includes log median income, log median age and median household size. The overidentification test is Hausman (1983)'s. "Regional prices" are average prices of the brand in other cities of the region in all twenty quarters. "Cost proxies" are region dummies, city density and supermarket wages.

The table tells a story in three steps. First, brand dummies matter. Moving from product characteristics (column i) to brand dummies (column ii) raises the price coefficient from −4.96 to −7.26, because the dummies absorb the persistent quality $x_j\beta + \bar{\xi}_j$. Using brand dummies as instruments instead of regressors (column iv) gives −8.17, close to column (ii), as Section 7.3.3 predicts. Even with brand dummies and demographics (column iii, not shown), OLS implies a mean own-price elasticity of 1.53 in absolute value (median 1.50, standard deviation 0.39). At that estimate 5.5 percent of the observations have inelastic demand (Nevo, 2001, p. 323).

Second, instrumenting for the market-specific deviation $\Delta\xi_{jt}$ raises the coefficient again. With regional prices as Hausman instruments (column v) the coefficient is −17.57, and every brand-city-quarter has elastic demand. In absolute value the mean elasticity is 3.38, the median 3.30, and the standard deviation 0.85 (Nevo, 2001, p. 325). With cost proxies (column vi) the coefficient is −17.12. Two instrument sets with different threats give nearly the same answer.

Third, the diagnostics are mixed. The first stages are strong, with F statistics between 124 and 5,119, but the overidentification test rejects in every column except the last. Adding demographics (columns vii to ix) lowers the test statistic and raises the price coefficient to about −23, which Nevo attributes to regional demand shocks correlated with demographics. Adding city dummies (column x) leaves the coefficient at −23.07, and the test no longer rejects (15.06 against 42.56).

A simulated market. The simulated market of Section 8.10.4 has ten yogurt-like products owned by four firms, 100 markets and random coefficient demand with mean price coefficient 3. There

the logit regression gives $\hat{\alpha} = 2.330$ by OLS and 2.641 by 2SLS. The first-stage F is 92.5, almost all of it from the price of milk. The six BLP-type instruments are jointly weak ($F = 2.32$). Characteristics are fixed by product, so these instruments vary only through the set of products offered. Each sum of sugar is nearly collinear with the corresponding count of products.

7.3.6 A Monte Carlo illustration: replicating Berry (1994)

Berry (1994, Section 8) closes with a Monte Carlo experiment that isolates the endogeneity bias. We replicate it with `figures/ch07/src/mc_logit_iv.py` (numpy, scipy and matplotlib, fixed seeds).

Design. Each sample has 500 independent duopoly markets of single-product firms. Utility and marginal cost are

$$\begin{aligned} u_{ij} &= \beta_0 + \beta_x x_j + \sigma_d \xi_j - \alpha p_j + \epsilon_{ij}, \qquad u_{i0} = \epsilon_{i0}, \\ mc_j &= \exp(\gamma_0 + \gamma_x x_j + \sigma_c \xi_j + \gamma_w w_j + \sigma_\omega \omega_j), \end{aligned} \tag{7.37}$$

where x_j, ξ_j, w_j and ω_j are independent standard normal and ϵ_{ij} is type-I extreme value. As in Berry, ξ_j is standardized and its effect on utility is $\sigma_d \xi_j$. It raises both utility and cost, while w_j shifts cost only. The parameters are $\beta_0 = 5$, $\beta_x = 2$, $\alpha = 1$, $\gamma_0 = 1$, $\gamma_x = 0.5$ and $\gamma_w = \sigma_\omega = \sigma_c = 0.25$ (Berry, 1994, p. 258). Two designs differ in σ_d. With $\sigma_d = 1$ the variance of $\beta_x x_j + \sigma_d \xi_j$ is $4 + 1 = 5$, and 80 percent of it comes from the observed x_j. With $\sigma_d = 3$ the variance is $4 + 9 = 13$, and $\frac{9}{13}$, almost 70 percent, comes from ξ_j.

Computation and estimators. We solve each market's Bertrand-Nash equilibrium by iterating the Lambert-W best responses (7.39) of Section 7.4.1. The largest violation of $m_j = \frac{1}{\alpha(1-s_j)}$ is below 1.5×10^{-13}. Shares are exact, and the outside share averages 0.31 ($\sigma_d = 1$) and 0.32 ($\sigma_d = 3$). As in Berry, we run OLS of $\ln s_j - \ln s_0$ on $(1, x_j, p_j)$ and 2SLS with two excluded instruments, the cost shifter w_j and the rival's characteristic x_{-j}.

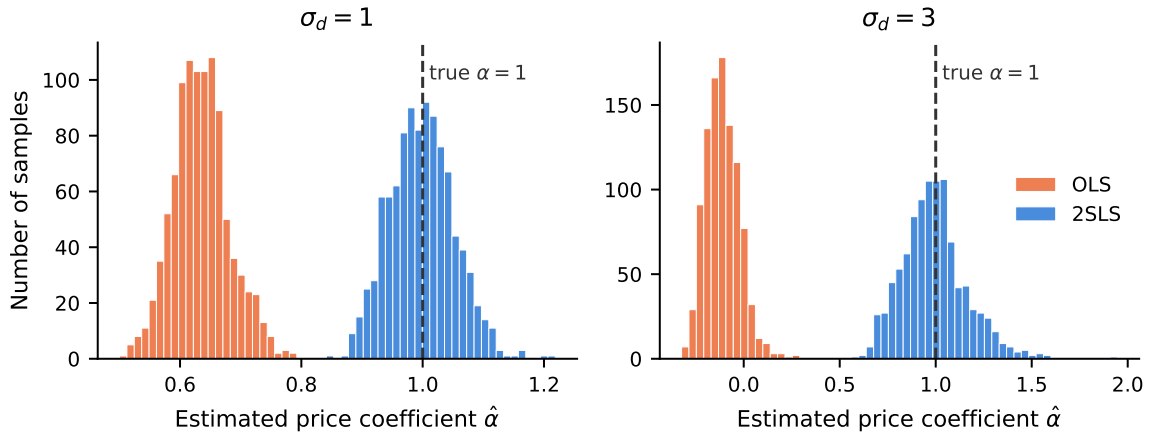

Figure 7.2: Sampling distributions of the estimated price coefficient $\hat{\alpha}$ in 1,000 samples of 500 duopoly markets, for the design of Berry (1994, Section 8). Left: $\sigma_d = 1$. Right: $\sigma_d = 3$. The dashed line marks the true value $\alpha = 1$. OLS means are 0.635 and −0.109, and 2SLS means are 0.999 and 0.992. Source: `figures/ch07/src/mc_logit_iv.py`.

Table 7.5: Monte Carlo estimates of the logit model: Berry (1994) and our replication.

		OLS		2SLS	
Parameter	True value	Berry (1994)	Replication	Berry (1994)	Replication

		(0.076)	(0.086)	(0.128)	(0.158)
Samples with $\hat{\alpha} < 0$		n.r.	90	n.r.	0
Products with inelastic demand (%)		n.r.	99.9	n.r.	0.06
Median first-stage F				n.r.	44.0

Notes: Each entry is the mean over 100 samples of 500 duopoly markets, with the standard deviation across samples in parentheses. Berry's columns are from Berry (1994, Table 1, p. 257), which reports "empirical means and (standard errors)." n.r. means not reported. Replication columns are produced by `figures/ch07/src/mc_logit_iv.py`. "Inelastic demand" means $\hat{\alpha} p_j (1 - s_j) < 1$, averaged over all products and samples. The excluded instruments are w_j and x_{-j}.

Results. Table 7.5 places Berry's numbers next to ours, and Figure 7.2 shows the sampling distributions of $\hat{\alpha}$. The qualitative findings replicate. OLS underestimates the price coefficient in every sample, while 2SLS is centered on the truth (means 1.010 and 1.002, against Berry's 0.995 and 0.979). The OLS bias is much larger when ξ explains more of mean utility. With $\sigma_d = 1$, OLS implies inelastic demand for 5.3 percent of products, and 99 of our 100 samples contain at least one such product. Berry notes that the OLS estimate then makes firms appear to price "on an inelastic portion of their demand curves." With $\sigma_d = 3$, he finds that OLS "sometimes" gives $\hat{\alpha} < 0$. In our replication this happens in 90 of 100 samples.

Our OLS bias is larger than Berry's (mean $\hat{\alpha}$ of 0.638 and -0.120, against 0.726 and 0.181). The 2SLS results agree closely, so the equilibrium computation and the estimators are unlikely sources of the gap. Berry does not report every detail, such as the treatment of markets with extreme shares or how his standard errors were computed. We report our numbers as they come out. The qualitative conclusions do not depend on the gap.

Proposition 7.14 accounts for the OLS numbers. In a large simulated sample with $\sigma_d = 1$ (20,000 markets), the projection of price on x_j has slope $\Gamma = 1.847$. With $\hat{\alpha}_{OLS} = 0.638$ the bias in the price coefficient is $b = 0.362$, and (7.27) predicts plim $\hat{\beta}_x = 2 - 1.847 \times 0.362 = 1.33$. The replication mean is 1.335. The bias grows with σ_d because the covariance between price and the error $\sigma_d \xi_j$ scales with σ_d twice. It scales once directly, and once through the markup, since by (7.25) each unit of ξ_j moves price by $\frac{\sigma_d s_j}{\alpha}$. The exogenous price variation from w_j and ω_j does not grow with σ_d.

The experiment also shows which instrument does the work. With $\sigma_d = 1$, the cost shifter alone gives a median first-stage F of 162. The rival's characteristic alone gives a median F of 1.0, and 2SLS with it alone has a standard deviation of 1.12 across samples. It is weak because x raises cost as well as utility. In the large sample a unit increase in x_j raises marginal cost by 1.69 and price by 1.85, so the net mean utility $\beta_0 + \beta_x x_j + \sigma_d \xi_j - \alpha p_j$ rises by only 0.15. A rival with a higher x is barely more attractive.

Table 7.6: Rival characteristics as the only instrument: duopoly versus many products.

J	T	Mean s_0	s.d. of markups	Median F	2SLS with z^{riv}		2SLS with w	OLS
					median $\hat{\alpha}$	IQR	median $\hat{\alpha}$	median $\hat{\alpha}$
2	500	0.280	0.898	40.9	1.008	[0.930, 1.082]	1.000	0.483

Notes: Design of (7.37) with $\sigma_d = 1$ and $\gamma_x = 0$, so that x does not enter marginal cost. Each sample has $N = 1{,}000$ products split into $T = \frac{1{,}000}{J}$ markets of J single-product firms, with 200 samples per row. The instrument z_j^{riv} is the sum of x over the other products in the market. IQR is the interquartile range across samples. The markup standard deviation is computed within each sample and averaged. Source: `figures/ch07/src/mc_logit_iv.py`.

Table 7.6 uses the same machinery to show the many-products problem of Armstrong (2016). We set $\gamma_x = 0$, so that a rival's characteristic shifts its appeal one for one, and vary the number of products per market J with 1,000 observations in total. In duopoly the rival characteristic is a strong instrument (median F of 40.9). As J grows, shares shrink, markups converge to $\frac{1}{\alpha} = 1$, and their standard deviation falls from 0.90 to 0.08. The first-stage F falls below 2 at $J = 10$, and the 2SLS estimate drifts toward OLS with exploding dispersion. The cost shifter is unaffected, with medians within 0.01 of the truth in every row.

7.4 The supply side: Bertrand pricing with logit demand

Combined with a model of pricing, demand estimates give markups and marginal costs and let us predict prices after a merger or a tax. With logit demand almost everything has a closed form: markups, best responses, the equilibrium aggregate, and pass-through. Chapter 4 proves these results for any ownership structure, and we restate them here with cross-references. We then use the markups to recover marginal costs, test conduct and simulate mergers. The closed forms make the logit a benchmark for numerical code, and they expose supply-side restrictions that mirror the logit's restrictions on substitution. Firms set prices simultaneously, marginal costs are constant, every firm knows all primitives (including every ξ_j), and the market has M consumers. We drop the market index t. The general theory is in Chapter 4 and Chapter 8.

7.4.1 Single-product firms

Firm j sells product j and earns $\pi_j = M(p_j - mc_j)s_j(\boldsymbol{p})$. Write $m_j = p_j - mc_j$ for its dollar markup.

Proposition 7.16 (Logit markups with single-product firms)**.** *Under logit demand, a single-product firm's best response to any vector of rival prices is characterized by its first-order condition (Proposition 4.24). By Proposition 4.7, in any Bertrand-Nash equilibrium*

$$p_j - mc_j = \frac{1}{\alpha(1 - s_j)}, \qquad \frac{p_j - mc_j}{p_j} = \frac{1}{\alpha p_j(1 - s_j)} = \frac{1}{\varepsilon_j}. \tag{7.38}$$

Markups exceed $\frac{1}{\alpha}$ and depend on product characteristics, prices and costs only through the product's own market share.

The markup is the single-product case of Proposition 4.7. With $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$ from Proposition 7.6, the derivative of profit factors as $Ms_j[1 - \alpha m_j(1 - s_j)]$. The bracket falls strictly once $m_j > 0$ and crosses zero exactly once, and Chapter 4 shows that the crossing is the global maximizer. Dividing the markup by p_j and using $\varepsilon_j = \alpha p_j(1 - s_j)$ gives the Lerner form.

Two products with the same share therefore have the same dollar markup, whatever their characteristics or costs. With small shares every markup is close to $\frac{1}{\alpha}$, so Lerner indices are roughly inversely proportional to price. This is the supply-side image of an own elasticity that rises almost proportionally with price (Section 7.1.4), and Section 7.10 contrasts it with random coefficient estimates.

The first-order condition is implicit, because s_j depends on p_j. It has a closed-form solution in terms of the *Lambert W function*, defined as the inverse of $u \mapsto ue^u$ on $[0, \infty)$, so that $W(z)e^{W(z)} = z$ for $z \geq 0$ (Corless et al., 1996). W is increasing, $W(0) = 0$, and $W'(z) = \frac{W(z)}{z(1+W(z))}$ for $z > 0$. Define

$$v_j = x_j\beta + \xi_j - \alpha\, mc_j, \qquad D_{-j} = 1 + \sum_{l \neq j} e^{\delta_l}.$$

The first is the mean utility product j would have if priced at marginal cost, so $\delta_j = v_j - \alpha m_j$. The second depends only on rivals' prices. Then $1 - s_j = \frac{D_{-j}}{D_{-j} + e^{\delta_j}}$, and the first-order condition

$\alpha m_j(1 - s_j) = 1$ becomes

$$\begin{aligned} \alpha m_j D_{-j} &= D_{-j} + e^{v_j - \alpha m_j} \\ (\alpha m_j - 1) D_{-j} &= e^{v_j - \alpha m_j} \\ (\alpha m_j - 1) e^{\alpha m_j - 1} &= \frac{e^{v_j - 1}}{D_{-j}}. \end{aligned}$$

The last line multiplies both sides by $\frac{e^{\alpha m_j - 1}}{D_{-j}}$. It has the form $ue^u = z$ with $u = \alpha m_j - 1$, so $u = W(z)$ and

$$BR_j(\boldsymbol{p}_{-j}) = mc_j + \frac{1}{\alpha}\Big[1 + W\Big(\frac{e^{v_j - 1}}{D_{-j}}\Big)\Big]. \tag{7.39}$$

This is (4.9) of Chapter 4, where D_{-j} is written Φ_{-j}. The best response lies between two bounds. As rival prices fall without limit, $D_{-j} \to \infty$ and the best response falls to $mc_j + \frac{1}{\alpha}$. As rival prices rise without limit, $D_{-j} \to 1$ and the best response rises to the monopoly price $mc_j + \frac{1}{\alpha}[1 + W(e^{v_j - 1})]$.

The slope of the best response follows from the chain rule. Since $\frac{\partial D_{-j}}{\partial p_l} = -\alpha e^{\delta_l}$ for $l \neq j$, the argument $z = \frac{e^{v_j - 1}}{D_{-j}}$ satisfies $\frac{\partial z}{\partial p_l} = \frac{\alpha z e^{\delta_l}}{D_{-j}}$, and

$$\frac{\partial BR_j}{\partial p_l} = \frac{1}{\alpha} W'(z) \frac{\partial z}{\partial p_l} = \frac{W(z)}{1 + W(z)} \frac{e^{\delta_l}}{D_{-j}}.$$

At the best response, $1 + W(z) = \alpha m_j = \frac{1}{1 - s_j}$, so $\frac{W(z)}{1 + W(z)} = s_j$. Also $\frac{e^{\delta_l}}{D_{-j}} = \frac{s_l}{1 - s_j}$. Hence

$$\frac{\partial BR_j}{\partial p_l} = \frac{s_j s_l}{1 - s_j} > 0, \qquad \sum_{l \neq j} \frac{\partial BR_j}{\partial p_l} = s_j \, \frac{1 - s_j - s_0}{1 - s_j} < s_j. \tag{7.40}$$

Prices are *strategic complements*: a rival's price increase raises the firm's best response. The response is less than one for one in total. The share at the best response is bounded by its monopoly value $\bar{s}_j = \frac{W(e^{v_j - 1})}{1 + W(e^{v_j - 1})} < 1$, because $z \leq e^{v_j - 1}$. The row sums of the Jacobian of the best-response map are therefore below $\max_j \bar{s}_j < 1$ at every price vector. Proposition 4.24 uses this bound to show that the map is a contraction, so the equilibrium is unique and best-response iteration converges to it from any starting point.

Figure 7.3 draws the two best responses of a symmetric duopoly. Each is increasing and flat, and they cross once. At the equilibrium the markup is $p^* - mc = 1.599$, which equals $\frac{1}{\alpha(1 - s_j)} = \frac{1}{0.625}$ up to rounding.

7.4.2 Multi-product firms

Now firm f owns the set $\mathcal{J}_f$ and maximizes $\pi_f = M \sum_{k \in \mathcal{J}_f} (p_k - mc_k) s_k(\boldsymbol{p})$. The first-order condition for $j \in \mathcal{J}_f$ is

$$s_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j} = 0. \tag{7.41}$$

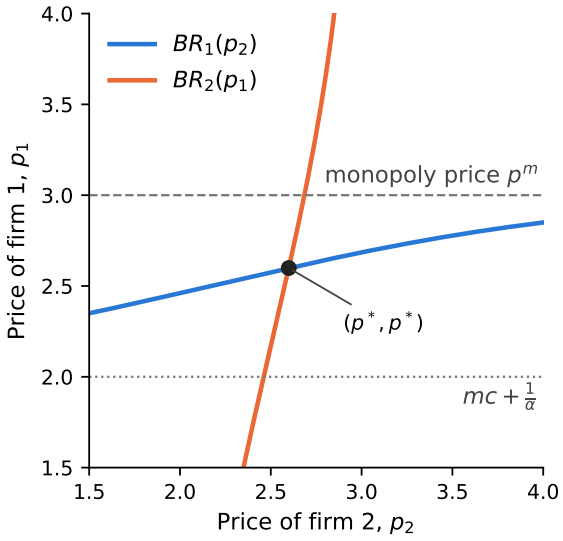

Figure 7.3: Best responses in a symmetric logit duopoly with an outside good, from (7.39). Both products have $x_j\beta + \xi_j = 3$ and $mc_j = 1$, and $\alpha = 1$. The horizontal lines bound BR_1: it approaches $mc + \frac{1}{\alpha} = 2$ as p_2 falls and the monopoly price $p^m = 3$ as p_2 rises. The unique equilibrium is $p^* = 2.599$ with shares $s_j = 0.375$, where the slope of each best response is $\frac{s_j^2}{1-s_j} = 0.224$. Source: `figures/ch07/src/logit_best_response.py`.

Stacking over all products with the ownership matrix Ω and the derivative matrix Δ, $\Delta_{jk} = \frac{\partial s_j}{\partial p_k}$, gives

$$\boldsymbol{s} + (\Omega \odot \Delta)^\top (\boldsymbol{p} - \boldsymbol{mc}) = 0, \qquad \boldsymbol{p} - \boldsymbol{mc} = -\left[(\Omega \odot \Delta)^\top\right]^{-1} \boldsymbol{s}, \tag{7.42}$$

as in Chapter 4. Because Ω is symmetric, $(\Omega \odot \Delta)^\top = \Omega \odot \Delta^\top$. With logit demand the matrix inversion is unnecessary.

Proposition 7.17 (Common markups with multi-product firms)**.** *By Proposition 4.7, under logit demand every solution of the first-order conditions* (7.41)*, and hence every Bertrand-Nash equilibrium, gives every product of firm f the same dollar markup*

$$m_f = \frac{1}{\alpha(1 - S_f)}, \qquad S_f = \sum_{k \in \mathcal{J}_f} s_k. \tag{7.43}$$

The proof in Chapter 4 substitutes the logit derivatives into (7.41). This gives $m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k$ for every $j \in \mathcal{J}_f$, and the right side does not depend on j.

The common markup has a clean interpretation. Substitute $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$ and $\frac{\partial s_k}{\partial p_j} = \alpha s_j s_k$ into (7.41) and divide by $\alpha s_j(1 - s_j)$:

$$m_j = \frac{1}{\alpha(1 - s_j)} + \sum_{k \in \mathcal{J}_f, k \neq j} D_{jk}\, m_k, \qquad D_{jk} = \frac{s_k}{1 - s_j}. \tag{7.44}$$

The first term is the single-product markup. The second is the value of the sales that a price increase on j diverts to the firm's other products, where D_{jk} is the logit diversion

ratio (Section 7.1.3). A multi-product firm internalizes this recapture, so it prices above the single-product level. In the logit, diversion is proportional to shares, so recapture depends on the firm's total share and on nothing else. The second term of (7.44) is the upward pricing pressure that a merger creates (Chapter 11). Because markups are common in dollars, the firm's cheaper products carry the higher percentage markups.

The best response of a multi-product firm also has a closed form. Holding rival prices fixed, every stationary point of π_f has common markups by Proposition 7.17. Let $E_f = \sum_{k\in\mathcal{J}_f} e^{v_k}$ and $D_{-f} = 1 + \sum_{l\notin\mathcal{J}_f} e^{\delta_l}$. With a common markup, $S_f = \frac{E_f e^{-\alpha m_f}}{D_{-f}+E_f e^{-\alpha m_f}}$, and the steps that led to (7.39) give

$$m_f^{BR} = \frac{1}{\alpha}\left[1 + W\left(\frac{E_f e^{-1}}{D_{-f}}\right)\right], \qquad p_k = mc_k + m_f^{BR} \text{ for } k \in \mathcal{J}_f. \tag{7.45}$$

This is (4.10) of Chapter 4. The firm's products enter only through the sum E_f, a property that the uniqueness proof of Theorem 4.25 exploits.

Example 4.8 solves both pricing games in one market with 25 products, five owners and $\alpha = 2$, and Table 4.2 reports the results. With single-product firms, markups range from 0.502 to 0.566, all close to $\frac{1}{\alpha} = 0.5$. Under the actual ownership each owner has one markup, equal to $\frac{1}{\alpha(1-S_f)}$. It ranges from 0.524 for the owner with the smallest combined share to 0.670 for the owner with the largest. Every price rises, the outside share rises from 0.137 to 0.160, and total profit rises by about 14 percent. Appendix C works through the full problem.

7.4.3 Existence and uniqueness of equilibrium

Counterfactuals need a unique equilibrium. Without it, a merger simulation does not tell us which of several post-merger price vectors to expect. Uniqueness can fail in general pricing games, and Chapter 4 discusses the conditions of Caplin and Nalebuff (1991) for single-product firms. For the logit, uniqueness holds for any ownership structure. The single-product case follows from Caplin and Nalebuff and from the contraction argument after (7.40). The multi-product case is due to Konovalov and Sándor (2010, Theorem 7, p. 279) and Nocke and Schutz (2018). In an *aggregative game* each firm's profit depends on its rivals' prices only through one aggregator, and consumer surplus is a monotone function of it (Asker and Nocke, 2021, p. 229, n. 127). The logit pricing game is aggregative, and its aggregator is the inclusive sum $\Lambda = 1 + \sum_k e^{\delta_k}$, which Chapter 4 writes as Φ.

Proposition 7.18 (Existence and uniqueness)**.** *With logit demand, constant marginal costs and any partition of the products among firms, the Bertrand-Nash pricing game has exactly one equilibrium. This is Theorem 4.25.*

The proof of Theorem 4.25 reduces the equilibrium to one equation in one unknown, the aggregate Λ. Each firm sets the common markup of Proposition 7.17, so its combined share is $S_f = \frac{E_f e^{-\alpha m_f}}{\Lambda}$, with E_f as in (7.45). Substituting $\alpha m_f = \frac{1}{1-S_f}$ gives

$$S_f\, e^{\frac{1}{1-S_f}} = \frac{E_f}{\Lambda}. \tag{7.46}$$

The left side rises strictly from 0 to $+\infty$ as S_f rises from 0 to 1. Each firm's share is therefore a continuous and strictly decreasing function $S_f(\Lambda)$ of the aggregate. The inside shares and the

outside share $\frac{1}{\Lambda}$ add up to one, so the equilibrium aggregate solves

$$\Psi(\Lambda) \equiv \sum_f S_f(\Lambda) + \frac{1}{\Lambda} = 1. \tag{7.47}$$

The function Ψ is strictly decreasing, exceeds one at $\Lambda = 1$ and tends to zero as $\Lambda \to \infty$. It has exactly one root $\Lambda^* > 1$, and the root pins down every share, markup and price.

The characterization doubles as an algorithm: solve (7.47) by bisection and read off shares, markups and prices. Best-response iteration with (7.45), the markup fixed point $\boldsymbol{p} \leftarrow \boldsymbol{mc} + \frac{1}{\alpha(1-S_f(\boldsymbol{p}))}$, and Newton's method are common alternatives. In the market of Example 4.8, $\Lambda^* = 7.314$ with single-product firms and 6.246 with multi-product firms, equal to $\frac{1}{s_0}$ in each case (Example 4.26). With non-logit demand uniqueness is not guaranteed, and restarting the solver from many points is the practical check (Chapter 8).

7.4.4 Pass-through

The *pass-through rate* $\rho = \frac{\mathrm{d}p}{\mathrm{d}mc}$ measures how much of a cost change reaches the price (Chapter 2). It governs the incidence of taxes, the effect of exchange rates on import prices, and the price effect of merger efficiencies.

Proposition 7.19 (Logit pass-through)**.** *Hold rivals' prices fixed. By parts (i) and (iii) of Proposition 4.38, the following hold.*

(i) A single-product firm passes through $\rho_j = \frac{\mathrm{d}p_j}{\mathrm{d}mc_j} = 1 - s_j$ of an increase in its marginal cost.

(ii) A multi-product firm facing the same increase in the marginal cost of all its products raises all its prices by $\rho_f = 1 - S_f$ per unit of cost.

In both cases pass-through is below one and falls with the firm's share.

The proof in Chapter 4 differentiates the markup condition $\alpha m_f(1 - S_f) = 1$. A common cost increase $\mathrm{d}mc$ lowers the firm's combined share, and the common markup falls by $S_f\,\mathrm{d}mc$, so each price rises by $(1 - S_f)\,\mathrm{d}mc$. A single-product firm is the case $S_f = s_j$.

Pass-through below one is the logit instance of a general result for log-concave demand. For a single-product firm with demand $q(p)$ at fixed rival prices, (2.58) gives

$$\rho = \frac{\mathrm{d}p}{\mathrm{d}mc} = \frac{1}{2 - \frac{qq''}{(q')^2}},$$

and $\rho < 1$ exactly when demand is log-concave at the optimum (Corollary 2.71). Bulow and Pfleiderer (1983) write the same pass-through rate in terms of the demand elasticity and its slope, as restated by Farrell and Shapiro (2010, p. 18 of the 2008 working paper). Weyl and Fabinger (2013) develop pass-through as a general tool for incidence under imperfect competition. Holding rivals' prices fixed, logit demand is log-concave in own price:

$$\frac{\mathrm{d}\ln s_j}{\mathrm{d}p_j} = -\alpha(1 - s_j), \qquad \frac{\mathrm{d}^2 \ln s_j}{\mathrm{d}p_j^2} = \alpha \frac{\mathrm{d}s_j}{\mathrm{d}p_j} = -\alpha^2 s_j(1 - s_j) < 0.$$

With $q = s_j$, $q' = -\alpha s_j(1 - s_j)$ and $q'' = \alpha^2 s_j(1 - s_j)(1 - 2s_j)$, the ratio $\frac{qq''}{(q')^2}$ equals $\frac{1-2s_j}{1-s_j}$, and the general formula returns $\rho_j = 1 - s_j$. In the market of Example 4.8 the largest owner has

$S_f = 0.2536$, and a numerical derivative of (7.45) gives pass-through 0.7464, equal to $1 - S_f$. The proposition holds rivals' prices fixed. When a cost shock hits all firms, rivals raise their prices as well. By strategic complementarity (7.40), equilibrium pass-through then exceeds $1 - s_j$ (Corollary 4.39).

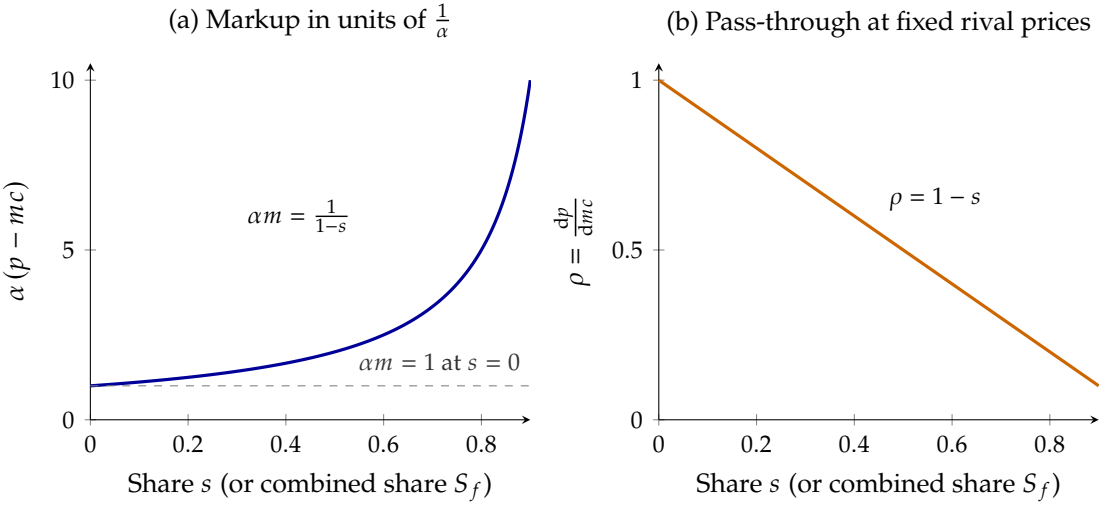

Figure 7.4: Logit markups and pass-through as functions of the firm's share. Panel (a): the dollar markup times α, from Propositions 7.16 and 7.17. Panel (b): the pass-through rate of Proposition 7.19. For a multi-product firm, read the horizontal axis as S_f.

Figure 7.4 summarizes the two results. Markups rise and pass-through falls with the firm's share, and nothing else about the product matters. The link to merger analysis is direct. Farrell and Shapiro (2010) define the upward pricing pressure on product j after a merger with the owner of k as $D_{jk}m_k$, the second term of (7.44). They evaluate it at pre-merger prices and before any credit for cost savings (p. 9 of their 2008 working paper). Asker and Nocke (2021, p. 231) state the same definition and read it as the merged firm's opportunity cost of keeping the price of j at its pre-merger level. It acts like a cost increase on j, so to first order the price of j rises by $\rho_j D_{jk} m_k = (1 - s_j)\frac{s_k}{1-s_j} m_k = s_k m_k$ under logit demand. Chapter 11 develops this approximation and its limits.

7.4.5 Recovering marginal costs and joint estimation

Given an estimate $\hat{\alpha}$ and an assumed ownership structure, the first-order conditions deliver marginal costs without any cost data. Suppose marginal cost is linear in observed cost shifters w_{jt} and a cost shock ω_{jt}, $mc_{jt} = w_{jt}\gamma + \omega_{jt}$. By Proposition 7.17,

$$p_{jt} = w_{jt}\gamma + \frac{1}{\alpha(1 - S_{ft})} + \omega_{jt}, \qquad \widehat{mc}_{jt} = p_{jt} - \frac{1}{\hat{\alpha}(1 - S_{ft})}. \tag{7.48}$$

With single-product firms ($S_{ft} = s_{jt}$) the first equation is equation (31) of Berry (1994, p. 255), whose parameters are γ and $\frac{1}{\alpha}$. His general version (equation 29) lets cost depend on output and writes the markup as $\frac{s_j}{\alpha}\left(\frac{\partial s_j}{\partial \delta_j}\right)^{-1}$, which covers any demand model. The nested logit version is Proposition 7.27.

There are two ways to estimate γ. The *two-step* approach regresses $\widehat{mc}_{jt}$ on w_{jt} by OLS. It is consistent when $\mathbb{E}[w_{jt}^{\top}\omega_{jt}] = 0$ and $\hat{\alpha}$ is consistent. Its usual standard errors are wrong,

because the dependent variable is a *generated regressand*. The error in the implied cost is

$$\widehat{mc}_{jt} - mc_{jt} = \frac{1}{\alpha(1 - S_{ft})} - \frac{1}{\hat{\alpha}(1 - S_{ft})} \approx \frac{\hat{\alpha} - \alpha}{\alpha^2(1 - S_{ft})},$$

which is nearly common to all products when shares are small, so it loads on the intercept of the cost regression. The simulated market of Section 8.10.4, which Appendix C works through, shows the size of the effect. A market bootstrap that re-estimates α raises the intercept's standard error there from 0.016 to 0.072, while the slopes' standard errors barely move. Valid inference uses such a bootstrap or the sandwich of a stacked GMM problem (Newey, 1984). Negative implied costs signal a problem with the demand estimates or the conduct assumption.

The *joint* approach estimates demand and supply together. Let $\theta = (\beta, \alpha, \gamma)$ and define the two structural errors

$$\xi_{jt}(\theta) = y_{jt} - x_{jt}\beta + \alpha p_{jt}, \qquad \omega_{jt}(\theta) = p_{jt} - \frac{1}{\alpha(1 - S_{ft})} - w_{jt}\gamma. \tag{7.49}$$

With demand instruments z^d_{jt} and supply instruments z^s_{jt}, the moment conditions are $\mathbb{E}[z^{d\top}_{jt}\xi_{jt}(\theta)] = 0$ and $\mathbb{E}[z^{s\top}_{jt}\omega_{jt}(\theta)] = 0$. GMM minimizes $\bar{g}(\theta)^\top W \bar{g}(\theta)$ for the stacked sample moments

$$\bar{g}(\theta) = \frac{1}{N}\sum_t \sum_{j \in \mathcal{J}_t} \begin{pmatrix} z^{d\top}_{jt}\,\xi_{jt}(\theta) \\ z^{s\top}_{jt}\,\omega_{jt}(\theta) \end{pmatrix}. \tag{7.50}$$

For a given α both errors are linear in (β, γ), which can be concentrated out, so the search is over α alone. The markup term is endogenous, because S_{ft} depends on prices and hence on ω_{jt}. Berry (1994, p. 255) lists its instruments: excluded demand characteristics, characteristics of other firms, and market population when markets differ in size.

Joint estimation helps when demand instruments are weak, because the markup term carries information about α if the supply instruments overidentify γ. It also exploits any correlation between ξ and ω, it is where conduct enters when conduct is tested, and it gives correct standard errors for γ. The cost is robustness. A wrong ownership or conduct assumption contaminates the demand estimates through the shared α. Berry notes that joint estimation "would take into account the cross-equation restrictions on parameters." Chapter 8 develops joint estimation with random coefficients, where the gains are larger.

7.4.6 Testing conduct and ownership with logit demand

The same first-order conditions can be evaluated under different assumptions about who sets which price. Let a *pricing coalition* be a set of products whose prices are chosen jointly. By Proposition 7.17, a coalition A sets the common markup $\frac{1}{\alpha(1-S_A)}$, where S_A is its combined share. Implied Lerner indices under four structures are therefore analytic:

$$\underbrace{\frac{1}{\alpha p_j(1 - s_j)}}_{\text{single product}}, \quad \underbrace{\frac{1}{\alpha p_j(1 - S_f)}}_{\text{actual ownership}}, \quad \underbrace{\frac{1}{\alpha p_j(1 - S_G)}}_{\text{joint pricing of } G}, \quad \underbrace{\frac{1}{\alpha p_j s_0}}_{\text{monopoly}}, \tag{7.51}$$

where G is a group of colluding products, and monopoly uses $1 - \sum_{k \geq 1} s_k = s_0$. Comparing the predicted margins with observed margins, or with outside information on costs, tests the structures. Only $\hat{\alpha}$ and the shares are needed.

Nevo (2001, Section 5.3) carries out this comparison for cereal, and Table 7.7 reproduces the logit column of his Table VIII. It uses the price coefficient of column (ix) of Table 7.4. Because only shares are needed, the logit margins can include brands outside the 25 in the sample, which the full model cannot (Nevo, 2001, pp. 332–333).

Table 7.7: Median price-cost margins in ready-to-eat cereal under alternative pricing structures, logit demand.

	Logit (Table V, column ix)
Single-product firms	33.6% (31.8%–35.6%)
Current ownership of 25 brands	35.8% (33.9%–38.0%)
Joint ownership of 25 brands	41.9% (39.7%–44.4%)
Current ownership of all brands	37.2% (35.2%–39.4%)
Monopoly or perfect price collusion	54.0% (51.1%–57.3%)

Notes: Source: Nevo (2001, Table VIII, p. 333), logit column. Margins are $\frac{p-mc}{p}$. Entries are medians over 27,862 brand-city-quarter observations, with 95 percent confidence intervals for the median in parentheses, based on the asymptotic distribution of the demand estimates. The logit computation is analytical. Table 8.28 reproduces the full table, including the random coefficients column.

Nevo compares the predictions with crude accounting estimates. The gross retail margin is about 46.0 percent, and the gap between national brands and private labels gives a lower bound of about 31 percent (Nevo, 2001, pp. 333–334). His full random coefficients model predicts a median margin of 35.8 percent with single-product firms. It is 42.2 percent (interval 29.1 to 55.8) under current ownership and 72.6 percent (62.2 to 97.2) under joint ownership of the 25 brands (Table 8.28). Using these intervals, he rejects joint profit maximization by the 25 brands and cannot reject multi-product Nash pricing. The logit column tells a different story. Joint ownership of the 25 brands raises the logit margin only from 35.8 to 41.9 percent, against 42.2 to 72.6 percent in the full model. With logit margins, joint ownership comes closer to the accounting margin than current ownership does, so a logit-based test could point toward collusion.

The logit understates the effect of joint pricing because of IIA. A coalition's markup depends only on $\frac{1}{1-S_G}$. With a market of one serving per person per day the outside share is large, so S_G is far from one even for 25 brands. Diversion is proportional to shares (Section 7.1.4), so most of the sales a brand loses go to the outside good, and merging brands recaptures little. In the random coefficient model cereals are closer substitutes for each other than for the outside good, so joint pricing recaptures much more. The assumed demand model shapes the conduct test as much as the data do.

Berry et al. (1995, p. 874) make the same point for cars. Their IV logit implies that "all models have about the same mark-up," from \$4,630 for the BMW to \$4,805 for the Chevy Cavalier. Shares measured against all households are tiny, so markups are close to $\frac{1}{\hat{\alpha}} = \frac{1}{0.216}$ thousand dollars, about \$4,630. Differences come only from the number of models a parent firm sells. GM sells the most and has the highest markups, while BMW has, "quite counter-intuitively," the lowest. If BMW's combined share is negligible, (7.43) and $1 - \frac{4{,}630}{4{,}805} \approx 0.036$ imply that GM's models together sold to roughly 3.6 percent of households. Section 7.10.3 translates these dollar

markups into Lerner indices, and the random coefficient markups of Chapter 8 vary far more across models.

Comparing implied margins across ownership structures is an alternative to estimating a conduct parameter (Chapter 3). It sidesteps the problem raised by Corts (1999, p. 227), who shows that in a dynamic oligopoly model the estimated conduct parameter can mismeasure market power severely. Bresnahan (1987) applies a nested test of this kind with the vertical model (Chapter 6).

Logit merger simulation follows directly. Asker and Nocke (2021, p. 230) credit Hausman et al. (1994), Werden and Froeb (1994) and Nevo (2000b) with pioneering *merger simulation*, which has three steps. The first estimates pre-merger demand. The second recovers pre-merger marginal costs from an assumption on pre-merger conduct, typically static Bertrand-Nash pricing. The third computes the post-merger equilibrium under assumptions on post-merger conduct and on merger-related cost savings, holding demand and the product set fixed. Werden and Froeb carry out these steps with logit demand. The first two steps are then analytic, and the third reduces to one equation in one unknown. Estimate α, recover marginal costs from (7.48) under the pre-merger ownership, and solve (7.47) under the post-merger ownership. If firms f and f' merge, the merged firm sets one markup $\frac{1}{\alpha(1-S_f-S_{f'})}$ at post-merger shares, and rivals respond. Because diversion follows shares, the predicted dollar price effects depend only on $\hat{\alpha}$, the ownership structure and the pre-merger shares (Chapter 11). When the size of the cost savings is unknown, the third step can instead find the smallest savings that leave consumer surplus unchanged (Asker and Nocke, 2021, pp. 230–231).

7.5 GEV models and the nested logit

The logit restricts substitution because its taste shocks are independent across products (Section 7.1.4). A consumer who leaves product j after a price increase is no more likely than anyone else to choose a product similar to j. Two routes break this property while keeping the model estimable from market shares. The first correlates the shocks of products that the analyst groups together. It leads to the generalized extreme value family and to the nested logit. The second lets taste coefficients vary across consumers. It leads to the random coefficients logit of Chapter 8. This section develops the first route. Section 7.6 then uses both the logit and the nested logit to measure consumer welfare.

7.5.1 Generalized extreme value models

We work with an additive random utility model. Consumer i obtains $u_{ij} = V_{ij} + \epsilon_{ij}$ from alternative $j = 0, 1, \ldots, J$, where V_{ij} is the deterministic part of utility. Throughout this subsection we drop the consumer index and write $V = (V_0, \ldots, V_J)$ and $y_j = e^{V_j}$. The choice probability of j is $P_j(V)$. The *social surplus function* is the expected maximum utility,

$$\mathcal{W}(V) = \mathbb{E}\Big[\max_{j=0,\ldots,J} (V_j + \epsilon_j)\Big]. \tag{7.52}$$

The logit assumes that the ϵ_j are independent type-I extreme value (Gumbel) variables. McFadden (1978) found a class of correlated distributions that keeps the closed forms of the logit. The class is indexed by a function of $J + 1$ positive arguments.

Definition 7.20 (GEV generating function)**.** A function $H : \mathbb{R}_+^{J+1} \to \mathbb{R}_+$ is a *GEV generating function* if it has the following three properties.

(G1) H is homogeneous of degree one: $H(\lambda y) = \lambda H(y)$ for every $\lambda > 0$.

(G2) $H(y) \to \infty$ as $y_j \to \infty$, for each j.

(G3) For any $r \geq 1$ distinct indices $j_1, \ldots, j_r$, the mixed partial derivative $\frac{\partial^r H}{\partial y_{j_1} \cdots \partial y_{j_r}}$ exists, is continuous, and is nonnegative when r is odd and nonpositive when r is even.

We write H_j and H_{jk} for the first and second partial derivatives of H. Condition (G1) produces the closed forms below. Condition (G2) makes each marginal distribution proper. Condition (G3) makes the function in part (i) of the next proposition a joint distribution function with a nonnegative density. The notation follows McFadden (1984, p. 1421), who calls the function H. Theorem 6.18 states and proves the first three parts of the next result. We restate them here together with two parts that this chapter also uses, the gradient property (iv) and the derivative formula (v).

Proposition 7.21 (McFadden's GEV theorem)**.** *Let H be a GEV generating function and let $y = (e^{V_0}, \ldots, e^{V_J})$.*

(i) $F(\epsilon_0, \ldots, \epsilon_J) = \exp\left[-H(e^{-\epsilon_0}, \ldots, e^{-\epsilon_J})\right]$ is the distribution function of a random vector whose marginals are Gumbel.

(ii) If ϵ has distribution F, the choice probabilities are

$$P_j(V) = \frac{y_j H_j(y)}{H(y)} = \frac{\partial \ln H(e^{V_0}, \ldots, e^{V_J})}{\partial V_j}. \tag{7.53}$$

(iii) The maximum utility $\max_j(V_j + \epsilon_j)$ is Gumbel with location $\ln H(y)$ and scale one, so that

$$\mathcal{W}(V) = \ln H(y) + \gamma_E, \tag{7.54}$$

where $\gamma_E \approx 0.5772$ is Euler's constant.

(iv) (Williams, Daly and Zachary.) The social surplus function is differentiable and $\frac{\partial \mathcal{W}(V)}{\partial V_j} = P_j(V)$ for every j.

(v) For all j and k,

$$\frac{\partial P_j}{\partial V_k} = P_j\big(\mathbf{1}\{j = k\} - P_k\big) + \frac{y_j y_k H_{jk}(y)}{H(y)}. \tag{7.55}$$

Proof. Parts (i), (ii) and (iii) are parts (a), (b) and (c) of Theorem 6.18. Part (i) is the theorem of McFadden (1978), and the proof of Theorem 6.18 derives (ii) and (iii) from it by homogeneity. Part (iv) is part (ii) of Theorem 6.7, which holds for every additive random utility model. In the GEV case it also follows by differentiating (7.54) and applying (ii). Only (v) is new.

For (v), take logs in (ii): $\ln P_j = V_j + \ln H_j(y) - \ln H(y)$. Differentiate with respect to V_k, using $\frac{\partial y_k}{\partial V_k} = y_k$:

$$\frac{\partial \ln P_j}{\partial V_k} = \mathbf{1}\{j = k\} + \frac{y_k H_{jk}(y)}{H_j(y)} - \frac{y_k H_k(y)}{H(y)} = \mathbf{1}\{j = k\} + \frac{y_k H_{jk}(y)}{H_j(y)} - P_k.$$

Multiplying by $P_j = \frac{y_j H_j}{H}$ gives (7.55). □

Part (v) shows what correlation buys. For $j \neq k$ the logit term $-P_j P_k$ is the cross derivative of a model with independent shocks and the same probabilities. The second term $\frac{y_j y_k H_{jk}}{H}$ is nonpositive by (G3). A GEV model therefore implies at least as much substitution between j and k as the logit at the same choice probabilities, and H_{jk} measures the excess. The formula is symmetric in j and k, which is the counterpart of Slutsky symmetry (Corollary 6.8). With mean utilities $V_k = \delta_k$ and $\delta_k = x_k\beta - \alpha p_k + \xi_k$, price derivatives follow from $\frac{\partial s_j}{\partial p_k} = -\alpha \frac{\partial P_j}{\partial \delta_k}$.

Two generating functions. The logit is the case $H(y) = \sum_{j=0}^{J} y_j$. Its first derivatives equal one and all higher derivatives vanish, so (ii) gives $P_j = \frac{y_j}{\sum_k y_k}$ and (v) gives the logit derivatives of Proposition 7.6. The *nested logit* groups the inside products into nests. Partition the inside products into G mutually exclusive and exhaustive nests $g = 1, \dots, G$, and place the outside good alone in nest 0. For a nesting parameter σ, let

$$H(y) = y_0 + \sum_{g=1}^{G} D_g(y)^{1-\sigma}, \qquad D_g(y) = \sum_{j \in g} y_j^{\frac{1}{1-\sigma}}. \tag{7.56}$$

Lemma 7.22 (Consistency of the nested logit)**.** *The function* (7.56) *is a GEV generating function for every $\sigma \in [0, 1)$. If $\sigma < 0$ and some nest contains two or more products, it violates (G3).*

Proof. For (G1), $D_g(\lambda y) = \lambda^{\frac{1}{1-\sigma}} D_g(y)$, so $D_g(\lambda y)^{1-\sigma} = \lambda D_g(y)^{1-\sigma}$. For (G2), if $y_j \to \infty$ with $j \in g$, then $D_g \to \infty$ and $D_g^{1-\sigma} \to \infty$ because $1 - \sigma > 0$. The outside good enters linearly.

For (G3), a mixed partial derivative over indices from two different nests is zero, which satisfies the weak sign condition. Take distinct indices $j_1, \dots, j_r$ in the same nest g. Write $\varphi(D) = D^{1-\sigma}$ and $a_j = \frac{\partial D_g}{\partial y_j} = \frac{1}{1-\sigma} y_j^{\frac{\sigma}{1-\sigma}} \geq 0$. Each a_j depends on y_j alone, so the chain rule gives

$$\frac{\partial^r H}{\partial y_{j_1} \cdots \partial y_{j_r}} = \varphi^{(r)}(D_g) \prod_{m=1}^{r} a_{j_m}.$$

The successive derivatives of φ are $\varphi'(D) = (1-\sigma)D^{-\sigma}$, $\varphi''(D) = -\sigma(1-\sigma)D^{-\sigma-1}$, $\varphi'''(D) = \sigma(\sigma+1)(1-\sigma)D^{-\sigma-2}$, and in general

$$\varphi^{(r)}(D) = (-1)^{r-1}(1-\sigma) \prod_{m=0}^{r-2} (\sigma + m)\, D^{1-\sigma-r}, \qquad r \geq 2.$$

For $\sigma \in [0, 1)$ every factor in the product is nonnegative, so the sign is $(-1)^{r-1}$, as (G3) requires. If $\sigma < 0$, then $\varphi''(D) > 0$ and the second mixed derivative of two products in the same nest is positive. □

The parameter range has an empirical counterpart. McFadden (1984, pp. 1425–1426) notes that estimates of the nesting parameters outside the unit interval violate the ranking of cross elasticities implied by the tree, and may indicate a misspecified tree. In the notation of Börsch-Supan (1990), our $1 - \sigma$ is the dissimilarity parameter. He shows that values with $\sigma < 0$ can still be consistent with utility maximization on a restricted region of mean utilities (Section 4 and Theorem 1, pp. 377–381). By Theorem 1, it suffices that the mixed partial derivatives of the choice probabilities be nonnegative on that region. In the two-level model this requires the choice probabilities of the nests to be large enough (Theorem 2, p. 385). With two nests of two alternatives each and a common $\sigma < -1$, these requirements conflict and no such region exists (p. 385). Applied work treats $\sigma \in [0, 1)$ as the admissible range. The next two subsections derive the nested logit a second way, from an explicit utility model.

7.5.2 The nested logit model

The nested logit relaxes IIA by grouping products. Within a nest, consumers substitute as in the logit. Products in different nests have less in common, so they are weaker substitutes. The idea parallels the grouping of goods in multi-stage budgeting (Chapter 5), and the same analyst judgment determines the groups.

Assumption 7.23 (Nested logit)**.** The inside products of market t are partitioned into nests $g = 1, \dots, G$, and the outside good forms nest 0 by itself. The utility of consumer i from product j in nest g is

$$u_{ij} = \delta_j + \zeta_{ig} + (1-\sigma)\epsilon_{ij}, \qquad \delta_j = x_j\beta - \alpha p_j + \xi_j, \tag{7.57}$$

and the utility of the outside good is a standard Gumbel variable ϵ_{i0}. The shocks ϵ_{ij} are i.i.d. standard Gumbel. The nest tastes ζ_{ig} are i.i.d. across consumers and nests with the distribution $C(\sigma)$ of Lemma 7.24, and they are independent of the ϵ_{ij}. The nesting parameter satisfies $0 \le \sigma < 1$.

The term ζ_{ig} is common to all products in nest g for consumer i. A consumer with a high draw likes every product of the nest, so the utilities of products in the same nest are positively correlated. Berry (1994, p. 252) points out that (7.57) is a random coefficients model. Let d_{jh} equal one if $j \in h$. Then $\zeta_{ig} = \sum_h d_{jh}\zeta_{ih}$ for $j \in g$, so the nest taste is a random coefficient on the nest dummies, with a distribution tied to σ. Unlike the full random coefficients model, correlation can depend only on groupings fixed before estimation, never on continuous characteristics. Nevo (2000a, p. 524) makes the same point, and Cardell (1997) shows that the two descriptions of the nested logit are equivalent. The distribution of ζ_{ig} is chosen so that the composite shock remains Gumbel.

Lemma 7.24 (Cardell, 1997)**.** *For every $\sigma \in [0,1)$ there is a unique distribution $C(\sigma)$ with the following property. If $\zeta \sim C(\sigma)$ and ϵ is a standard Gumbel variable independent of ζ, then $\zeta + (1-\sigma)\epsilon$ is a standard Gumbel variable. Equivalently, the random variable $X = e^{\frac{\zeta}{1-\sigma}}$ satisfies*

$$\mathbb{E}\big[e^{-cX}\big] = \exp\big(-c^{1-\sigma}\big) \qquad \text{for every } c > 0. \tag{7.58}$$

We do not prove existence, which Cardell (1997) establishes along with the density of ζ. The equivalence is a short computation. Conditioning on ζ,

$$\mathbb{P}\big(\zeta + (1-\sigma)\epsilon \le t\big) = \mathbb{E}\Big[\exp\Big(-e^{-\frac{t-\zeta}{1-\sigma}}\Big)\Big] = \mathbb{E}\big[e^{-cX}\big], \qquad c = e^{-\frac{t}{1-\sigma}}.$$

The standard Gumbel distribution function is $\exp(-e^{-t}) = \exp(-c^{1-\sigma})$, which gives (7.58). A Laplace transform determines a distribution, which explains uniqueness. The function $c \mapsto \exp(-c^a)$ with $0 < a \le 1$ is the Laplace transform of the positive stable law of index a (Feller, 1971). So ζ is $(1-\sigma)$ times the logarithm of a positive stable variable of index $1-\sigma$. At $\sigma = 0$ the stable variable equals one and $\zeta = 0$.

Proposition 7.25 (Nested logit shares)**.** *Under Assumption 7.23, define the inclusive sum of nest g as $D_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma}}$. Then the within-nest share, the nest share, the product share and the outside share are*

$$s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}, \qquad s_g = \frac{D_g^{1-\sigma}}{1 + \sum_{h=1}^{G} D_h^{1-\sigma}}, \qquad s_j = s_{j|g}\, s_g, \qquad s_0 = \frac{1}{1 + \sum_{h=1}^{G} D_h^{1-\sigma}}. \tag{7.59}$$

The composite shocks $\zeta_{ig} + (1-\sigma)\epsilon_{ij}$ have the GEV distribution generated by (7.56).

Proof. We give two derivations. The first uses Proposition 7.21. The second builds the shares nest by nest.

GEV derivation. Fix a nest g and numbers t_j for $j \in g$. Conditioning on ζ_{ig} and using the independence of the ϵ_{ij},

$$\mathbb{P}\big(\zeta_{ig} + (1-\sigma)\epsilon_{ij} \le t_j \text{ for all } j \in g\big) = \mathbb{E}\Big[\prod_{j\in g} \exp\Big(-e^{-\frac{t_j-\zeta_{ig}}{1-\sigma}}\Big)\Big] = \mathbb{E}\Big[\exp\Big(-X\sum_{j\in g} e^{-\frac{t_j}{1-\sigma}}\Big)\Big],$$

with $X = e^{\frac{\zeta_{ig}}{1-\sigma}}$. By (7.58) the last expression equals $\exp\big[-\big(\sum_{j\in g} e^{-\frac{t_j}{1-\sigma}}\big)^{1-\sigma}\big]$. Nests are independent and the outside shock contributes $\exp(-e^{-t_0})$. The joint distribution function is therefore $\exp[-H(e^{-t_0},\dots,e^{-t_J})]$ with H from (7.56). Apply (7.53) with $y_j = e^{\delta_j}$ and $y_0 = 1$. For $j \in g$,

$$H_j(y) = (1-\sigma)D_g^{-\sigma}\cdot\frac{1}{1-\sigma}y_j^{\frac{\sigma}{1-\sigma}} = D_g^{-\sigma}y_j^{\frac{\sigma}{1-\sigma}}, \qquad y_jH_j(y) = D_g^{-\sigma}e^{\frac{\delta_j}{1-\sigma}}.$$

Dividing by $H(y) = 1 + \sum_h D_h^{1-\sigma}$,

$$s_j = \frac{e^{\frac{\delta_j}{1-\sigma}}D_g^{-\sigma}}{1+\sum_h D_h^{1-\sigma}} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}\cdot\frac{D_g^{1-\sigma}}{1+\sum_h D_h^{1-\sigma}}.$$

The two factors are $s_{j|g}$ and s_g. For the outside good, $y_0H_0 = 1$ gives s_0.

Sequential derivation. Within nest g the term ζ_{ig} is common to all products, so it does not affect which product of the nest is best. Dividing utilities by $1-\sigma$ shows that the best product in the nest maximizes $\frac{\delta_j}{1-\sigma} + \epsilon_{ij}$. This is a logit with mean utilities $\frac{\delta_j}{1-\sigma}$, so $s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}$ by (7.1) without the outside good. By max-stability of the Gumbel (Lemma 6.9),

$$\max_{j\in g}\big(\delta_j + (1-\sigma)\epsilon_{ij}\big) = (1-\sigma)\max_{j\in g}\Big(\frac{\delta_j}{1-\sigma} + \epsilon_{ij}\Big) = I_g + (1-\sigma)\tilde{\epsilon}_{ig}, \qquad I_g = (1-\sigma)\ln D_g,$$

where $\tilde{\epsilon}_{ig}$ is standard Gumbel and independent across nests. The best utility available in nest g is $I_g + \zeta_{ig} + (1-\sigma)\tilde{\epsilon}_{ig}$. By Lemma 7.24, the composite term $\zeta_{ig} + (1-\sigma)\tilde{\epsilon}_{ig}$ is standard Gumbel, independent across nests and of ϵ_{i0}. The choice of nest is therefore a logit with mean utilities I_g and 0 for the outside good:

$$s_g = \frac{e^{I_g}}{1+\sum_h e^{I_h}} = \frac{D_g^{1-\sigma}}{1+\sum_h D_h^{1-\sigma}}.$$

Finally, the identity of the best product within a nest is independent of the value of the within-nest maximum (Equation (6.22)). The event that j is best within g is therefore independent of the event that nest g wins, and $s_j = s_{j|g}s_g$. □

The quantity $I_g = (1-\sigma)\ln D_g$ is the *inclusive value* of nest g. It is the location of the best utility the nest offers before the nest taste is added. It summarizes the whole nest in one number, much as a group price index summarizes a group in multi-stage budgeting. Let $\bar{\delta}_g = \max_{k\in g}\delta_k$. Because $D_g \ge e^{\frac{\bar{\delta}_g}{1-\sigma}}$, the inclusive value is at least $\bar{\delta}_g$. With J_g identical products of mean utility δ, it equals $\delta + (1-\sigma)\ln J_g$, so a nest gains value from variety at rate $1-\sigma$.

Correlation within nests. The composite shock of product $j \in g$ is $\zeta_{ig} + (1-\sigma)\epsilon_{ij}$, a standard Gumbel variable with variance $\frac{\pi^2}{6}$. The term $(1-\sigma)\epsilon_{ij}$ has variance $(1-\sigma)^2\frac{\pi^2}{6}$. Since ζ_{ig} and ϵ_{ij} are independent,

$$\operatorname{Var}(\zeta_{ig}) = \frac{\pi^2}{6} - (1-\sigma)^2\frac{\pi^2}{6} = \left[1-(1-\sigma)^2\right]\frac{\pi^2}{6}.$$

For two products $j \neq k$ in the same nest, the only common component is ζ_{ig}, so $\operatorname{Cov}(u_{ij}, u_{ik}) = \operatorname{Var}(\zeta_{ig})$. Dividing by the common variance $\frac{\pi^2}{6}$,

$$\operatorname{Corr}(u_{ij}, u_{ik}) = 1-(1-\sigma)^2 = \sigma(2-\sigma), \qquad j,k \in g,\ j \neq k. \tag{7.60}$$

Utilities of products in different nests are uncorrelated. The correlation rises from zero at $\sigma = 0$ to one as $\sigma \to 1$. At $\sigma = 0.5$ it is 0.75.

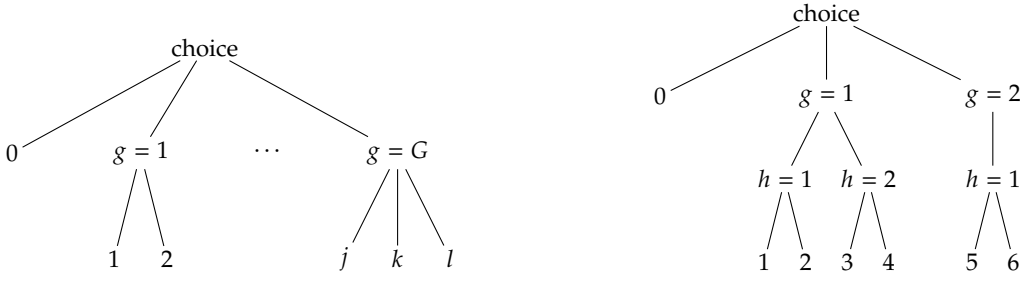
The two limits. At $\sigma = 0$ the nest tastes vanish, $D_g^{1-\sigma} = \sum_{k\in g} e^{\delta_k}$, and (7.59) is the logit share (7.1). The limit $\sigma \to 1$ answers the question of which products consumers buy when utilities within a nest become perfectly correlated. Let r_g be the number of products in g whose mean utility equals $\bar{\delta}_g$. Then

$$s_{j|g} = \frac{1}{\sum_{k\in g} e^{\frac{\delta_k-\delta_j}{1-\sigma}}} \longrightarrow \begin{cases} \frac{1}{r_g} & \text{if } \delta_j = \bar{\delta}_g, \\ 0 & \text{otherwise,} \end{cases}$$

because every exponent $\frac{\delta_k-\delta_j}{1-\sigma}$ with $\delta_k > \delta_j$ diverges to $+\infty$. For the nest level,

$$D_g^{1-\sigma} = e^{\bar{\delta}_g}\Big(\sum_{k\in g} e^{\frac{\delta_k-\bar{\delta}_g}{1-\sigma}}\Big)^{1-\sigma} \longrightarrow e^{\bar{\delta}_g}\cdot\lim_{\sigma\to 1} r_g^{1-\sigma} = e^{\bar{\delta}_g},$$

since the sum converges to r_g. Nest shares converge to $\frac{e^{\bar{\delta}_g}}{1+\sum_h e^{\bar{\delta}_h}}$. In the limit only the product with the highest mean utility in each nest is bought, and each nest behaves like a single product with that mean utility. Products within a nest become perfect substitutes, while nests remain logit substitutes for one another. Figure 7.5 shows the one-level tree and the two-level tree of Section 7.5.6.



(a) One level **(b)** Two levels

Figure 7.5: Nesting trees. In panel (a) the outside good 0 is alone in its nest and the inside products are grouped into nests $g = 1, \ldots, G$. The nest choice is a logit in the inclusive values $I_g = (1-\sigma)\ln D_g$, and the choice within a nest is a logit with scale $1-\sigma$. In panel (b) each group g is split into subgroups h, with within-subgroup parameter σ_1 and within-group parameter $\sigma_2 \leq \sigma_1$.

7.5.3 Substitution patterns

All substitution patterns follow from one derivative. Taking logs in (7.59),

$$\begin{aligned}\ln s_j &= \ln s_{j|g} + \ln s_g \\ &= \frac{\delta_j}{1-\sigma} - \ln D_g + (1-\sigma)\ln D_g - \ln\Big(1 + \sum_h D_h^{1-\sigma}\Big) \\ &= \frac{\delta_j}{1-\sigma} - \sigma \ln D_g - \ln\Big(1 + \sum_h D_h^{1-\sigma}\Big).\end{aligned}$$

Differentiate each term with respect to δ_k. The first term gives $\frac{\mathbf{1}\{j=k\}}{1-\sigma}$. For the second, $\frac{\partial \ln D_g}{\partial \delta_k} = \frac{1}{1-\sigma} s_{k|g}$ if $k \in g$ and zero otherwise. For the third, if k belongs to nest h,

$$\frac{\partial}{\partial \delta_k} \ln\Big(1 + \sum_{h'} D_{h'}^{1-\sigma}\Big) = \frac{(1-\sigma) D_h^{-\sigma} \cdot \frac{1}{1-\sigma} e^{\frac{\delta_k}{1-\sigma}}}{1 + \sum_{h'} D_{h'}^{1-\sigma}} = s_{k|h}\, s_h = s_k.$$

Collecting terms,

$$\frac{\partial \ln s_j}{\partial \delta_k} = \frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{k|g}\, \mathbf{1}\{k \in g\} - s_k, \qquad j \in g. \tag{7.61}$$

The same expression follows from (7.55) with the generating function (7.56). Since $\frac{\partial \delta_k}{\partial p_k} = -\alpha$, the price derivatives are

$$\frac{\partial s_j}{\partial p_j} = -\alpha s_j \Big[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j\Big], \tag{7.62}$$

$$\frac{\partial s_j}{\partial p_k} = \alpha s_j \Big[\frac{\sigma}{1-\sigma} s_{k|g} + s_k\Big], \qquad k \in g,\ k \neq j, \tag{7.63}$$

$$\frac{\partial s_j}{\partial p_k} = \alpha s_j s_k, \qquad k \notin g. \tag{7.64}$$

The bracket in (7.62) equals $\frac{1-\sigma s_{j|g} - (1-\sigma)s_j}{1-\sigma}$, which is positive because $s_{j|g} \leq 1$ and $s_j < 1$. Multiplying by $\frac{p_j}{s_j}$ or $\frac{p_k}{s_j}$ gives the elasticities. With the own elasticity written as a positive number,

$$\varepsilon_j = \alpha p_j \Big[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j\Big], \qquad \varepsilon_{jk} = \begin{cases} \alpha p_k \Big[\frac{\sigma}{1-\sigma} s_{k|g} + s_k\Big], & k \in g, \\ \alpha p_k s_k, & k \notin g. \end{cases} \tag{7.65}$$

These formulas have four implications.

(a) Within a nest, substitution is proportional to shares. The cross elasticity ε_{jk} for $k \in g$ depends on k alone, so a rise in p_k raises the shares of all of k's nest-mates in the same proportion. Equivalently, $\frac{s_j}{s_l} = e^{\frac{\delta_j - \delta_l}{1-\sigma}}$ for $j, l \in g$, so IIA holds within each nest.

(b) Across nests, substitution is also proportional to shares. A rise in p_k raises the shares of all products outside k's nest, and of the outside good, by the same proportion $\alpha s_k \, \mathrm{d}p_k$, exactly as in the logit.

(c) The same-nest cross elasticity exceeds the cross elasticity for products in other nests by $\alpha p_k \frac{\sigma}{1-\sigma} s_{k|g}$. This is the extra substitution among similar products that the logit lacks.

(d) IIA fails between products in different nests. For $j \in g$ and $l \in h \neq g$, $\frac{s_j}{s_l} = e^{\frac{\delta_j - \delta_l}{1-\sigma}} \left(\frac{D_h}{D_g}\right)^{\sigma}$ depends on every product of the two nests.

The own elasticity keeps the main defect of the logit. For small shares it is close to $\frac{\alpha p_j}{1-\sigma}(1 - \sigma s_{j|g})$, which rises almost in proportion to price. As Nevo (2000a, p. 524) puts it, the nested logit "does not help with the problem of own-price elasticities".

Diversion ratios. Recall from Section 7.1.3 that the diversion ratio $D_{jk} = -\frac{\partial s_k}{\partial p_j}\left(\frac{\partial s_j}{\partial p_j}\right)^{-1}$ is the fraction of the sales that j loses after a small price increase that go to k. For k in the same nest as j, (7.63) with the roles of j and k exchanged gives $\frac{\partial s_k}{\partial p_j} = \alpha s_k \left[\frac{\sigma}{1-\sigma} s_{j|g} + s_j\right]$. Because $s_k s_{j|g} = s_{k|g} s_g s_{j|g} = s_j s_{k|g}$, this equals $\alpha s_j \left[\frac{\sigma}{1-\sigma} s_{k|g} + s_k\right]$. Dividing by minus (7.62) and multiplying numerator and denominator by $1 - \sigma$,

$$D_{jk} = \begin{cases} \frac{\sigma s_{k|g} + (1-\sigma) s_k}{1 - \sigma s_{j|g} - (1-\sigma) s_j}, & k \in g, \\ \frac{(1-\sigma) s_k}{1 - \sigma s_{j|g} - (1-\sigma) s_j}, & k \notin g. \end{cases} \tag{7.66}$$

The diversion to the outside good, D_{j0}, has the second form with s_0 in place of s_k. The ratios sum to one. Summing the numerators over $k \in g$ with $k \neq j$, over the other nests, and over the outside good gives

$$\sigma(1 - s_{j|g}) + (1 - \sigma)(1 - s_j) = 1 - \sigma s_{j|g} - (1 - \sigma) s_j,$$

which is the denominator. At $\sigma = 0$ every ratio reduces to the logit value $\frac{s_k}{1 - s_j}$. Now let $\sigma \to 1$ with the shares held fixed and $s_{j|g} < 1$. Then all diversion stays within the nest, in proportion to within-nest shares. The condition on $s_{j|g}$ matters. Writing the denominator as $\sigma(1 - s_{j|g}) + (1 - \sigma)(1 - s_j)$,

$$D_{j0} = \frac{(1 - \sigma) s_0}{\sigma(1 - s_{j|g}) + (1 - \sigma)(1 - s_j)},$$

which vanishes only if $\frac{1 - s_{j|g}}{1 - \sigma}$ grows without bound. A product alone in its nest has $s_{j|g} = 1$, so $D_{j0} = \frac{s_0}{1 - s_j}$ for every σ. The limit also fails when mean utilities, rather than shares, are held fixed and j is the unique best product in its nest. Then $1 - s_{j|g}$ falls exponentially in $\frac{1}{1-\sigma}$, and D_{j0} tends to $\frac{s_0}{1 - s_j}$ at the limiting shares. Table 7.8 collects the formulas of this section and the next three subsections.

Red bus, blue bus. The classic example shows what nesting achieves (Section 7.1.4). A commuter chooses between a car and a red bus with equal mean utilities, so each has share $\frac{1}{2}$. A blue bus identical to the red bus is added. Place the car alone in one nest and the two buses in another, and normalize the car's mean utility to zero, as for an outside good. With bus mean utility $\delta = 0$, the bus nest has $D_{\text{bus}} = 2$ and $D_{\text{bus}}^{1-\sigma} = 2^{1-\sigma}$. By (7.59),

$$s_{\text{car}} = \frac{1}{1 + 2^{1-\sigma}}, \qquad s_{\text{red}} = s_{\text{blue}} = \frac{1}{2} \cdot \frac{2^{1-\sigma}}{1 + 2^{1-\sigma}} = \frac{2^{-\sigma}}{1 + 2^{1-\sigma}}. \tag{7.67}$$

Table 7.8: Logit and nested logit formulas

Object	Logit	Nested logit ($j \in g$)
Share s_j	$\frac{e^{\delta_j}}{1+\sum_k e^{\delta_k}}$	$\frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g^\sigma\left(1+\sum_h D_h^{1-\sigma}\right)}$
Inversion	$\delta_j = \ln s_j - \ln s_0$	$\delta_j = \ln s_j - \ln s_0 - \sigma \ln s_{j\|g}$
Own elasticity ε_j	$\alpha p_j(1-s_j)$	$\alpha p_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}s_{j\|g} - s_j\right]$
Cross elasticity, $k \in g$	$\alpha p_k s_k$	$\alpha p_k\left[\frac{\sigma}{1-\sigma}s_{k\|g} + s_k\right]$
Cross elasticity, $k \notin g$	$\alpha p_k s_k$	$\alpha p_k s_k$
Diversion D_{jk}, $k \in g$	$\frac{s_k}{1-s_j}$	$\frac{\sigma s_{k\|g} + (1-\sigma)s_k}{1-\sigma s_{j\|g} - (1-\sigma)s_j}$
Diversion D_{jk}, $k \notin g$ or $k = 0$	$\frac{s_k}{1-s_j}$	$\frac{(1-\sigma)s_k}{1-\sigma s_{j\|g} - (1-\sigma)s_j}$
Single-product markup	$\frac{1}{\alpha(1-s_j)}$	$\frac{1-\sigma}{\alpha\left[1-\sigma s_{j\|g} - (1-\sigma)s_j\right]}$
Multi-product markup	$\frac{1}{\alpha(1-S_f)}$	$\frac{1-\sigma}{\alpha(1-\sigma S_{f\|g})(1-\Phi_f)}$
Consumer surplus, up to C	$\frac{1}{\alpha}\ln\left(1+\sum_k e^{\delta_k}\right)$	$\frac{1}{\alpha}\ln\left(1+\sum_h D_h^{1-\sigma}\right)$
Removing j, change in CS	$\frac{1}{\alpha}\ln(1-s_j)$	$\frac{1}{\alpha}\ln\left[1-s_g+s_g(1-s_{j\|g})^{1-\sigma}\right]$

Notes: $D_g = \sum_{k\in g} e^{\frac{\delta_k}{1-\sigma}}$, $s_{j|g} = \frac{s_j}{s_g}$, and $\delta_j = x_j\beta - \alpha p_j + \xi_j$. Own elasticities are positive numbers. S_f is the combined share of firm f, $S_{f|g}$ its share within nest g, and $\Phi_f = \sum_h \frac{(1-\sigma)S_{fh}}{1-\sigma S_{f|h}}$ (Proposition 7.28). Welfare formulas are per consumer, at fixed prices, with the outside good alone in its nest (Proposition 7.30 and Corollary 7.31).

At $\sigma = 0$ every mode has share $\frac{1}{3}$, the logit answer. At $\sigma = 0.5$ the car keeps 0.414 and each bus has 0.293. As $\sigma \to 1$ the shares approach $\left(\frac{1}{2}, \frac{1}{4}, \frac{1}{4}\right)$, the commonsense answer. Figure 7.6 plots the three shares against σ. The nested logit resolves the paradox only because the analyst put the two buses in the same nest.

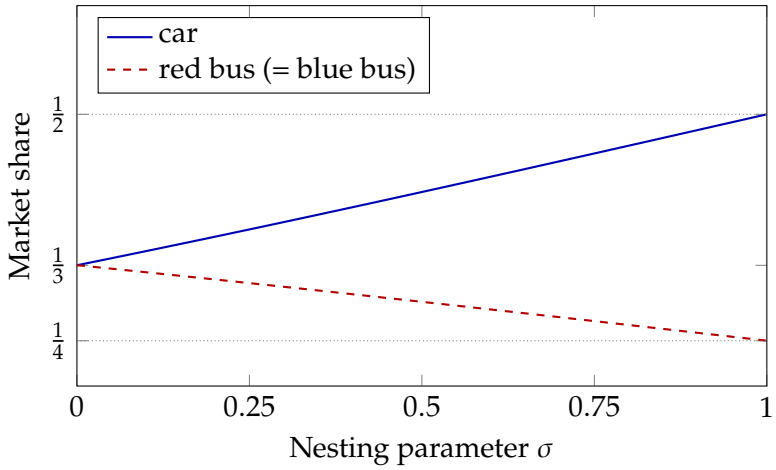


Figure 7.6: Red bus, blue bus. Shares of the car and of each bus from (7.67) when the two buses form one nest and the car is alone in its nest, all with equal mean utilities. The logit ($\sigma = 0$) gives $\frac{1}{3}$ to each mode. As $\sigma \to 1$ the car keeps $\frac{1}{2}$ and the buses split the other half.

7.5.4 Estimation

Like the logit, the nested logit can be inverted in closed form, and the inverted equation is linear in the parameters.

Proposition 7.26 (Nested logit inversion)**.** *Under Assumption 7.23, let the observed shares $s_j > 0$ and $s_0 > 0$ sum to one. Let $\bar{s}_g = \sum_{k \in g} s_k$ be the observed nest shares and $s_{j|g} = \frac{s_j}{\bar{s}_g}$ the observed within-nest shares. For a given $\sigma \in [0, 1)$, the unique mean utilities that reproduce the observed shares are*

$$\delta_j = \ln s_j - \ln s_0 - \sigma \ln s_{j|g}. \tag{7.68}$$

With $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$ in market t, the shares satisfy

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \sigma \ln s_{j|g,t} + \xi_{jt}. \tag{7.69}$$

Proof. Start from the expression for $\ln s_j$ derived before (7.61) and subtract $\ln s_0 = -\ln(1 + \sum_h D_h^{1-\sigma})$:

$$\ln s_j - \ln s_0 = \frac{\delta_j}{1-\sigma} - \sigma \ln D_g.$$

This still contains the unobserved inclusive sum. The within-nest share gives $\ln s_{j|g} = \frac{\delta_j}{1-\sigma} - \ln D_g$, so $\ln D_g = \frac{\delta_j}{1-\sigma} - \ln s_{j|g}$. Substituting,

$$\begin{aligned} \ln s_j - \ln s_0 &= \frac{\delta_j}{1-\sigma} - \frac{\sigma \delta_j}{1-\sigma} + \sigma \ln s_{j|g} \\ &= \delta_j + \sigma \ln s_{j|g}, \end{aligned}$$

which rearranges to (7.68). Any δ that reproduces the shares must therefore equal (7.68).

To show that (7.68) reproduces the shares, compute its inclusive sums. Using $s_k = \bar{s}_g s_{k|g}$,

$$e^{\frac{\delta_k}{1-\sigma}} = \left(\frac{s_k}{s_0}\right)^{\frac{1}{1-\sigma}} s_{k|g}^{-\frac{\sigma}{1-\sigma}} = \left(\frac{\bar{s}_g}{s_0}\right)^{\frac{1}{1-\sigma}} s_{k|g}.$$

Summing over $k \in g$ gives $D_g = \left(\frac{\bar{s}_g}{s_0}\right)^{\frac{1}{1-\sigma}}$, so $D_g^{1-\sigma} = \frac{\bar{s}_g}{s_0}$. The model's within-nest share is then $\frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g} = s_{j|g}$. Its nest share is $\frac{\bar{s}_g s_0^{-1}}{1+\sum_h \bar{s}_h s_0^{-1}} = \frac{\bar{s}_g}{s_0+\sum_h \bar{s}_h} = \bar{s}_g$, because the shares sum to one. Both factors match the data, so the model reproduces every s_j. □

Berry (1994, eqs. 26–28, p. 253) reaches the same equation by eliminating D_g through the nest share, $D_g^{1-\sigma} = \frac{\bar{s}_g}{s_0}$, the identity used in the second half of the proof (Section 7.7.5 follows his route). The regression (7.69) is the logit regression (7.16) with one additional regressor, the log within-nest share. Its coefficient is the nesting parameter. Berry (1994, n. 7) notes that the formula extends, "easily (but somewhat tediously)", to several levels of nests and to nest-specific parameters σ_g. Section 7.5.6 carries out the two-level case.

One inside nest. The cheapest nesting puts all inside goods in one nest and the outside good in the other. Then $s_{j|g} = \frac{s_j}{1-s_0}$, and (7.69) becomes

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \sigma \ln \frac{s_{jt}}{1-s_{0t}} + \xi_{jt}. \tag{7.70}$$

The model requires no classification of products, so it is often run as a robustness check on the logit. With one inside nest and inclusive sum D, the share formula is

$$s_j = \frac{e^{\frac{\delta_j}{1-\sigma}} D^{-\sigma}}{1 + D^{1-\sigma}} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D^\sigma + D},$$

which is the form Einav (2007, eq. 3) uses for movies (Section 7.8).

The nesting parameter then measures how much additional products expand the category rather than steal business from rivals. Suppose the market has J identical inside products with mean utility δ. The total inside share is $1 - s_0 = \frac{J^{1-\sigma} e^\delta}{1+J^{1-\sigma} e^\delta}$, whose elasticity with respect to J is $(1-\sigma)s_0$. At $\sigma = 0$ each new product draws consumers from the outside good as in the logit. As $\sigma \to 1$ new copies only divide a fixed category. Raising the mean utility δ_j of an existing product is different. At given shares, $\frac{\partial \ln(1-s_0)}{\partial \delta_j} = s_0 s_{j|g}$ for every σ, which is the logit value $\frac{s_0 s_j}{1-s_0}$. A uniform rise Δ in all inside prices multiplies $D^{1-\sigma}$ by $e^{-\alpha\Delta}$, so

$$\frac{\mathrm{d} \ln(1-s_0)}{\mathrm{d}\Delta} = -\alpha s_0,$$

the same as in the logit. For a given price coefficient, σ leaves the category response unchanged. It raises the own elasticity of a product with a small within-nest share by a factor close to $\frac{1}{1-\sigma}$. Miller and Weinberg (2017, p. 1774) use the one-nest model for beer. Their richer specifications add random coefficients that interact consumer income with price and product characteristics (Table IV). They note that the nesting parameter keeps the elasticities from being overly sensitive to the assumed market size (Section 7.2.5 and Chapter 11).

Endogeneity of the within-nest share. The within-nest share depends on ξ_{jt}. From (7.59), $\frac{\partial \ln s_{j|g}}{\partial \xi_j} = \frac{1-s_{j|g}}{1-\sigma} > 0$, so the regressor $\ln s_{j|g,t}$ is positively correlated with the error. A high-quality product also lowers the within-nest shares of its nest-mates, so the regressor is endogenous for every product in the nest. OLS therefore tends to bias $\hat{\sigma}$ upward, toward one. Prices are endogenous as in the logit (Section 7.3). Estimating (7.69) needs at least two excluded instruments, one for p_{jt} and one for $\ln s_{j|g,t}$, and the two must move the regressors in different ways.

Instruments for the within-nest share shift the crowding of a product's nest without shifting its own unobserved quality. Common choices follow.

- The number of products in the nest, J_{gt}. More nest-mates lower $s_{j|g}$ mechanically.
- Sums or averages of the characteristics of the other products in the nest. Berry (1994, p. 254) suggests "the characteristics of other firms in the group". These are the nest-level versions of the BLP instruments of Section 7.3.2, and the differentiation instruments of Gandhi and Houde (2019) refine them.
- Cost shifters of the other products in the nest, which move their prices and hence $s_{j|g}$.
- Application-specific counts. Einav (2007) uses the number of movies showing in the same week.

These instruments are valid if the number and characteristics of nest-mates are mean independent of ξ_{jt}. Endogenous entry threatens this condition. Firms add products to nests and markets where demand is high, so J_{gt} may be correlated with ξ_{jt}. Product and market fixed effects absorb persistent demand differences and reduce the concern, provided entry does not respond to transitory shocks.

What identifies σ. Fix a product's mean utility and add a rival to its nest. The rival lowers $\ln s_{j|g}$. By (7.69), it lowers $\ln \frac{s_j}{s_0}$ by σ times as much. A rival added to a different nest changes neither the within share nor the ratio $\frac{s_j}{s_0}$. With $\sigma = 0$ the ratio $\frac{s_j}{s_0}$ does not respond at all, which is IIA. With σ near one it falls almost one for one with the within share. A rival that does not beat the best product in the nest then steals customers almost only from its nest-mates. A better rival also draws from the outside good, because it raises the nest's best mean utility. Comparing the same product across markets with exogenously different nest-mates therefore traces out σ. On the supply side, Berry (1994, pp. 255–256) adds that the joint behavior of prices, product shares and group shares in the pricing equation helps identify σ (Section 7.5.5). Estimates of σ outside $[0, 1)$ signal a misspecified tree or invalid instruments (Lemma 7.22).

Estimation from individual choices. With data on individual choices, the nested logit can be estimated by maximum likelihood, as the logit is in Section 7.1.5. Let consumer i have utility index V_{ij} in place of δ_j, with the outside good normalized to zero. For j in nest g, split the index into a part $z_{ig}\gamma$ that is constant within the nest and a part $w_{ij}b$ that varies within it, $V_{ij} = z_{ig}\gamma + w_{ij}b$. The inclusive sum $D_{ig} = \sum_{k \in g} e^{\frac{V_{ik}}{1-\sigma}}$ then satisfies

$$\ln D_{ig} = \frac{z_{ig}\gamma}{1-\sigma} + I_{ig}, \qquad I_{ig} = \ln \sum_{k \in g} \exp\left(\frac{w_{ik}b}{1-\sigma}\right).$$

Substituting into Proposition 7.25, the choice probability factors into a within-nest and a nest

probability,

$$P_{ij|g} = \exp\left(\frac{w_{ij}b}{1-\sigma} - I_{ig}\right), \qquad P_{ig} = \frac{\exp\left(z_{ig}\gamma + (1-\sigma)I_{ig}\right)}{1 + \sum_h \exp\left(z_{ih}\gamma + (1-\sigma)I_{ih}\right)}. \tag{7.71}$$

The log-likelihood sums $\ln P_{ij|g} + \ln P_{ig}$ over the observed choices. Unlike the logit likelihood of Proposition 7.10, it "is not concave in all parameters, and is highly non-linear in the inclusive value coefficients" (McFadden, 1984, p. 1426). A search can then stop at a local maximum, so it should start from several points.

Equation (7.71) suggests a *sequential estimator*. The first step fits a logit to the choices within each nest, which estimates $\frac{b}{1-\sigma}$. The second step computes the estimated inclusive values $\hat{I}_{ig}$ and fits a logit to the choice of nest, with regressors z_{ig} and $\hat{I}_{ig}$. The coefficient on $\hat{I}_{ig}$ estimates $1-\sigma$. Each step is a concave logit problem. McFadden notes that the estimator is consistent but often inefficient. Its second-step standard errors are wrong, because the inclusive values are estimated, and correction formulae exist (p. 1426). One Newton step on the full likelihood from the sequential estimates is asymptotically equivalent to full maximum likelihood. In practice the strong nonlinearity can make this one-step estimator erratic, so several iterations may be needed. In McFadden's housing example (Table 7.2) only *OPCOST* and *YNH* vary among renters, so only their coefficients enter the first step. There the two estimators agree to the third decimal place, with log-likelihoods of -10.7868 for the sequential estimates and -10.7862 at the full maximum (p. 1432).

Choosing the nests. The nests must be fixed before estimation, a limitation the nested logit shares with multi-stage budgeting (Chapter 5). The classification is often unclear. Is a minivan a car or a truck? Are store-brand and national-brand cereals in the same nest? Is a family sedan closer to a compact car or to a luxury car? Different nestings imply different substitution patterns, and the data may not discriminate between them. With several levels the order of the nests also matters. Nevo (2000a, n. 18) notes that classifying computers first into branded and unbranded and then into frontier and non-frontier technology implies different substitution than the reverse order, even with the same classification. Practical checks include estimating nest-specific parameters σ_g, comparing non-nested trees by fit, and checking that all estimates lie in $[0, 1)$.

A Monte Carlo experiment. We illustrate these points with a simulation. Each sample has 500 markets with two inside nests and an outside good. In the main design the number of products in each nest is drawn uniformly from $\{1, \ldots, 5\}$ in every market. Each product has its own owner. Mean utility is $\delta_j = \beta_0 + \beta_x x_j - \alpha p_j + \xi_j$ with $\beta_0 = 2$, $\beta_x = 1$, $\alpha = 1$ and $\sigma = 0.5$. Marginal cost is $c_j = \exp(0.5 + 0.25x_j + 0.25w_j + 0.1\xi_j + 0.25\omega_j)$, where x_j, ξ_j, w_j and ω_j are independent standard normal variables. Prices are the single-product Bertrand-Nash equilibrium of Proposition 7.27. The average outside share is 0.28 and the average within-nest share is 0.33. There are five excluded instruments. The first two are the own cost shifter w_j and the number of products in the own nest. The other three are sums over rival products. They add up x over the other products in the own nest, x over the products of the other nest, and w over the other products in the own nest. We draw 500 samples. A second design fixes three products in every nest, so the count instrument disappears.

Table 7.9 reports the results. OLS gives $\hat{\sigma} = 0.801$ against a true value of 0.5 and cuts the price coefficient to a third of its true value. Instrumenting the price alone fixes most of the price bias, with $\hat{\alpha} = 0.870$. The nesting parameter stays near 0.79, however, and the implied own elasticity of 7.16 is almost twice the true value of 3.83. Treating the within-nest share as

Table 7.9: Monte Carlo estimates of the nested logit regression

		Nest sizes vary across markets				Fixed size
Parameter	True	OLS	IV, price only	IV, both	Logit IV	IV, both
β_0	2.0	0.920	2.258	2.003	1.561	1.997
		(0.055)	(0.120)	(0.115)	(0.204)	(0.121)
β_x	1.0	0.462	0.760	1.001	1.417	0.998
		(0.022)	(0.036)	(0.034)	(0.053)	(0.047)
α	1.0	0.334	0.870	1.002	1.228	0.998
		(0.022)	(0.049)	(0.045)	(0.082)	(0.057)
σ	0.5	0.801	0.787	0.499	0	0.500
		(0.009)	(0.010)	(0.019)		(0.031)
Mean own elasticity	3.83	2.91	7.16	3.83	2.71	3.83
		(0.19)	(0.40)	(0.19)	(0.18)	(0.20)

Notes: Means across 500 simulated samples of 500 markets, with standard deviations across samples in parentheses. Columns 3 to 6 use the main design, in which each of the two nests has between one and five products. Column 7 fixes three products per nest. "IV, price only" instruments the price and treats $\ln s_{j|g}$ as exogenous. "IV, both" instruments both. "Logit IV" imposes $\sigma = 0$. The mean own elasticity averages ε_j from (7.65) over products at the estimated parameters. Its true value is 3.83 in the main design and 3.82 in the fixed-size design. Mean first-stage F statistics of the excluded instruments are 304 for price and 277 for $\ln s_{j|g}$ in the main design, and 336 and 183 in the fixed-size design. Computed by `figures/ch07/src/mc_nested_logit.py`.

exogenous is therefore costly even with a valid price instrument. Instrumenting both regressors recovers every parameter. Imposing the logit ($\sigma = 0$) with the same instruments biases $\hat{\alpha}$ and $\hat{\beta}_x$ upward. It also understates the mean own elasticity by about 29 percent, because the factor $\frac{1}{1-\sigma}$ is missing from the elasticity formula. With fixed nest sizes, the characteristics of nest-mates still identify σ. The standard deviation of $\hat{\sigma}$ rises from 0.019 to 0.031, which shows that variation in the number of products adds information.

7.5.5 Pricing with nested logit demand

The nested logit keeps the analytic markups of the logit. We first treat single-product firms and then derive a closed form for multi-product firms.

Proposition 7.27 (Single-product markups)**.** *Under Assumption 7.23 with constant marginal cost mc_j, the first-order condition of a single-product firm selling $j \in g$ implies*

$$p_j - mc_j = \frac{1-\sigma}{\alpha\left[1 - \sigma s_{j|g} - (1-\sigma)s_j\right]}. \tag{7.72}$$

Proof. The firm maximizes $M(p_j - mc_j)s_j(p)$. The first-order condition is $s_j + (p_j - mc_j)\frac{\partial s_j}{\partial p_j} = 0$. By (7.62),

$$\frac{\partial s_j}{\partial p_j} = -\frac{\alpha s_j}{1-\sigma}\left[1 - \sigma s_{j|g} - (1-\sigma)s_j\right].$$

Substituting and dividing by $s_j > 0$,

$$1 - \frac{\alpha(p_j - mc_j)}{1-\sigma}\left[1 - \sigma s_{j|g} - (1-\sigma)s_j\right] = 0,$$

which rearranges to (7.72). □

This is equation (33) of Berry (1994, p. 255). With $mc_j = w_j\gamma + \omega_j$ it becomes a linear supply equation, $p_j = w_j\gamma + \frac{1-\sigma}{\alpha[1-\sigma s_{j|g}-(1-\sigma)s_j]} + \omega_j$, which can be estimated jointly with (7.69) as in Section 7.4.5. When $\sigma = 0$ only the product share matters, as in the logit markup $\frac{1}{\alpha(1-s_j)}$. As $\sigma \to 1$ with $s_{j|g} < 1$ held fixed, only the within-nest share matters. A product alone in its nest keeps the logit markup for every σ. The markup is at least $\frac{1-\sigma}{\alpha}$, so the logit floor $\frac{1}{\alpha}$ falls as products become closer substitutes. If $\sigma \to 1$ and a nest holds many products with small within shares, the markup goes to zero, which is Bertrand competition with perfect substitutes.

Proposition 7.28 (Multi-product markups)**.** *Under Assumption 7.23 with constant marginal costs, let firm f own the products $\mathcal{J}_f$. Write $S_{fh} = \sum_{k\in\mathcal{J}_f\cap h} s_k$ for its combined share in nest h and $S_{f|h} = \frac{S_{fh}}{s_h}$ for its share within nest h. At an interior Bertrand-Nash equilibrium, all of the firm's products in a nest g carry the same markup,*

$$m_{fg} = \frac{1-\sigma}{\alpha\big(1-\sigma S_{f|g}\big)\big(1-\Phi_f\big)}, \qquad \Phi_f = \sum_h \frac{(1-\sigma)S_{fh}}{1-\sigma S_{f|h}}, \tag{7.73}$$

where the sum runs over the nests in which f sells, and $0 \le \Phi_f < 1$.

Proof. Write $m_k = p_k - mc_k$. The firm maximizes $M\sum_{k\in\mathcal{J}_f} m_k s_k(p)$. The first-order condition for $j \in \mathcal{J}_f \cap g$ is

$$s_j + \sum_{k\in\mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} = 0.$$

By (7.61) with the roles of j and k exchanged, and $\frac{\partial \delta_j}{\partial p_j} = -\alpha$,

$$\frac{\partial s_k}{\partial p_j} = -\alpha s_k\left[\frac{\mathbf{1}\{k=j\}}{1-\sigma} - \frac{\sigma}{1-\sigma}s_{j|g}\mathbf{1}\{k\in g\} - s_j\right].$$

Substituting into the first-order condition,

$$s_j - \frac{\alpha m_j s_j}{1-\sigma} + \frac{\alpha\sigma}{1-\sigma}s_{j|g}\sum_{k\in\mathcal{J}_f\cap g} m_k s_k + \alpha s_j \sum_{k\in\mathcal{J}_f} m_k s_k = 0.$$

Divide by s_j and use $\frac{s_{j|g}}{s_j} = \frac{1}{s_g}$ and $\frac{s_k}{s_g} = s_{k|g}$. Multiplying by $\frac{1-\sigma}{\alpha}$,

$$m_j = \frac{1-\sigma}{\alpha} + \sigma\sum_{k\in\mathcal{J}_f\cap g} m_k s_{k|g} + (1-\sigma)\sum_{k\in\mathcal{J}_f} m_k s_k.$$

The right side depends on j only through its nest g. Hence $m_j = m_{fg}$ for every $j \in \mathcal{J}_f\cap g$. The first sum then equals $m_{fg}S_{f|g}$ and the second equals $\sum_h m_{fh}S_{fh}$. Let $A_f = \frac{1-\sigma}{\alpha} + (1-\sigma)\sum_h m_{fh}S_{fh}$, which does not depend on g. Then

$$m_{fg}\big(1-\sigma S_{f|g}\big) = A_f, \qquad \text{so} \qquad m_{fg} = \frac{A_f}{1-\sigma S_{f|g}}.$$

Substituting back into the definition of A_f,

$$A_f = \frac{1-\sigma}{\alpha} + A_f\sum_h \frac{(1-\sigma)S_{fh}}{1-\sigma S_{f|h}} = \frac{1-\sigma}{\alpha} + A_f\Phi_f,$$

so $A_f = \frac{1-\sigma}{\alpha(1-\Phi_f)}$, which gives (7.73). For the bound, each term of Φ_f equals $s_h \frac{(1-\sigma)S_{f|h}}{1-\sigma S_{f|h}} \leq s_h$, since $(1-\sigma)x \leq 1-\sigma x$ for $x \leq 1$. Hence $\Phi_f \leq \sum_h s_h \leq 1 - s_0 < 1$. □

Two checks confirm the formula. For a single product, $S_{f|g} = s_{j|g}$, $S_{fg} = s_j$ and $\Phi_f = \frac{(1-\sigma)s_j}{1-\sigma s_{j|g}}$. The product $(1-\sigma s_{j|g})(1-\Phi_f)$ equals $1 - \sigma s_{j|g} - (1-\sigma)s_j$, which gives (7.72). At $\sigma = 0$, $\Phi_f = \sum_h S_{fh} = S_f$ and $m_{fg} = \frac{1}{\alpha(1-S_f)}$, the logit result of Proposition 7.17. The formula has two layers of internalized cannibalization. The factor $1 - \sigma S_{f|g}$ captures recapture within the nest, which grows with σ and with the firm's within-nest share. The factor $1 - \Phi_f$ captures recapture across all of the firm's nests through the common outside option.

Example 7.29 (Ownership and markups)**.** Consider a market with two inside nests. Nest A has three products with shares 0.15 each, nest B has two products with shares 0.10 each, and $s_0 = 0.35$. Let $\alpha = 1$. We compute the markup of a nest-A product implied by (7.73) at these observed shares, as one does when recovering costs from data. Table 7.10 reports three ownership structures. Under the logit, joint ownership of two nest-A products raises the markup by 21.4 percent, and joint ownership of a nest-A and a nest-B product raises it by 13.3 percent. At $\sigma = 0.5$ the same changes raise it by 46.8 and 7.9 percent. At $\sigma = 0.8$ they raise it by 73.0 and 3.6 percent. Common ownership matters far more within a nest than across nests once σ is large. The logit cannot make this distinction, which is why merger simulation with logit demand spreads price effects evenly (Chapter 11).

Table 7.10: Implied markups of a nest-A product under alternative ownership

Ownership	$\sigma = 0$	$\sigma = 0.5$	$\sigma = 0.8$
Single-product firms	1.176	0.659	0.284
One firm owns two nest-A products	1.429	0.968	0.492
One firm owns a nest-A and a nest-B product	1.333	0.711	0.295
Percent increase, two nest-A products	21.4	46.8	73.0
Percent increase, nest-A and nest-B products	13.3	7.9	3.6

Notes: Illustrative shares 0.15 for each of three nest-A products, 0.10 for each of two nest-B products, $s_0 = 0.35$, and $\alpha = 1$. Markups in dollars from (7.73) at fixed shares. Computed by `figures/ch07/src/nl_markup_example.py`.

The equilibrium can be computed in several ways. Iterating on the markup equation, $p \leftarrow mc + m(p)$, is the simplest method. In our Monte Carlo experiment it settled into a two-cycle in some markets with one dominant product. Iterating on exact best responses converged in every market of the experiment. Each best response solves a one-dimensional equation, because the left side of the first-order condition (7.72) rises in the own price and the right side falls.

7.5.6 The two-level nested logit

Some markets have two natural dimensions of grouping. Cars differ by segment and by country of origin. Painkillers differ by active substance and by form. The two-level nested logit, as used by Verboven (1996), splits each group g into subgroups h and adds a second nest taste. For product j in subgroup h of group g,

$$u_{ij} = \delta_j + \zeta_{ig} + (1-\sigma_2)\zeta_{ihg} + (1-\sigma_1)\epsilon_{ij}, \tag{7.74}$$

with the outside good alone in its group. The parameter σ_1 measures the correlation of utilities within a subgroup and σ_2 the correlation within a group.

The model is consistent with utility maximization when $0 \le \sigma_2 \le \sigma_1 < 1$. To see why, apply Lemma 7.24 twice. Write the subgroup part of (7.74) as

$$(1-\sigma_2)\Big[\zeta_{ihg} + \frac{1-\sigma_1}{1-\sigma_2}\epsilon_{ij}\Big].$$

The bracket is Gumbel if $\zeta_{ihg} \sim C(\tau)$ with $1-\tau = \frac{1-\sigma_1}{1-\sigma_2}$, which requires $\tau \in [0,1)$, that is $\sigma_1 \ge \sigma_2$. The group part, ζ_{ig} plus $1-\sigma_2$ times a Gumbel variable, is then Gumbel if $\zeta_{ig} \sim C(\sigma_2)$.

The shares follow from the sequential derivation in the proof of Proposition 7.25, applied level by level. Within subgroup hg the terms ζ_{ig} and ζ_{ihg} are common to all products, so the choice of product is a logit with scale $1-\sigma_1$. Let $D_{hg} = \sum_{k \in hg} e^{\frac{\delta_k}{1-\sigma_1}}$. By max-stability of the Gumbel, the best utility in subgroup hg is

$$(1-\sigma_1)\ln D_{hg} + \zeta_{ig} + (1-\sigma_2)\Big[\zeta_{ihg} + \frac{1-\sigma_1}{1-\sigma_2}\tilde{\epsilon}_{ihg}\Big],$$

where $\tilde{\epsilon}_{ihg}$ is standard Gumbel. The bracket is standard Gumbel, as shown above, and ζ_{ig} is common to all subgroups of g. So the choice of subgroup within g is a logit with scale $1-\sigma_2$ in the values $(1-\sigma_1)\ln D_{hg}$, which gives $s_{h|g}$ below. Let $D_g = \sum_{h \in g} D_{hg}^{\frac{1-\sigma_1}{1-\sigma_2}}$. Applying max-stability once more, the best utility in group g is $(1-\sigma_2)\ln D_g + \zeta_{ig} + (1-\sigma_2)\tilde{\epsilon}_{ig}$ with $\tilde{\epsilon}_{ig}$ standard Gumbel. Since $\zeta_{ig} \sim C(\sigma_2)$, the last two terms form a standard Gumbel variable. The choice of group is therefore a logit in the values $(1-\sigma_2)\ln D_g$, with 0 for the outside good. Together these steps give

$$s_{j|hg} = \frac{e^{\frac{\delta_j}{1-\sigma_1}}}{D_{hg}}, \qquad s_{h|g} = \frac{D_{hg}^{\frac{1-\sigma_1}{1-\sigma_2}}}{D_g}, \qquad s_g = \frac{D_g^{1-\sigma_2}}{1+\sum_{g'} D_{g'}^{1-\sigma_2}}, \tag{7.75}$$

with the inclusive sums D_{hg} and D_g defined above. The product share is $s_j = s_{j|hg}\, s_{h|g}\, s_g$.

The estimating equation. Taking logs of the three factors and subtracting $\ln s_0 = -\ln(1 + \sum_{g'} D_{g'}^{1-\sigma_2})$,

$$\begin{aligned}\ln s_j - \ln s_0 &= \frac{\delta_j}{1-\sigma_1} - \ln D_{hg} + \frac{1-\sigma_1}{1-\sigma_2}\ln D_{hg} - \ln D_g + (1-\sigma_2)\ln D_g \\ &= \frac{\delta_j}{1-\sigma_1} - \frac{\sigma_1-\sigma_2}{1-\sigma_2}\ln D_{hg} - \sigma_2 \ln D_g.\end{aligned}$$

Eliminate the group inclusive sum first. From the subgroup share, $\ln D_g = \frac{1-\sigma_1}{1-\sigma_2}\ln D_{hg} - \ln s_{h|g}$. Substituting,

$$\begin{aligned}\ln s_j - \ln s_0 &= \frac{\delta_j}{1-\sigma_1} - \Big[\frac{\sigma_1-\sigma_2}{1-\sigma_2} + \frac{\sigma_2(1-\sigma_1)}{1-\sigma_2}\Big]\ln D_{hg} + \sigma_2 \ln s_{h|g} \\ &= \frac{\delta_j}{1-\sigma_1} - \sigma_1 \ln D_{hg} + \sigma_2 \ln s_{h|g},\end{aligned}$$

because $\sigma_1 - \sigma_2 + \sigma_2 - \sigma_1\sigma_2 = \sigma_1(1 - \sigma_2)$. Next eliminate the subgroup inclusive sum using $\ln D_{hg} = \frac{\delta_j}{1-\sigma_1} - \ln s_{j|hg}$:

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \sigma_1 \ln s_{j|hg,t} + \sigma_2 \ln s_{h|g,t} + \xi_{jt}. \tag{7.76}$$

The regression adds the log within-subgroup share and the log subgroup share within the group. When $\sigma_1 = \sigma_2 = \sigma$ the two terms combine into $\sigma \ln s_{j|g}$, the one-level model with groups as nests. Both shares are endogenous, so the equation needs three excluded instruments, for example counts and characteristics of products in the same subgroup and in the same group.

Substitution. Differentiating the logs of (7.75) as in Section 7.5.3 gives, for j in subgroup h of group g,

$$\frac{\partial \ln s_j}{\partial \delta_k} = \frac{\mathbf{1}\{j = k\}}{1 - \sigma_1} - \left(\frac{1}{1 - \sigma_1} - \frac{1}{1 - \sigma_2}\right) s_{k|hg} \mathbf{1}\{k \in hg\} - \frac{\sigma_2}{1 - \sigma_2} s_{k|g} \mathbf{1}\{k \in g\} - s_k,$$

where $s_{k|g} = s_{k|hg} s_{h|g}$ is k's share within the group. Cross elasticities are largest within a subgroup, intermediate within a group, and smallest across groups when $\sigma_1 \geq \sigma_2 \geq 0$.

Applications. Goldberg (1995) uses a multi-level nested logit for cars (Chapter 8). Verboven (1996) applies the two-level model to price discrimination in the European car market. The groups are six classes (mini and small, medium, large, executive, luxury and sports). Each class splits into domestic and foreign cars (Verboven, 1996, pp. 251 and 254). Björnerstedt and Verboven (2016) nest analgesics by active substance and by form. They compare merger predictions with the outcome of an actual merger (Chapter 11). Their study is one of the ex-post evaluations of merger simulation listed by Asker and Nocke (2021, p. 231). Berry et al. (2006) combine a nested logit with two consumer types for airline travel and write the nesting parameter as $\lambda = 1 - \sigma$ (Chapter 9). Miller and Weinberg (2017) add random coefficients to the one-nest model (Chapter 11).

7.5.7 Other GEV models and the limits of nesting*

Nested logit trees force a hierarchy. A product belongs to one nest at each level, and the order of the levels matters. Other members of the GEV family relax these restrictions while keeping closed forms. A key property makes them easy to build. A sum of GEV generating functions with nonnegative weights, at least one of them positive, is again a GEV generating function, because (G1) to (G3) are preserved under such sums.

Bresnahan et al. (1997) propose the *principles of differentiation GEV* model (PD GEV) for personal computers. Each principle d partitions the products into categories, for example branded versus unbranded and frontier versus non-frontier technology. Every product belongs to one category under each principle. A generating function of this kind is

$$H(y) = y_0 + \sum_d a_d \sum_{c \in d} \left(\sum_{j \in c} y_j^{\frac{1}{1-\sigma_d}} \right)^{1-\sigma_d}, \qquad a_d \geq 0, \quad \sum_d a_d = 1, \tag{7.77}$$

where c runs over the categories of principle d and $\sigma_d \in [0, 1)$. By (7.53), the share of j is a weighted average of nested logit expressions, one for each principle,

$$s_j = \frac{\sum_d a_d D_{c_d(j)}^{1-\sigma_d} s_{j|c_d(j)}}{H(y)}.$$

Here $c_d(j)$ is j's category under principle d. The terms D_c and $s_{j|c}$ are the inclusive sum and the within-category share, both computed with σ_d. Two products that share a category under either principle are closer substitutes, and no principle has to come first. Nevo (2000a, p. 525) summarizes that the model removes the ordering problem and otherwise "retains all the advantages and disadvantages of the nested logit".

The *generalized nested logit* of Wen and Koppelman (2001) lets a product belong to several nests with allocation weights. This captures, for example, a minivan that is partly a car and partly a truck. The *ordered GEV* model of Small (1987, p. 409) applies to alternatives with a natural order. Examples are the number of cars a household owns and the time of day of a work trip. Its taste shocks are correlated among alternatives that are close in the order, and the correlation does not rise with their distance (pp. 409–410).

What nesting does not fix. Every GEV model keeps the closed forms because it keeps much of the logit's structure. Within a nest, substitution remains proportional to shares, so differences between nest-mates are invisible to the model (Nevo, 2000a, p. 524). Own elasticities still rise almost in proportion to price (Section 7.5.3). Tastes are not linked to consumer demographics, so the model cannot say who substitutes to what. The nests are imposed before estimation. Hausman (1997, p. 230) concludes that the nested logit "can solve some of these problems but still suffers from the IIA problem at each level of choice". Grigolon and Verboven (2014, p. 916) compare the nested logit and the random coefficients logit within a random coefficients nested logit. They use a simulation study and data from the European car market. They reject both special cases against the general model. The random coefficients logit gives different substitution patterns and a wider market definition than the two nested models, but the predicted price effects of mergers are robust across models. Random coefficients, developed in Chapter 8, make substitution depend on continuous characteristics and on demographics. Section 7.10 returns to this comparison with evidence.

7.6 Welfare in logit models

Discrete choice models measure consumer welfare in closed form. The GEV theorem gives the expected maximum utility, and quasi-linear utility converts it into dollars. This section derives the log-sum formula for the logit and the nested logit, applies it to price changes, product removal, product proliferation and new goods, and states its limitations.

7.6.1 The log-sum formula

Let utility be quasi-linear in income y_i,

$$u_{ij} = \alpha(y_i - p_j) + x_j\beta + \xi_j + e_{ij}, \quad j \in \mathcal{J}, \qquad u_{i0} = \alpha y_i + e_{i0}, \tag{7.78}$$

where the shock vector e_i has a GEV distribution with generating function H. In the logit e_{ij} is the Gumbel shock ϵ_{ij}. In the nested logit it is the composite $\zeta_{ig} + (1-\sigma)\epsilon_{ij}$. Mean utility relative to the outside good is $\delta_j = x_j\beta - \alpha p_j + \xi_j$ and $\delta_0 = 0$. The marginal utility of income is α for every consumer. The *expected consumer surplus* is the expected maximum utility in dollars, defined up to an additive constant C that cancels from every comparison.

Proposition 7.30 (Log-sum consumer surplus)**.** *Under* (7.78)*, the expected compensating variation of a change from a choice set $\mathcal{J}^0$ with mean utilities δ^0 to a choice set $\mathcal{J}^1$ with mean utilities δ^1 is*

$$\Delta CS = \frac{1}{\alpha}\Big[\ln H\big(e^{\delta^1}\big) - \ln H\big(e^{\delta^0}\big)\Big]. \tag{7.79}$$

Here $H(e^{\delta}) = H(1, e^{\delta_1}, \dots, e^{\delta_J})$, and absent products have $e^{\delta_k} = 0$. Expected consumer surplus per consumer is $CS = \frac{1}{\alpha} \ln H(e^{\delta}) + C$. In particular,

$$\textit{logit:} \qquad CS = \frac{1}{\alpha} \ln \left(1 + \sum_{k \in \mathcal{J}} e^{\delta_k} \right) + C, \tag{7.80}$$

$$\textit{nested logit:} \qquad CS = \frac{1}{\alpha} \ln \left(1 + \sum_{g=1}^{G} D_g^{1-\sigma} \right) + C. \tag{7.81}$$

In both models $CS = -\frac{1}{\alpha} \ln s_0 + C$, and $\frac{\partial CS}{\partial p_j} = -s_j$.

Proof. Write $V_j = \alpha y + \delta_j$ for the deterministic utilities. With quasi-linear utility, the expected compensating variation is the change in expected maximum utility divided by α, as derived in (6.12). Applying Proposition 7.21(iii) to the expected maximum before and after the change,

$$\mathbb{E}[CV] = \frac{1}{\alpha} \Big[\ln H\big(e^{V^1}\big) - \ln H\big(e^{V^0}\big) \Big].$$

Homogeneity (G1) gives $H(e^V) = H(e^{\alpha y} e^{\delta}) = e^{\alpha y} H(e^{\delta})$, so $\ln H(e^V) = \alpha y + \ln H(e^{\delta})$. The income terms cancel, which proves (7.79). Equations (7.80) and (7.81) substitute the two generating functions, with $y_0 = 1$. In both functions the outside good enters linearly, so $H_0 = 1$ and (7.53) gives $s_0 = \frac{1}{H(e^{\delta})}$. Hence $\ln H(e^{\delta}) = -\ln s_0$. Finally, by (7.53), $\frac{\partial CS}{\partial p_j} = \frac{1}{\alpha} \cdot (-\alpha) \frac{\partial \ln H}{\partial \delta_j} = -s_j$. □

The formula is due to Williams (1977), Small and Rosen (1981) and McFadden (1981). Section 6.3.3 derives the logit case, and Theorem 6.7 gives the general gradient property that underlies the last statement. The derivative $\frac{\partial CS}{\partial p_j} = -s_j$ is the discrete choice version of Roy's identity. Expected consumer surplus therefore changes, for a small price change, by minus expected demand times the price change, exactly as with an ordinary demand curve. Total surplus in market t is $M_t \, CS_t$, and welfare changes add across markets.

The representation $CS = -\frac{1}{\alpha} \ln s_0 + C$ gives the welfare change

$$\Delta CS = \frac{1}{\alpha} \ln \frac{s_0^0}{s_0^1}. \tag{7.82}$$

In any GEV model with the outside good alone in its nest, the welfare change depends only on the price coefficient and on the outside share before and after the change. Models disagree about welfare because they estimate different values of α and predict different counterfactual outside shares. The market size, which determines s_0, therefore matters for welfare as much as for elasticities (Section 7.2.5).

7.6.2 Applications

Price changes. A change in prices from p^0 to p^1 with a fixed choice set changes surplus by (7.79). In the logit this is $\frac{1}{\alpha} \ln \frac{\Lambda^1}{\Lambda^0}$ with $\Lambda = 1 + \sum_k e^{\delta_k}$. For small changes, the Roy identity gives $\Delta CS \approx -\sum_j s_j \Delta p_j$ per consumer. Merger simulations report the change in (7.79) between the pre-merger and the post-merger equilibrium prices (Chapter 11).

Corollary 7.31 (Removing a product)**.** *Hold all other prices fixed and remove product j, which belongs to nest g. The change in expected consumer surplus per consumer is*

$$\textit{logit:} \qquad \Delta CS = \frac{1}{\alpha}\ln(1 - s_j), \tag{7.83}$$

$$\textit{nested logit:} \qquad \Delta CS = \frac{1}{\alpha}\ln\left[1 - s_g + s_g\left(1 - s_{j|g}\right)^{1-\sigma}\right], \tag{7.84}$$

where all shares are those before the removal. Adding a clone of j, a product with the same mean utility in the same nest, changes surplus by $\frac{1}{\alpha}\ln(1 + s_j)$ in the logit and by $\frac{1}{\alpha}\ln\left[1 - s_g + s_g(1 + s_{j|g})^{1-\sigma}\right]$ in the nested logit.

Proof. In the logit, removal lowers Λ by e^{δ_j}, so

$$\frac{\Lambda^1}{\Lambda^0} = \frac{\Lambda^0 - e^{\delta_j}}{\Lambda^0} = 1 - s_j.$$

In the nested logit only the inclusive sum of nest g changes. It falls to $D_g - e^{\frac{\delta_j}{1-\sigma}} = D_g(1 - s_{j|g})$, so $D_g^{1-\sigma}$ falls to $D_g^{1-\sigma}(1 - s_{j|g})^{1-\sigma}$. Dividing the new value of $1 + \sum_h D_h^{1-\sigma}$ by the old one,

$$\frac{H^1}{H^0} = 1 - \frac{D_g^{1-\sigma}}{H^0} + \frac{D_g^{1-\sigma}}{H^0}\left(1 - s_{j|g}\right)^{1-\sigma} = 1 - s_g + s_g\left(1 - s_{j|g}\right)^{1-\sigma}.$$

Proposition 7.30 converts the ratios into surplus. A clone adds e^{δ_j} to Λ in the logit, and it raises D_g to $D_g(1 + s_{j|g})$ in the nested logit. The same steps give the clone formulas. □

At $\sigma = 0$ the nested logit formula reduces to the logit one. If j is alone in its nest, $s_{j|g} = 1$ and the loss is again $\frac{1}{\alpha}\ln(1 - s_j)$. For given shares with $s_{j|g} < 1$, the factor $(1 - s_{j|g})^{1-\sigma}$ tends to one as $\sigma \to 1$, and the loss vanishes. Consumers lose nothing when a product disappears if a perfect substitute remains in its nest. Take a product with share 0.15 in a nest with share 0.45. Its removal costs 0.163 utils per consumer under the logit, 0.086 under the nested logit with $\sigma = 0.5$, and 0.036 with $\sigma = 0.8$. These are dollar amounts after division by α. The formulas hold rivals' prices fixed. In equilibrium the remaining firms would raise prices after an exit and lower them after an entry, which Bresnahan (1997) stresses in the context of new goods (Chapter 10).

Clones and variety. Suppose the market offers J identical inside products with mean utility δ, all in one nest. The expected maximum utility is

$$\mathcal{W}(J) = \ln\left(1 + J^{1-\sigma}e^{\delta}\right) + \gamma_E. \tag{7.85}$$

Under the logit it grows like $\ln J$ without bound. Each added copy brings a new set of taste shocks and a new group of consumers who like it best, even though nothing physical is new. This is the sense in which the shocks "never exhaust" the product space (Section 6.7). The nested logit tempers the effect. Utility grows like $(1 - \sigma)\ln J$, and in the limit $\sigma \to 1$ it stays at $\ln(1 + e^{\delta})$, the value of a single product. Figure 7.7 plots (7.85) for $\delta = 0$. Even at $\sigma = 0.9$, fifty identical products are worth more than one. Nesting reduces the problem. It nearly removes it only if the analyst places the clones in a common nest with σ close to one.

New goods and infinite virtual prices. The *virtual price* of a product is the price at which its demand falls to zero. Valuing a new good amounts to integrating its demand curve from the

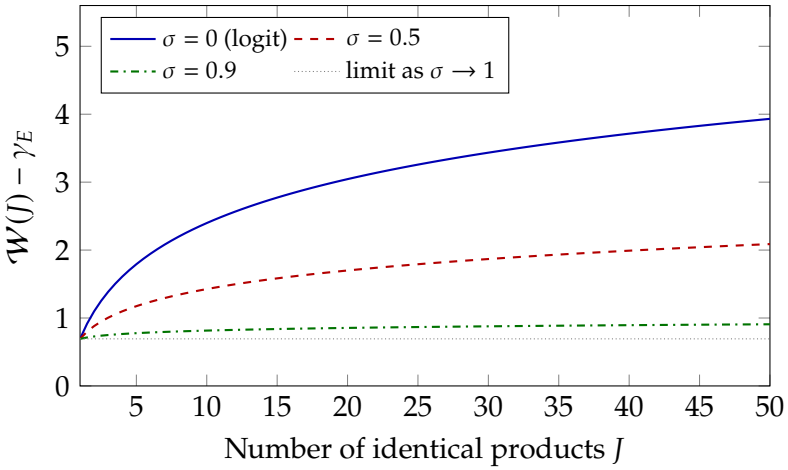

Figure 7.7: Expected maximum utility with J identical products in one nest, from (7.85) with mean utility $\delta = 0$ and an outside good. Under the logit the value of variety grows like $\ln J$. The nested logit slows the growth to $(1-\sigma)\ln J$, and only the limit $\sigma \to 1$ values fifty copies like one product.

virtual price down to the actual price (Hausman, 1997). In the logit the share of j is positive at every finite price, so the virtual price is infinite. The welfare integral still converges, because the logit share decays exponentially in price. By the Roy identity of Proposition 7.30, and because Λ approaches its value without j as $p_j \to \infty$,

$$\int_{p_j}^{\infty} s_j(t)\,\mathrm{d}t = \frac{1}{\alpha}\ln\frac{\Lambda^{\text{with } j}}{\Lambda^{\text{without } j}} = -\frac{1}{\alpha}\ln\left(1-s_j\right), \tag{7.86}$$

where s_j is the share of the new product after its introduction. This is (7.83) with the sign reversed. For small shares the value is close to $\frac{s_j}{\alpha}$. The logit markup of a single-product firm is $\frac{1}{\alpha(1-s_j)}$, so its variable profit per consumer is $\frac{s_j}{\alpha(1-s_j)}$. The ratio of consumer surplus to variable profit is $-\frac{(1-s_j)\ln(1-s_j)}{s_j}$, which lies below one and tends to one as $s_j \to 0$. In the logit, a small new product therefore creates roughly as much consumer surplus as variable profit, whatever its characteristics.

This mechanical link is the core of the critique of logit welfare analysis. Hausman (1997, p. 230) writes that the IIA problem "typically leads to a vast overestimate of the consumer's surplus from a new good." The reason, he adds, is that "the model does not incorporate sufficiently the similarities to existing goods." The CES demand system has the same feature: an infinite virtual price and a gain from every new variety (Chapters 5 and 10). Nesting the new product with close substitutes lowers its value through (7.84). Random coefficients let the data decide how close the new product is to existing ones. Trajtenberg (1989) values CT scanners with a nested multinomial logit, and Petrin (2002) contrasts logit and random coefficients valuations of the minivan. Chapter 10 covers both.

7.6.3 Caveats

Income effects. The log-sum formula relies on a constant marginal utility of income. Many applications instead use $\alpha \ln(y_i - p_j)$, as Berry et al. (1995) do, so that richer consumers are less price sensitive. The marginal utility of income then varies across consumers and across the

products they buy. Expected maximum utility no longer converts into dollars by division by a constant, and the expected compensating variation must be computed consumer by consumer. For each simulated consumer we draw the random coefficients and the shocks e_{ij}, and we hold the draw fixed across the two choice sets. We then solve for the income change that makes her realized maximum utility after the change equal to the one before it, and we average across consumers. Under the log form each such compensation has a closed form (Section 10.9.6). The computation reuses the random coefficient draws of the estimator of Chapter 8 and adds draws of the shocks.

A tempting shortcut integrates out the shocks first. For each draw of the random coefficients, it solves for the income change that restores expected maximum utility. The result is an ex ante compensation, paid before the shocks are known, and it generally differs from the mean compensating variation. Take a consumer with income y who has only the outside good, with utility $\ln y + \epsilon_{i0}$, and add a free alternative with utility $\ln y + \epsilon_{i1}$. The expected maximum of two independent standard type-I extreme value shocks exceeds that of one by $\ln 2$, so restoring expected maximum utility requires $\ln(y - C) + \ln 2 = \ln y$, or $C = \frac{y}{2}$. The realized compensation is $y\left[1 - e^{\epsilon_{i0} - \max(\epsilon_{i0}, \epsilon_{i1})}\right]$. Because $\epsilon_{i1} - \epsilon_{i0}$ is logistic, the mean realized compensation is $(1 - \ln 2)y \approx 0.307y$. The two measures coincide when utility is linear in income, so the log-sum formula needs no such distinction.

What the shocks mean. The welfare formulas treat the shocks ϵ_{ij} as tastes that consumers enjoy. Section 7.1.1 listed other readings, from unobserved characteristics to measurement error and mistakes. If the shocks are mistakes, the log-sum counts them as real utility and overstates welfare. Under every reading, the model gives each product its own dimension of taste and a group of consumers who prefer it. The result is positive shares, markups of at least $\frac{1-\sigma}{\alpha}$, and positive value from every added product. This is the "too many characteristics" problem. It biases estimated markups and the value of new goods upward, and it keeps products with zero sales out of the direct inversion of observed shares. Section 7.10.4 examines its consequences and the remedies proposed in the literature.

Scale and the outside good. Welfare in dollars does not depend on the scale normalization of the shocks. Scaling all shocks by a constant scales α and the mean utilities by the same constant, and the ratio in (7.79) is unchanged. Welfare does depend on the definition of the outside good and of market size, through (7.82). A study that doubles the assumed number of potential buyers changes s_0 in every market and changes every welfare number with it.

7.7 Case study: Berry (1994) and the mean-utility method

The estimating equations of Sections 7.2 to 7.5 go back to one article, Berry (1994). This section reads it in its own terms. We cite its equation numbers so that a reader can follow the original, and we point back to the sections above for derivations already given. Page numbers refer to the journal pagination.

7.7.1 The question

Berry asks how to estimate demand and cost from a cross section of oligopoly markets with differentiated products, when prices are correlated with demand factors that the econometrician does not observe. In homogeneous-goods markets the demand error has long been read as unobserved demand factors, which the supply relation shows to be correlated with price.

Ignoring that correlation produces upward-sloping demand curves and similar anomalies (p. 243). Berry argues that differentiated products raise the same problem whenever some characteristics are unobserved, and that unobserved characteristics are common. Style is hard to quantify. Physically similar products differ in perceived quality, durability, status or service. The relevant characteristics may outnumber the observations.

Instrumental variables fix the problem for a homogeneous good. In a discrete-choice model, however, price and the unobserved characteristic both enter the share equation nonlinearly, which blocks a direct application. The alternatives of the time, reviewed in Section 7.2.1, were unattractive. A constant-elasticity system (Berry's equation (1)) is linear, but N goods bring N^2 elasticities, and restricting them a priori is arbitrary. Discrete choice models without unobserved characteristics produce anomalies such as the upward-sloping demand for CT scanners in Trajtenberg (1989). Berry derives demand from a utility model with few parameters and finds a way to keep instrumental variables. The article is methodological. Its evidence is a set of Monte Carlo experiments (Section 7.7.8).

7.7.2 The model

There are R independent markets. Market r has N_r firms, each selling one product. Product j has observed characteristics $z_j = (x_j, w_j)$, where x_j shifts demand and w_j shifts marginal cost, an unobserved demand characteristic ξ_j and an unobserved cost shock ω_j. Firms and consumers observe everything. The econometrician observes prices, quantities and $z = (z_1, \dots, z_N)$.

Assumption 7.32 (Exogenous characteristics)**.** In each market $(\xi_j, \omega_j)_{j=1}^{N}$ is mean independent of z, and markets are independent.

Berry himself calls this assumption "unreasonable in many cases" (p. 245). Utility is

$$u_{ij} = x_j\beta_i - \alpha p_j + \xi_j + \epsilon_{ij} = \delta_j + \mu_{ij} + \epsilon_{ij}, \qquad \delta_j = x_j\beta - \alpha p_j + \xi_j, \tag{7.87}$$

with random coefficients $\beta_{ik} = \beta_k + \sigma_k \nu_{ik}$ and $\mu_{ij} = \sum_k x_{jk}\sigma_k \nu_{ik}$ (Berry's equations (2) to (5)). Berry writes $\tilde{\beta}_i$ and ζ_{ik} where we write β_i and ν_{ik}, and he calls the composite deviation $v_{ij} = \mu_{ij} + \epsilon_{ij}$ by the name ν_{ij}. The mean utility δ_j collects everything common to all consumers.

Remark 7.33 (What an i.i.d. shock restricts). Let $\mu_{ij} = 0$, so that tastes vary only through a shock ϵ_{ij} that is i.i.d. across consumers and products, with any continuous distribution. Then $s_j = s_j(\boldsymbol{\delta})$, and since p_k enters only δ_k, $\frac{\partial s_j}{\partial p_k} = -\alpha \frac{\partial s_j}{\partial \delta_k}$. Shares determine $\boldsymbol{\delta}$ uniquely (Proposition 7.11), so products j and j' with equal shares have equal mean utilities. Exchangeable shocks then give $\frac{\partial s_j}{\partial \delta_k} = \frac{\partial s_{j'}}{\partial \delta_k}$, so j and j' have the same cross elasticity with respect to any third price p_k. This holds whether j and j' are two subcompacts or a subcompact and a luxury car (p. 246). The restriction comes from the i.i.d. additive error alone, so an i.i.d. probit shares it (Hausman and Wise, 1978). Random coefficients remove it, because those who leave j after a price rise have tastes β_i that favor products resembling j.

Each consumer buys one unit of the best alternative. With $f(\cdot \mid x, \sigma)$ the density of $\boldsymbol{\nu}_i$ and $A_j(\boldsymbol{\delta}) = \{\boldsymbol{\nu}_i : \delta_j + \nu_{ij} > \delta_k + \nu_{ik}\ \forall k \neq j\}$, the share is $s_j = \int_{A_j(\boldsymbol{\delta})} f(\boldsymbol{\nu} \mid x, \sigma)\, d\boldsymbol{\nu}$ (equation (6)), and quantity is $q_j = M s_j$ (equation (7)). With finitely many consumers, observed shares would carry sampling error of variance $\frac{s_j(1-s_j)}{M}$ (footnote 4), so Berry assumes a continuum. An outside good, whose price does not respond to inside prices, ensures that a general price increase reduces aggregate output (p. 247). Berry assumes M is observed, as in BLP, where it is the number of households (Section 7.2.5).

Firm j has costs $C_j(q_j, w_j, \omega_j, \gamma)$ and marginal cost c_j, so its profit is $p_j M s_j - C_j$ (equation (8)). At an interior pure-strategy Nash equilibrium in prices,

$$p_j = c_j + s_j \left| \frac{\partial s_j}{\partial p_j} \right|^{-1} \tag{7.88}$$

(equation (9)).

7.7.3 The inversion and the estimator

In $s_j = s_j(x, \boldsymbol{p}, \xi, \theta)$ (equation (10)) the error enters nonlinearly, so instrumental variables do not apply directly. Berry transforms the shares so that ξ appears linearly. With a known density of consumer unobservables, $s_j = s_j(\boldsymbol{\delta})$ (equation (11)), and the model fits observed shares exactly at the true $\boldsymbol{\delta}$. The paper's Appendix shows that, with $\delta_0 = 0$, each interior share vector is produced by exactly one $\boldsymbol{\delta} \in \mathbb{R}^N$ (Proposition 7.11 reproduces the proof). Inverting,

$$\delta_j(s) = x_j\beta - \alpha p_j + \xi_j \tag{7.89}$$

(equation (12)), the linear equation that Section 7.2.1 motivates. When the density has parameters σ, the inverse depends on them, $\delta_j(s, \sigma) = x_j\beta - \alpha p_j + \xi_j$ (equation (21), which the paper prints with $+\alpha p_j$ by a slip). With instruments satisfying $\mathbb{E}[\xi_j \mid z] = 0$ the estimator is

$$\hat{\theta} = \arg\min_{\theta} \; \xi(\theta)^\top Z W Z^\top \xi(\theta), \qquad \xi_j(\theta) = \delta_j(s, \sigma) - x_j\beta + \alpha p_j, \tag{7.90}$$

nonlinear in σ (Hansen, 1982) and two-stage least squares when σ is known (Section 7.3.4). Each element of σ requires an extra excluded instrument.

Berry's remarks on the structure of the data (pp. 249–250) appear in Section 7.2.2. With many markets the ξ_j may be correlated arbitrarily within a market, while a single market requires ξ_j independent across firms (footnote 6). In both cases $\delta_j(s)$ plays the role that quantity plays in a homogeneous-goods demand regression with cost instruments.

7.7.4 Instruments as Berry states them

Berry names two families of demand instruments (p. 249), which Section 7.3.2 discusses at length. The first is cost variables excluded from x_j, such as input prices that vary across firms. The second is the characteristics of other firms, x_k for $k \neq j$, which are excluded from u_{ij} but correlated with p_j through the markup in (7.88). Berry et al. (1995) developed the second family into the BLP instruments.

The logit makes the markup channel explicit. With single-product firms the markup is $\frac{1}{\alpha(1-s_j)}$ (Proposition 7.16). At fixed prices, a rise in a rival's characteristic x_{kl} changes s_j by $\frac{\partial s_j}{\partial \delta_k}\beta_l = -s_j s_k \beta_l$, so the markup changes by

$$\frac{\partial}{\partial x_{kl}} \left[\frac{1}{\alpha(1 - s_j)} \right] = -\frac{s_j s_k \beta_l}{\alpha(1 - s_j)^2},$$

which is negative when $\beta_l > 0$. The rival characteristic moves p_j, while Assumption 7.32 makes it uncorrelated with ξ_j. For the within-group share of the nested logit, Berry suggests "the characteristics of other firms in the group" (p. 254). For the supply relation below he lists excluded demand characteristics, rivals' characteristics, and market population as a shifter of output (p. 255).

7.7.5 The worked examples

Logit. With $\beta_i = \beta$ and type-I extreme value shocks, $s_j = \frac{e^{\delta_j}}{\sum_{k=0}^{N} e^{\delta_k}}$ (equation (13)), and with $\delta_0 = 0$,

$$\ln s_j - \ln s_0 = x_j\beta - \alpha p_j + \xi_j \tag{7.91}$$

(equation (14)), which is (7.16). Berry calls the case unusual, since $\boldsymbol{\delta}$ must usually be found numerically, and notes that the logit "produces unreasonable substitution patterns" (p. 250).

Vertical differentiation in Bresnahan's form. In the vertical model of Bresnahan (1987), consumers agree on quality and disagree on its value: $u_{ij} = \psi_j \nu_i - p_j$ with quality $\psi_j = x_j\beta + \xi_j$ (equations (15) and (16)). The taste ν_i has distribution F with density f and mean one, which normalizes the units of quality and sets $\alpha \equiv 1$. Order products so that $\psi_0 < \psi_1 < \cdots < \psi_N$. Consumer i prefers j to $j-1$ when $\psi_j \nu_i - p_j > \psi_{j-1}\nu_i - p_{j-1}$, that is, when ν_i exceeds

$$\Delta_j = \frac{p_j - p_{j-1}}{\psi_j - \psi_{j-1}}$$

(equation (17)). With $\Delta_0 = -\infty$, $\Delta_{N+1} = +\infty$ and increasing cutoffs, i buys j when $\Delta_{j+1} > \nu_i > \Delta_j$, so

$$s_j = F(\Delta_{j+1}) - F(\Delta_j) \tag{7.92}$$

(equation (18)). Solving for Δ_j from the top product down gives $\Delta_N = F^{-1}(1 - s_N)$ and $\Delta_j = F^{-1}(F(\Delta_{j+1}) - s_j)$ (equation (19)). With $\psi_0 = p_0 = 0$, the cutoff definition then yields $\psi_j = \psi_{j-1} + \frac{p_j - p_{j-1}}{\Delta_j}$ (equation (20)), and $\delta_j = \psi_j - p_j$. If $\mathbb{E}[\xi_j \mid x] = 0$, least squares of ψ_j on x_j estimates β, with no price instrument, because price is not a regressor. Berry calls the two examples opposite extremes (p. 251). The logit has one taste shock per product and makes all products substitutes. The vertical model has one taste and makes only quality neighbors substitutes. Chapter 6 derives the same recursion for the form $u_{ij} = \delta_j - \nu_i p_j$.

Nested logit through the group share. Following Cardell (1997), products fall into groups $g = 0, 1, \ldots, G$ with the outside good alone in group 0, and for $j \in g$

$$u_{ij} = \delta_j + \zeta_{ig} + (1 - \sigma)\epsilon_{ij}$$

(equation (22)), with ζ_{ig} distributed as in Lemma 7.24. Writing ζ_{ig} as $\sum_h d_{jh}\zeta_{ih}$ with group dummies d_{jh} shows a random-coefficients model with random coefficients on group dummies only, so correlation depends on groupings fixed before estimation (p. 253). The shares (equations (23) to (25)) are those of Proposition 7.25, with $D_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma}}$, group share $s_g = \frac{D_g^{1-\sigma}}{\sum_h D_h^{1-\sigma}}$ and $D_0 = 1$, so that $s_0 = \frac{1}{\sum_h D_h^{1-\sigma}}$. Taking logs of s_j and s_0,

$$\ln s_j - \ln s_0 = \frac{\delta_j}{1 - \sigma} - \sigma \ln D_g \tag{7.93}$$

(equation (26)). Berry removes the unobserved D_g with the group share. Since $\frac{s_g}{s_0} = D_g^{1-\sigma}$, we have $\ln D_g = \frac{\ln s_g - \ln s_0}{1-\sigma}$. Substituting into (7.93), multiplying by $1 - \sigma$, and solving for δ_j,

$$\begin{aligned} \delta_j &= (1 - \sigma)(\ln s_j - \ln s_0) + \sigma(\ln s_g - \ln s_0) \\ &= \ln s_j - \sigma(\ln s_j - \ln s_g) - \ln s_0 = \ln s_j - \sigma \ln s_{j|g} - \ln s_0 \end{aligned}$$

(equation (27)), because $s_{j|g} = \frac{s_j}{s_g}$. Substituting $\delta_j = x_j\beta - \alpha p_j + \xi_j$ gives $\ln s_j - \ln s_0 = x_j\beta - \alpha p_j + \sigma \ln s_{j|g} + \xi_j$ (equation (28)), which is (7.69). Section 7.5.4 eliminates D_g through the within-group share instead, and both routes reach the same equation.

Random coefficients. In the full model the inversion is numerical, and the share integral needs simulation (Pakes, 1986), as developed by Berry et al. (1995). Berry sees a trade-off (p. 254). The nested logit suits costly computation or predetermined classes of products, and random coefficients suit richer substitution patterns. Table 7.11 summarizes the examples, including the pricing equations derived next.

Table 7.11: The examples of Berry (1994): inversion, pricing equation, and instruments

Model	Mean utility $\delta_j(s)$	Single-product markup $p_j - c_j$	Extra parameters and instruments
Logit, eqs. (13), (14), (31)	$\ln s_j - \ln s_0$	$\frac{1}{\alpha(1-s_j)}$	None beyond one excluded instrument for p_j (cost shifters, rivals' x_k)
Nested logit, eqs. (22) to (28), (33)	$\ln s_j - \sigma \ln s_{j\|g} - \ln s_0$	$\frac{1-\sigma}{\alpha\,[1-\sigma s_{j\|g}-(1-\sigma)s_j]}$	σ, with characteristics of other firms in the group as instruments for $\ln s_{j\|g}$
Vertical, eqs. (15) to (20), (32)	$\psi_j - p_j$, from the recursion for Δ_j and ψ_j	$s_j\left[\frac{f(\Delta_{j+1})}{\psi_{j+1}-\psi_j} + \frac{f(\Delta_j)}{\psi_j-\psi_{j-1}}\right]^{-1}$	None if F is known ($\alpha \equiv 1$), else the parameters of F
Random coefficients, eqs. (2) to (6)	Numerical inversion (Chapter 8)	$\frac{1}{\alpha}\, s_j\left(\frac{\partial s_j}{\partial \delta_j}\right)^{-1}$, numerical	(σ_k), with at least one extra instrument per σ_k

Notes: Equation numbers are those of Berry (1994). All markups assume single-product Nash pricing. In the vertical model the term in $f(\Delta_{N+1})$ is zero for the top product.

7.7.6 The pricing equation and joint estimation

Section 6 of the paper adds the first-order conditions. Price enters only through δ_j, so $\frac{\partial s_j}{\partial p_j} = -\alpha \frac{\partial s_j}{\partial \delta_j}$, and given the density both δ_j and $\frac{\partial s_j}{\partial \delta_j}$ are known functions of the data. With marginal cost $c_j = \bar{c}(q_j, w_j, \gamma) + \omega_j$, (7.88) becomes

$$p_j = \bar{c}(q_j, w_j, \gamma) + \frac{1}{\alpha}\, s_j \left(\frac{\partial s_j}{\partial \delta_j}\right)^{-1} + \omega_j \tag{7.94}$$

(equation (29)). The regressors q_j, s_j and $\frac{\partial s_j}{\partial \delta_j}$ are correlated with ω_j and need the instruments listed above. Demand (equation (21)) and supply (equation (29)) share α and σ, and joint estimation imposes these cross-equation restrictions (p. 255). The moments are $\mathbb{E}[z_j^d \xi_j(\theta)] = 0$ and $\mathbb{E}[z_j^s \omega_j(\theta)] = 0$, with $\omega_j(\theta)$ the residual of (7.94) at $\boldsymbol{\delta}(s, \sigma)$ (Section 7.4.5).

With $c_j = w_j\gamma + \omega_j$ (equation (30)), the analytic examples give the markups of Table 7.11. The logit gives $p_j = w_j\gamma + \frac{1}{\alpha}\frac{1}{1-s_j} + \omega_j$ (equation (31)), so the supply side estimates $\frac{1}{\alpha}$ directly. In

the vertical model, $\frac{\partial \Delta_{j+1}}{\partial p_j} = -\frac{1}{\psi_{j+1}-\psi_j}$ and $\frac{\partial \Delta_j}{\partial p_j} = \frac{1}{\psi_j-\psi_{j-1}}$, so differentiating (7.92) gives the markup in the table. Price minus markup, $y_j = w_j\gamma + \omega_j$, is then data, and γ follows from least squares (equation (32)). The nested logit gives

$$p_j = w_j\gamma + \frac{1-\sigma}{\alpha\left[1-\sigma s_{j|g}-(1-\sigma)s_j\right]} + \omega_j \tag{7.95}$$

(equation (33)), the single-product case of Proposition 7.27. At $\sigma = 0$ only s_j affects the markup, and as $\sigma \to 1$ with $s_{j|g} < 1$ held fixed only $s_{j|g}$ does. So the joint behavior of prices, product shares and group shares helps identify σ (p. 256).

7.7.7 Why the obvious alternatives fail

Section 7 of the paper rejects three alternatives, which Section 7.2.1 develops in detail. Estimating each ξ_j as a fixed effect fails by the logic of grouped data. Integrating ξ out of the share function at fixed prices contradicts the pricing equation (7.88), because prices respond to ξ. The reduced form of Bresnahan (1987) and Berry (1990) (equations (34) and (35)) tolerates measurement error in prices and quantities, which is how Bresnahan models the error. It needs costly integrals over implicitly defined functions, however, and a unique equilibrium for almost all values of the unobservables. Caplin and Nalebuff (1991) prove uniqueness for the logit and the vertical model, exactly the cases where the inversion is easy. The mean-utility method "does not rely on the existence of a unique equilibrium" (p. 243).

7.7.8 Monte Carlo evidence

Section 7.3.6 states Berry's design in (7.37) and replicates it. Each simulated sample has 500 duopoly markets with Bertrand-Nash prices (p. 258). Each design has 100 samples, estimated by least squares and by instrumental variables with w_j and the rival's x_k as instruments. The non-price part of mean utility has variance $\beta_x^2 + \sigma_d^2$. With $\sigma_d = 1$ the observed x_j accounts for $\frac{4}{5}$ of it, and with $\sigma_d = 3$ the unobserved term accounts for $\frac{9}{13}$, almost 70 percent.[1]

Berry's Table 1 sits next to our replication in Table 7.5. With $\sigma_d = 1$, least squares gives $\hat{\alpha} = 0.726$ (0.029) and instrumental variables 0.995 (0.039), against a true value of 1. With $\sigma_d = 3$ the figures are 0.181 (0.076) and 0.979 (0.128). The coefficients on x_j and the constant show the same pattern (Table 7.5). Prices rise with ξ_j through the markup and through cost, so by Proposition 7.14 least squares understates α, and more so when σ_d is large. In many samples the least-squares estimate implies pricing on the inelastic part of demand, and with $\sigma_d = 3$ it sometimes implies upward-sloping demand. Tables 7.3 and 7.4 show the same pattern in field data.

7.7.9 Interpretation, limitations, and contribution

Berry's conclusion states the idea: mean utilities "can then be treated in much the same fashion as observed output quantities in the homogeneous goods model" (p. 260). The demand side needs no distribution for ξ, no model of price setting and no unique equilibrium. A supply side can be added when the researcher accepts Nash pricing.

[1] Later on the same page Berry says the observed characteristic accounts for "only 25%" in this design. The stated parameters imply $\frac{4}{13}$, about 31 percent.

Berry lists the main limitations himself (pp. 258–260). Demand is static and single-unit, and the taste distribution is known up to parameters. The inversion "may be quite sensitive" to measurement error in shares. Characteristics are assumed exogenous, and a solution "awaits further progress on dynamic models of firm behavior." Berry also flags two data problems that later work developed. His Section 9 lists the estimation of the market size M as open and points to Berry (1990) and Greenstein (1992) (p. 258). His footnote 4 notes that with M distinct consumers the observed shares carry sampling error with variance $\frac{s_j(1-s_j)}{M}$, which he assumes away by treating consumers as a continuum (p. 247). Berry, Linton, and Pakes (2004b) develop limit theory as the number of products grows, allowing for sampling error in the shares and simulation error in the predicted shares. The estimator is asymptotically normal if the consumer sample and the number of simulation draws grow fast enough relative to the number of products. Section 7.2.5 shows how results depend on the assumed market size. A third problem, zero shares, breaks the inversion (Gandhi et al., 2023). The analytic examples also inherit logit substitution patterns and assume single-product firms (Section 7.4.2 treats multi-product pricing).

Berry states what any extension must supply (p. 259). A richer utility model needs its own invertibility result, showing that given the parameters each vector of observed shares is explained by one vector of demand unobservables. A richer pricing model needs an analogue of equation (29), showing that data and parameters together determine the cost unobservable.

The article made instrumental-variables estimation the default for discrete-choice demand on aggregate data. Berry notes that his model implies a hedonic equilibrium pricing function of product characteristics, which links it to the hedonic literature (p. 244, n. 1). Its focus on price-setting firms and unobserved characteristics differs from the typical hedonic study. He reports two early applications (p. 260). The working-paper version of Berry et al. (1995) found that allowing for unobserved characteristics correlated with prices improves the estimated own-price elasticities. Greenstein (1992) estimated a vertical model of the computer industry with unobserved characteristics. Berry et al. (1995) added random coefficients, simulation, a contraction for the inversion and approximate optimal instruments (Chapter 8). Invertibility was later shown under weaker conditions (Berry et al., 2013), and nonparametric identification was studied by Berry and Haile (2014). The method underlies Einav (2007) below, Nevo (2001) in Chapter 8, Berry et al. (2006) in Chapter 9 and merger simulation in Chapter 11, and standard software implements it (Conlon and Gortmaker, 2020).

7.8 Case study: Einav (2007), seasonality in motion pictures

Einav (2007) uses a one-nest nested logit for a purpose far from price elasticities. Ticket prices are nearly uniform, so the paper estimates no price coefficient. The model separates two sources of seasonal sales: demand that varies over the year, and the number and quality of movies on offer.

7.8.1 Question, setting, and data

Moviegoing sometimes more than doubles within two weeks, and the first week brings almost 40 percent of an average movie's box office (p. 127). With virtually no price competition, the release date is a main short-run strategic variable, and timing decisions create a seasonal pattern in releases. Observed seasonality thus mixes underlying demand with the number and quality of available movies. The split matters for strategy. If demand drives seasonality,

distributors should release when demand is high. If quality drives it, they should release in low seasons, when competition is soft. Einav calls a market response that reinforces demand swings, for example more or better movies in high seasons, an *amplification effect*. A response that offsets them, such as higher prices in high seasons, is a *dampening effect* (p. 128).

The institutional facts that follow describe the industry as Einav reports it around the time of his study (pp. 129–130). Distributors set release dates, negotiated with exhibitors and ran national advertising. A wide release typically opened in several thousand theaters at once. Exhibitors paid distributors the greater of 90 percent of revenue net of house expenses or a share of gross revenue that started near 70 percent and then declined. Distributors collected about half of box office. When Einav wrote, after his 1985–1999 sample period, domestic box office was as little as 15 percent of a movie's revenue, down from about 35 percent in the early 1980s (p. 130). Other revenue came from cable and television rights, the video and DVD markets, and foreign box office. Higher domestic box office was believed to raise these ancillary revenues, so Einav treats maximizing domestic box office as a reasonable approximation to the distributor's objective (p. 130).

The data cover all movies released in the United States from 1985 to 1999 (ACNielsen EDI). They give weekly revenue and screens for the first 10 weeks, which bring more than 90 percent of revenue (pp. 131–132). Weekly shares are revenue divided by the ticket price and the U.S. population, both interpolated from annual figures. Children and senior citizens buy discounted tickets, so this calculation understates the shares of movies aimed at them. The fraction of discounted tickets varies mainly across movies and little within a movie, so the movie fixed effects address this concern (footnote 11). Of 3,523 titles, Einav keeps those that reach a wide release of at least 600 screens in some week. He drops 97 titles with a long platform release that did not reach a wide release within 10 weeks of their official release date. He also leaves out the first nine weeks of 1985 (footnote 13). The final sample has 1,956 titles, 16,103 weekly observations and 94 percent of revenue. Mean total revenue is $34.8 million and the median $20.0 million. The share of the population that sees a movie in its first ten weeks averages 2.78 percent, with a median of 1.71 percent. Production cost, reported for 1,604 titles, averages $29.7 million in December 1999 dollars (Table 2). Table 1 reports industry trends. In December 1999 dollars the average ticket price was $5.54 in 1985 and $5.00 in 1999. Over the same years wide releases rose from 103 to 143 a year, and the industry share, annual admissions over the U.S. population, grew from 2.69 to 5.03 (pp. 131–132). Holidays shift from year to year, so 56 calendar-week dummies keep each holiday in a fixed week, for example Labor Day in week 38 and Thanksgiving in week 51.

7.8.2 The model

Consumer i's utility from movie j in week t and from not going to the movies are

$$u_{ijt} = \phi_j - \lambda(t - r_j) + \xi_{jt} + \zeta_{it} + (1-\sigma)\epsilon_{ijt}, \qquad u_{i0t} = -\tau_t + \zeta'_{it} + (1-\sigma)\epsilon_{i0t} \tag{7.96}$$

(Einav's equations (1) and (2)). The quality ϕ_j is written θ_j in the paper, and we rename it because θ is the conduct parameter in this book. The release week is r_j, λ is a common weekly decay, and ξ_{jt} is a movie-week deviation from it. The week effect τ_t enters the outside good, so underlying seasonality is the time-varying value of not going to the movies, which Einav reads as the opportunity cost of time. The shocks ϵ are type-I extreme value and ζ_{it}, ζ'_{it} have Cardell's distribution, so movies form one nest and the outside good another.

Adding τ_t to every alternative leaves choices unchanged, sets the outside good's mean utility to zero, and gives movie j the mean utility $\delta_{jt} = \phi_j - \lambda(t - r_j) + \tau_t + \xi_{jt}$. Proposition 7.25

with one inside nest, the set $\mathcal{J}_t$ of movies showing in week t, gives

$$s_{jt} = \frac{e^{\frac{\delta_{jt}}{1-\sigma}}}{D_t} \cdot \frac{D_t^{1-\sigma}}{1 + D_t^{1-\sigma}} = \frac{e^{\frac{\delta_{jt}}{1-\sigma}}}{D_t^{\sigma} + D_t}, \qquad D_t = \sum_{k \in \mathcal{J}_t} e^{\frac{\delta_{kt}}{1-\sigma}}$$

(equations (3) and (4)). The inversion of Proposition 7.26, with within-industry share $\frac{s_{jt}}{1-s_{0t}}$, then gives the estimating equation

$$\ln s_{jt} - \ln s_{0t} = \phi_j + \tau_t - \lambda(t - r_j) + \sigma \ln \frac{s_{jt}}{1 - s_{0t}} + \xi_{jt} \tag{7.97}$$

(equation (5)). Movie effects capture cast, plot and prerelease advertising, which Einav treats as fixed effects because observables explain little of quality. The dependent variable is close to log revenue, so linear decay is proportional decay, reflecting saturation and a preference for seeing movies early. As $\sigma \to 0$ the model is a simple logit. Einav reads the limit $\sigma \to 1$ as removing substitution between movies and the outside good (p. 134). In that limit a new movie that does not beat the best movie showing only steals from other movies. A better movie still draws from the outside good, because $D_t^{1-\sigma}$ tends to $e^{\max_k \delta_{kt}}$ as $\sigma \to 1$. With one movie of mean utility zero the inside share is $\frac{1}{2}$ for every σ. Adding a movie of mean utility one raises it to $\frac{e}{1+e} \approx 0.731$ in the limit. Lower σ attributes more seasonality to the number and quality of movies.

The paper writes the decay as $-\lambda(t - r_j)$ but reports the estimated coefficient on $t - r_j$, which is $-\lambda$. Its benchmark estimate of -0.220 means $\lambda = 0.220$, the value its later calculations use. Table 7.12 prints coefficients as the paper does.

7.8.3 Identification and estimation

Two assumptions do the work (p. 135). The decay of mean utility is orthogonal to the release date, which identifies movie qualities. Variation across years in the number of movies released in a given calendar week is exogenous, which identifies market expansion.

There is one national market, so the same movie cannot be observed released on different dates. Weekly revenues give several observations per movie instead. A movie released in a high-demand week keeps playing in later weeks, under different seasonal demand and against different rivals. Comparing movies observed in the same weeks identifies relative qualities, and 15 years supply many choice sets per calendar week. Einav's example shows the logic.

Example 7.34 (Einav's two-season example)**.** A year has two seasons of market sizes 1 and $M > 1$, and two movies are released per year, one per season, of qualities 1 and $\phi_H > 1$. A movie of quality ϕ in a season of size m sells $m\phi$, and the better movie is always released in season 2. If each movie plays for one season, sales are 1 and $M\phi_H$, and only the product $M\phi_H$ is identified. Suppose instead that each movie plays two seasons, with quality multiplied by a common factor $d < 1$ in the second. With $R_{q,m}$ the sales of the quality-q movie in the season of size m,

$$R_{1,1} = 1, \qquad R_{1,M} = Md, \qquad R_{H,M} = M\phi_H, \qquad R_{H,1} = d\phi_H.$$

The last three equations have three unknowns. Since $\frac{R_{1,M}R_{H,M}}{R_{H,1}} = M^2$,

$$M = \sqrt{\frac{R_{1,M}R_{H,M}}{R_{H,1}}}, \qquad d = \frac{R_{1,M}}{M}, \qquad \phi_H = \frac{R_{H,M}}{M}.$$

With our illustrative values $M = 2$, $\phi_H = 1.5$ and $d = 0.5$, the data are $R_{1,M} = 1$, $R_{H,M} = 3$ and $R_{H,1} = 0.75$, and the formulas return $M = \sqrt{\frac{3}{0.75}} = 2$, $d = 0.5$ and $\phi_H = 1.5$. If decay differed by release season, a fourth unknown would break identification.

With more movies and seasons, decay may differ across movies, provided it does not vary with the release date once observables are controlled for. The assumption concerns the decay of utility. Revenue decay does depend on the release date, through seasonal demand. The main threat is that studios know decay and release fast-decay movies late in the summer. Einav replies that the industry thinks in terms of expected total revenue and that decay is predictable ex post more than ex ante. The assumption is also more plausible for movies released close together (p. 136). Section 7.8.5 tests it.

Market expansion is identified from the long panel. If more movies of comparable quality open on Memorial Day 1999 than in 1998, similar total revenues imply weak expansion (σ near one) and higher revenues imply strong expansion (low σ). Einav's example also allows better movies, but a movie better than every rival raises total revenues even with σ near one. The within-industry share rises with ξ_{jt}, so it needs an instrument. The benchmark uses the number of movies showing in the week, n_t, since more movies lower each movie's within-industry share. Week dummies absorb any tendency to release more movies in high-demand weeks, so the identifying variation is across years within a calendar week. Movie effects absorb the quality of a strong movie that deters rivals. The remaining requirement is that n_t is uncorrelated with the decay shocks ξ_{jt}. Variation comes from production uncertainty: projects are committed a year or two ahead, completion and quality are uncertain, and studios avoid holding finished movies (pp. 136–137). The estimator is two-stage least squares of (7.97) with 1,956 movie effects, 56 week dummies and the decay term, and n_t as the excluded instrument.

7.8.4 Results

Table 7.12 and Figure 7.8 report the benchmark. Controlling for movie quality dampens estimated seasonality. The standard deviation of the week coefficients is 0.238 with movie fixed effects and 0.356 without (p. 138). Endogenous quality thus amplifies seasonality by about 50 percent, since $\frac{0.356}{0.238} \approx 1.50$. In the paper's summary, about a third of seasonal variation in sales comes from the number and quality of movies (pp. 129 and 143).

Underlying demand resembles revenue, high in summer and the holidays and low in spring and fall, but the differences are informative (p. 138). Memorial Day, the Fourth of July and Thanksgiving, the big release weekends, have high underlying demand, though less so relative to adjacent weeks than revenues suggest. Labor Day, when few movies open, has much higher underlying demand than its revenue implies. Underlying demand is flat over the summer and drops sharply after Labor Day, whereas revenues peak in early July and decline gradually, because the biggest movies open early in the summer.

With $\lambda = 0.220$ and $\hat{\sigma} = 0.524$, Einav reports weekly revenue decay of 37 percent. For a movie too small to move D_t, $\ln s_{jt}$ equals $\frac{\delta_{jt}}{1-\sigma}$ plus terms in D_t, so one more week changes log share by $-\frac{0.220}{0.476} = -0.462$, and $1 - e^{-0.462} = 0.37$. Ten decay dummies give an almost linear pattern. A linear time trend is not identified (footnote 19). If mean utility included $b\,t$, writing $b\,t = b\,r_j + b(t - r_j)$ shows that it loads onto the movie effects, $\phi_j + b\,r_j$, and onto the decay, $\lambda - b$. The movie effects, which show no trend, measure quality relative to an outside good that may itself be changing.

Table 7.13 projects the estimated movie effects on observables. Production cost, advertising

Table 7.12: Benchmark estimates and subperiod decay in Einav (2007)

Panel A. Benchmark model (inset table of Figure 3)			
	With movie FE	Without movie FE	
Weeks since release $t - r_j$ (coefficient = $-\lambda$)	−0.220	−0.163	
	(0.0014)	(0.005)	
Nesting parameter σ	0.524	0.577	
	(0.030)	(0.011)

and Oscar recognition raise estimated quality, and restrictive ratings lower it. The adjusted R^2 is at most 0.387, which Einav reads as the justification for fixed effects.

Table 7.13: Projection of the estimated movie fixed effects on observables (Einav, 2007, Table 3)

Notes: Standard errors in parentheses. * significant at the 10 percent level, ** at the 1 percent level. Omitted categories are rating PG and genre action. Blank cells are variables not included. Samples are smaller than 1,956 because production cost and advertising are missing for some movies. Source: Einav (2007), Table 3.

7.8.5 Robustness

Predicted shares reproduce the observed seasonal pattern well, but the model underpredicts revenue in early summer and the holidays and overpredicts it elsewhere (Figure 4, p. 139). Movies released in strong seasons decay more slowly. Interacting decay with movie size, instrumented by production cost times decay, shows that better movies decay more slowly and improves fit, but underlying seasonality barely moves. Letting decay vary by release season gives −0.194 for holiday releases, −0.206, −0.216 and −0.214 for winter, spring and early summer, and −0.249 and −0.244 for late summer and fall (pp. 139–140). Equality of the first four is not rejected, and equality of the last two with the others is rejected. The summer week effects are unchanged.

Results are almost identical after dropping the first three weeks of each run, for movies with a full 10-week run and for Friday releases (p. 140). Panel B of Table 7.12 shows faster decay in later subperiods, consistent with wider openings, while underlying seasonality is stable. Alternative instruments, the budget of competing movies, the number in the same genre, or the number released within a three-week or five-week window, give similar results. The window counts address one source of endogeneity. Fewer movies may be shown in a week when a strong movie is released. If distributors can move a release date by only a few weeks, counts over a window around the week account for this response (footnote 20). Instruments interacted with a measure of the movie's ex-ante size, such as production cost, are weaker. They give low estimates of σ and somewhat different results, but adding them to the main instruments leaves the reported results in place (footnote 21). The nested logit ties expansion from more movies to expansion from better movies through one parameter. Ackerberg and Rysman (2005) suggest adding the log number of products as a regressor, which here is the instrument. Including it through functional form or with other instruments changes little (pp. 140–141).

7.8.6 Implications for release dates

Set $\xi_{jt} = 0$ and write $Q_{kt} = \exp\left(\frac{\phi_k - \lambda(t - r_k)}{1-\sigma}\right)$ for the decay-adjusted quality index and $C_t = \sum_{k \in \mathcal{J}_t} Q_{kt}$ for the *competition effect*. Since $D_t = \exp\left(\frac{\tau_t}{1-\sigma}\right) C_t$, dividing numerator and denominator of s_{jt} by $\exp\left(\frac{\tau_t}{1-\sigma}\right)$ gives

$$s_{jt} = \frac{Q_{jt}}{C_t^{\sigma}} \left[e^{-\tau_t} + C_t^{1-\sigma} \right]^{-1} \tag{7.98}$$

(Einav's equation (6)). The market-size term $e^{-\tau_t}$ is small when underlying demand is high. Competition matters more as σ rises, because movies then steal more from each other. With fixed prices and nearly zero marginal cost, a price-taking distributor picks r_j to maximize $\sum_{t=r_j}^{r_j+H} s_{jt}$ for a horizon H, taking rivals' dates as given (pp. 141–142). Competition peaks at the start of the summer and at Christmas. Labor Day combines high underlying demand with soft competition, and a small movie could double its revenue by opening then instead of on Thanksgiving (p. 143). Large movies, Einav cautions, internalize their effect on competition.

If the industry could coordinate, with n_w small divisible movies of quality index $e^{\frac{\bar{\phi}}{1-\sigma}}$ opening in week w, then $C_w^{1-\sigma} = n_w^{1-\sigma} e^{\bar{\phi}}$. Summing (7.98) over movies gives the industry share $\frac{C_w^{1-\sigma}}{e^{-\tau_w} + C_w^{1-\sigma}}$, and the industry solves

$$\max_{\{n_w\}} \sum_{w=1}^{W} \frac{n_w^{1-\sigma} e^{\bar{\phi}}}{e^{-\tau_w} + n_w^{1-\sigma} e^{\bar{\phi}}} \quad \text{subject to} \quad \sum_{w=1}^{W} n_w = N, \qquad \frac{e^{-\tau_w}(1-\sigma) n_w^{-\sigma} e^{\bar{\phi}}}{\left(e^{-\tau_w} + n_w^{1-\sigma} e^{\bar{\phi}}\right)^2} = \mu \tag{7.99}$$

(equations (7) and (8), with ε in the paper for $\bar{\phi}$ and μ the Lagrange multiplier). The left side of the first-order condition has a positive cross-partial in τ_w and n_w at the estimates, so the optimum puts more movies in high-demand weeks. The observed pattern yields a total industry share of 3.94 (observed: 3.92), and the optimum raises it only to 3.98, about 1 percent (p. 143). Quality is fixed in total, and with σ above 0.5 redistribution mostly moves revenue across movies.

7.8.7 Interpretation and limitations

Einav attributes amplification to uniform ticket prices (Orbach and Einav, 2007). The market can respond to high demand only through the number and quality of movies (p. 144). He expects amplification in video rental, music and books, and dampening where capacity constraints raise peak prices, as in tourism and airlines. The paper also shows when a logit-type model suffices. There is no price coefficient, and the model is never asked for cross-price substitution, the case anticipated by the remark in Section 7.1.4. The limitations follow from the identifying assumptions. Decay must not depend on the release date, and the season-specific estimates show some dependence. Underlying seasonality must be stable across years, the market is the population, and the mix of moviegoers is constant over the year. A single σ ties two kinds of expansion, and the release exercise treats distributors as price takers. Einav (2010) models the timing game as a sequential-move game with private information. He finds release dates too clustered on holiday weekends, and that shifting some holiday releases by a week or two would raise revenue.

7.9 Case study: Hendel (1999), multiple discrete choice

Every model so far has a consumer buy one unit of one product. Hendel (1999) drops both restrictions for business purchases of personal computers. We work mainly from the 1994 working paper (Hendel, 1994). Its pages carry the prefix WP, and all equation and table numbers refer to it. Citations of the published article give its own pages. The two versions may differ in specification and numbers.

7.9.1 Question and motivating facts

Hendel estimates PC demand by business establishments as an input to three questions (WP pp. 2–3). The first is the "computerization puzzle," the absence of measured productivity gains from computers in aggregate data. The second is the gain from technical progress in components, and the third is quality adjustment in price indices. Table 7.14 reproduces Table I, the joint frequency of the number of PCs and the number of PC types held by 5,234 establishments that hold at least one PC. Only 1,369 hold a single PC and 2,367 a single type, while twelve hold more than 2,000 units. Hendel concludes that multiple discreteness is the main feature of the data and that aggregation misleads, since one firm buying 2,000 units differs from 2,000 firms buying one (WP p. 6).

Table 7.14: Joint frequency of the number of PCs and the number of PC types held (Hendel, 1994, Table I)

	Number of PC types held									
Number of PCs	1	2	3	4–6	7–9	10–19	20–49	50–99	100+	Total
1	1,369									1,369
2	335	308								643
3–4	271	215	196							682
5–6	123	99	129	29						380
7–10	104	111	152	52	7					426
11–15	39	59	102	56	26					282
16–35	68	84	154	99	65	8	2			480
36–60	24	31	68	45	61	15	5			249
61–100	12	12	51	39	47	16	8			185
101–300	16	17	59	74	100	56	21	3		346
301–600	4	3	18	26	29	23	8	0	1	112
601–1,000	2	0	3	8	8	11	6	1	0	39
1,001–2,000	0	1	1	7	5	7	4	3	1	29
2,000+	0	0	2	3	2	2	0	1	2	12
Total	2,367	940	935	438	350	138	54	8	4	5,234

7.9.2 The model

We rename Hendel's symbols. The establishment is i (his f), its tasks are $k = 1, \ldots, K_i$ (his j and J_f), and PC types are $j = 1, \ldots, J$ (his i). The curvature of task returns is a, where he writes

α, which would clash with the price coefficient. The brand weight W_{ijk} keeps his name and is unrelated to the weighting matrix W.

Establishment i with demographics D_i has $K_i \sim \text{Poisson}(\lambda_i)$ potential tasks, with $\lambda_i = g_0 + g_1\, emp_i + g_2\, soft_i$, where emp_i is employment and $soft_i$ the number of software types (WP equation (23)). Profit is additive across tasks (equation (4)), which rules out complementarities between tasks. With X_{ijk} units of type j in task k and rental prices P_j, the return on task k is

$$\pi_{ik} = \Big(\sum_j W_{ijk} X_{ijk}\Big)^{a} S(D_i) - \sum_j P_j X_{ijk}, \qquad W_{ijk} = \big(A_{ik} \cdot C_j\big)^{m(D_i)}, \qquad 0 < a < 1 \tag{7.100}$$

(equations (5) and (6)). The vector C_j stacks a brand indicator and j's observed attributes (MHz, memory, word size). The random coefficients A_{ik} hold perceptions of each brand's unobserved quality (reliability, service, compatibility) and valuations of the attributes. Perceptions are normal with brand-specific means and a common variance, and the MHz valuation is normal. The *return shifter* is $S(D_i) = \varsigma_0 + (\varsigma_1 + \varsigma_{1,rd}\, drd_i) emp_i$, where the paper writes s_0 and s_1 for our ς_0 and ς_1. The taste for quality is $m(D_i) = m_0 + m_1 wh_i + m_{1,rd}\, drd_i$, with wh_i the number of white-collar workers and drd_i an R&D indicator (equations (24) and (25)). With no adjustment costs and a perfect resale market, a PC costs its one-year rental price, the purchase price less next year's resale value. Lacking data on used prices, Hendel computes the resale value from the 25 percent annual fall in quality-adjusted prices found by Berndt and Griliches (1993). An old machine costs a fraction d_0 of the new rental price (WP p. 24).

One brand per task. Brands enter a task through the index $E_{ik} = \sum_j W_{ijk} X_{ijk}$ of effective units, at linear cost. For any E_{ik},

$$\sum_j P_j X_{ijk} = \sum_j \frac{P_j}{W_{ijk}} W_{ijk} X_{ijk} \;\geq\; \Big(\min_j \frac{P_j}{W_{ijk}}\Big) E_{ik},$$

with equality when only the type with the highest *performance-to-price ratio* $\frac{W_{ijk}}{P_j}$ is used. With continuous random coefficients ties have probability zero, so each task uses one brand (WP pp. 11 and 19). Multiple brands per establishment come from multiple tasks.

Units within a task. Ignoring integer constraints, the first-order condition for type j is $a W_{ijk}^{a} X^{a-1} S(D_i) = P_j$ (equation (10)), so

$$X^*_{ijk} = \left(\frac{a W_{ijk}^{a} S(D_i)}{P_j}\right)^{\frac{1}{1-a}} \tag{7.101}$$

(equation (11)). Using the first-order condition, cost equals $a W_{ijk}^{a} (X^*)^{a} S(D_i)$, so

$$\pi^*_{ijk} = (1-a)\, W_{ijk}^{a} S(D_i) (X^*)^{a} = (1-a)\, W_{ijk}^{a} S(D_i) \left(\frac{a W_{ijk}^{a} S(D_i)}{P_j}\right)^{\frac{a}{1-a}} = (1-a)\, S(D_i)^{\frac{1}{1-a}} \left(\frac{a W_{ijk}}{P_j}\right)^{\frac{a}{1-a}}$$

(equation (12)), where S has exponent $1 + \frac{a}{1-a} = \frac{1}{1-a}$ and W has exponent $a + \frac{a^2}{1-a} = \frac{a}{1-a}$. The maximized return rises with $\frac{W_{ijk}}{P_j}$. With integer units the best brand can change, for example when its optimum is 3.5 units (WP p. 12). Returns are concave in X, so the integer optimum is

$\lfloor X^* \rfloor$ or $\lceil X^* \rceil$, and the algorithm compares these $2J$ candidates (WP p. 20). When $X^* < 1$ the lower candidate is zero, meaning no PC for the task.

Horizontal and vertical differentiation. Brand perceptions that differ across establishments create horizontal differentiation. The exponent $m(D_i)$ creates vertical differentiation. If buyers agree on a quality index q facing a convex price schedule $P(q)$, equation (12) has them maximize $\frac{q^m}{P(q)}$, whose first-order condition is $m = \frac{P'(q^*)q^*}{P(q^*)}$ (WP Appendix 2). When the price elasticity of quality rises with q, as Hendel argues from convexity, buyers with higher m choose better machines.[2] A multiplicative taste would not work, since scaling all W leaves the ranking of $\frac{W}{P}$ unchanged. In Bresnahan's single-unit vertical model it works because buyers purchase one unit (WP endnote 4). By (7.101), $S(D_i)$ moves the number of units but, entering every brand's return through the factor $S^{\frac{1}{1-a}}$, leaves the brand choice unchanged. The taste $m(D_i)$ moves the brand choice. Hendel argues that these distinct roles identify the two functions (WP p. 13).

7.9.3 Estimation

Expected purchases average the task-level choices over tasks and random coefficients,

$$X_i^e(D_i, \theta) = \sum_{K=0}^{\infty} \mathbb{P}(K_i = K \mid D_i) \sum_{k=1}^{K} \int X_{ik}^*(D_i, A, \theta)\, \mu(\mathrm{d}A \mid D_i, \theta) \tag{7.102}$$

(WP equation (15)), where X_{ik}^* is the J-vector of task purchases and μ the normal distribution of the coefficients. The prediction error $e_i(\theta) = X_i^e(D_i, \theta) - X_i$ has mean zero given D_i at the true θ, so $G(\theta) = \mathbb{E}[T(D_i) \otimes e_i(\theta)] = 0$ for any function T of demographics (equations (16) to (18)). Hendel minimizes a quadratic form in the sample analogue over the F establishments, $G_F(\theta) = \frac{1}{F} \sum_{i=1}^{F} T(D_i) \otimes (X_i^e(\theta) - X_i)$ with the efficient weighting matrix (Hansen, 1982). Demographics are valid instruments by construction, since predictions condition on them.

The integral is simulated (McFadden, 1989; Pakes and Pollard, 1989). For each establishment and simulation round, Hendel draws a number of tasks and the coefficients of each task, and solves each integer problem. The moments are linear in simulated purchases, so the estimator is consistent as F grows with the number of draws fixed (WP pp. 18–19). A device keeps draws fixed while λ_i changes in the search (WP Appendix 3). Let $E_1, E_2, \ldots$ be i.i.d. exponential with mean one and $Y_k = \sum_{l \le k} E_l$, which is gamma with shape k. Integrating by parts $k - 1$ times,

$$\mathbb{P}(Y_k < \lambda) = 1 - \sum_{l=0}^{k-1} \frac{e^{-\lambda} \lambda^l}{l!} = \mathbb{P}(N \ge k), \qquad N \sim \text{Poisson}(\lambda),$$

so the number of partial sums below λ is Poisson with mean λ. Holding the exponential draws fixed holds the randomness constant across trial parameters. The simulated objective is then a step function, a case covered by Pakes and Pollard (1989). Standard errors from numerical derivatives proved sensitive to the step, so Hendel averages over three steps and also reports a bootstrap (WP endnote 12).

Hendel argues that the joint distribution of units and types in Table 7.14 identifies the task process (WP p. 20). We add an observation on the moments he uses, which are brand-level

[2] The main text of the working paper writes this condition with W in place of the index (equation (13)). We follow its Appendix 2.

purchase totals interacted with demographics (45 moments for 15 types). Tasks are i.i.d. given D_i and independent of K_i, so Wald's identity gives

$$\mathbb{E}[X_i \mid D_i] = \lambda_i \, \mathbb{E}\big[X_{ik}^{*}(D_i, A_{ik}, \theta) \mid D_i\big].$$

These moments see the task process only through λ_i. It multiplies per-task purchases, which scale with $S(D_i)^{\frac{1}{1-a}}$ apart from integer effects. Tasks and the return shifter are therefore separated through the integer constraint and through variables that enter only one function, $soft_i$ in λ_i. Moments on the number of types held would use Table 7.14 more directly.

7.9.4 Data and results

Prices and attributes of microcomputers from 1976 to 1989 come from Berndt and Griliches (1993), who collected them from magazine advertisements (WP pp. 21–23). Holdings come from the Comtec survey of about 8,000 representative non-farm establishments in 1984 and 1988, stratified by size and sector with extrapolation weights. Large establishments are oversampled. Unweighted means are 241.55 employees and 35.05 PCs, and weighted means 15.49 and 1.96 (Tables II and III). Estimation uses 123 randomly chosen establishments out of 546 in banking (finance, insurance and real estate), with more than 1,000 purchases. The choice set has 15 types (WP Appendix 4). They are four IBM models (8086, 8088, 286, 386), three Apple models, two each from Zenith and Compaq, three clones and the AT&T 8086. The IBM 286 leads with a price of $2,700 and a 37.3 percent share of 1986–1988 sales.

Table 7.15: Parameter estimates for the banking sector (Hendel, 1994, Table V)

Parameter	Meaning	Estimate	Numerical s.d.	Bootstrap s.d.
ς_0	Intercept of $S(D_i)$	0.61	n.a.	0.19
ς_1	Slope of $S(D_i)$ in employment	0.47	0.18	0.06
m_1	Slope of $m(D_i)$ in white-collar workers	6×10^{-4}	1.3×10^{-4}	10^{-5}
a	Task-return exponent	0.29	0.03	0.04
$\mathrm{Var}(A_j)$	Variance of brand perceptions	3.50	0.55	0.92
A_M	Mean valuation of MHz	0.89	0.24	0.16
$\mathrm{Var}(A_M)$	Variance of MHz valuation	1.48	0.78	0.23
A_R	Valuation of memory (RAM)	0.53	0.11	0.06
A_{B16}	16-bit dummy	0.78	0.87^{b}	n.a.
A_{B32}	32-bit dummy	1.17	2.93^{b}	n.a.
g_1	Task mean, slope in employment	2.42	1.34^{a}	0.32
g_2	Task mean, slope in software types	0.78	0.18	0.10
d_0	Relative cost of keeping an old PC	0.79	0.09	0.19
Objective function $G_F(\theta) = 405$, with 45 moments and 25 parameters				

Notes: Simulated method of moments, 123 banking establishments. Numerical standard deviations average numerical derivatives over three step sizes. Bootstrap standard deviations are taken across 50 bootstrap rounds, around the mean bootstrap estimate. The paper's note c says that 50 establishments were drawn at random from the empirical distribution, which we read as the size of each bootstrap sample. ^{a} significant at the 10 percent level, ^{b} not significant (the paper's markers). The intercepts g_0 and m_0 are fixed at 0.1 and 1.0. The paper writes α_0 (A_0 in the table) for the exponent we call a. Brand-specific mean perceptions are in the paper's Table VII. Source: Hendel (1994), Table V.

Table 7.15 reproduces Table V. The curvature $a = 0.29$ lies in $(0, 1)$, as interior solutions require. Larger establishments buy more PCs (ς_1), and establishments with more white-collar

workers prefer higher quality (m_1). The significant variance of brand perceptions, 3.50, means buyers perceive the same machine differently, a horizontal dimension. MHz has a significant mean and variance, memory a significant coefficient, and users trade 1.6K of expandable memory for one more MHz. Word size is insignificant. The task process rises with size and software variety. Keeping an old PC costs $d_0 = 0.79$ of a new one, with a t-statistic of 2.29 for $1 - d_0$, and the implied 20 percent gap matches new and used prices (WP pp. 26–28). Mean perceptions (Table VII) average 54.1 for IBM, 40.9 for Compaq, 28.5 for Apple, 20.1 for clones, 16.5 for Zenith and 2.9 for AT&T. The objective, 405, is treated as χ^2 with 20 degrees of freedom. Hendel quotes a 5 percent cutoff of 30 (the exact value is 31.4), so the model is rejected (WP p. 26).

A separate estimation adds the R&D and education sectors to banking and reports sector effects in Table VI (WP p. 25). It omits the word-size dummies of Table V, so its estimates are not directly comparable with those of Table 7.15. Table 7.16 reproduces it. The extra employment slope of $S(D_i)$ for R&D establishments, $\varsigma_{1,rd} = 0.69$, is significant, so their purchases are more sensitive to size. Hendel expects this from complementarity between labor and PCs in R&D, and it fits their higher ratio of PCs to employees (WP Table IV). The R&D shift in the taste for quality, $m_{1,rd} = 0.70$ with a standard deviation of 7.00, is insignificant. There is no vertical dimension tied to the sector, which fits the observation that R&D establishments do not hold more valuable PCs than banks. The education sector's extra employment slope is also insignificant. Its extra taste for Apple machines, 4.20, is "borderline significant" in Hendel's words, with a ratio to its standard deviation of 1.39. He equates it to about 4 MHz, so a school values an Apple like a non-Apple machine with 4 more MHz (WP pp. 26–28). The working paper's text calls it Table VI on WP pp. 25–27 and Table VII on WP p. 28.

Table 7.16: Sector effects when R&D and education establishments are added (Hendel, 1994, Table VI)

Parameter	Meaning	Estimate	Std. dev.
$\varsigma_{1,rd}$	Extra employment slope of $S(D_i)$, R&D sector	0.69	0.11
$\varsigma_{1,ed}$	Extra employment slope of $S(D_i)$, education sector	1.00	3.33
$m_{1,rd}$	R&D dummy in $m(D_i)$, vertical by sector	0.70	7.00
A_{Apple}	Extra valuation of Apple, education sector	4.20	3.02

Notes: Simulated method of moments on banking, R&D and education establishments, estimated separately from Table 7.15 and without the word-size dummies. The paper writes s_{1RD}, s_{1ED} and M_{1RD} for our $\varsigma_{1,rd}$, $\varsigma_{1,ed}$ and $m_{1,rd}$. Source: Hendel (1994), Table VI (WP p. 47).

Elasticities come from numerically differentiating simulated demand (Table VIII). The text implies that the table's rows index the product whose price changes and its columns the product whose demand responds. Only this reading matches three statements of the text (WP p. 31), which calls the table Table VII. The IBM 286 and IBM 386 are each other's closest substitutes, and the Zenith 8088 responds most to the IBM 8088 price. The Apple 68020 responds strongly to the IBM 286 price, a machine in a similar price and attribute range, with a cross elasticity of 38.29. Own elasticities are printed as negative numbers, from −0.13 (Apple 68000) and −0.93 (IBM 8086) to −7.9 (Apple 68020). Two below one in absolute value sit uneasily with Nash pricing.

7.9.5 Welfare and implications

Hendel values PCs with Hotelling's lemma. Let $\Pi_i(\boldsymbol{P})$ be maximized profit from PCs at rental prices $\boldsymbol{P}$, relative to the outside option of no PCs, so $\Pi_i(\infty) = 0$ and $\frac{\partial \Pi_i}{\partial P_j} = -X_{ij}(\boldsymbol{P})$. Integrating from the 1988 prices $\boldsymbol{P}^0$,

$$\Pi_i(\boldsymbol{P}^0) - \Pi_i(\infty) = \int_{\boldsymbol{P}^0}^{\infty} X_i(\boldsymbol{P}) \cdot \mathrm{d}\boldsymbol{P},$$

the area under the input demand curve. In practice he evaluates the estimated profit function at predicted behavior and extrapolates with survey weights (WP p. 29). Banking held 729,922 PCs in 1988 and earned about \$1.2 billion from them, about \$1,300 per PC per year against an average annual rental price of \$1,443.[3] The ratio, about 90 percent, is the reported return on investment, an upper bound because training costs are omitted. Hendel puts the gain at 3.5 percent of the sector's 1988 profits of \$41.8 billion.[4] A simulated standard deviation is about \$0.2 billion (WP endnote 14). Treating each type held as one task gives a lower bound of \$956.25 million (WP p. 31). Bresnahan's estimate for mainframes in 1972 is a surplus of \$225 to \$417 million on \$68 million of spending, in 1989 dollars (Bresnahan, 1986). The profit function is cardinal, anchored in money by PC prices, and the gain is relative to minicomputers, mainframes or no equipment (WP p. 30).

Assuming static Nash pricing, the IBM 386, an \$8,000 machine, has marginal revenue of \$6,350, an implied markup of \$1,650 (WP pp. 31–32). Making all microprocessors 10 percent faster at unchanged prices raises end-user surplus by 4 percent, ignoring supplier responses. A hedonic price elasticity with respect to MHz of 0.458 (Berndt and Griliches, 1993) gives 4.58 percent, so hedonic prices are close to marginal benefits here.

7.9.6 Limitations, relation to logit, and contribution

The model rules out complementarities across tasks, and one brand per task holds by construction, so two brands in one job count as two tasks (WP p. 19). Tasks are unobserved, and mapping software types into tasks failed (WP endnote 8). Durability enters only through a rental price. The intercepts g_0 and m_0 are fixed, the sample is 123 establishments in one sector, and the overidentification test rejects. Prices vary only across 15 types in one cross section, and brand means absorb quality. The price response therefore rests largely on the structure of the task problem, in which a governs both scale and price response.

The working paper has normal random coefficients and no extreme value shock, so it is not a logit. The published article has no extreme value shock either. Its random coefficients on all brand dummies and on MHz are normal, and the number of potential tasks is Poisson (Hendel, 1999, p. 437). A logit reading is still instructive. By WP equation (12), $\ln \pi^*_{ijk} = c_{ik} + \frac{a}{1-a}[m(D_i)\ln(A_{ik} \cdot C_j) - \ln P_j]$, where c_{ik} does not depend on the brand. Suppose the brand-specific part of $m(D_i)\ln(A_{ik} \cdot C_j)$ had an additive i.i.d. standard type-I extreme value component, so that $\ln W_{ijk} = w_{ijk} + \epsilon_{ijk}$, where w_{ijk} is the part of $\ln W_{ijk}$ other than this shock. Ignoring integer constraints, each task would choose the brand that maximizes $w_{ijk} - \ln P_j + \epsilon_{ijk}$, because the positive factor $\frac{a}{1-a}$ does not change the ranking. The brand choice would then be a logit with index $w_{ijk} - \ln P_j$, so the coefficient on $-\ln P_j$ is one, the inverse of the shock's unit scale. A coefficient of $\frac{a}{1-a}$ requires a different assumption, in which the standard extreme value shock is added to $\ln \pi^*_{ijk}$ itself. With the random MHz coefficient either version would be a

[3] Dividing \$1.2 billion by 729,922 gives about \$1,640 per PC. The working paper does not explain the difference.

[4] The ratio of the reported figures, $\frac{1.2}{41.8}$, is about 2.9 percent.

mixed logit, and establishment demand a Poisson mixture of such choices. This interpretation is ours. Hendel notes that his framework allows any distributional assumption, not just extreme value (Hendel, 1999, pp. 424–425).

Hendel made multiple discreteness an estimable demand structure with microfoundations. Discrete-continuous models allow one discrete choice and a continuous quantity (Dubin and McFadden, 1984; Hanemann, 1984), and Manski and Sherman (1980) allow up to two cars per household. Tasks allow any number of units of any brands while each task stays a simple discrete choice. Dubé (2004) applies the idea to soft drinks, and Gentzkow (2007) allows goods to be complements in a multiple-choice model of newspapers (Chapter 10).

7.10 The limits of logit and the road to random coefficients

The logit and nested logit are cheap, transparent and linear after inversion, and Einav (2007) shows that they serve when elasticities are not the object. When elasticities, markups or substitution are the object, their restrictions bind. Berry et al. (1995) estimate both a logit and a random-coefficients model on the same automobile data, which makes the comparison clean.

7.10.1 Own-price elasticities rise with price

The logit own elasticity is $\varepsilon_j = \alpha p_j(1 - s_j) \approx \alpha p_j$, since each car's share of all households is very small. BLP's IV logit gives $\hat{\alpha} = 0.216$ (0.123), with prices in thousands of 1983 dollars (Table 7.3). For 13 models of 1990, BLP's Table V reports the random-coefficients elasticities, which Table 8.13 reproduces and Figure 8.8 plots against the logit benchmark. The IV logit implies elasticities from about 1.1 for the Mazda 323 ($5,049) to about 8.1 for the BMW 735i ($37,490). The random-coefficients model reverses the ranking. Its elasticities lie between 6.0 and 6.6 for the four cheapest models and fall to 3.5 for the BMW and 3.1 for the Lexus LS400. The most elastic demands are in the crowded compact and subcompact segments, with the Buick Century (6.8) as an exception (p. 879).

The logit pattern follows from a common price coefficient. Buyers of expensive cars are assumed to be as sensitive to a dollar as buyers of cheap ones, so the elasticity, price coefficient times price, is largest for expensive cars. A referee suggested to BLP that $\ln p$ in place of p would give more reasonable markups. It did, but substitution patterns remained "quite unreasonable" (p. 874, footnote 26).

7.10.2 Substitution goes to the outside good

The diversion ratio to the outside good, $D_{j0} = -\frac{\partial s_0}{\partial p_j}\left(\frac{\partial s_j}{\partial p_j}\right)^{-1}$, is the share of those leaving j after a small price rise who buy nothing. In the logit, $\frac{\partial s_0}{\partial p_j} = \alpha s_j s_0$ and $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$, so $D_{j0} = \frac{s_0}{1-s_j}$. Most households buy no new car in a year, so s_0 is near 0.9. BLP's Table VII, reproduced in Table 8.15, reports this diversion ratio for the same 13 models. The logit column lies between 90.46 and 90.88 percent, and BLP state that it is $\frac{s_0}{1-s_j}$. The random-coefficients column generally falls with price, from 27.1 percent for the Mazda 323 and 28.0 for the Ford Escort to 10.1 for the Lexus LS400 and the BMW 735i. Buyers of these luxury cars who react to a price rise mostly switch to other luxury cars. BLP still find these numbers "a bit large" (p. 881).

A logit therefore overstates how much industry demand falls when prices rise, and it understates competition between close substitutes, because diversion is proportional to shares

whatever the similarity of products. BLP's random-coefficients semi-elasticities make the Lexus the closest substitute to the BMW 735i, the Cadillac to the Lincoln, and the Accord to the Taurus (p. 881). In a logit every car's closest substitute is the best seller. For merger analysis, which turns on diversion between the merging products (Chapter 11), this is the wrong pattern.

7.10.3 Markups are nearly equal

With logit demand a firm sets the same dollar markup $\frac{1}{\alpha(1-S_f)}$ on all its products (Proposition 7.17), never below $\frac{1}{\alpha}$. Section 7.4.6 showed what this implies for BLP's IV logit. Markups lie between \$4,630 (BMW) and \$4,805 (Chevy Cavalier), highest for GM, which makes the most models, and "quite counter-intuitively" lowest for BMW (p. 874). The floor $\frac{1}{0.216} = 4.63$ thousand dollars is BMW's markup. Percentage markups then fall steeply with price. By our computation the implied Lerner indices are $\frac{4.805}{5.797} = 0.83$ for the Cavalier and $\frac{4.63}{37.49} = 0.12$ for the BMW, and 83 percent is implausible for an economy car. The same rigidity affects conduct counterfactuals. With logit demand, joint ownership of 25 cereal brands raises Nevo's median margin only to 41.9 percent, against 72.6 percent in his full model (Tables 7.7 and 8.28, Nevo, 2001). The logit spreads substitution evenly across brands and the outside good.

7.10.4 Too many characteristics

Each new product brings its own ϵ_{ij} and a set of consumers who like it most, even if it is identical or inferior to an existing product. The red and blue buses of Section 7.1.4 are the standard example. Three biases follow. A clone of product j raises consumer surplus by $\frac{1}{\alpha}\ln(1+s_j)$, and with J identical products expected maximum utility grows like $\ln J$ without bound (Section 7.6.2, Figure 7.7). Logit valuations of new goods are therefore biased upward (Chapter 10). Markups never vanish: with J symmetric single-product firms, each share $s = \frac{e^{\delta-\alpha p}}{1+Je^{\delta-\alpha p}}$ goes to zero as $J \to \infty$, so the markup $\frac{1}{\alpha(1-s)}$ converges to $\frac{1}{\alpha} > 0$ however crowded the market. In the mirror image, every product has a positive predicted share, so products with zero sales cannot enter the direct inversion of observed shares (Section 7.2.5). Estimators that model the sampling of shares can still use them (Gandhi et al., 2023).

There are four responses. Ackerberg and Rysman (2005) make the role of the logit shock depend on the number of products, which Einav (2007) describes as adding the log number of products as a regressor. Nesting tempers the problem within nests, since a clone in the same nest adds little as $\sigma \to 1$. The pure characteristics model of Berry and Pakes (2007) drops the shock, at the cost of shares that are not smooth in $\boldsymbol{\delta}$ and an inversion that is no longer a contraction. The hedonic approach of Bajari and Benkard (2005) recovers each consumer's tastes from the gradient of a hedonic price function and needs a dense product space. Chapters 6 and 8 develop these models.

7.10.5 Heterogeneity is the cure

By Remark 7.33, these restrictions come from the i.i.d. additive structure, so changing the distribution of the shock does not remove them. Heterogeneity in tastes that is correlated across similar products does. With $u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j + \epsilon_{ij}$, tastes distributed across consumers, and s_{ij} the logit probability of consumer i, shares are $s_j = \int s_{ij}\,\mathrm{d}F(i)$ and

$$\frac{\partial s_j}{\partial p_k} = \int \alpha_i s_{ij} s_{ik}\,\mathrm{d}F(i) \quad (k \neq j), \qquad \frac{\partial s_j}{\partial p_j} = -\int \alpha_i s_{ij}(1-s_{ij})\,\mathrm{d}F(i).$$

Cross effects are large when the same consumers are likely to buy both products, that is, when the products are similar in the dimensions over which tastes vary. The own elasticity can fall with price if buyers of expensive products have low α_i. Diversion to the outside good, $\int \alpha_i s_{ij} s_{i0}\, dF(i)$ divided by $\int \alpha_i s_{ij}(1 - s_{ij})\, dF(i)$, is small for products whose buyers rarely choose the outside good. The nested logit is the special case with random coefficients on nest dummies (Section 7.7.5). Table 7.17 summarizes, and Chapter 8 develops the general model.

Table 7.17: What logit, nested logit, and random-coefficients logit deliver

	Logit	Nested logit	Random-coefficients logit
Shares	Closed form	Closed form	Integral, simulated
Inversion	$\ln s_j - \ln s_0$	$\ln s_j - \sigma \ln s_{j\|g} - \ln s_0$	Numerical contraction
Estimation	Linear IV	Linear IV, two endogenous regressors	Nonlinear GMM with nested inversion
Substitution	Proportional to shares (IIA)	Proportional to shares within and across nests, more within the nest. IIA holds only within a nest	Toward products with similar characteristics
Own elasticity	$\alpha p_j(1 - s_j)$, rises with price	Rises with price	Can fall with price
Diversion to outside good	$\frac{s_0}{1-s_j}$	$\frac{(1-\sigma)s_0}{1-\sigma s_{j\|g}-(1-\sigma)s_j}$	Depends on who buys j
Multi-product markups	Equal within firm	Equal within firm and nest	Vary by product
Main inputs	Shares, prices, instruments	Plus nest assignment and instruments for $s_{j\|g}$	Plus instruments for the taste dispersion, ideally demographics or micro data

Notes: Single-market formulas with the outside good normalized to zero mean utility. Nested-logit entries are derived in Section 7.5, and random-coefficients entries in Chapter 8.

The logit and the one-nest nested logit remain useful first looks and robustness checks, and they are adequate when the question does not turn on substitution patterns. Einav's seasonality decomposition is such a question. Merger simulation, markup measurement and the valuation of new goods are not, and for those the random-coefficients model of Chapter 8 is the starting point.

7.11 Bibliographic notes

The logit has two origins. Luce (1959) derived it from the axiom of independence of irrelevant alternatives, and Debreu (1960) objected with the example that became the red bus and the blue bus. McFadden (1974) derived the conditional logit from random utility maximization with type-I extreme value shocks and proved that its likelihood is globally concave. McFadden (1978) introduced the generalized extreme value family. His survey (McFadden, 1984) remains the most complete treatment of random utility models, specification tests and the nested

logit, and Hausman and McFadden (1984) developed the test of independence of irrelevant alternatives. Train (2009) is the standard textbook on discrete choice and simulation. Anderson et al. (1992) develop the representative-consumer and address interpretations of the logit and their implications for oligopoly pricing.

The nested logit as a utility model rests on the distribution of Cardell (1997). Verboven (1996) applied a two-level version to oligopoly pricing in the European car market, and Börsch-Supan (1990) studied the admissible range of the nesting parameters. Other members of the generalized extreme value family include the ordered model of Small (1987) and the principles of differentiation model of Bresnahan et al. (1997). The generalized nested logit of Wen and Koppelman (2001) is a third. Grigolon and Verboven (2014) compare nesting with random coefficients. The log-sum measure of consumer surplus is due to Williams (1977), Small and Rosen (1981) and McFadden (1981).

Berry (1994) made discrete choice demand estimable from market data with endogenous prices. His inversion, and its extension to random coefficients by Berry et al. (1995), are the foundation of modern demand estimation. Nevo (2000a) gives a practical guide to both models, and Conlon and Gortmaker (2020) discuss best practices and software. Berry et al. (2013) prove invertibility under connected substitutes, and Berry and Haile (2014) study nonparametric identification with market-level data. On instruments, Chamberlain (1987) characterizes efficient instruments under conditional moment restrictions, and Reynaert and Verboven (2014) approximate them in random coefficients demand models. Armstrong (2016) shows when characteristic-based instruments lose their power as the number of products grows, and Gandhi and Houde (2019) propose differentiation instruments. Hausman et al. (1994) introduced prices in other markets as instruments, and Nevo (2001) defended them for cereal. On the supply side, Caplin and Nalebuff (1991) establish uniqueness of equilibrium with single-product firms. Konovalov and Sándor (2010) and Nocke and Schutz (2018) extend it to multi-product firms with logit demand. Werden and Froeb (1994) pioneered merger simulation with logit demand, alongside Hausman et al. (1994) and Nevo (2000b). Asker and Nocke (2021) survey merger simulation, upward pricing pressure and their ex-post evaluations. Bulow and Pfleiderer (1983) and Weyl and Fabinger (2013) study pass-through, and Corts (1999) shows how conduct parameters can mismeasure market power.

The case studies show the range of the toolkit. Einav (2007) uses a nested logit without prices to separate seasonal demand from the seasonality of movie releases, and Einav (2010) estimates the release-date timing game behind it. Hendel (1999) extends discrete choice to buyers of many units of several brands, a line continued by Dubé (2004) and Gentzkow (2007). The limits of the logit collected in Section 7.10 motivate the random coefficients model of Chapter 8. They also motivate the pure characteristics model of Berry and Pakes (2007), the hedonic approach of Bajari and Benkard (2005) and the crowding correction of Ackerberg and Rysman (2005).

7.12 Exercises

1. *Logit algebra and the category elasticity.*

   (a) Derive Proposition 7.6 from (7.1). Show that every off-diagonal entry in column k of the elasticity matrix, including the entry of the outside good, equals $\alpha p_k s_k$.

   (b) Raise every inside price by the same amount Δ. Show that the total inside share changes at the rate $-\alpha s_0(1 - s_0)$ per unit of Δ, and derive (7.6).

(c) In the market of Example 7.7, compute the percentage fall in total inside sales after a 5 percent increase in every inside price, first with the linear approximation (7.7) and then exactly. Compare the answer with the own-price elasticities in Table 7.1, and explain what it implies for a hypothetical monopolist test.

2. *Market size.* Consider two markets with one inside product each. In market 1 the price is low and the true outside share is $s_{01} = 0.2$. In market 2 the price is high and $s_{02} = 0.6$.

   (a) The researcher doubles the market size in both markets ($\kappa = 2$). Use (7.22) to compute the change in the dependent variable of (7.16) in each market.

   (b) Without market fixed effects, sign the effect of this error on the estimated price coefficient in a regression across the two markets. Relate your answer to Example 7.13.

   (c) Explain why a regression with market fixed effects cannot estimate α from these two observations.

   (d) Now let each market contain several inside products whose prices differ within the market, and let valid instruments for price also vary within markets. Explain why market fixed effects then remove the bias in $\hat{\alpha}$ caused by the wrong market size but leave the diversion ratios to the outside good misstated.

3. *The nested logit.*

   (a) Without using the general formula in the proof of Lemma 7.22, verify the sign conditions (G3) of Definition 7.20 up to third order for the generating function (7.56).

   (b) Derive $\text{Corr}(u_{ij}, u_{ik}) = \sigma(2 - \sigma)$ for two products in the same nest.

   (c) Redo the red bus and blue bus example of Section 7.5.3 when the car has mean utility v_c and each bus has mean utility v_b. Show that, as $\sigma \to 1$, the shares converge to those of a logit between the car and a single bus.

   (d) Use Panels A and B of Table 7.2. Compute the Wald statistic for the restriction that the inclusive value coefficient equals one, and the likelihood ratio statistic from the two log-likelihoods. Compare them with McFadden's values, and explain which hypothesis the t-statistic of 1.64 tests. Then use (7.71) to state which coefficients the first step of the sequential estimator identifies in this example.

4. *Multi-product pricing with nested logit demand.*

   (a) Derive Proposition 7.28.

   (b) Specialize the formula to a firm that owns one product in each of two nests. Write Φ_f and the two markups in terms of the product shares and within-nest shares.

   (c) Hold all shares fixed and suppose each of the two products has at least one nest-mate. Show that the percentage increase in the markup of either product, relative to separate ownership, falls as σ rises. Compare with Table 7.10, and explain what this implies for merger simulation.

5. *The two-level nested logit.* Derive the estimating equation (7.76) from the shares (7.75), showing every step. Show that it collapses to (7.69) when $\sigma_1 = \sigma_2$. State which regressors are endogenous, how many excluded instruments are needed, and propose instruments for each.

6. *Equilibrium pass-through.* Consider N symmetric single-product firms with logit demand, a common marginal cost c and common non-price utility.

   (a) Show that a common change in all prices changes each share by $\mathrm{d}s = -\alpha s s_0 \, \mathrm{d}p$.

   (b) Differentiate the symmetric first-order condition $\alpha(p - c)(1 - s) = 1$ to show that the equilibrium pass-through of a cost shock common to all firms is

   $$\frac{\mathrm{d}p}{\mathrm{d}c} = \frac{(1 - s)^2}{(1 - s)^2 + s s_0}.$$

   (c) Show that this exceeds the pass-through $1 - s$ of Proposition 7.19 whenever $N \geq 2$, that it equals $1 - s$ when $N = 1$, and that it tends to one as $N \to \infty$. Explain the role of strategic complementarity.

7. *Einav's model of movie demand.*

   (a) Derive the share formula and the estimating equation (7.97) of Section 7.8.2 from Propositions 7.25 and 7.26.

   (b) Derive the decomposition (7.98). Explain why competition matters more for a movie's share when σ is large.

   (c) Show that, for a movie too small to affect the inclusive sum, one more week since release lowers log share by $\frac{\lambda}{1-\sigma}$. Explain why a linear time trend in mean utility is not identified separately from the movie effects and the decay.

8. *Computation.* Simulate T markets with J single-product firms each, logit demand with one observed characteristic, a cost shifter and an unobserved characteristic that raises both utility and cost. Solve for equilibrium prices with (7.39).

   (a) Estimate (7.16) by OLS and by two-stage least squares, first with the cost shifter and then with the sum of rivals' characteristics as the excluded instrument. Report first-stage F statistics.

   (b) Hold the total number of products TJ fixed and repeat for $J = 2, 5, 10$ and 25. Explain why the characteristic-based instrument weakens as J grows, and compare your results with Table 7.6.

   (c) Recover marginal costs from (7.48) at the estimated $\hat{\alpha}$. Compare a bootstrap over markets with the naive standard errors of the cost regression.

Chapter 8

Random Coefficients Logit: The BLP Model

Suppose two car makers propose to merge. To predict the effect on prices we need to know how buyers of each model would respond to a price increase, and where they would go. With a hundred models on the market, a demand system in product space has ten thousand own- and cross-price elasticities (Chapter 5). The logit model of Chapter 7 needs only a handful of parameters, but it pays for its economy with substitution patterns that depend on market shares alone. It predicts that buyers who leave a luxury sedan spread over all other models in proportion to their sales, and that most of them stop buying cars altogether. Neither prediction is plausible, and a merger analysis built on them would be wrong.

This chapter studies the model that resolves the tension, the *random coefficients logit* of Berry et al. (1995), often called BLP. Consumers differ in how much they value each characteristic and how much they dislike paying. Each consumer makes a logit choice, and market shares average these choices over the distribution of tastes. Consumers who like large cars rank all large cars highly, so a price increase on one large car sends its buyers mostly to other large cars. Substitution follows the characteristics of the products. The number of parameters grows with the number of characteristics, however many products the market offers.

BLP solve three problems at once. The first is to obtain plausible substitution patterns among many products from few parameters. The second is the endogeneity of prices when only market-level data on shares, prices and characteristics are available. Firms see product quality that the econometrician does not, and they price accordingly. The third is computation. The market shares of the model are integrals with no closed form, and the unobserved quality enters them nonlinearly. BLP compute the integrals by simulation and recover unobserved quality by inverting the share equations numerically. A generalized method of moments estimator then treats the recovered quality as the error term of an instrumental variables problem.

The chapter builds directly on Chapter 7. There we derived the logit shares $s_j = \frac{e^{\delta_j}}{1+\sum_k e^{\delta_k}}$ and the inversion $\delta_j = \ln s_j - \ln s_0$ of Berry (1994), which turns demand estimation into a linear instrumental variables regression. We also saw the costs of the logit. Its own-price elasticity $\alpha p_j(1-s_j)$ rises almost in proportion to price, and its single-product markup $\frac{1}{\alpha(1-s_j)}$ is nearly the same for every product. Its cross elasticities satisfy the independence of irrelevant alternatives (IIA). The nested logit relaxes this property only within groups of products that the researcher must specify in advance. Random coefficients instead generate correlation in the composite error through the characteristics of the products, and the data determine how strong it is.

Mixtures of logits, known as *mixed logit* or *heterogeneous logit* models, were used in

transportation research well before BLP (Boyd and Mellman, 1980; Cardell and Dunbar, 1980). The innovation of Berry et al. (1995) is a computable estimator for aggregate data with endogenous prices, joined to a model of oligopoly pricing. Their framework is now the standard tool for demand estimation in industrial organization, with applications to mergers, trade policy, new goods and many other questions.

The chapter has a theoretical half and an empirical half. Sections 8.1 to 8.3 specify the model, derive its substitution patterns and explain how to compute market shares by simulation. Sections 8.4 to 8.6 develop the estimator. They prove that the share equations can be inverted by a contraction, and they derive the nested fixed point GMM estimator and its asymptotic variance. They then ask what instruments identify the model, including the nonparametric results of Berry and Haile (2014). Sections 8.7 to 8.9 add the supply side, micro data and the practical and conceptual limits of the model. Section 8.10 estimates the model step by step on a simulated market whose true parameters we know. The empirical half consists of five case studies. Section 8.11 studies the automobile market of Berry et al. (1995), and Section 8.12 the practitioner's guide of Nevo (2000a). Section 8.13 turns to the cereal study of Nevo (2001). Sections 8.14 and 8.15 cover two studies that use consumer-level data, Berry et al. (2004a) and Goldberg (1995).

We draw on several earlier chapters. Multiproduct Bertrand pricing, the ownership matrix and the distinction between product space and characteristic space come from Chapter 4. Random utility, the outside good, the vertical model and the pure characteristics model come from Chapter 6. The generalized method of moments, instrumental variables and simulation estimators are reviewed in Sections A.3, A.5 and A.7, and the contraction mapping and implicit function theorems in Sections B.2 and B.7. In turn, Chapter 9 uses a two-type version of the model, Chapter 10 uses it to value new products, and Chapter 11 uses it to simulate mergers. Appendix C poses the simulated market of Section 8.10 as a worked problem.

Two conventions hold throughout the chapter. The symbol θ denotes a vector of demand and cost parameters, split into linear parameters θ_1 and nonlinear parameters θ_2. It is unrelated to the conduct parameter of Chapter 3. The elasticity $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$ is signed, so its diagonal element ε_{jj} is negative. In the theory sections the own-price elasticity $\varepsilon_j = -\varepsilon_{jj}$ is a positive number. Tables reproduced from papers keep the papers' signs, and their notes say so.

8.1 The random coefficients logit model

The random coefficients logit model describes a population of consumers who differ in how much they value each product characteristic and how much they dislike paying. Each consumer makes a logit choice given her tastes. Market shares average these individual choice probabilities over the distribution of tastes in the population. This section builds the model in steps. We start from the general random utility formulation of Berry et al. (1995) and specialize it to the linear form used in most applications (Nevo, 2000a, 2001). We then discuss income effects, normalizations and the maintained assumptions. The section ends with the market share function, special cases, the role of the unobserved product characteristic, and the data the model requires.

8.1.1 Primitives

We observe markets $t = 1, \ldots, T$. A *market* is a population of consumers who face the same set of products at the same prices. Its definition depends on the data. Berry et al. (1995) treat the

national new car market in each year from 1971 to 1990 as a market, so $T = 20$. Nevo (2001) observes ready-to-eat cereal sales in a panel of cities and defines a market as a city-quarter, which gives 1,124 markets (Nevo, 2000a, p. 517). Other studies split one geographic market into income groups (Nevo, 2000a, p. 517).

Market t offers the inside products $j \in \mathcal{J}_t = \{1, \ldots, J_t\}$ and an outside good $j = 0$, which stands for not buying any of the inside products. The market has M_t potential consumers, its *market size*. If q_{jt} units of product j are sold, its market share is $s_{jt} = \frac{q_{jt}}{M_t}$, and the outside share is $s_{0t} = 1 - \sum_{j \in \mathcal{J}_t} s_{jt}$. Product j has a row vector of K observed characteristics x_{jt}, a price p_{jt}, and an *unobserved product characteristic* ξ_{jt}. Consumers and firms observe ξ_{jt}. The econometrician does not.

Consumer i is described by a vector of characteristics ζ_i, which may include income, demographics, and tastes that no data set records. In the general formulation of Berry et al. (1995, p. 845), the utility of consumer i from product j is a scalar function

$$U(\zeta_i, p_{jt}, x_{jt}, \xi_{jt}; \theta), \tag{8.1}$$

where θ is a vector of parameters. It includes the parameters of the utility surface and those of the distribution of ζ_i. Throughout this chapter θ denotes this vector of demand (and later cost) parameters.

Consumer i buys product j if and only if j gives her the highest utility. The set of consumer types who choose j is

$$A_{jt}(\theta) = \left\{\zeta : U(\zeta, p_{jt}, x_{jt}, \xi_{jt}; \theta) \geq U(\zeta, p_{rt}, x_{rt}, \xi_{rt}; \theta) \text{ for } r = 0, 1, \ldots, J_t\right\}. \tag{8.2}$$

Suppose ties occur with probability zero and let P_0 be the distribution of ζ in the population. The market share of product j is the mass of consumers in A_{jt},

$$s_{jt}(p_t, x_t, \xi_t; \theta) = \int_{\zeta \in A_{jt}(\theta)} P_0(\mathrm{d}\zeta), \tag{8.3}$$

which is equation (2.2) of Berry et al. (1995, p. 845). Here p_t, x_t and ξ_t collect the prices and characteristics of all products in market t. Demand for product j is $q_{jt} = M_t s_{jt}(p_t, x_t, \xi_t; \theta)$. Every product's demand depends on the prices and characteristics of all products, because they shape the sets A_{jt}.

Nevo (2000a, p. 521) splits ζ_i into three parts: observed demographics D_i, unobserved consumer characteristics ν_i, and product-specific shocks $(\epsilon_{i0t}, \ldots, \epsilon_{iJt})$. The labels "observed" and "unobserved" refer to auxiliary data. We know something about the distribution of D_i (for example from a population survey), and nothing about the distribution of ν_i beyond a parametric assumption. With this split, (8.3) factors as

$$\begin{aligned} s_{jt} &= \int_{A_{jt}} \mathrm{d}P^*(D, \nu, \epsilon) \\ &= \int_{A_{jt}} \mathrm{d}P^*(\epsilon \mid D, \nu)\, \mathrm{d}P^*(\nu \mid D)\, \mathrm{d}P^*(D) \\ &= \int_{A_{jt}} \mathrm{d}P^*_\epsilon(\epsilon)\, \mathrm{d}P^*_\nu(\nu)\, \mathrm{d}\hat{P}_D(D), \end{aligned} \tag{8.4}$$

where P^* denotes population distributions and $\hat{P}_D$ the distribution of demographics taken from auxiliary data (Nevo, 2000a, eq. (4)). The second line is the factorization of a joint distribution into conditional distributions. The third line uses the independence of ϵ, ν and D, which we assume below.

8.1.2 The linear random coefficients specification

Most applications use a utility that is linear in characteristics and price. Let u_{ijt} be the *conditional indirect utility* of consumer i from product j in market t, her indirect utility conditional on choosing j. Nevo (2000a, eq. (1)) specifies

$$u_{ijt} = \alpha_i(y_i - p_{jt}) + x_{jt}\beta_i + \xi_{jt} + \epsilon_{ijt}, \tag{8.5}$$

where y_i is income and α_i is the marginal utility of income. The $K \times 1$ vector β_i holds her taste coefficients, and ϵ_{ijt} is a mean-zero idiosyncratic shock. The term $\alpha_i(y_i - p_{jt})$ is the utility of the income left for other goods. It is linear in income, so the specification comes from a quasilinear direct utility with no income effects.

The taste coefficients vary across consumers with observed and unobserved characteristics. We stack the characteristics that may carry random coefficients into the row vector $\tilde{x}_{jt} = (x_{jt}, p_{jt})$ of dimension $K + 1$, and the corresponding coefficients into the column vector $b_i = (\beta_i^\top, -\alpha_i)^\top$. The model of taste heterogeneity is

$$b_i = \begin{pmatrix} \beta_i \\ -\alpha_i \end{pmatrix} = \begin{pmatrix} \beta \\ -\alpha \end{pmatrix} + \Pi D_i + \Sigma \nu_i, \qquad \nu_i \sim F_\nu, \qquad D_i \sim F_{Dt}. \tag{8.6}$$

Here D_i is a $d \times 1$ vector of demographics with a market-specific distribution F_{Dt}. The $(K+1)\times 1$ vector ν_i holds unobserved tastes with a known distribution F_ν, usually the standard normal $N(0, I_{K+1})$. The $(K + 1) \times d$ matrix Π measures how tastes vary with demographics, and the $(K + 1) \times (K + 1)$ matrix Σ scales the unobserved tastes (Nevo, 2000a, eq. (2)). With standard normal ν_i, the matrix $\Sigma\Sigma^\top$ is the covariance matrix of the unobserved part of tastes. Applications usually take Σ diagonal, so that σ_k is the standard deviation of the unobserved taste for characteristic k.[1]

The last element of (8.6) gives the price coefficient. Let ι_p be the $(K + 1) \times 1$ vector that selects the price element. Then

$$\alpha_i = \alpha - \iota_p^\top(\Pi D_i + \Sigma \nu_i). \tag{8.7}$$

Price therefore carries a random coefficient whenever the price row of Π or of Σ is nonzero. We state this explicitly because the price coefficient is the most important random coefficient for the elasticities and markups of later sections.

We now combine (8.5) and (8.6). First expand the income term and collect price with the other characteristics:

$$\begin{aligned} u_{ijt} &= \alpha_i y_i - \alpha_i p_{jt} + x_{jt}\beta_i + \xi_{jt} + \epsilon_{ijt} \\ &= \alpha_i y_i + \tilde{x}_{jt} b_i + \xi_{jt} + \epsilon_{ijt}. \end{aligned}$$

Next substitute the taste model for b_i:

$$\begin{aligned} u_{ijt} &= \alpha_i y_i + \tilde{x}_{jt}\left[(\beta^\top, -\alpha)^\top + \Pi D_i + \Sigma \nu_i\right] + \xi_{jt} + \epsilon_{ijt} \\ &= \alpha_i y_i + \left[x_{jt}\beta - \alpha p_{jt} + \xi_{jt}\right] + \tilde{x}_{jt}(\Pi D_i + \Sigma \nu_i) + \epsilon_{ijt}. \end{aligned}$$

[1] Nevo (2000a, eq. (2)) and Nevo (2001, eq. (3)) order the coefficient vector as $(\alpha_i, \beta_i^\top)^\top$, with the price coefficient entering utility as $-\alpha_i p_{jt}$. The two conventions differ only in the order of the rows and in the sign of the price row of Π and Σ.

Finally name the two bracketed parts:

$$u_{ijt} = \alpha_i y_i + \delta_{jt} + \mu_{ijt} + \epsilon_{ijt}, \qquad \delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \qquad \mu_{ijt} = \tilde{x}_{jt}(\Pi D_i + \Sigma \nu_i). \tag{8.8}$$

This is equation (3) of Nevo (2000a) and equation (4) of Nevo (2001), in our notation. The term $\alpha_i y_i$ is the same for every option, including the outside good, so it drops out of all choices. The *mean utility* δ_{jt} is common to all consumers in market t. The *consumer-specific deviation* μ_{ijt} interacts consumer and product characteristics. Since $\mathbb{E}[\nu_i] = 0$, it has mean zero when D_i is measured as a deviation from its mean, and then δ_{jt} is the population mean of the non-idiosyncratic utility. In the notation of Berry et al. (1995, eq. (6.1)), $u_{ij} = \delta(x_j, p_j, \xi_j; \theta_1) + \mu(x_j, p_j, \nu_i; \theta_2) + \epsilon_{ij}$.

The decomposition splits the parameters into two groups. The *linear parameters* $\theta_1 = (\alpha, \beta)$ enter only the mean utility, and they enter it linearly. The *nonlinear parameters* $\theta_2 = (\Pi, \Sigma)$ enter only μ_{ijt}, and shares depend on them nonlinearly. The estimator of Section 8.5 exploits this split: given θ_2, the mean utilities can be recovered from shares, and θ_1 then solves a linear instrumental variables problem.

The same structure appears in the micro-data model of Berry et al. (2004a, eqs. (1)–(4)). Their taste for characteristic k is $\tilde{\beta}_{ik} = \bar{\beta}_k + \sum_r z_{ir}\beta^o_{kr} + \beta^u_k \nu_{ik}$, where z_i are observed household attributes. Substituting into utility gives $u_{ij} = \delta_j + \sum_{k,r} x_{jk} z_{ir} \beta^o_{kr} + \sum_k x_{jk}\nu_{ik}\beta^u_k + \epsilon_{ij}$ with $\delta_j = \sum_k x_{jk}\bar{\beta}_k + \xi_j$. Their $\bar{\beta}$, z_i, β^o and β^u are our β, D_i, Π and a diagonal Σ, and price is one of their characteristics. They stress that the interaction terms determine substitution: as the variance of tastes for a characteristic rises, products that are similar in that characteristic become better substitutes (Berry et al., 2004a, p. 72).

The linearity of (8.8) is a convenience. Berry and Haile (2014, Example 1) consider the more general linear random coefficients model

$$v_{ijt} = x_{jt}\beta_{it} - \alpha_{it} p_{jt} + \xi_{jt} + \epsilon_{ijt}, \tag{8.9}$$

where the vector $(\beta_{it}, \alpha_{it}, \epsilon_{i1t}, \ldots, \epsilon_{iJt})$ is independent and identically distributed across consumers and markets. Its joint distribution is arbitrary and may have correlated components. They show that one characteristic with a degenerate (nonrandom) coefficient is enough for the index restriction that drives their nonparametric identification results, which Section 8.6 develops.

8.1.3 Income effects

The quasilinear form (8.5) rules out income effects. Nevo (2000a, p. 518) judges this reasonable for ready-to-eat cereal and unreasonable for cars, where the price is a large fraction of income. Berry et al. (1995, eq. (2.6)) instead nest the random coefficients in a Cobb-Douglas utility over expenditure on other goods and the characteristics of the car bought:

$$U(\zeta_i, p_j, x_j, \xi_j; \theta) = (y_i - p_j)^{\alpha}\, G(x_j, \xi_j, \nu_i)\, e^{\epsilon_{ij}}. \tag{8.10}$$

They take G linear in logs with random coefficients. With $u_{ij} = \ln U_{ij}$, this gives (Berry et al., 1995, eqs. (2.7a), (2.7b))

$$u_{ij} = \alpha \ln(y_i - p_j) + x_j\beta + \xi_j + \sum_k \sigma_k x_{jk}\nu_{ik} + \epsilon_{ij}, \qquad j = 1, \ldots, J, \tag{8.11}$$

$$u_{i0} = \alpha \ln y_i + \xi_0 + \sigma_0 \nu_{i0} + \epsilon_{i0}. \tag{8.12}$$

The marginal disutility of price is

$$\frac{\partial u_{ij}}{\partial p_j} = -\frac{\alpha}{y_i - p_j}, \tag{8.13}$$

so price sensitivity falls with income. Only utility differences matter for choices, and the income terms enter the difference between (8.11) and (8.12) as

$$\alpha \ln(y_i - p_j) - \alpha \ln y_i = \alpha \ln\!\left(1 - \frac{p_j}{y_i}\right) = -\alpha \frac{p_j}{y_i} - \frac{\alpha}{2}\left(\frac{p_j}{y_i}\right)^2 - \cdots .$$

For prices small relative to income, the effective price coefficient of consumer i is approximately $\frac{\alpha}{y_i}$. It is inversely proportional to income.

A general way to describe the role of income writes $u_{ij} = f(y_i, p_j) + \delta_j + \cdots$. Three sign conditions are natural:

$$f_y > 0, \qquad f_p < 0, \qquad f_{py} \geq 0. \tag{8.14}$$

More income left over raises utility, a higher price lowers it, and the marginal disutility of price falls (weakly) with income. For the Cobb-Douglas case $f = \alpha \ln(y - p)$ we have $f_y = \frac{\alpha}{y-p} > 0$, $f_p = -\frac{\alpha}{y-p} < 0$ and $f_{py} = \frac{\alpha}{(y-p)^2} > 0$. The quasilinear case $f = \alpha(y - p)$ has $f_{py} = 0$. Nevo (2000a, p. 518) notes that a flexible function $f(y_i - p_{jt})$ can also be used, citing the working paper version of Petrin (2002).

In estimation, Berry et al. (1995, eqs. (6.14a), (6.14b)) make income lognormal, with a year-specific mean m_t and a standard deviation $\hat{\sigma}_y$ estimated from the March Current Population Survey (CPS). Writing $y_{it} = e^{m_t + \hat{\sigma}_y \nu_{iy}}$, the final utilities are

$$u_{ijt} = \alpha \ln\!\left(e^{m_t + \hat{\sigma}_y \nu_{iy}} - p_{jt}\right) + x_{jt}\beta + \xi_{jt} + \sum_k \sigma_k x_{jkt} \nu_{ik} + \epsilon_{ijt}, \tag{8.15}$$

$$u_{i0t} = \alpha \ln\!\left(e^{m_t + \hat{\sigma}_y \nu_{iy}}\right) + \xi_{0t} + \sigma_0 \nu_{i0} + \epsilon_{i0t}, \tag{8.16}$$

where $(\nu_{iy}, \nu_{i0}, \ldots, \nu_{iK})$ are independent standard normal draws. The authors hold this vector of draws fixed over the years of their panel (Berry et al., 1995, p. 868). Two features of this specification matter later. First, price does not enter the mean utility $\delta_{jt} = x_{jt}\beta + \xi_{jt}$. It enters only through $\alpha \ln(y_{it} - p_{jt})$, so α is a nonlinear parameter, and the numerical search runs over (α, σ) (Berry et al., 1995, Section 6.5). Second, the logarithm requires $y_{it} > p_{jt}$. We read the specification as removing product j from the choice set of a consumer whose income does not exceed its price.

8.1.4 The outside good and normalizations

The outside good lets total inside demand respond to prices. Without it, every consumer buys one inside product, so a uniform rise Δ in all inside prices, relative to other sectors, leaves total inside quantity unchanged. When price enters utility linearly, as in (8.5), the rise lowers every inside utility of consumer i by the same amount $\alpha_i \Delta$. Her choice probabilities, and hence the quantity of every product, are then unchanged as well (Nevo, 2000a, p. 520). This second implication needs price to enter linearly. Under (8.11) the utility change $\alpha \ln(y_i - p_j - \Delta) - \alpha \ln(y_i - p_j)$ is larger in absolute value for more expensive products. Individual shares then move toward cheaper products while their sum stays at one. Nevo (2000a, p. 520) writes the utility of the outside option as

$$u_{i0t} = \alpha_i y_i + \xi_{0t} + \pi_0 D_i + \sigma_0 \nu_{i0} + \epsilon_{i0t}. \tag{8.17}$$

Three normalizations reduce it to $u_{i0t} = \alpha_i y_i + \epsilon_{i0t}$, and hence, after dropping the common term $\alpha_i y_i$, to $u_{i0t} = \epsilon_{i0t}$.

The first normalization fixes the location of utility. Choices depend only on utility differences. Subtracting (8.17) from (8.8) gives

$$u_{ijt} - u_{i0t} = (\delta_{jt} - \xi_{0t}) + (\mu_{ijt} - \pi_0 D_i - \sigma_0 \nu_{i0}) + (\epsilon_{ijt} - \epsilon_{i0t}).$$

The mean utility of the outside good enters only through the differences $\delta_{jt} - \xi_{0t}$, so it cannot be separated from the inside mean utilities. We set $\xi_{0t} = 0$. If the value of the outside option varies across markets, the normalization reinterprets each ξ_{jt} as $\xi_{jt} - \xi_{0t}$ (Berry and Haile, 2014, n. 12).

The second normalization concerns heterogeneity in the value of the outside good. The terms $\pi_0 D_i$ and $\sigma_0 \nu_{i0}$ enter the utility of every inside good with the same coefficient, minus one. They act exactly like random coefficients on a constant characteristic that every inside product has. They cannot be separated from the constant's rows of Π and Σ, and we set $\pi_0 = 0$ and $\sigma_0 = 0$ (Nevo, 2000a, p. 520). Berry et al. (1995, p. 849, n. 6) keep $\sigma_0 \nu_{i0}$ and note that it is equivalent to a random coefficient on the constant for the inside goods. Their motivation is that the value of not buying a new car varies in ways the data do not record, for example with access to public transportation and with used car holdings.

The third normalization fixes the scale. Multiplying every utility by a positive constant leaves choices unchanged. Assuming that ϵ_{ijt} has the standard type-I extreme value distribution, with variance $\frac{\pi^2}{6}$, fixes the scale. All coefficients are measured relative to the standard deviation of the idiosyncratic shock.

8.1.5 Maintained assumptions and the two roles of characteristics

A characteristic plays two roles in the model (Nevo, 2000a, p. 527). Through β it shifts the mean utility δ_{jt}. Through the rows of Π and Σ it shapes μ_{ijt}, and with it the substitution patterns. Nevo recommends keeping the two roles separate. Nothing requires the same characteristics to appear in both places. The mean utility can contain many characteristics, and even a full set of product dummies when markets are many relative to products. The deviation μ_{ijt} should contain the few characteristics that drive substitution. The computational burden of estimation grows with the number of nonlinear parameters, so parsimony matters most in θ_2. A characteristic without a random coefficient has zero rows in Π and Σ.

Product dummies cannot replace characteristics in the second role. Letting the data determine every pair's substitution freely would require $\frac{J(J-1)}{2}$ parameters, the same count as an unrestricted covariance matrix for ϵ_{ijt} (Nevo, 2000a, p. 528). Avoiding that count is the purpose of projecting products onto characteristics.

Assumption 8.1 (Random coefficients logit)**.**

(A1) The shocks ϵ_{ijt} are independent and identically distributed type-I extreme value across consumers, products and markets, and independent of $(x_t, p_t, \xi_t, D_i, \nu_i)$.

(A2) The unobserved tastes ν_i have a known distribution F_ν and are independent of D_i. The demographics D_i have a known distribution F_{Dt} in each market. Both are independent of the product variables (x_t, p_t, ξ_t).

(A3) Each consumer buys one unit of the option that gives her the highest utility.

(A4) All consumers in a market face the same choice set and the same prices.

(A5) Each market has a continuum of consumers of known mass M_t, so that observed market shares equal the model's choice probabilities.

Each assumption has a cost. Assumption (A3) rules out buying several products at once. Nevo (2001, n. 13) observes that many households buy several brands of cereal on one shopping trip, but most people eat one brand at a time. Defining the choice occasion as the consumption occasion makes single choice a reasonable approximation. When it is not, the model can be read as an approximation, or the researcher can model multiple discrete choices explicitly as in Hendel (1999) (Chapter 7). Assumption (A4) is a simplification. The methods extend to choice sets that differ across markets and across consumers (Nevo, 2000a, n. 8). If consumers pay different prices, a list or average price measures each consumer's price with error. This is one more reason for prices to be correlated with the error term (Nevo, 2000a, p. 518). Assumption (A5) abstracts from sampling error in shares. Section 8.5 returns to it, since the sampling variance of shares enters the asymptotic variance of the estimator.

8.1.6 Market shares

Under Assumption 8.1 we integrate the extreme value shocks analytically, conditional on (D_i, ν_i). The standard logit algebra of Chapter 6 gives the probability that consumer i buys product j:

$$s_{ijt} = \frac{\exp(\delta_{jt} + \mu_{ijt})}{1 + \sum_{k \in \mathcal{J}_t} \exp(\delta_{kt} + \mu_{ikt})}, \qquad s_{i0t} = \frac{1}{1 + \sum_{k \in \mathcal{J}_t} \exp(\delta_{kt} + \mu_{ikt})}, \tag{8.18}$$

which is equation (6.6) of Berry et al. (1995). The 1 in the denominator is the exponential of the normalized outside utility. The market share averages these probabilities over the distribution of consumer characteristics (Berry et al., 1995, eq. (6.7)):

$$s_{jt}(\delta_t; \theta_2) = \int \int s_{ijt} \, \mathrm{d}F_\nu(\nu) \, \mathrm{d}F_{Dt}(D). \tag{8.19}$$

We write the share as a function of the vector of mean utilities $\delta_t = (\delta_{1t}, \ldots, \delta_{J_t t})^\top$ and of θ_2. Characteristics and prices enter through δ_t and through μ_{ijt}. We abbreviate the double integral as $\int \cdot \, \mathrm{d}F$. The integral has no closed form, and Section 8.3 explains how to compute it. The next result collects the properties of the share function that the rest of the chapter uses.

Proposition 8.2 (Properties of the share function)**.** *Fix θ_2, the characteristics $\tilde{x}_t$ and the distribution $F = F_\nu \times F_{Dt}$. The map $\delta_t \mapsto s_t(\delta_t; \theta_2)$ from $\mathbb{R}^{J_t}$ to $\mathbb{R}^{J_t}$ has the following properties.*

(i) It maps into the interior of the unit simplex: $s_{jt} > 0$ for every j, and $s_{0t} = 1 - \sum_j s_{jt} = \int s_{i0t} \, \mathrm{d}F > 0$.

(ii) It is infinitely differentiable, with

$$\frac{\partial s_{jt}}{\partial \delta_{kt}} = \int s_{ijt} \left(\mathbf{1}\{j = k\} - s_{ikt} \right) \mathrm{d}F. \tag{8.20}$$

(iii) Each share is strictly increasing in its own mean utility and strictly decreasing in the mean utility of every other inside product.

(iv) The Jacobian $\frac{\partial s_t}{\partial \delta_t^\top}$ is strictly diagonally dominant, with $\sum_k \frac{\partial s_{jt}}{\partial \delta_{kt}} = \int s_{ijt} \, s_{i0t} \, \mathrm{d}F > 0$ for each j. In particular, it is nonsingular.

Proof. Drop the market index. For (i), fix (D, ν). Each s_{ij} in (8.18) lies in $(0,1)$ and $\sum_j s_{ij} = 1 - s_{i0} < 1$. Integrating against the probability measure F preserves strict positivity and the adding-up identity.

For (ii), write $A_i = 1 + \sum_k e^{\delta_k + \mu_{ik}}$, so that $s_{ij} = \frac{e^{\delta_j + \mu_{ij}}}{A_i}$. The quotient rule gives

$$\frac{\partial s_{ij}}{\partial \delta_j} = \frac{e^{\delta_j+\mu_{ij}} A_i - e^{\delta_j+\mu_{ij}} e^{\delta_j+\mu_{ij}}}{A_i^2} = s_{ij} - s_{ij}^2, \qquad \frac{\partial s_{ij}}{\partial \delta_k} = -\frac{e^{\delta_j+\mu_{ij}} e^{\delta_k+\mu_{ik}}}{A_i^2} = -s_{ij} s_{ik} \quad (k \neq j).$$

Both cases are $s_{ij}(\mathbf{1}\{j = k\} - s_{ik})$. Differentiating again shows by induction that every partial derivative of s_{ij} of any order is a polynomial in $(s_{i1}, \ldots, s_{iJ})$ with coefficients that do not depend on (D, ν). Each such polynomial is bounded in absolute value by a constant, because every s_{ik} lies in $[0,1]$. A constant is integrable against a probability measure, so the dominated convergence theorem allows us to differentiate under the integral sign to every order. Applied to the first derivatives, it gives (8.20).

For (iii), the integrand of $\frac{\partial s_j}{\partial \delta_j}$ is $s_{ij}(1 - s_{ij}) > 0$ and that of $\frac{\partial s_j}{\partial \delta_k}$, $k \neq j$, is $-s_{ij} s_{ik} < 0$, for every (D, ν).

For (iv), sum (8.20) over k:

$$\sum_k \frac{\partial s_j}{\partial \delta_k} = \int s_{ij}\Big(1 - \sum_k s_{ik}\Big) \mathrm{d}F = \int s_{ij} s_{i0} \, \mathrm{d}F > 0.$$

By (iii) the diagonal entry is positive and the off-diagonal entries are negative, so the sum equals $\left|\frac{\partial s_j}{\partial \delta_j}\right| - \sum_{k \neq j} \left|\frac{\partial s_j}{\partial \delta_k}\right|$. It is positive, which is strict diagonal dominance of row j. A strictly diagonally dominant matrix is nonsingular by the Lévy-Desplanques theorem. □

Properties (iii) and (iv) are the ingredients of the inversion of the share map in Section 8.4. The row sums in (iv) also govern how fast that inversion converges. They are small when the consumers who buy j rarely choose the outside good.

8.1.7 Special cases and relatives

Several familiar models are special cases or limits of (8.18) and (8.19).

The logit model sets $\Pi = 0$ and $\Sigma = 0$. Then $\mu_{ijt} = 0$, every consumer has the same choice probabilities, and (Berry et al., 1995, eqs. (6.3), (6.4))

$$s_{jt} = \frac{e^{\delta_{jt}}}{1 + \sum_k e^{\delta_{kt}}}, \qquad \delta_{jt} = \ln s_{jt} - \ln s_{0t}. \tag{8.21}$$

Chapter 7 studies this model and its inversion in detail.

Remark 8.3 (Nested logit as a random coefficients model). Let $d_{jg} = 1$ if product j belongs to nest g, and write $u_{ijt} = \delta_{jt} + \sum_g d_{jg} \zeta_{ig} + (1 - \sigma)\epsilon_{ijt}$. Here ζ_{ig} is common to all products in nest g and has the distribution for which $\zeta_{ig} + (1 - \sigma)\epsilon_{ijt}$ is again type-I extreme value (Cardell, 1997). This utility generates the nested logit shares of Chapter 7. The nested logit is therefore a random coefficients model with random coefficients on the nest dummies and a particular distribution for them (Berry et al., 1995, p. 851), (Nevo, 2000a, p. 524). It requires a priori information on the order and the content of the nests. A normal random coefficient on a segment dummy is the random coefficients analog, and it can sit beside random coefficients on continuous characteristics.

When the unobserved tastes take finitely many values, the integral becomes a finite sum. If ν_i equals ν_r with probability ψ_r, $r = 1, \ldots, R$, and there are no demographics, then

$$s_{jt} = \sum_{r=1}^{R} \psi_r \frac{\exp(\delta_{jt} + \tilde{x}_{jt}\Sigma\nu_r)}{1 + \sum_k \exp(\delta_{kt} + \tilde{x}_{kt}\Sigma\nu_r)}. \tag{8.22}$$

These *latent class* models need no simulation. Berry et al. (2006) use two types of air travelers within a nested logit, and Chapter 9 studies their model.

At the other extreme, dropping the idiosyncratic shock gives the *pure characteristics model* $u_{ijt} = \delta_{jt} + \mu_{ijt}$ of Berry and Pakes (2007). It is the limit of the utility $\delta_{jt} + \mu_{ijt} + \tau\epsilon_{ijt}$ as the scale τ of the logit shock falls to zero. Chapter 6 introduces it, and Section 8.9 explains why it is harder to estimate and when it gives different answers.

Finally, mixtures of logits are very flexible. McFadden and Train (2000) show that, under mild regularity conditions, the choice probabilities of any random utility model can be approximated as closely as one wishes by a mixed logit model. Nevo (2001, pp. 316–317) cites the working paper version of this result. He uses it to argue that the full model can approximate any choice model, including the multinomial probit of Hausman and Wise (1978). The theorem concerns approximation of choice probabilities. It does not say that a given parametric specification, such as normal tastes on a few characteristics, is close to the truth.

8.1.8 Why the model needs an unobserved product characteristic

The unobserved characteristic ξ_{jt} has two jobs. The first is to let the model fit aggregate data at all. Suppose $\xi_{jt} = 0$, as in much earlier work on discrete choice. Then the model predicts the share of every product exactly, given (x_t, p_t) and θ, and only sampling error separates data from model. With M_t consumers making independent choices, the observed share has standard deviation $\sqrt{\frac{s_{jt}(1-s_{jt})}{M_t}}$ around the model share. Berry et al. (1995, p. 859) note that the number of U.S. households is on the order of 100 million. For a car with share 0.01 this standard deviation is

$$\sqrt{\frac{0.01 \times 0.99}{10^8}} \approx 9.9 \times 10^{-6},$$

which is 0.1 percent of the share. Any visible misfit is then thousands of standard errors away from zero, and a chi-square test of the model's restrictions rejects with probability close to one. This is the "over fitting" problem of Berry et al. (1995, p. 850).

The second job is economic. In homogeneous-goods markets, aggregate demand has a disturbance that captures demand determinants common to the consumers of a market. The term ξ_{jt} is its analog for differentiated products (Berry et al., 1995, p. 850). In the car market it reflects "style, prestige, reputation, and past experience," and characteristics missing from the data (Berry et al., 1995, pp. 850–851). In other markets it includes unobserved promotional activity, brand equity and systematic demand shocks (Nevo, 2000a, p. 517). Depending on the data, parts of ξ_{jt} can be captured by dummy variables, for example $\xi_{jt} = \xi_j + \xi_t + \tilde{\xi}_{jt}$ with product and market effects. Producers know ξ_{jt} when they set prices, so equilibrium prices depend on it. This correlation between price and the structural error is the simultaneity problem of Section 8.6 (Berry et al., 1995, Section 2.2).

The specification makes ξ_{jt} a common valuation. It enters δ_{jt} and not μ_{ijt}, so all consumers value it equally. Nevo (2000a, p. 518) notes that this is consistent with vertical differentiation,

because the price coefficient varies across consumers. One could instead model the distribution of the valuation of ξ.

The idiosyncratic shock ϵ_{ijt} also deserves an interpretation, because welfare calculations treat it as part of utility. Four readings are common. It may capture psychological biases, which is a problem for welfare analysis because the log-sum formula then counts mistakes as utility. It may reflect measurement error. It may stand for consumer or product characteristics that we do not observe. Or it may be an approximation error that lets a smooth model rationalize discrete choices. Each product brings its own dimension of ϵ, which has consequences for crowded markets and for the value of new products. Section 8.9 and Chapter 10 discuss this "too many characteristics" problem.

8.1.9 Data requirements

Estimation with market-level data requires market shares, prices and product characteristics in each market (Nevo, 2000a, Section 3.1). Information on the distribution of demographics in each market is useful, and so are marketing variables such as advertising and promotions. Some parameters are identified from a single market, but Nevo (2000a, pp. 526–527) recommends data on several markets with variation in relative prices and in the products offered. Section 8.6 explains why that variation identifies the nonlinear parameters.

Market shares require a quantity variable and a market size. Berry et al. (1995) count cars sold. They set M_t to the number of U.S. households in each year, taken from the *Statistical Abstract of the United States* (Berry et al., 1995, p. 869). Nevo (2001) converts pounds of cereal into servings and takes the potential market to be one serving per capita per day. Bresnahan et al. (1997) take the potential market for computers to be the number of office-based employees (Nevo, 2000a, p. 527).

The choice of M_t determines the outside share, which is rarely observed directly. Nevo (2000a, p. 527) offers four rules. The market must be large enough for the outside good to have a positive share. With historical data, eventual growth of the market reveals the potential market. Results should be checked for sensitivity to the definition, and an alternative should be considered if they are sensitive. A market size has two parts, the variable to which it is proportional and the proportionality factor. The factor can be estimated, as in Berry et al. (2006). In Nevo's experience the variable is the harder and more important choice.

The logit case shows why M_t matters. Scaling the market size by $\lambda > 1$ divides every inside share by λ and raises the outside share. The logit inversion $\delta_{jt} = \ln s_{jt} - \ln s_{0t}$ then moves every mean utility by $-\ln \lambda - \ln s_{0t}(\lambda) + \ln s_{0t}(1)$, a common amount within the market. The own elasticities $\alpha p_{jt}(1 - s_{jt})$ barely change when shares are small. The diversion to the outside good, $\frac{s_{0t}}{1-s_{jt}}$, rises toward one. Conclusions about competition between inside products and the outside option therefore depend directly on the assumed market size.

Product characteristics come from manufacturers' descriptions, the trade press, or the researcher's prior classification (Nevo, 2000a, p. 527). Demographic distributions come from population surveys such as the CPS (Nevo, 2000a, p. 528). Section 8.3.3 describes how both studies draw demographics for simulation.

8.2 Substitution patterns and elasticities

The reason to estimate random coefficients is to obtain plausible substitution patterns from few parameters. This section derives the share derivatives, elasticities and diversion ratios of the

model and shows how they differ from those of the logit. We use the notation of Section 8.1 with the market index suppressed when no confusion arises. Following our convention, the elasticity of the share of j with respect to the price of k is $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, which is negative for $k = j$. The own-price elasticity $\varepsilon_j = -\varepsilon_{jj} = -\frac{\partial s_j}{\partial p_j}\frac{p_j}{s_j}$ is a positive number.

8.2.1 The logit benchmark and its restrictions

In the logit model, $s_j = \frac{e^{\delta_j}}{1+\sum_k e^{\delta_k}}$ with $\delta_j = x_j\beta - \alpha p_j + \xi_j$. Its elasticities are (Nevo, 2000a, p. 522)

$$\varepsilon_j = \alpha p_j(1 - s_j), \qquad \varepsilon_{jk} = \alpha p_k s_k \quad (k \neq j). \tag{8.23}$$

Nevo identifies two problems. The first concerns own elasticities. Market shares are usually small, so the factor $\alpha(1 - s_j)$ is nearly constant and own elasticities are nearly proportional to own prices. A cheap product then has a low elasticity. The single-product pricing rule $\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j}$ (Chapter 4) gives

$$p_j - mc_j = \frac{p_j}{\alpha p_j(1 - s_j)} = \frac{1}{\alpha(1 - s_j)}, \tag{8.24}$$

which is almost the same dollar markup for every product. The percentage markup is therefore higher for cheap products. This is possible only if a cheap product's marginal cost is lower as a fraction of its price than an expensive product's (Nevo, 2000a, p. 522). The pattern comes from the functional form. With $\ln p_j$ in place of p_j in utility, the own elasticity would be roughly constant instead.

The second problem concerns cross elasticities. In (8.23), ε_{jk} depends only on the share and price of product k. Every product gains the same percentage from a rise in p_k. Two examples make the point. Suppose an inexpensive Yugo and an expensive Mercedes had the same share. A rise in the price of a BMW would then raise the demand for both by the same amount (Berry et al., 1995, p. 847). Quaker Cap'n Crunch is a children's cereal and Post Grape Nuts is a nutrition cereal. If they had similar shares, consumers leaving General Mills Lucky Charms, another children's cereal, would move to each in the same proportion (Nevo, 2000a, p. 523). Intuition says that consumers who leave a large car move to other large cars, and that consumers who leave a children's cereal move to other children's cereals.

Nevo (2000a, p. 523) explains the source through second choices. A consumer buys a product either because its mean utility is high or because her idiosyncratic shock for it is high. When Lucky Charms becomes more expensive, the consumers who leave it switch to their second choice. In the logit, rankings differ across consumers only through independent shocks. The second choices of the leavers are therefore distributed like those of the whole population, which is in proportion to market shares.

The restriction does not depend on the extreme value distribution. Suppose $u_{ij} = \delta_j + \epsilon_{ij}$ with ϵ_{ij} independent and identically distributed with any distribution function P. Then (Berry et al., 1995, eq. (2.4))

$$s_j = \int \prod_{q \neq j} P(\delta_j - \delta_q + \epsilon)\, P(\mathrm{d}\epsilon), \tag{8.25}$$

which depends only on the vector δ. The price derivatives $\frac{\partial s_j}{\partial p_k} = -\alpha\frac{\partial s_j}{\partial \delta_k}$ are then functions of δ alone. Since there is a unique δ for each vector of shares, all substitution effects depend only on

market shares and not on the characteristics of the products (Berry et al., 1995, p. 847). A probit with independent errors has the same problem. Its source is the absence of heterogeneity in tastes for characteristics, and the logit distribution plays no role. The same argument shows that two products with the same share have the same own-price derivative. With single-product firms they must have the same markup, whatever their prices and their positions in the product space (Berry et al., 1995, p. 847).

8.2.2 Share derivatives in the random coefficients logit

We now derive the price derivatives of (8.19). To cover both the linear specification and the Cobb-Douglas specification of Berry et al. (1995), write $V_{ij} = \delta_j + \mu_{ij}$ for the non-idiosyncratic utility and assume that p_k enters only V_{ik}, with

$$\frac{\partial V_{ik}}{\partial p_k} = -\alpha_{ik}. \tag{8.26}$$

In the linear specification, $\alpha_{ik} = \alpha_i$ from (8.7) for every product. In the Cobb-Douglas specification, $\alpha_{ik} = \frac{\alpha}{y_i - p_k}$ by (8.13).

Proposition 8.4 (Share derivatives and elasticities)**.** *Suppose there is an integrable function $g(D, \nu)$ with $|\alpha_{ik}(p')|\, s_{ik}(p') \le g(D, \nu)$ for all k and all price vectors p' in a neighborhood of p. Then, for $j, k \in \mathcal{J}$ with $k \neq j$,*

$$\frac{\partial s_j}{\partial p_j} = -\int \alpha_{ij}\, s_{ij}(1 - s_{ij})\, \mathrm{d}F, \tag{8.27}$$

$$\frac{\partial s_j}{\partial p_k} = \int \alpha_{ik}\, s_{ij}\, s_{ik}\, \mathrm{d}F, \tag{8.28}$$

$$\frac{\partial s_0}{\partial p_k} = \int \alpha_{ik}\, s_{i0}\, s_{ik}\, \mathrm{d}F. \tag{8.29}$$

The elasticities are

$$\varepsilon_j = \frac{p_j}{s_j} \int \alpha_{ij}\, s_{ij}(1 - s_{ij})\, \mathrm{d}F, \qquad \varepsilon_{jk} = \frac{p_k}{s_j} \int \alpha_{ik}\, s_{ij}\, s_{ik}\, \mathrm{d}F. \tag{8.30}$$

In the linear specification with $\mathbb{E}|\alpha_i| < \infty$, the domination condition holds with $g = |\alpha_i|$.

Proof. Fix (D, ν). By the quotient rule computations in the proof of Proposition 8.2, $\frac{\partial s_{ij}}{\partial V_{ik}} = s_{ij}(\mathbf{1}\{j = k\} - s_{ik})$ for inside goods, and $\frac{\partial s_{i0}}{\partial V_{ik}} = -\frac{e^{V_{ik}}}{A_i^2} = -s_{i0}s_{ik}$. Since p_k enters only V_{ik}, the chain rule and (8.26) give

$$\frac{\partial s_{ij}}{\partial p_j} = -\alpha_{ij}s_{ij}(1 - s_{ij}), \qquad \frac{\partial s_{ij}}{\partial p_k} = \alpha_{ik}s_{ij}s_{ik}, \qquad \frac{\partial s_{i0}}{\partial p_k} = \alpha_{ik}s_{i0}s_{ik}.$$

Each of these is bounded in absolute value by $|\alpha_{ik}|s_{ik}$, because $s_{ij} \le 1$ and $1 - s_{ij} \le 1$. On a neighborhood of p this bound is at most $g(D, \nu)$, which is integrable. The dominated convergence theorem, in its form for differentiation under the integral sign, lets us integrate the derivatives against F. This gives (8.27) to (8.29). The elasticities follow from the definitions. In the linear specification, $|\alpha_{ik}|s_{ik} \le |\alpha_i|$ and α_i does not depend on p. □

With the linear specification, $\alpha_{ij} = \alpha_i$ and (8.27) and (8.28) replace the logit derivatives $-\alpha s_j(1 - s_j)$ and $\alpha s_j s_k$ by integrals of individual logit derivatives. These are the elasticities of Nevo (2000a, p. 525). With the Cobb-Douglas specification they are equations (6.9a) and (6.9b) of Berry et al. (1995), with $\frac{\partial \mu_{ij}}{\partial p_j} = -\frac{\alpha}{y_i - p_j}$.[2]

Bayes' rule turns (8.30) into statements about buyers. The probability that a consumer of type (D, ν) buys j is s_{ij}, so the distribution of consumer types among the buyers of j has density $\frac{s_{ij}}{s_j}$ with respect to F. Hence

$$\varepsilon_j = p_j \, \mathbb{E}\big[\alpha_{ij}(1 - s_{ij}) \mid i \text{ buys } j\big], \qquad \varepsilon_{jk} = p_k \, \mathbb{E}\big[\alpha_{ik} \, s_{ik} \mid i \text{ buys } j\big]. \tag{8.31}$$

The own elasticity is the price times the average price sensitivity of the product's buyers, each weighted by the probability $1 - s_{ij}$ that she has somewhere else to go. Expensive products are bought mostly by consumers with low α_i, so their elasticities need not be high. The cross elasticity ε_{jk} is large when the buyers of j are likely to buy k, which happens when j and k are close in the characteristics that carry random coefficients. In the logit, $\alpha_{ij} = \alpha$ and $s_{ij} = s_j$ for all consumers, and (8.31) reduces to (8.23).

Nevo (2000a, pp. 525–526) illustrates the own-elasticity point. If the consumers of Kellogg's Corn Flakes are very price sensitive, its own elasticity is high despite its low price and the linear price term. In the random coefficients model, substitution patterns are driven by differences in price sensitivity across the consumers of different products. Functional form alone no longer determines them. The normal distribution in (8.6) gives a small fraction of consumers a negative α_i. These consumers like higher prices. A lognormal price coefficient, as in Berry et al. (2004a), rules this out.

8.2.3 Diversion ratios

The *diversion ratio* from product j to product k is the fraction of the sales that j loses after a small rise in its price that goes to k,

$$D_{jk} = \frac{\partial s_k}{\partial p_j} \Big(-\frac{\partial s_j}{\partial p_j} \Big)^{-1}, \qquad k \in \{0\} \cup \mathcal{J}, \; k \neq j. \tag{8.32}$$

The symbol D_{jk} carries two product indices. It should not be confused with the demographic vector D_i. Diversion ratios play a central part in merger analysis (Chapter 11). In the logit, $D_{jk} = \frac{\alpha s_j s_k}{\alpha s_j (1 - s_j)} = \frac{s_k}{1 - s_j}$, so diversion is proportional to the share of the destination.

Proposition 8.5 (Diversion as a weighted average of individual diversion)**.** *Use the linear specification and suppose $\alpha_i \geq 0$ almost surely, with $\mathbb{P}(\alpha_i > 0) > 0$. Then*

$$D_{jk} = \int \omega_{ij} \, \frac{s_{ik}}{1 - s_{ij}} \, \mathrm{d}F, \qquad \omega_{ij} = \frac{\alpha_i s_{ij}(1 - s_{ij})}{\int \alpha_{i'} s_{i'j}(1 - s_{i'j}) \, \mathrm{d}F(i')}, \tag{8.33}$$

for every $k \in \{0\} \cup \mathcal{J}$ with $k \neq j$. The weights ω_{ij} are nonnegative and integrate to one, and $\frac{s_{ik}}{1 - s_{ij}}$ is the logit diversion ratio of consumer i. In particular, $\sum_{k \neq j} D_{jk} = 1$, where the sum includes the outside good.

[2] In the specification (8.15), price enters only μ_{ij}, so Berry et al. (1995) write the derivatives with $\frac{\partial \mu_{ij}}{\partial p_j}$ in place of our $-\alpha_{ij}$.

Proof. For an inside good k, Proposition 8.4 gives the numerator $\frac{\partial s_k}{\partial p_j} = \int \alpha_i s_{ik} s_{ij} \, \mathrm{d}F$. Multiply and divide the integrand by $1 - s_{ij}$, which is positive:

$$\frac{\partial s_k}{\partial p_j} = \int \alpha_i s_{ij}(1 - s_{ij}) \, \frac{s_{ik}}{1 - s_{ij}} \, \mathrm{d}F.$$

The denominator of (8.32) is $\int \alpha_i s_{ij}(1 - s_{ij}) \, \mathrm{d}F$, which is positive under the assumptions. Dividing gives (8.33). The same steps apply to $k = 0$ with (8.29). The weights are nonnegative because $\alpha_i \geq 0$, and they integrate to one by construction. For each consumer, $\sum_{k \neq j} s_{ik} = 1 - s_{ij}$, so the individual diversion ratios sum to one and so does their weighted average. □

The weights identify whose behavior determines diversion. A consumer receives weight $\alpha_i s_{ij}(1 - s_{ij})$, the slope of her purchase probability with respect to p_j. Consumers who never consider j, or who buy it whatever happens, receive little weight. The marginal, price-sensitive buyers of j receive the most. Diversion goes to the products that these marginal buyers like.

Corollary 8.6 (Diversion to the outside good)**.** *Under the assumptions of Proposition 8.5,*

$$D_{j0} = \int \varpi_{ij} \, \frac{s_{i0}}{1 - s_{ij}} \, \mathrm{d}F, \tag{8.34}$$

whereas the logit gives $D_{j0} = \frac{s_0}{1 - s_j}$ with $s_0 = \int s_{i0} \, \mathrm{d}F$. The diversion to the outside good lies below the logit value exactly when the ϖ-weighted average of $\frac{s_{i0}}{1 - s_{ij}}$ lies below $\frac{s_0}{1 - s_j}$. This happens when the marginal buyers of j rarely choose the outside good.

The corollary explains one of the most striking results of Berry et al. (1995). Their Table VII reports, for 13 cars of 1990, the percentage of consumers who leave a car after a price rise and choose the outside good. The logit value $\frac{s_0}{1 - s_j}$ is about 90 percent for every car, from 90.458 (Honda Accord) to 90.883 (BMW 735i). The random coefficients estimates range from 27.996 (Ford Escort) down to 10.090 (Lexus LS400) and 10.101 (BMW 735i) (Berry et al., 1995, Table VII). The marginal buyers of a luxury car are consumers who almost always buy some car, and they switch to other luxury cars. Section 8.11 reproduces the table.

8.2.4 Correlated utilities and the characteristics that matter

The random coefficients act through the correlation they induce in the utilities of different products for the same consumer. Define the composite deviation $e_{ij} = \mu_{ij} + \epsilon_{ij}$, so that $u_{ij} = \delta_j + e_{ij}$ apart from the common income term. In the logit, $e_{ij} = \epsilon_{ij}$ is independent across products.

Proposition 8.7 (Covariance of the composite deviation)**.** *Suppose $\nu_i \sim N(0, I_{K+1})$ and D_i has mean zero and covariance matrix V_D, independent of ν_i. Let $\mathcal{V} = \Pi V_D \Pi^\top + \Sigma\Sigma^\top$. Then, for inside products j and k,*

$$\operatorname{Cov}(e_{ij}, e_{ik}) = \tilde{x}_j \, \mathcal{V} \, \tilde{x}_k^\top + \frac{\pi^2}{6} \mathbf{1}\{j = k\}. \tag{8.35}$$

Without demographics, $\operatorname{Cov}(e_{ij}, e_{ik}) = \tilde{x}_j \Sigma\Sigma^\top \tilde{x}_k^\top$ for $j \neq k$.

Proof. The vector $w_i = \Pi D_i + \Sigma \nu_i$ has mean zero and covariance $\Pi V_D \Pi^\top + \Sigma I \Sigma^\top = \mathcal{V}$, because D_i and ν_i are independent. Since $\mu_{ij} = \tilde{x}_j w_i$ is linear in w_i, $\operatorname{Cov}(\mu_{ij}, \mu_{ik}) = \tilde{x}_j \mathcal{V} \tilde{x}_k^\top$. The shocks ϵ_{ij} are independent of w_i and of each other, with variance $\frac{\pi^2}{6}$. Adding the covariances gives (8.35). □

The proposition answers the question of which characteristics shape substitution. Only characteristics with nonzero rows in Π or Σ enter $\mathcal{V}$. A characteristic that enters only the mean utility does not affect the correlation structure. The variance of the utility difference between two products is

$$\operatorname{Var}(e_{ij} - e_{ik}) = (\tilde{x}_j - \tilde{x}_k)\,\mathcal{V}\,(\tilde{x}_j - \tilde{x}_k)^{\top} + \frac{\pi^2}{3}. \tag{8.36}$$

Products that are close in the metric defined by $\mathcal{V}$ have utilities that move together across consumers. A consumer who ranks one of them highly ranks the other highly too. This is the mechanism behind the large cross elasticities between similar products. The matrix $\mathcal{V}$ has $\frac{(K+1)(K+2)}{2}$ free elements at most, against $\frac{J(J-1)}{2}$ for an unrestricted covariance matrix of ϵ (Nevo, 2000a, p. 525).

Remark 8.8 (Independence of irrelevant alternatives holds for each consumer). For a given (D_i, ν_i), the ratio of choice probabilities is $\frac{s_{ij}}{s_{ik}} = \exp(V_{ij} - V_{ik})$, which does not depend on the other products. Each consumer's choices satisfy independence of irrelevant alternatives. The property fails for market shares. The ratio $\frac{s_j}{s_k} = \frac{\int s_{ij}\,\mathrm{d}F}{\int s_{ik}\,\mathrm{d}F}$ changes when a third product enters or changes price, because the third product draws disproportionately from consumers with particular tastes. Aggregation over heterogeneous consumers removes the restriction.

8.2.5 Own-price elasticities and markups need not rise with price

A two-type example shows how heterogeneity in price sensitivity reverses the logit pattern of own elasticities.

Example 8.9 (Two types of consumers)**.** Half the consumers are price sensitive, with $\alpha_H = 4$, and half are not, with $\alpha_L = 1$. There are two inside goods. Good 1 is cheap, with $p_1 = 1$ and quality index $q_1 = 2$. Good 2 is expensive, with $p_2 = 2$ and $q_2 = 3.5$. A consumer of type r has non-idiosyncratic utilities $V_{rj} = q_j - \alpha_r p_j$ and logit choice probabilities. This is a latent class model (8.22) with a random coefficient on price only.

The utilities are $V_H = (2-4, 3.5-8) = (-2, -4.5)$ and $V_L = (2-1, 3.5-2) = (1, 1.5)$. The type-$H$ denominator is $1 + e^{-2} + e^{-4.5} = 1.1464$ and the type-L denominator is $1 + e^{1} + e^{1.5} = 8.2000$. Table 8.1 reports the resulting choice probabilities. Aggregate shares average the two types:

$$s_1 = \frac{0.1180 + 0.3315}{2} = 0.2248, \qquad s_2 = \frac{0.0097 + 0.5465}{2} = 0.2781.$$

The buyers of the two goods differ sharply. Type H accounts for $\frac{0.5 \times 0.1180}{0.2248} = 26.3$ percent of the buyers of good 1 and only $\frac{0.5 \times 0.0097}{0.2781} = 1.7$ percent of the buyers of good 2.

For the own elasticity of good 2, (8.30) gives

$$\begin{aligned}
\varepsilon_2 &= \frac{p_2}{s_2}\left[\tfrac{1}{2}\alpha_H s_{H2}(1 - s_{H2}) + \tfrac{1}{2}\alpha_L s_{L2}(1 - s_{L2})\right] \\
&= \frac{2}{0.2781}\left[\tfrac{1}{2}(4)(0.0097)(0.9903) + \tfrac{1}{2}(1)(0.5465)(0.4535)\right] \\
&= \frac{2}{0.2781}(0.1431) = 1.029.
\end{aligned}$$

The same computation for good 1 gives $\varepsilon_1 = \frac{1}{0.2248}(0.3190) = 1.419$. The expensive good is less elastic than the cheap good although its price is twice as high. A logit with the same shares and

the mean price coefficient $\bar{\alpha} = 2.5$ gives the opposite ranking, $\varepsilon_1 = 2.5(1)(1 - 0.2248) = 1.938$ and $\varepsilon_2 = 2.5(2)(1 - 0.2781) = 3.609$.

The single-product markups $p_j - mc_j = \frac{p_j}{\varepsilon_j}$ follow. The two-type model gives 0.705 for good 1 and 1.943 for good 2. The logit gives almost equal markups, 0.516 and 0.554, as (8.24) predicts. Diversion to the outside good also differs. The two-type model gives $D_{10} = 0.709$ and $D_{20} = 0.351$. The logit gives $\frac{s_0}{1-s_1} = 0.641$ and $\frac{s_0}{1-s_2} = 0.689$. The marginal buyers of the cheap good are price-sensitive consumers who often choose the outside good, so random coefficients raise its outside diversion above the logit value. The marginal buyers of the expensive good rarely choose the outside good, so its outside diversion falls.

Table 8.1: The two-type example: choice probabilities and own elasticities

	s_1	s_2	s_0	ε_1	ε_2
Type H ($\alpha_H = 4$)	0.1180	0.0097	0.8723	3.528	7.922
Type L ($\alpha_L = 1$)	0.3315	0.5465	0.1220	0.669	0.907
Market, two types	0.2248	0.2781	0.4971	1.419	1.029
Market, logit with $\bar{\alpha} = 2.5$	0.2248	0.2781	0.4971	1.938	3.609

Notes: Goods have prices $p = (1, 2)$ and quality indices $q = (2, 3.5)$, and each type has population share one half. Type rows report the type's logit probabilities and its own elasticities $\alpha_r p_j (1 - s_{rj})$. The market rows use (8.30) for the two-type model and (8.23) for the logit. Computed by `figures/ch08/src/twotype_example.py`.

8.2.6 A numerical illustration

Figure 8.1 compares the two models in two small markets. Both models are calibrated to the same shares and the same mean price coefficient. The logit uses the analytic inversion (8.21), and the random coefficients model uses the contraction of Section 8.4. Integrals are computed with Gauss-Hermite product rules (Section 8.3.5), so the figure contains no simulation error.

Panel (a) follows the thought experiment of Nevo (2000a, p. 529). Products A and B have similar characteristics, and products B and C have the same share. A rise in the price of A raises the shares of B, C and the outside good by the same 0.40 percent in the logit. With random coefficients, B gains 0.83 percent, C gains 0.04 percent and the outside good gains 0.22 percent. Of the sales that A loses, the logit sends 12.5 percent to B, 12.5 percent to C and 75.0 percent to the outside good. The random coefficients model sends 37.4 percent to B, 2.0 percent to C and 60.7 percent to the outside good. Nevo uses the same experiment to explain identification. Observed relative changes in the shares of B and C discriminate between the two models and pin down the dispersion of tastes.

Panels (b) and (c) show the full elasticity matrices for six products, three small cheap cars and three large expensive cars, each with share 0.05. The logit matrix has constant columns, as (8.23) requires, and own elasticities that rise in proportion to price, from 1.90 to 4.56. The random coefficients matrix has a block structure. Cross elasticities lie between 0.27 and 0.33 among small cars and between 0.49 and 0.67 among large cars, but only between 0.02 and 0.07 across the two groups. Own elasticities rise less steeply, from 1.57 to 3.35. Diversion to the outside good is 73.7 percent for every product under the logit and between 57.3 and 62.1 percent under random coefficients.

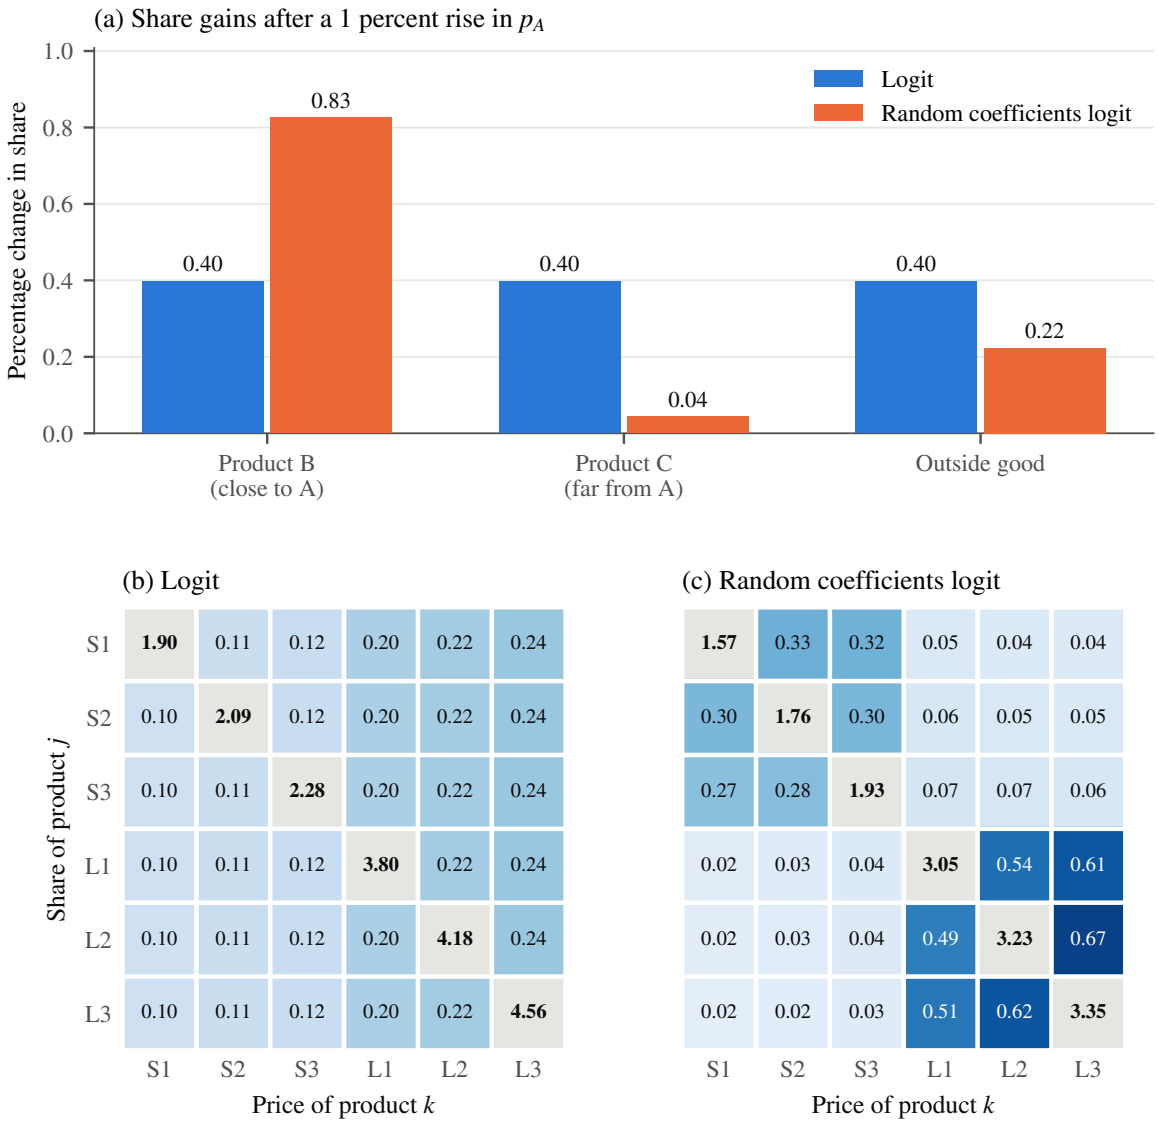

Figure 8.1: Substitution in the logit and random coefficients logit models. Panel (a): three products with characteristic $x = (1.0, 0.9, -1.0)$, prices $p = (1, 1, 1)$ and shares $s = (0.20, 0.10, 0.10)$, so A and B are close and B and C have equal shares. Bars show the percentage change in the shares of B, C and the outside good after a 1 percent rise in p_A. The random coefficients model has normal random coefficients on the constant (standard deviation 1.0) and on x (standard deviation 2.5), and $\alpha = 2$ in both models. Panels (b) and (c): six products with shares 0.05, sizes $(-1.0, -0.9, -0.8, 0.8, 0.9, 1.0)$ and prices $(1.0, 1.1, 1.2, 2.0, 2.2, 2.4)$. Cell (j, k) is the elasticity of the share of j with respect to the price of k. Grey diagonal cells report the positive own elasticity $\varepsilon_j = -\varepsilon_{jj}$. The random coefficients model has standard deviations 1.0 (constant), 2.0 (size) and 0.5 (price), with $\alpha_i = 2 - 0.5\nu_{ip}$. Both models fit the same shares. Computed by `figures/ch08/src/fig_substitution.py`.

8.2.7 Further contrasts

The vertical model of Chapter 6 also has heterogeneous consumers, but only along one dimension. Cross elasticities are then nonzero only between products adjacent in the price ranking. Berry et al. (1995, p. 852) give an example. Suppose the ranking contains a \$24,998 family station wagon, a \$24,999 sports car and a \$25,000 family station wagon, in that order. The vertical model guarantees that the two wagons are not substitutes for each other, while the sports car is a substitute for both. Random coefficients on several characteristics let products be differentiated in several dimensions at once.

Remark 8.10 (Fitting a logit when tastes are heterogeneous). Suppose the data come from the random coefficients model and we estimate the logit regression $\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \text{error}$ by instrumental variables. Write $r_{jt} = \ln s_{jt} - \ln s_{0t} - \delta_{jt}$ for the gap between the logit inversion and the true mean utility. The regression error is $\xi_{jt} + r_{jt}$. The gap depends on prices, because less price-sensitive consumers sort into expensive products. By (8.31), the log share of an expensive product falls with its price at a rate set by the low price sensitivity of its buyers, more slowly than α. An instrument that moves prices, such as a cost shifter, also moves r_{jt}. The instrument is then correlated with the regression error even if it is independent of ξ_{jt}. When less price-sensitive consumers sort into expensive products in this way, the logit price coefficient tends to be biased toward zero. The argument is heuristic, and Section 8.10 measures the correlation and the bias in a simulated market.

Remark 8.11 (Price changes and product deletions). Berry et al. (2004a, p. 94) distinguish two substitution patterns. After a price rise, only a selected group of a product's buyers leave, the more price-sensitive ones. After the product is deleted, all of its buyers must choose again. The model makes the difference explicit. If j is removed, a consumer who would have bought j chooses k with probability $\frac{s_{ik}}{1-s_{ij}}$ by Remark 8.8. The fraction of j's buyers who move to k is therefore

$$D_{jk}^{\text{del}} = \int \frac{s_{ij}}{s_j} \frac{s_{ik}}{1 - s_{ij}} \, \mathrm{d}F. \tag{8.37}$$

It averages the same individual diversion ratios as (8.33), with weights $\frac{s_{ij}}{s_j}$ instead of ω_{ij}. The two coincide in the logit, where both equal $\frac{s_k}{1-s_j}$. With heterogeneous tastes they differ, and the deletion pattern is the relevant one for questions such as the closing of a brand (Section 8.14).

8.3 Computing the share integral by simulation

The share integral (8.19) has the dimension of (D_i, v_i), the number of demographics plus the number of random coefficients. It has no closed form once that dimension exceeds zero, and Berry et al. (1995, p. 866) note that numerical integration becomes difficult once the dimension grows beyond two or three. They replace the integral by a simulation estimator, a technique that Pakes (1986) introduced as aggregation by simulation (Berry et al., 1995, p. 848). This section describes the standard simulator, its error, the importance sampler of Berry et al. (1995), the treatment of demographics, deterministic alternatives, and safe numerical evaluation.

8.3.1 The smooth simulator

Draw n_s consumers (D_i, ν_i), $i = 1, \dots, n_s$, from $F_{Dt} \times F_\nu$. The *smooth simulator* of the share of product j is the average of the individual logit probabilities (Berry et al., 1995, eq. (6.10)):

$$s_{jt}^{n_s}(\delta_t; \theta_2) = \frac{1}{n_s} \sum_{i=1}^{n_s} s_{ijt}. \tag{8.38}$$

With diagonal Σ, each term is written out as

$$s_{ijt} = \frac{\exp\big(\delta_{jt} + \sum_k \tilde{x}_{jtk}(\sigma_k \nu_{ik} + \pi_{k1} D_{i1} + \cdots + \pi_{kd} D_{id})\big)}{1 + \sum_{m \in \mathcal{J}_t} \exp\big(\delta_{mt} + \sum_k \tilde{x}_{mtk}(\sigma_k \nu_{ik} + \pi_{k1} D_{i1} + \cdots + \pi_{kd} D_{id})\big)},$$

which gives equation (11) of Nevo (2000a). The sums over k run over the characteristics that carry random coefficients.

The simulator has four properties (Berry et al., 1995, p. 865). It is unbiased for s_{jt}. Its values are positive. Together with the simulated outside share $\frac{1}{n_s}\sum_i s_{i0t}$ the shares sum to one. It is a smooth function of (δ_t, θ_2). Because the extreme value shocks are integrated analytically, its variance comes only from the draws of (D_i, ν_i). The next lemma makes the last point precise by comparing it with the *frequency simulator*, which also draws the shocks ϵ_{ijt} and counts the simulated consumers who choose j.

Lemma 8.12 (Smooth versus frequency simulator)**.** *Let $s_j^{freq} = \frac{1}{n_s}\sum_{i=1}^{n_s} \mathbf{1}\{j = \arg\max_k u_{ik}\}$, where each simulated consumer has draws $(D_i, \nu_i, \epsilon_{i0}, \dots, \epsilon_{iJ})$. Both simulators are unbiased for s_j, and*

$$\operatorname{Var}\big(s_j^{freq}\big) = \frac{s_j(1-s_j)}{n_s} = \operatorname{Var}\big(s_j^{n_s}\big) + \frac{1}{n_s}\mathbb{E}\big[s_{ij}(1-s_{ij})\big], \qquad \operatorname{Var}\big(s_j^{n_s}\big) = \frac{\operatorname{Var}(s_{ij})}{n_s}. \tag{8.39}$$

Proof. Let I_{ij} be the indicator that simulated consumer i chooses j. Conditional on (D_i, ν_i), it is a Bernoulli variable with mean s_{ij}. By the law of iterated expectations, $\mathbb{E}[I_{ij}] = \mathbb{E}[s_{ij}] = s_j$, so both simulators are unbiased. Unconditionally I_{ij} is Bernoulli with mean s_j, so $\operatorname{Var}(I_{ij}) = s_j(1-s_j)$. The law of total variance gives

$$\operatorname{Var}(I_{ij}) = \mathbb{E}\big[\operatorname{Var}(I_{ij} \mid D_i, \nu_i)\big] + \operatorname{Var}\big(\mathbb{E}[I_{ij} \mid D_i, \nu_i]\big) = \mathbb{E}\big[s_{ij}(1-s_{ij})\big] + \operatorname{Var}(s_{ij}).$$

The draws are independent across simulated consumers, so dividing by n_s gives the variances of the two averages. □

The smooth simulator is the conditional expectation of the frequency simulator given the draws of (D_i, ν_i). Conditioning removes the variance $\frac{1}{n_s}\mathbb{E}[s_{ij}(1-s_{ij})]$. The frequency simulator has two further defects. It is a step function of (δ, θ_2), with zero derivatives almost everywhere and jumps in between, so gradient-based optimizers cannot use it. It also equals zero with positive probability for small products, and then $\ln s_j^{\text{freq}}$ is undefined and the share equations cannot be inverted.

8.3.2 Simulation error in log shares*

The estimator of Section 8.5 uses the simulated shares through their logarithms, in the inversion step. An unbiased simulator of s_j is a biased simulator of $\ln s_j$. Let $c_j = \frac{\sqrt{\operatorname{Var}(s_{ij})}}{s_j}$ be the coefficient of variation of the individual purchase probabilities of product j.

Proposition 8.13 (Bias of the simulated log share)**.** *Let $s_j^{n_s}$ be the smooth simulator with independent draws, and suppose* $\operatorname{Var}(s_{ij}) > 0$.

(i) $\mathbb{E}[s_j^{n_s}] = s_j$ *and* $\operatorname{Var}(s_j^{n_s}) = \frac{\operatorname{Var}(s_{ij})}{n_s}$.

(ii) $\mathbb{E}[\ln s_j^{n_s}] < \ln s_j$.

(iii) If $s_{ij} \geq \underline{s} > 0$ *for all* (D_i, ν_i)*, then*

$$\mathbb{E}\big[\ln s_j^{n_s}\big] - \ln s_j = -\frac{\operatorname{Var}(s_j^{n_s})}{2s_j^2} + O\big(n_s^{-\frac{3}{2}}\big) = -\frac{c_j^2}{2n_s} + O\big(n_s^{-\frac{3}{2}}\big). \tag{8.40}$$

Proof. Part (i) restates Lemma 8.12. For (ii), the logarithm is strictly concave and $s_j^{n_s}$ is not degenerate because $\operatorname{Var}(s_{ij}) > 0$. Jensen's inequality gives $\mathbb{E}[\ln s_j^{n_s}] < \ln \mathbb{E}[s_j^{n_s}] = \ln s_j$.

For (iii), write $Y = s_j^{n_s}$ and expand $\ln Y$ around s_j with the Lagrange form of the remainder:

$$\ln Y = \ln s_j + \frac{Y - s_j}{s_j} - \frac{(Y - s_j)^2}{2s_j^2} + \frac{(Y - s_j)^3}{3\bar{Y}^3},$$

where $\bar{Y}$ lies between Y and s_j. Take expectations. The linear term has mean zero by (i). The quadratic term has mean $-\frac{\operatorname{Var}(Y)}{2s_j^2}$. Both Y and s_j are at least $\underline{s}$, so $\bar{Y} \geq \underline{s}$ and the remainder is bounded in absolute value by $\frac{\mathbb{E}|Y - s_j|^3}{3\underline{s}^3}$. For an average of n_s independent bounded variables, $\mathbb{E}|Y - s_j|^3 \leq (\mathbb{E}(Y - s_j)^4)^{\frac{3}{4}}$, and the fourth central moment of such an average is $O(n_s^{-2})$. The remainder is therefore $O(n_s^{-\frac{3}{2}})$. Substituting $\operatorname{Var}(Y) = \frac{\operatorname{Var}(s_{ij})}{n_s}$ gives the second form. □

The lower bound in (iii) holds when the support of (D_i, ν_i) is bounded. With normal tastes it fails, but the second-order term still describes the bias well in practice, as the evidence below shows. The bias is of order $\frac{1}{n_s}$ and its size is governed by c_j. The coefficient of variation is large when the purchase probability of j is concentrated on a small group of consumers. Small niche products have the largest c_j and the largest bias.

The bias passes to the mean utilities. For given θ_2, the inversion of Section 8.4 finds the $\hat{\delta}_t$ that solves $s_t^{n_s}(\hat{\delta}_t; \theta_2) = s_t^{\text{obs}}$. A first-order expansion around the true δ_t, using the nonsingular Jacobian of Proposition 8.2, gives

$$\hat{\delta}_t - \delta_t \approx -\Big[\frac{\partial s_t}{\partial \delta_t^\top}\Big]^{-1} \big(s_t^{n_s}(\delta_t; \theta_2) - s_t(\delta_t; \theta_2)\big). \tag{8.41}$$

The leading term has mean zero and variance of order $\frac{1}{n_s}$. This is the simulation component of the asymptotic variance of the estimator in Section 8.5, which Berry et al. (1995, p. 859) call V_3. The second-order terms, like those in (8.40), add a bias of order $\frac{1}{n_s}$. At the true δ_t the simulated log shares are too low on average, so the inversion tends to push $\hat{\delta}_t$ up, most for products with dispersed purchase probabilities.

The bias has a consequence for estimation that the variance does not have. Independent draws across markets make the leading simulation errors independent across markets. They average out of the sample moments as the number of markets grows. The bias of order $\frac{1}{n_s}$ is present in every market with the same sign, and it does not average out. Consistency therefore

requires n_s to grow with the sample. Berry et al. (1995, p. 859) cite asymptotic results of Berry and Pakes, then in progress, for their utility specification. These results require the number of consumers and the number of simulation draws to grow at the rate J^3. Berry et al. (2004b) develop limit theorems of this kind for asymptotics in the number of products. Berry and Pakes (2007, Section 4.4) report the rates that these theorems require. The number of draws must grow at the slower rate J^2 in logit-style models and at rate J in the vertical model (Section 8.9.4). BLP's rate refers to their own utility specification and to results that were still in progress.

Figure 8.2 and Table 8.2 quantify these effects in one simulated market with five inside products, shares $(0.10, 0.05, 0.03, 0.015, 0.005)$ and an outside share of 0.80. The market has normal random coefficients on a constant, a characteristic and price. The coefficients of variation c_j are 1.49, 0.97, 0.94, 1.51 and 2.99. The product with share 0.10 is expensive and bought mostly by consumers who like its characteristics, so its c_j exceeds those of the two middle products.

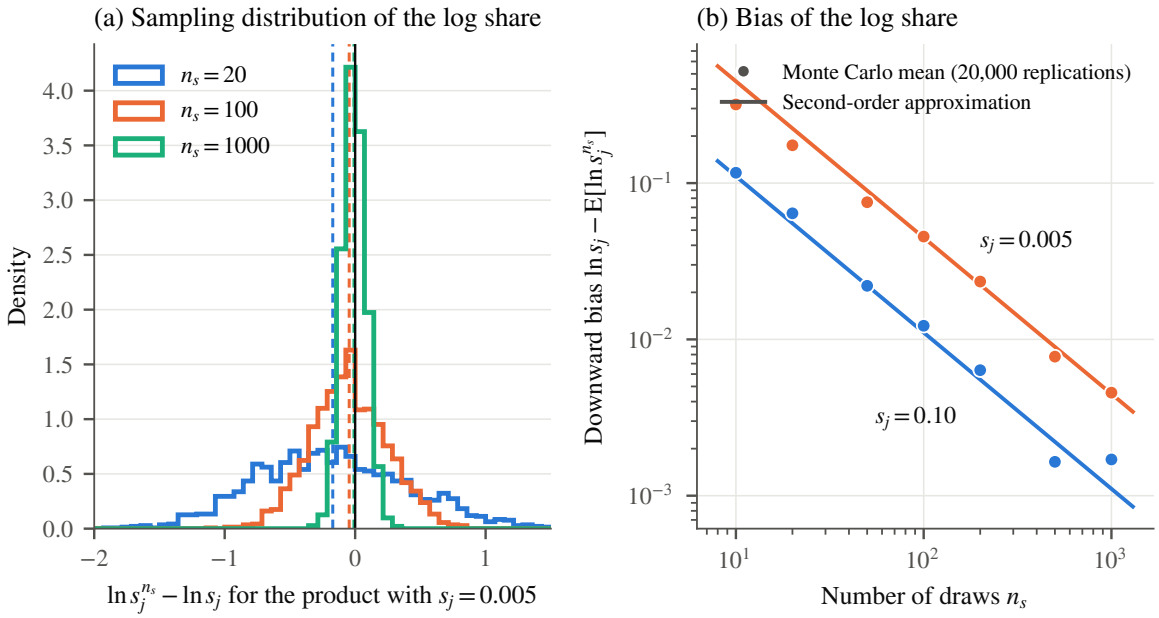

Figure 8.2: Simulation error in simulated log shares, for one market with outside share 0.80 and inside shares $(0.10, 0.05, 0.03, 0.015, 0.005)$. Tastes are normal with standard deviations 1.0 on the constant, 1.5 on a characteristic $x = (1.0, 0.5, 0.0, -0.5, -1.0)$ and 0.5 on price, prices are $(2.0, 1.6, 1.2, 1.0, 0.8)$ and $\alpha = 2$. True shares come from a 64,000-node Gauss-Hermite rule and agree with 10^6 pseudo-random draws to within 0.002 in relative terms. Panel (a): distribution of $\ln s_j^{n_s} - \ln s_j$ for the product with share 0.005 over 2,000 replications with fresh pseudo-random draws. Dashed lines mark the means. Panel (b): downward bias of the simulated log share (dots, 20,000 replications per n_s) and the second-order approximation $\frac{\mathrm{Var}(s_{ij})}{2n_s s_j^2}$ of Proposition 8.13 (lines). Computed by `figures/ch08/src/fig_simulation.py`.

Panel (a) of Figure 8.2 shows the sampling distribution of the simulated log share of the smallest product. With 20 draws it is wide and skewed to the left, and its mean lies well below zero. With 1,000 draws it is concentrated near zero. Panel (b) shows that the downward bias falls like $\frac{1}{n_s}$. The second-order approximation is accurate from about 50 draws for the product with share 0.10 and from about 100 draws for the product with share 0.005. For the product with share 0.005, the bias is 0.175 with 20 draws (approximation 0.224), 0.046 with 100 draws (approximation 0.045), and 0.005 with 1,000 draws (approximation 0.004). With 10 or 20 draws

the approximation overstates the bias of the smallest product, because higher-order terms matter when the simulator is very noisy.

Table 8.2: Error in the inverted mean utility caused by simulation

	Market share of the product				
Draws n_s	0.10	0.05	0.03	0.015	0.005
20	0.037	0.010	0.021	0.063	0.198
	(0.547)	(0.362)	(0.273)	(0.368)	(0.627)
100	−0.008	−0.009	−0.008	−0.006	0.015
	(0.250)	(0.163)	(0.126)	(0.177)	(0.328)
1,000	0.003	0.001	−0.000	−0.002	−0.006
	(0.077)	(0.051)	(0.040)	(0.056)	(0.104)

Notes: Each entry is the mean of $\hat{\delta}_j - \delta_j$ over 500 replications, with its standard deviation in parentheses. In each replication we draw n_s consumers and solve $s^{n_s}(\hat{\delta}; \theta_2) = s$ by the contraction of Section 8.4, at the true θ_2 and the true shares. The market is the one of Figure 8.2. The standard error of each mean is its standard deviation divided by $\sqrt{500} \approx 22.4$. Computed by `figures/ch08/src/fig_simulation.py`.

Table 8.2 turns to the mean utilities. With 20 draws, the inverted $\hat{\delta}_j$ of the product with share 0.005 is too high by 0.198 on average, with a standard error of $\frac{0.627}{22.4} = 0.028$. The product with share 0.015 is too high by 0.063 (standard error 0.016). These are the upward biases predicted above. Their size is small relative to the standard deviations, which range from 0.27 to 0.63. The standard deviations fall roughly like $\frac{1}{\sqrt{n_s}}$, from about 0.4 on average with 20 draws to about 0.07 with 1,000 draws. With 100 or more draws the mean errors are within two standard errors of zero.

8.3.3 Draws in practice

Three rules govern the use of simulation draws in estimation.

The draws are taken once, before estimation, and held fixed while the optimizer varies the parameters. If new draws were taken at each evaluation, the objective would be a different random function each time it is evaluated. The search would chase the simulation noise and fail to converge. The asymptotic theory of simulation estimators also requires draws that do not change with θ (Berry et al., 1995, p. 867), (Pakes and Pollard, 1989).

Draws are usually independent across markets. Then simulation errors are independent across markets and their leading terms average out of the moments, so a moderate number of draws per market can suffice when markets are many. The bias term of Proposition 8.13 is the exception, as explained above. Berry et al. (1995) instead hold the same draws of $(\nu_{iy}, \nu_{i0}, \ldots, \nu_{iK})$ fixed over all years of their panel, while the income distribution shifts through m_t (Berry et al., 1995, p. 868).

The number of draws trades accuracy against computing time. Nevo (2000a, pp. 538, 540) draws 20 consumers per market in his illustrative application and notes that more draws or better simulation methods would improve efficiency. The evidence above shows that 20 pseudo-random draws leave sizable errors in the shares of small products.

Demographics need their own draws. Berry et al. (1995, p. 868, n. 21) tried taking draws of income from the CPS for each year. They found that this less restrictive procedure gave

imprecise simulators, in particular for changes in the upper tail of the income distribution. They therefore kept a lognormal income distribution with year-specific means. They did not estimate a separate standard deviation for each year because those estimates were imprecise. Nevo (2001, n. 25) samples 40 individuals from the CPS for each city and year, 200 for each city in total. He reports that the results were robust to increasing the number of individuals where possible. Empirical draws of D_i are combined with independent draws of ν_i from F_ν.

8.3.4 Importance sampling*

Pseudo-random draws from F_ν waste effort when few consumers buy any inside product. In the car market most households do not buy a new car in a given year. Most draws then have purchase probabilities near zero and contribute little to any share. Berry et al. (1995, Section 6.3) reduce the variance of the simulator by importance sampling. To keep notation light, let ν collect all simulated consumer characteristics, with density $p_0(\nu)$, and write $f_j(\nu, \theta)$ for the individual choice probability (8.18).

Take any density $h(\nu, \theta)$ that is positive wherever p_0 is. The share can be rewritten as (Berry et al., 1995, eq. (6.11))

$$s_j(\theta) = \int f_j(\nu, \theta)\, p_0(\nu)\, \mathrm{d}\nu = \int \left[\frac{f_j(\nu, \theta)\, p_0(\nu)}{h(\nu, \theta)}\right] h(\nu, \theta)\, \mathrm{d}\nu. \tag{8.42}$$

Averaging the bracketed term over draws from h gives an unbiased simulator. Its variance is the variance of the bracketed term under h, divided by the number of draws. The variance is zero for the choice (Berry et al., 1995, eq. (6.12))

$$h_j^*(\nu, \theta) = \frac{f_j(\nu, \theta)\, p_0(\nu)}{s_j(\theta)}, \tag{8.43}$$

because the bracketed term then equals $s_j(\theta)$ for every draw. This density over-samples consumers whose characteristics make them likely to buy product j.

The optimal density cannot be used directly, for three reasons (Berry et al., 1995, pp. 866–867). It requires $s_j(\theta)$, the integral we want to compute. It depends on θ, while the draws must stay fixed as the optimizer varies θ. It differs across products, so each simulated share would come from its own draws. The inversion of Section 8.4 instead computes all shares from one distribution of consumers.

Berry et al. build a feasible version from a preliminary estimate θ', obtained with the smooth simulator. They target the probability of buying some car, $\bar{f}(\nu, \theta') = \sum_{j=1}^{J} f_j(\nu, \theta')$, whose integral is the total inside share $\bar{s}(\theta') = 1 - s_0(\theta')$. Draws come from p_0 by acceptance and rejection: a draw ν is accepted with probability $\bar{f}(\nu, \theta')$. By Bayes' rule the density of an accepted draw is

$$h(\nu) = \frac{p_0(\nu)\, \mathbb{P}(\text{accept} \mid \nu)}{\mathbb{P}(\text{accept})} = \frac{p_0(\nu)\, \bar{f}(\nu, \theta')}{\int p_0(\nu')\, \bar{f}(\nu', \theta')\, \mathrm{d}\nu'} = \frac{p_0(\nu)\, \bar{f}(\nu, \theta')}{\bar{s}(\theta')}. \tag{8.44}$$

Substituting this h into (8.42) gives the bracketed term $\frac{\bar{s}(\theta')}{\bar{f}(\nu, \theta')} f_j(\nu, \theta)$. With n_s accepted draws

$\nu_1, \ldots, \nu_{n_s}$, the simulator is (Berry et al., 1995, eq. (6.13))[3]

$$s_j\left[\theta, P_h^*(\theta')_{n_s}\right] = \frac{1}{n_s}\sum_{i=1}^{n_s} \frac{\bar{s}(\theta')}{\bar{f}(\nu_i, \theta')} f_j(\nu_i, \theta). \tag{8.45}$$

The draws are fixed once θ' is chosen, and every share uses the same draws. Since $\bar{s}(\theta')$ is computed only once, it can be computed with many draws at little cost.

The construction removes one source of noise. At $\theta = \theta'$ the weighted integrand is $\bar{s}(\theta')$ times $\frac{f_j(\nu,\theta')}{\bar{f}(\nu,\theta')}$, the probability of choosing j given that the consumer buys some car. That ratio lies between zero and one. Summed over j it equals $\bar{s}(\theta')$ for every draw, so the simulated total inside share has no simulation error at all. The variation that remains comes only from which car a buyer chooses.

Common draws do not make the simulated shares add up to one, although Berry et al. (1995, p. 867) use them for that purpose. Write $w_i = \frac{\bar{s}(\theta')}{\bar{f}(\nu_i,\theta')}$ for the weight of draw i and $\bar{w} = \frac{1}{n_s}\sum_i w_i$ for the mean weight. Applying (8.45) to all $J+1$ options and using $\sum_{j=0}^{J} f_j = 1$ gives $\sum_{j=0}^{J} s_j = \bar{w}$. Each weight has expectation one under h, so $\bar{w}$ equals one only on average. The contraction uses only the inside shares, and this random total does not break it. The simulated inside shares equal $\bar{w}$ times the shares computed under the probability weights $\frac{w_i}{n_s \bar{w}}$. Theorem 8.14, applied to this distribution of draws, gives a unique solution whenever the observed inside shares sum to less than $\bar{w}$. With a small inside share and many draws, $\bar{w}$ is close to one and the condition is mild. Self-normalizing the weights would make the shares sum to one exactly, at the cost of a finite-sample bias that vanishes as n_s grows.

Table 8.3 compares the two simulators in the market of Figure 8.2, whose total inside share is 0.20. With 100 draws, importance sampling cuts the relative root mean squared error of the largest product's share from 15.3 to 4.8 percent. For the second product it falls from 10.0 to 2.8 percent. The gains are small for the two smallest products, from 15.0 to 13.5 percent and from 29.4 to 25.5 percent. Their buyers are a small subset of car buyers, so conditioning on buying some car leaves most of their simulation noise in place. A preliminary estimate that understates every standard deviation by 20 percent loses little of the gain.

Table 8.3: Smooth simulator and importance sampling: relative root mean squared error (percent)

	Market share of the product				
Simulator	0.10	0.05	0.03	0.015	0.005
Smooth simulator	15.31	9.95	9.52	14.98	29.35
Importance sampling, $\theta' = \theta$	4.83	2.84	6.79	13.51	25.46
Importance sampling, $\sigma' = 0.8\sigma$	5.55	2.90	6.35	13.28	26.31

Notes: Each entry is $100\sqrt{\mathbb{E}\left[(\frac{\hat{s}_j}{s_j} - 1)^2\right]}$ over 1,000 replications with $n_s = 100$ draws (accepted draws for importance sampling). The importance sampler is (8.45). In the last row the preliminary estimate θ' multiplies every standard deviation by 0.8 and uses the mean utilities that fit the shares at those values. The acceptance rate equals the total inside share, 0.20. Mean errors of the importance sampler are below 0.6 percent in absolute value. Computed by `figures/ch08/src/fig_simulation.py`.

[3] Equation (6.13) of Berry et al. (1995) is printed without the factor $\frac{1}{n_s}$. The average is needed for the simulator to be unbiased.

8.3.5 Quadrature and quasi-Monte Carlo*

Pseudo-random draws are not the only way to approximate (8.19). Any rule of the form $\sum_q w_q s_{ij}(\nu_q)$ with nodes ν_q and weights w_q can replace the simple average, and the share equations and their inversion are unchanged.

A *Gauss-Hermite product rule* uses, in each dimension, the Q nodes and weights that integrate polynomials of degree up to $2Q-1$ exactly against the normal density. For a standard normal variable,

$$\int g(\nu)\,\phi(\nu)\,\mathrm{d}\nu \approx \sum_{q=1}^{Q} \frac{w_q}{\sqrt{\pi}}\, g\left(\sqrt{2}\,x_q\right), \tag{8.46}$$

where (x_q, w_q) are the Gauss-Hermite nodes and weights for the weight function e^{-x^2}. The product rule takes all combinations of the one-dimensional nodes, so it needs Q^L nodes for L random coefficients. It is very accurate for smooth integrands in low dimensions and becomes expensive quickly as L grows. *Sparse grids* combine lower-order product rules so that the number of nodes grows polynomially in L (Heiss and Winschel, 2008). *Quasi-Monte Carlo* methods, such as Halton sequences, replace pseudo-random draws by deterministic sequences that fill the unit cube more evenly. The points are mapped to normal draws by the inverse distribution function (Train, 2009, Section 9.3.3). A randomly scrambled Halton sequence keeps the even coverage and allows replications. The `pyblp` software of Conlon and Gortmaker (2020, Section 3) implements all of these rules. By default it scrambles each Halton sequence and discards its first 1,000 points.

Table 8.4 compares the three approaches in the market of Figure 8.2, which has three random coefficients. At equal numbers of nodes, scrambled Halton draws reduce the error of pseudo-random draws by a factor of about 2 to 20, and the gain grows with the number of nodes. The Gauss-Hermite product rule is accurate to a few hundredths of a percent with 125 nodes and to about 10^{-5} percent with 1,000 nodes. The product rule's advantage shrinks with more random coefficients. It also shrinks when demographic distributions are known only through empirical draws, which quadrature cannot use directly.

Table 8.4: Accuracy of integration rules: relative error of simulated shares (percent)

	Number of nodes		
Rule	125	1,000	8,000
Product with $s_j = 0.10$			
Pseudo-random draws	12.45	4.84	1.56
Scrambled Halton draws	3.41	0.53	0.076
Gauss-Hermite product rule	2.9×10^{-2}	1.9×10^{-5}	3.0×10^{-10}
Product with $s_j = 0.005$			
Pseudo-random draws	27.63	10.29	3.30
Scrambled Halton draws	13.38	2.45	0.46
Gauss-Hermite product rule	4.5×10^{-2}	2.5×10^{-5}	6.2×10^{-10}

Notes: Market of Figure 8.2, with three normal random coefficients. Entries for random rules are relative root mean squared errors over 200 replications. Entries for the Gauss-Hermite rule, which uses 5, 10 and 20 nodes per dimension, are absolute relative errors against a rule with 40 nodes per dimension. Computed by `figures/ch08/src/fig_simulation.py`.

8.3.6 Safe numerical evaluation*

Evaluating (8.18) naively can overflow. Mean utilities and random coefficient terms can be large during the search, and e^V exceeds the largest double-precision number once V exceeds about 709. The logit formula is invariant to subtracting the same constant from every utility of a consumer, including the zero utility of the outside good. Let $m_i = \max\{0, \max_k V_{ik}\}$. Then

$$s_{ij} = \frac{e^{V_{ij} - m_i}}{e^{-m_i} + \sum_k e^{V_{ik} - m_i}}, \qquad \ln s_{ij} = V_{ij} - m_i - \ln\Big(e^{-m_i} + \sum_k e^{V_{ik} - m_i}\Big). \tag{8.47}$$

Every exponent is now at most zero, and at least one term in the denominator equals one, so neither overflow nor division by zero can occur. The second expression, the log-sum-exp form, also gives accurate log shares for very small probabilities. All computations in this chapter use (8.47).

8.4 Inverting the share equations: the BLP contraction

The model of Section 8.1 maps mean utilities into market shares. Estimation needs the reverse map. The reason is that the unobserved quality ξ_{jt} enters the model only through the mean utility $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, and it enters linearly. Suppose we can recover the vector δ_t from the observed shares. Then ξ_{jt} becomes a known function of the data and the parameters, and instrumental variable methods apply as in a linear demand model. Berry et al. (1995, pp. 850–851) make the point directly. The orthogonality between ξ and the instruments cannot be used "without first transforming the observed quantity, price, and characteristic data into a linear function of ξ." This section shows that the transformation exists, that it is unique, and that a simple iteration computes it.

8.4.1 The inversion problem

Fix the nonlinear parameters $\theta_2 = (\Pi, \Sigma)$ and a market t with J_t inside products. Recall from Section 8.1 that the model share of product j is

$$s_{jt}(\delta_t; \theta_2) = \int \frac{\exp(\delta_{jt} + \mu_{ijt})}{1 + \sum_{k \in \mathcal{J}_t} \exp(\delta_{kt} + \mu_{ikt})} \, \mathrm{d}F(D_i, \nu_i), \qquad \mu_{ijt} = \tilde{x}_{jt}(\Pi D_i + \Sigma \nu_i), \tag{8.48}$$

where $\tilde{x}_{jt} = (x_{jt}, p_{jt})$ collects the characteristics that carry random coefficients. We write s_{ijt} for the integrand, the choice probability of a consumer with attributes (D_i, ν_i), and $s_{i0t} = 1 - \sum_k s_{ikt}$ for that consumer's probability of choosing the outside good. The *inversion problem* is to find, for each market, the vector $\delta_t \in \mathbb{R}^{J_t}$ that solves

$$s_{jt}(\delta_t; \theta_2) = s_{jt}^{\text{obs}}, \qquad j = 1, \ldots, J_t, \tag{8.49}$$

where s_{jt}^{obs} is the observed share (Nevo, 2000a, eq. 10). The system has J_t equations in J_t unknowns. Markets separate, because δ_t affects only the shares of market t. We denote the solution by $\delta_t(s_t^{\text{obs}}; \theta_2)$, or $\delta_t(\theta_2)$ when the data are understood.

In three familiar models the inverse has a closed form. In the logit model $\Pi = \Sigma = 0$, so $s_{jt} = \frac{e^{\delta_{jt}}}{1 + \sum_k e^{\delta_{kt}}}$ and $s_{0t} = \frac{1}{1 + \sum_k e^{\delta_{kt}}}$. Dividing,

$$\frac{s_{jt}}{s_{0t}} = e^{\delta_{jt}},$$

and taking logarithms gives

$$\delta_{jt} = \ln s_{jt}^{\text{obs}} - \ln s_{0t}^{\text{obs}}, \tag{8.50}$$

which is equation (6.4) of Berry et al. (1995). In the nested logit model with nesting parameter σ the same algebra applied within and across nests gives $\delta_{jt} = \ln s_{jt} - \ln s_{0t} - \sigma \ln s_{j|g,t}$, where $s_{j|g,t}$ is the share of j within its nest g (Berry, 1994). Chapter 7 derives this formula. The principles of differentiation generalized extreme value (PD-GEV) model of Bresnahan et al. (1997) also has an analytic inverse (Nevo, 2000a, p. 532). In each case the ratios of shares isolate δ_{jt} because the shares have a closed form. Random coefficients destroy the closed form, since (8.48) is an integral. The inverse must then be computed numerically, and this must be done again for every trial value of θ_2.

Two features of (8.49) matter for what follows. First, the observed shares appear on the right-hand side. The inversion therefore fits the observed shares exactly, and all discrepancies between model and data are attributed to ξ_{jt}. Second, the logit inversion (8.50) is the exact solution when $\theta_2 = 0$. It is the natural starting value for the numerical methods below.

8.4.2 Existence and uniqueness

The first question is whether (8.49) has a solution and whether the solution is unique. Berry (1994, p. 249 and Appendix) answered both questions for a general family of discrete choice models. Berry et al. (1995, Appendix I) gave a second proof that also delivers an algorithm. We state the result for the random coefficients logit model and prove it through the BLP route.

Theorem 8.14 (Invertibility of the share system)**.** *Fix θ_2 and a market t. Suppose the distribution F of (D_i, ν_i) satisfies $\int e^{\mu_{ijt}}\, \mathrm{d}F < \infty$ for every j. Then for every vector $s = (s_1, \ldots, s_{J_t})$ with $s_j > 0$ for all j and $\sum_j s_j < 1$, there is exactly one $\delta \in \mathbb{R}^{J_t}$ such that $s_t(\delta; \theta_2) = s$. Moreover, a truncated version of the iteration $\delta \mapsto \delta + \ln s - \ln s_t(\delta; \theta_2)$ converges to this δ from any starting value.*

The integrability condition holds in the usual specifications. With normal taste shocks and demographics of bounded support, $\int e^{\mu_{ijt}}\, \mathrm{d}F$ is a moment generating function evaluated at a finite point. The proof rests on an abstract fixed point theorem, which we state and prove first.

Theorem 8.15 (Berry et al., 1995, Appendix I)**.** *Consider $\mathbb{R}^J$ with the sup norm $\|y\| = \max_j |y_j|$. Let $f : \mathbb{R}^J \to \mathbb{R}^J$ satisfy the following conditions.*

(1) f is continuously differentiable. For all j and k and all y, $\frac{\partial f_j(y)}{\partial y_k} \geq 0$ and $\sum_{k=1}^{J} \frac{\partial f_j(y)}{\partial y_k} < 1$.

(2) f is bounded below: $\min_j \inf_y f_j(y) \equiv \underline{y} > -\infty$.

(3) There is a value $\bar{y}$ with the following property. If $y_j \geq \bar{y}$ for some j, then $f_k(y) < y_k$ for some k (not necessarily equal to j).

Then f has a unique fixed point y^* in $\mathbb{R}^J$. Moreover, let $Y = [\underline{y}, \bar{y}]^J$ and define the truncated map $\hat{f} : \mathbb{R}^J \to Y$ by $\hat{f}_j(y) = \min\{f_j(y), \bar{y}\}$. Then $\hat{f}$ is a contraction on Y with modulus strictly less than one, and the iterates $\hat{f}^{\,h}(y)$ converge to y^* from any $y \in \mathbb{R}^J$.

Proof. If condition (3) holds for $\bar{y}$, it holds for every larger value. We may therefore assume $\bar{y} > \underline{y}$. The proof has four steps.

Step 1. We show that $\hat{f}$ maps $\mathbb{R}^J$ into Y. For any y, $\hat{f}_j(y) \leq \bar{y}$ by construction. Also $f_j(y) \geq \underline{y}$ by condition (2), so $\hat{f}_j(y) \geq \min\{\underline{y}, \bar{y}\} = \underline{y}$.

Step 2. We show that $\hat{f}$ is a contraction on Y. Take $y, y' \in Y$ and let $\lambda = \|y - y'\|$. Write $\mathbf{1}$ for the vector of ones, so that $y + \lambda\mathbf{1} \geq y'$ element by element. Fix a component j and assume without loss of generality that $\hat{f}_j(y') \geq \hat{f}_j(y)$. If $f_j(y) \geq \bar{y}$, then $\hat{f}_j(y) = \bar{y} \geq \hat{f}_j(y')$, so $\hat{f}_j(y') - \hat{f}_j(y) = 0$. Otherwise $\hat{f}_j(y) = f_j(y)$. Condition (1) makes f_j nondecreasing in every argument, and taking the minimum with a constant preserves this. Hence

$$\begin{aligned} 0 \leq \hat{f}_j(y') - \hat{f}_j(y) &\leq \hat{f}_j(y + \lambda\mathbf{1}) - \hat{f}_j(y) \\ &\leq f_j(y + \lambda\mathbf{1}) - f_j(y) \\ &= \int_0^{\lambda} \sum_{k=1}^{J} \frac{\partial f_j(y + z\mathbf{1})}{\partial y_k} \, \mathrm{d}z. \end{aligned}$$

The first inequality uses monotonicity and $y' \leq y + \lambda\mathbf{1}$. The second uses $\hat{f}_j \leq f_j$ and $\hat{f}_j(y) = f_j(y)$. The equality is the fundamental theorem of calculus applied to $z \mapsto f_j(y + z\mathbf{1})$, with the chain rule. Now define the compact set

$$\mathcal{W} = \{y + z\mathbf{1} : y \in Y, \; z \in [0, \bar{y} - \underline{y}]\}$$

and the number

$$\kappa = \max_j \max_{w \in \mathcal{W}} \sum_{k=1}^{J} \frac{\partial f_j(w)}{\partial y_k}.$$

The maximum exists because the row sum is continuous and $\mathcal{W}$ is compact. Each row sum is below one at every point, so $\kappa < 1$. Since $y, y' \in Y$, we have $\lambda \leq \bar{y} - \underline{y}$, so every point $y + z\mathbf{1}$ with $z \in [0, \lambda]$ lies in $\mathcal{W}$. The integrand is therefore at most κ, and

$$|\hat{f}_j(y') - \hat{f}_j(y)| \leq \kappa\lambda = \kappa\|y' - y\|.$$

This holds for every j, so $\|\hat{f}(y') - \hat{f}(y)\| \leq \kappa\|y' - y\|$.

Step 3. We show that the fixed point of $\hat{f}$ is a fixed point of f. The set Y is closed, hence complete. By the contraction mapping theorem (Appendix B), $\hat{f}$ has a unique fixed point y^* in Y. By Step 1 the iterates from any starting value enter Y after one step, and they then converge to y^*. Suppose some component satisfies $y_j^* = \bar{y}$. Condition (3) gives an index k with $f_k(y^*) < y_k^*$. Then $\hat{f}_k(y^*) \leq f_k(y^*) < y_k^*$, which contradicts $\hat{f}(y^*) = y^*$. Hence $y_j^* < \bar{y}$ for all j. For each j, $\hat{f}_j(y^*) = y_j^* < \bar{y}$ forces $\hat{f}_j(y^*) = f_j(y^*)$. So $f(y^*) = y^*$.

Step 4. We show that f has no other fixed point. Let $f(y) = y$ for some $y \in \mathbb{R}^J$. Condition (2) gives $y_j = f_j(y) \geq \underline{y}$ for all j. If $y_j \geq \bar{y}$ for some j, condition (3) gives k with $f_k(y) < y_k$, a contradiction. So $y \in Y$ and $y_j < \bar{y}$ for all j, which gives $\hat{f}(y) = f(y) = y$. Uniqueness of the fixed point of $\hat{f}$ on Y then yields $y = y^*$. □

Berry et al. (1995, p. 887) note that the proof imposes the upper bound $\bar{y}$, "although in practice we never had to impose this bound." The truncation is a device of the proof. We now apply the theorem to the map

$$\Phi_t(\delta_t) = \delta_t + \ln s_t^{\text{obs}} - \ln s_t(\delta_t; \theta_2), \tag{8.51}$$

defined element by element. A vector δ_t is a fixed point of Φ_t exactly when it solves (8.49). The next result supplies condition (1).

Corollary 8.16 (Derivatives of the BLP map)**.** *In the random coefficients logit model, for all j and all $k \neq j$,*

$$\frac{\partial \Phi_{jt}}{\partial \delta_{jt}} = \frac{1}{s_{jt}} \int s_{ijt}^2 \, \mathrm{d}F > 0, \qquad \frac{\partial \Phi_{jt}}{\partial \delta_{kt}} = \frac{1}{s_{jt}} \int s_{ijt} s_{ikt} \, \mathrm{d}F > 0,$$

and the row sums satisfy

$$\sum_{k \in \mathcal{J}_t} \frac{\partial \Phi_{jt}}{\partial \delta_{kt}} = 1 - \frac{1}{s_{jt}} \int s_{ijt} s_{i0t} \, \mathrm{d}F = 1 - \int s_{i0t} \, \frac{s_{ijt}}{s_{jt}} \, \mathrm{d}F \in (0, 1). \tag{8.52}$$

Proof. Drop the market index. Write $V_{ij} = \delta_j + \mu_{ij}$, so that $s_{ij} = \frac{e^{V_{ij}}}{1 + \sum_m e^{V_{im}}}$. The quotient rule gives the individual derivatives

$$\frac{\partial s_{ij}}{\partial \delta_j} = s_{ij}(1 - s_{ij}), \qquad \frac{\partial s_{ij}}{\partial \delta_k} = -s_{ij} s_{ik} \quad (k \neq j).$$

These derivatives are bounded by one in absolute value, so we may differentiate (8.48) under the integral sign by dominated convergence (Proposition 8.2). This gives $\frac{\partial s_j}{\partial \delta_j} = \int s_{ij}(1 - s_{ij}) \, \mathrm{d}F$ and $\frac{\partial s_j}{\partial \delta_k} = -\int s_{ij} s_{ik} \, \mathrm{d}F$. Differentiating (8.51),

$$\frac{\partial \Phi_j}{\partial \delta_j} = 1 - \frac{1}{s_j} \frac{\partial s_j}{\partial \delta_j} = 1 - \frac{1}{s_j} \int s_{ij} \, \mathrm{d}F + \frac{1}{s_j} \int s_{ij}^2 \, \mathrm{d}F = \frac{1}{s_j} \int s_{ij}^2 \, \mathrm{d}F,$$

because $\int s_{ij} \, \mathrm{d}F = s_j$. For $k \neq j$, $\frac{\partial \Phi_j}{\partial \delta_k} = -\frac{1}{s_j} \frac{\partial s_j}{\partial \delta_k} = \frac{1}{s_j} \int s_{ij} s_{ik} \, \mathrm{d}F$. Both are positive since $s_{ij} \in (0, 1)$. Summing over k,

$$\sum_k \frac{\partial \Phi_j}{\partial \delta_k} = \frac{1}{s_j} \int s_{ij} \Big(s_{ij} + \sum_{k \neq j} s_{ik} \Big) \, \mathrm{d}F = \frac{1}{s_j} \int s_{ij}(1 - s_{i0}) \, \mathrm{d}F = 1 - \frac{1}{s_j} \int s_{ij} s_{i0} \, \mathrm{d}F.$$

The last integral is positive and smaller than s_j, so the row sum lies in $(0, 1)$. □

The identity $\sum_k \frac{\partial s_{ij}}{\partial \delta_k} = s_{ij} s_{i0}$, used implicitly in the proof, has a simple reading. Raising every inside mean utility by the same amount is equivalent to lowering the utility of the outside good. It moves consumers of type i from the outside good to j at the rate $s_{ij} s_{i0}$.

Proof of Theorem 8.14. We verify the three conditions of Theorem 8.15 for $f = \Phi$ with $\ln s^{\text{obs}}$ replaced by $\ln s$, dropping the market index.

Condition (1). The share function is infinitely differentiable (Proposition 8.2), so Φ is continuously differentiable. Corollary 8.16 gives nonnegative partial derivatives and row sums below one.

Condition (2). Write $s_j(\delta) = e^{\delta_j} B_j(\delta)$, with

$$B_j(\delta) = \int \frac{e^{\mu_{ij}}}{1 + \sum_k e^{\delta_k + \mu_{ik}}} \, \mathrm{d}F.$$

Then $\Phi_j(\delta) = \delta_j + \ln s_j - \delta_j - \ln B_j(\delta) = \ln s_j - \ln B_j(\delta)$. The function B_j falls in every δ_k and is bounded above by $\int e^{\mu_{ij}} \, \mathrm{d}F$, its limit when all $\delta_k \to -\infty$. Hence

$$\Phi_j(\delta) \geq \underline{\delta}_j \equiv \ln s_j - \ln \int e^{\mu_{ij}} \, \mathrm{d}F,$$

which is finite by the integrability assumption. Set $\underline{y} = \min_j \underline{\delta}_j$ (Berry et al., 1995, p. 888). The bound $\underline{\delta}_j$ is the mean utility that would generate share s_j if every consumer's denominator in (8.48) were equal to one.

Condition (3). We follow Berry (1994, p. 261). For each j, consider the market in which only product j is available, so that the outside share is $s_0^{(j)}(\delta_j) = \int \frac{1}{1+e^{\delta_j+\mu_{ij}}}\,\mathrm{d}F$. This function is continuous and strictly decreasing, with limits one and zero as $\delta_j \to -\infty$ and $\delta_j \to +\infty$. Let $\bar{\delta}_j$ solve $s_0^{(j)}(\bar{\delta}_j) = s_0$, where $s_0 = 1 - \sum_k s_k \in (0,1)$, and choose $\bar{y} > \max_j \bar{\delta}_j$. Suppose $\delta_j \geq \bar{y}$ for some j. Every consumer's outside probability falls when we add products, so

$$s_0(\delta) = \int \frac{1}{1 + \sum_k e^{\delta_k + \mu_{ik}}}\,\mathrm{d}F \leq s_0^{(j)}(\delta_j) < s_0^{(j)}(\bar{\delta}_j) = s_0.$$

The inside shares at δ therefore sum to more than $\sum_k s_k$. At least one product k has $s_k(\delta) > s_k$, and for that product $\Phi_k(\delta) = \delta_k + \ln s_k - \ln s_k(\delta) < \delta_k$.

Theorem 8.15 now delivers a unique fixed point of Φ, which is the unique solution of $s(\delta;\theta_2) = s$, and the convergence of the truncated iteration. □

Remark 8.17 (Berry's argument and its generalization). Berry (1994, pp. 260–261) proves existence with Brouwer's fixed point theorem applied to the *element-by-element inverse* $r_j(\delta_{-j}, s_j)$, the value of δ_j that matches s_j given the other mean utilities. For uniqueness he uses a diagonal dominance property that is worth recording. Let δ_0 be the mean utility of the outside good, normally fixed at zero. Adding a constant to all of $(\delta_0, \delta_1, \ldots, \delta_J)$ leaves every share unchanged, so $\sum_{k=0}^{J} \frac{\partial s_j}{\partial \delta_k} = 0$. Since $\frac{\partial s_j}{\partial \delta_k} < 0$ for every $k \neq j$, including $k = 0$,

$$\frac{\partial s_j}{\partial \delta_j} = \sum_{k \neq j,\, k \geq 1} \left|\frac{\partial s_j}{\partial \delta_k}\right| + \left|\frac{\partial s_j}{\partial \delta_0}\right| > \sum_{k \neq j,\, k \geq 1} \left|\frac{\partial s_j}{\partial \delta_k}\right|.$$

The Jacobian $\frac{\partial s}{\partial \delta'}$ is therefore strictly diagonally dominant with a positive diagonal, and in particular nonsingular. Berry's argument needs only that the share function be differentiable with own derivatives positive, cross derivatives negative, and the obvious limits. A strictly positive and continuous density of consumer unobservables suffices (Berry, 1994, p. 260). Berry et al. (2013) weaken these requirements to the "connected substitutes" condition, which Section 8.6.6 states.

8.4.3 Speed of convergence and the practice of the inner loop*

Corollary 8.16 tells us how fast the iteration converges near the solution. The Jacobian of Φ_t has nonnegative entries, so its operator norm in the sup norm is its largest row sum. At the solution this row sum is a local rate. Once the iterates are close, each step shrinks the error by at most about this factor. By (8.52), the row sum of product j is one minus the average outside-good probability among the consumers who buy j. The weights $\frac{s_{ijt}}{s_{jt}}$ in (8.52) are the distribution of consumer types conditional on buying j. The modulus is close to one when the buyers of some product rarely choose the outside good. This happens when the aggregate outside share is small, and also when the outside option is chosen mainly by consumers who seldom buy inside goods. Dubé et al. (2012, Section 7) document the cost in Monte Carlo experiments. Their Lipschitz constant is the largest row sum maximized over the demand shocks ξ. The values they report are a lower bound on it, computed from the data and the model parameters

(their p. 2233). As the outside share falls from 0.91 to 0.35, this value rises from 0.891 to 0.997. The total number of contraction iterations needed for estimation rises from about 10,400 to 262,000 (their Tables III and IV).

The standard contraction bound makes the cost explicit, but it needs a uniform modulus. Write δ_t^* for the solution, and let $\kappa_t < 1$ bound the largest row sum of the Jacobian of Φ_t on every segment that joins an iterate to δ_t^*. The mean value theorem then gives $\|\Phi_t(\delta_t^h) - \delta_t^*\| \le \kappa_t \|\delta_t^h - \delta_t^*\|$ at each step, and hence

$$\|\delta_t^h - \delta_t^*\| \le \kappa_t^h \, \|\delta_t^0 - \delta_t^*\|.$$

Reducing the initial error by a factor 10^{-m} therefore takes

$$h \ge \frac{m \ln 10}{-\ln \kappa_t} \approx \frac{2.3\, m}{1 - \kappa_t}$$

iterations, where the approximation uses $-\ln \kappa \approx 1 - \kappa$ for κ near one. The required number of iterations grows like $\frac{1}{1-\kappa_t}$.

The row sum at the solution alone does not deliver this bound. Take one product with observed share 0.5. Then $\Phi(\delta) = \ln 0.5 + \ln(1 + e^{\delta})$, with fixed point zero and derivative $\frac{e^{\delta}}{1+e^{\delta}}$, which equals 0.5 there. From $\delta^0 = 10$, one step gives $\delta^1 = 9.31$, far above the value 5 that the factor 0.5 would allow. The iterates stay in $[0, 10]$, where the uniform modulus is $\frac{e^{10}}{1+e^{10}} \approx 0.99995$, and the bound with this modulus holds. Far from the solution, the local rate can be much too optimistic.

Figure 8.3 illustrates with three simulated markets. Each has ten inside products and random coefficients on the constant, on one characteristic and on price, and we use $n_s = 1{,}000$ draws. The markets differ only in a common shift of the mean utilities, chosen so that the outside share is about 0.9, 0.5 and 0.1. The largest row sum at the solution is 0.357, 0.725 and 0.948 in the three markets. Starting from the logit inversion (8.50), the plain iteration needs 25, 63 and 332 evaluations of the share function to bring the sup-norm error below 10^{-13}. The observed linear rates are 0.28, 0.63 and 0.92, a little below these local rates. On a grid of 21 points per segment, the largest row sum on the segments between the iterates and the solution is 0.487, 0.737 and 0.948. These are uniform moduli for the three paths. In the third market the largest grid value is attained at the solution, so the bound with $\kappa = 0.948$ applies. It predicts about 550 iterations, and the observed rate predicts about 336, close to the realized 332.

Starting values and the multiplicative form

The logit inversion is the natural first starting value, since it is exact at $\theta_2 = 0$. Inside an estimation routine the outer optimizer changes θ_2 by small amounts, and the solution at the previous trial value is a better start. This warm start can cut the number of iterations considerably. Exponentiating the update gives the equivalent form

$$e^{\delta_{jt}^{h+1}} = e^{\delta_{jt}^{h}} \, \frac{s_{jt}^{\text{obs}}}{s_{jt}(\delta_t^h; \theta_2)},$$

which works with e^{δ} directly and avoids a logarithm and an exponential per product and iteration. Each iteration raises δ_{jt} when the model underpredicts the share of j and lowers it when the model overpredicts. The individual choice probabilities should be computed with the overflow-safe evaluation of Section 8.3.

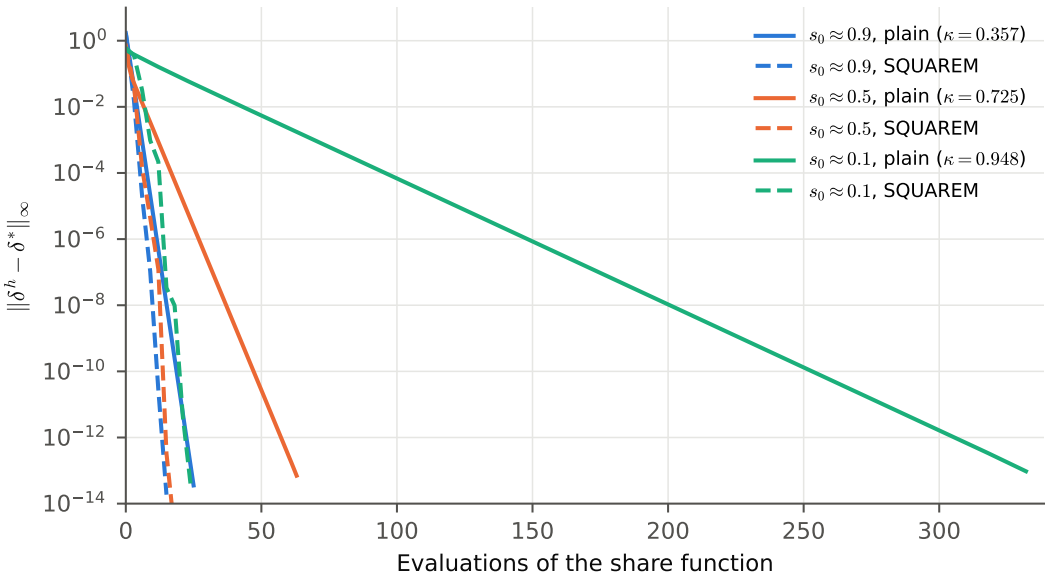

Figure 8.3: Convergence of the share inversion in three simulated markets with outside shares near 0.9, 0.5 and 0.1. Each market has $J = 10$ products, random coefficients with standard deviations $(1.0, 1.0, 0.5)$ on the constant, a characteristic and price, and $n_s = 1{,}000$ draws. Solid lines show the plain iteration $\delta^{h+1} = \Phi(\delta^h)$. Dashed lines show SQUAREM, the extrapolation method described below, on the same map. The horizontal axis counts evaluations of the share function. The legend reports the largest row sum κ of the Jacobian of Φ at the solution, the local rate. Computed in `fig_contraction.py`.

The stopping rule

The iteration stops when successive iterates are close. The next result converts this observable criterion into a bound on the distance to the solution.

Proposition 8.18 (Inner-loop error)**.** *Suppose Φ_t is a contraction with modulus $\kappa < 1$ on a set that contains the iterates and the solution δ_t^*. If the iteration stops at the first H with $\|\delta_t^H - \delta_t^{H-1}\| \le \epsilon_{in}$, then*

$$\|\delta_t^H - \delta_t^*\| \le \frac{\kappa}{1-\kappa}\,\epsilon_{in}.$$

Proof. Since $\delta_t^* = \Phi_t(\delta_t^*)$ and $\delta_t^H = \Phi_t(\delta_t^{H-1})$,

$$\begin{aligned}\|\delta_t^H - \delta_t^*\| &= \|\Phi_t(\delta_t^{H-1}) - \Phi_t(\delta_t^*)\| \le \kappa\|\delta_t^{H-1} - \delta_t^*\| \\ &\le \kappa\big(\|\delta_t^{H-1} - \delta_t^H\| + \|\delta_t^H - \delta_t^*\|\big) \le \kappa\epsilon_{in} + \kappa\|\delta_t^H - \delta_t^*\|.\end{aligned}$$

Collecting the terms in $\|\delta_t^H - \delta_t^*\|$ gives $(1-\kappa)\|\delta_t^H - \delta_t^*\| \le \kappa\epsilon_{in}$. □

The proof uses the modulus only for the step from δ_t^{H-1}, so a bound on the row sums along the segment from δ_t^{H-1} to δ_t^* suffices. The row sum at the solution can serve as κ when it bounds the row sums along that segment. When κ is near one, the error can exceed the tolerance by orders of magnitude. In the third market of Figure 8.3, the largest row sum on the final segment is $\kappa = 0.948$. Stopping at a step size of 10^{-4} leaves a true error of 1.0×10^{-3}, against a bound of 1.7×10^{-3}. Stopping at 10^{-8} leaves 1.0×10^{-7}. The error is about ten times the tolerance.

The inner error then contaminates the outer problem. Let $e = \tilde{\delta} - \delta(\theta_2)$ be the inversion error, stacked over markets. Section 8.5 shows that the structural error is $\xi(\theta_2) = \boldsymbol{M}\delta(\theta_2)$ for a matrix $\boldsymbol{M}$ that does not depend on θ_2 given the weighting matrix. The computed moments therefore carry the error $\frac{1}{N}\boldsymbol{Z}^\top \boldsymbol{M} e$. This error varies with θ_2 in an erratic way, because the number of inner iterations jumps from one trial value to the next. A finite-difference derivative with step Δ inherits an error of order $\frac{\|e\|}{\Delta}$. With $\|e\|$ near 10^{-6} and Δ near 10^{-6}, the error in the computed gradient is of order one. Dubé et al. (2012, Sections 4.2 and 6) show that a loose inner tolerance can keep the outer optimizer from converging. If the researcher then loosens the outer tolerance, the reported solution may not be a local minimum. In their synthetic data, no run with inner tolerance 10^{-4} and outer tolerance 10^{-6} reports convergence (their Table I). The practical rule is to set the inner tolerance close to machine precision, for example 10^{-12} to 10^{-14} in the sup norm, and well below the outer tolerance. With the warm start this costs little.

Acceleration

Two methods speed up the inner loop. The first is SQUAREM, a squared extrapolation method of Varadhan and Roland (2008) designed for slowly converging fixed point iterations. Reynaerts et al. (2012, Section 2.3) apply it to the BLP map. One cycle of the variant we use computes two plain steps, extrapolates and ends with one more plain step (Varadhan and Roland, 2008, Table 1). The step length a is that of their scheme SqS3, set to -1 whenever it exceeds -1 (their eqs. (9) and (20) and Section 6):

$$r = \Phi(\delta) - \delta, \qquad v = \Phi(\Phi(\delta)) - 2\Phi(\delta) + \delta, \qquad a = \min\Big\{ -\frac{\|r\|_2}{\|v\|_2}, -1 \Big\},$$
$$\delta' = \delta - 2ar + a^2 v, \qquad \delta^{new} = \Phi(\delta').$$

With $a = -1$ the cycle reduces to three plain steps. A more negative a extrapolates along the direction in which the iterates have been moving. In Figure 8.3 SQUAREM reaches an error of 10^{-13} after 15, 18 and 24 evaluations of the share function, against 25, 63 and 332 for the plain iteration. Its advantage grows with the modulus. The second method applies Newton's method to the system $\ln s_t(\delta_t; \theta_2) = \ln s_t^{\text{obs}}$:

$$\delta_t^{h+1} = \delta_t^h - \Big[\frac{\partial \ln s_t(\delta_t^h; \theta_2)}{\partial \delta_t^\top} \Big]^{-1} \big(\ln s_t(\delta_t^h; \theta_2) - \ln s_t^{\text{obs}} \big).$$

The Jacobian is available in closed form from the proof of Corollary 8.16, and it is nonsingular by Remark 8.17. Newton's method converges quadratically near the solution but may overshoot far from it. A common hybrid runs the contraction first and switches to Newton steps once the iterates are close.

Remark 8.19 (Dampening in the random coefficients nested logit). When random coefficients are combined with a nested logit error with nesting parameter $\rho \in [0, 1)$, the undampened map need not be a contraction. We write the nesting parameter as ρ in this remark, because σ here denotes the standard deviations of the random coefficients. Grigolon and Verboven (2014, pp. 919 and 934–935) show for the plain nested logit that dampening the step by the factor $1 - \rho$ restores BLP's sufficient conditions for a contraction. They state that the argument extends to random coefficients and use the same dampened map in the random coefficients nested logit. The dampened iteration is $\delta^{h+1} = \delta^h + (1 - \rho)\big(\ln s^{\text{obs}} - \ln s(\delta^h) \big)$. Their printed equation (7) attaches the factor $1 - \rho$ to $\ln s(\delta^h)$ alone. Conlon and Gortmaker (2020, eq. 15 and

n. 20) point out this typesetting error. In the plain nested logit, $\delta_j = (1-\rho)\ln s_j + \rho \ln s_g - \ln s_0$, where s_g is the share of j's nest. Holding the nest and outside shares fixed, a change in $\ln s_j$ therefore maps into a change of $1-\rho$ times as much in δ_j, and the dampened step has this scale. Chapter 11 uses this model for merger simulation.

8.5 The GMM estimator

With the inversion in hand, estimation follows the logic of instrumental variables. This section derives the estimator, the shortcut that concentrates out the linear parameters, the algorithm, its gradient, the weighting matrix, and the asymptotic variance with simulation error. It ends with a reformulation as a constrained optimization problem.

8.5.1 Why the error must be the structural error

A direct approach would choose the parameters to make predicted shares close to observed shares,

$$\min_{\theta} \left\| s\left(x, p, \delta(x, p, \xi; \theta_1); \theta_2\right) - s^{\text{obs}} \right\|,$$

as in equation (7) of Nevo (2000a). Nevo (2000a, pp. 530–531) gives two reasons against it. First, all parameters enter nonlinearly, and with many brand and time dummies the nonlinear search becomes costly. Second, and more fundamentally, the approach cannot handle the correlation between prices and ξ. The residual $s^{\text{obs}} - s(\cdot)$ is a nonlinear function of ξ. The standard nonlinear simultaneous equations model allows parameters and variables to enter nonlinearly, but it requires an additively separable error (Nevo, 2000a, p. 531). The share residual does not have this form. At the true parameters the predicted share depends on the unknown vector ξ. Setting $\xi = 0$ in the prediction leaves a residual that is a nonlinear function of ξ. An orthogonality condition between instruments and ξ then implies no such condition for the residual.

Berry (1994) proposed to define the econometric error as the structural error ξ_{jt} itself. The link to economic theory is then direct, and we can reason about which variables are plausibly uncorrelated with unobserved quality (Nevo, 2000a, p. 531). The cost is the inversion of Section 8.4.

8.5.2 Moment conditions

The identifying assumption of Berry et al. (1995, eq. 4.1) is a conditional moment restriction. Let $\mathcal{Z}_t$ denote the exogenous variables of market t: the observed characteristics of all products and the cost shifters. BLP assume

$$\mathbb{E}[\xi_{jt} \mid \mathcal{Z}_t] = 0 \quad \text{and} \quad \mathbb{E}[\omega_{jt} \mid \mathcal{Z}_t] = 0, \tag{8.53}$$

where ω_{jt} is the cost unobservable of Section 8.7. Prices and quantities are left out of the conditioning set because the model makes them functions of ξ and ω. The characteristics are included because the model does not explain how they are chosen (Berry et al., 1995, p. 854). Section 8.6 discusses how plausible this is. In this section we treat demand alone.

A conditional moment restriction implies that ξ_{jt} is uncorrelated with every function of $\mathcal{Z}_t$. We choose L such functions and collect them in the row vector $z_{jt} \in \mathbb{R}^{1\times L}$, the *instruments* for observation (j,t). The unconditional moment conditions are

$$\mathbb{E}\left[z_{jt}^{\top}\, \xi_{jt}(\theta_0)\right] = 0, \tag{8.54}$$

which is equation (8) of Nevo (2000a). The structural error as a function of the parameters is

$$\xi_{jt}(\theta) = \delta_{jt}(s_t^{\text{obs}}; \theta_2) - x_{jt}\beta + \alpha p_{jt} \tag{8.55}$$

(Nevo, 2000a, eq. 13). The observed shares enter through the inversion. For a trial θ_2, the inversion finds the mean utilities that rationalize the data. The error is the gap between those mean utilities and the ones predicted by the linear parameters (α, β). When the specification includes brand and time dummies, they appear on the right-hand side of (8.55) and the error becomes the market-specific deviation $\tilde{\xi}_{jt}$ of Section 8.6.5.

We stack the $N = \sum_t J_t$ observations. Let $\delta(\theta_2)$ be the N-vector of inverted mean utilities, $\boldsymbol{X}$ the $N \times K_1$ matrix whose rows are (x_{jt}, p_{jt}) augmented with any dummies, and $\theta_1 = (\beta^\top, -\alpha)^\top$ the corresponding coefficient vector. This is the vector of linear parameters (α, β) of Section 8.1.2, ordered and signed to match the columns of $\boldsymbol{X}$. Then

$$\xi(\theta) = \delta(\theta_2) - \boldsymbol{X}\theta_1.$$

Let $\boldsymbol{Z}$ be the $N \times L$ matrix of instruments. The sample moments and the GMM objective are

$$g_N(\theta) = \frac{1}{N}\boldsymbol{Z}^\top \xi(\theta), \qquad Q_N(\theta) = g_N(\theta)^\top W g_N(\theta) = \frac{1}{N^2}\,\xi(\theta)^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \xi(\theta), \tag{8.56}$$

for a positive definite $L \times L$ weighting matrix W. This is equation (9) of Nevo (2000a) and equation (6) of Nevo (2001), who write W as the inverse of an estimate of $\mathbb{E}[\boldsymbol{Z}^\top \xi \xi^\top \boldsymbol{Z}]$. The GMM estimator is $\hat{\theta} = \arg\min_\theta Q_N(\theta)$. The order condition requires $L \geq K_1 + K_2$, where $K_2 = \dim \theta_2$. The rank condition requires that $\mathbb{E}[z_{jt}^\top \frac{\partial \xi_{jt}(\theta_0)}{\partial \theta^\top}]$ have full column rank. Appendix A reviews the general theory.

8.5.3 Concentrating out the linear parameters

The objective (8.56) is quadratic in θ_1 for fixed θ_2. The linear parameters can therefore be solved in closed form (Berry et al., 1995, p. 868).

Proposition 8.20 (Concentrating out θ_1)**.** *Suppose $\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{X}$ is nonsingular. For each θ_2, the value of θ_1 that minimizes $Q_N(\theta_1, \theta_2)$ is*

$$\hat{\theta}_1(\theta_2) = \left(\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{X}\right)^{-1} \boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \delta(\theta_2). \tag{8.57}$$

The implied structural error is $\xi(\theta_2) = \boldsymbol{M}\delta(\theta_2)$ with $\boldsymbol{M} = I_N - \boldsymbol{X}(\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{X})^{-1} \boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top$. The GMM estimator of θ_2 minimizes the profiled objective

$$Q_N^c(\theta_2) = \frac{1}{N^2}\,\delta(\theta_2)^\top \boldsymbol{M}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{M}\,\delta(\theta_2), \tag{8.58}$$

and $\hat{\theta}_1 = \hat{\theta}_1(\hat{\theta}_2)$.

Proof. Fix θ_2 and write $\delta = \delta(\theta_2)$. The objective is

$$Q_N = \frac{1}{N^2}(\delta - \boldsymbol{X}\theta_1)^\top \boldsymbol{Z} W \boldsymbol{Z}^\top (\delta - \boldsymbol{X}\theta_1).$$

Its gradient with respect to θ_1 is

$$\frac{\partial Q_N}{\partial \theta_1} = -\frac{2}{N^2}\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top (\delta - \boldsymbol{X}\theta_1).$$

Setting it to zero gives the normal equations $\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{X}\, \theta_1 = \boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \delta$, whose solution is (8.57). The Hessian $\frac{2}{N^2} \boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{X}$ is positive definite, so this is the unique minimum. Substituting, $\delta - \boldsymbol{X}\hat{\theta}_1(\theta_2) = \boldsymbol{M}\delta$, and the objective at the minimum is (8.58). Finally, $\min_{\theta_1,\theta_2} Q_N = \min_{\theta_2} \min_{\theta_1} Q_N = \min_{\theta_2} Q_N^c(\theta_2)$. □

The matrix $\boldsymbol{M}$ depends on the data and on W only. It can be computed once for each weighting matrix, and each objective evaluation then requires one matrix-vector product. The nonlinear search runs over θ_2 alone, which typically has a handful of elements. The number of random coefficients therefore drives the cost of estimation. The mean utility can include many characteristics, and even brand dummies, at little cost (Section 8.1).

Corollary 8.21 (Logit and nested logit as 2SLS)**.** *In the logit model θ_2 is empty and $\delta_{jt} = \ln s_{jt}^{obs} - \ln s_{0t}^{obs}$. With $W = (\frac{1}{N}\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}$, the estimator (8.57) is two-stage least squares of $\ln s_{jt} - \ln s_{0t}$ on $\boldsymbol{X}$ with instruments $\boldsymbol{Z}$. In the nested logit model the same holds after adding $\ln s_{j|g,t}$ to $\boldsymbol{X}$ as a second endogenous regressor with coefficient σ.*

Proof. Write $P_Z = \boldsymbol{Z}(\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}\boldsymbol{Z}^\top$. The scalar $\frac{1}{N}$ in W cancels from (8.57), which becomes $(\boldsymbol{X}^\top P_Z \boldsymbol{X})^{-1}\boldsymbol{X}^\top P_Z \delta$, the 2SLS formula. In the nested logit model $\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \sigma \ln s_{j|g,t} + \xi_{jt}$, which is linear in (β, α, σ). □

Nevo (2000a, p. 533 and n. 22) and Nevo (2001, p. 319) make the same point. The weighting matrix $(\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}$ is efficient when the errors are homoskedastic.

8.5.4 The nested fixed point algorithm

The estimator nests the inversion (a fixed point problem) inside the minimization. We call the procedure the *nested fixed point* (NFXP) algorithm. Berry et al. (1995, p. 863) describe four steps for each evaluation of the moments. They estimate the market shares by simulation and solve for the demand unobservables. They then compute the cost unobservables as price minus the markup, and they interact both unobservables with the instruments. In our notation the algorithm reads as follows.

1. Before the search, draw (D_i, ν_i), $i = 1, \ldots, n_s$, for each market and hold the draws fixed for the whole estimation. Choose the first-step weighting matrix $W = (\frac{1}{N}\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}$ and compute $\boldsymbol{M}$.

2. The outer optimizer proposes a value $\theta_2^{(k)}$. Compute $\mu_{ijt} = \tilde{x}_{jt}(\Pi D_i + \Sigma \nu_i)$ for all draws, products and markets.

3. In each market, iterate $\delta_t^{h+1} = \Phi_t(\delta_t^h)$ from the last solution until $\|\delta_t^{h+1} - \delta_t^h\|_\infty < \epsilon_{in}$, using the simulated share $s_t^{n_s}$ of Section 8.3.

4. Compute $\hat{\theta}_1(\theta_2^{(k)})$ by (8.57) and $\xi(\theta_2^{(k)}) = \boldsymbol{M}\delta(\theta_2^{(k)})$. With a supply side, also compute the markups and the cost unobservable ω (Section 8.7).

5. Evaluate $Q_N^c(\theta_2^{(k)})$ and its gradient (Proposition 8.22). Return them to the optimizer, which either stops or returns to step 2.

6. After convergence, compute the second-step weighting matrix from the first-step residuals (Section 8.5.6) and repeat steps 2 to 5.

Figure 8.4 displays the algorithm. Two remarks concern the outer search. Berry et al. (1995, p. 868) use the Nelder-Mead simplex method, which needs no derivatives. Nevo (2001, p. 319) uses a quasi-Newton method with an analytic gradient and reports that it "was found to work much faster." Holding the draws fixed is essential for the outer search. Fresh draws at each evaluation would make the objective a random function of θ_2, and no optimizer would converge (Pakes and Pollard, 1989).

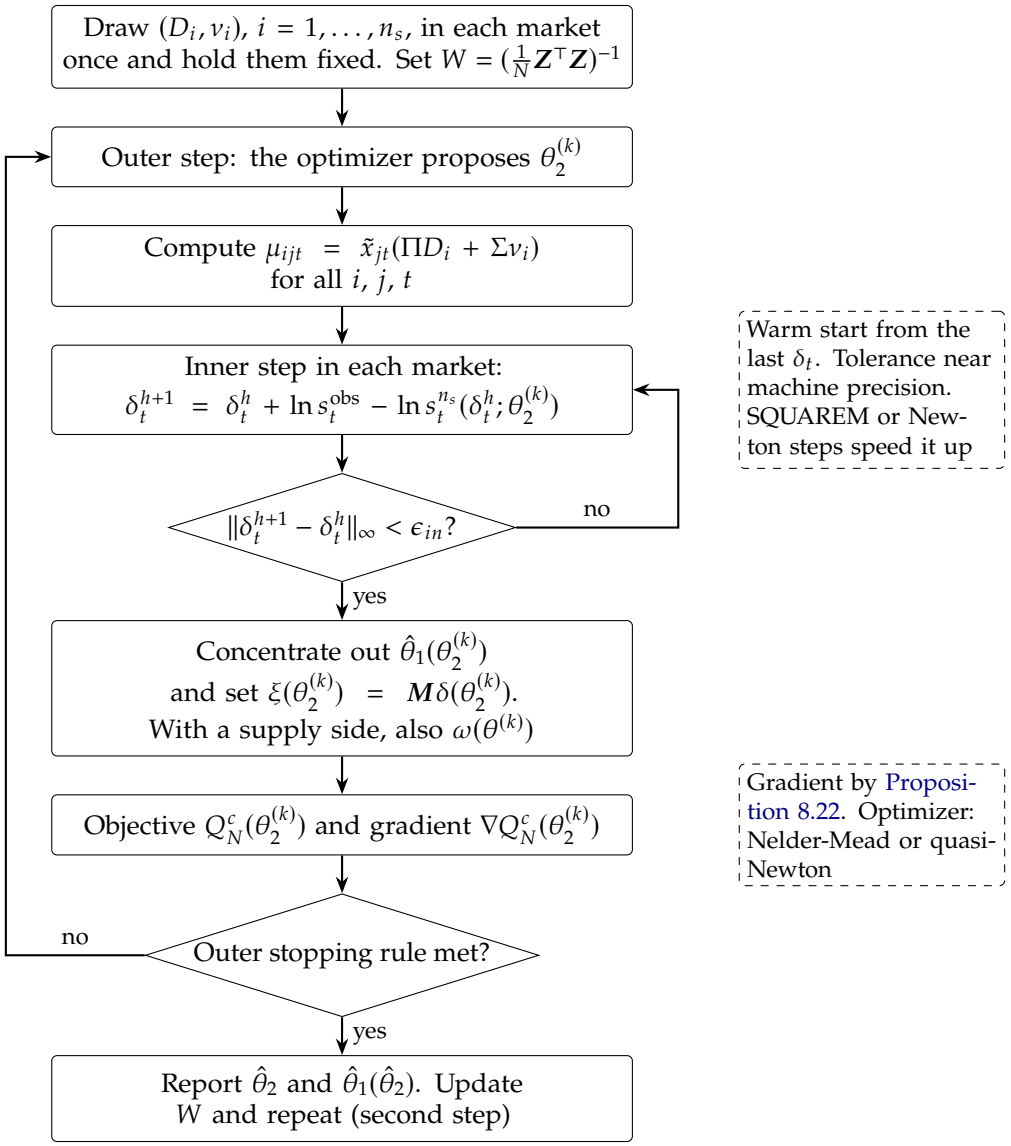

Figure 8.4: The nested fixed point algorithm. The outer loop searches over the nonlinear parameters θ_2. For each trial value the inner loop inverts the share equations market by market, the linear parameters are concentrated out, and the profiled GMM objective is evaluated.

8.5.5 The gradient*

Quasi-Newton methods need the gradient of Q_N^c. Because $\delta(\theta_2)$ is defined implicitly by the share equations, its derivative comes from the implicit function theorem (Appendix B).

Proposition 8.22 (Gradient of the profiled objective)**.** *For each market, $\delta_t(\theta_2)$ is continuously differentiable and*

$$\frac{\partial \delta_t}{\partial \theta_2^\top} = -\Big[\frac{\partial s_t}{\partial \delta_t^\top}\Big]^{-1} \frac{\partial s_t}{\partial \theta_2^\top}. \tag{8.59}$$

In the random coefficients logit model with diagonal $\Sigma = \operatorname{diag}(\sigma_1, \dots, \sigma_{K+1})$ and demographic coefficients π_{kd}, the derivatives on the right are

$$\begin{aligned}
\frac{\partial s_{jt}}{\partial \delta_{kt}} &= \int s_{ijt}\big(\mathbf{1}\{j=k\} - s_{ikt}\big)\,\mathrm{d}F, \\
\frac{\partial s_{jt}}{\partial \sigma_k} &= \int s_{ijt}\,\nu_{ik}\Big(\tilde{x}_{jtk} - \sum_{m \in \mathcal{J}_t} s_{imt}\tilde{x}_{mtk}\Big)\,\mathrm{d}F, \\
\frac{\partial s_{jt}}{\partial \pi_{kd}} &= \int s_{ijt}\,D_{id}\Big(\tilde{x}_{jtk} - \sum_{m \in \mathcal{J}_t} s_{imt}\tilde{x}_{mtk}\Big)\,\mathrm{d}F.
\end{aligned} \tag{8.60}$$

The gradient of the profiled objective is

$$\nabla Q_N^c(\theta_2) = \frac{2}{N^2}\Big(\frac{\partial \delta}{\partial \theta_2^\top}\Big)^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \xi(\theta_2). \tag{8.61}$$

Proof. The inverted mean utilities satisfy the identity $s_t(\delta_t(\theta_2); \theta_2) = s_t^{\text{obs}}$ for all θ_2. Differentiating with respect to $\theta_2^\top$ gives

$$\frac{\partial s_t}{\partial \delta_t^\top}\frac{\partial \delta_t}{\partial \theta_2^\top} + \frac{\partial s_t}{\partial \theta_2^\top} = 0.$$

The Jacobian $\frac{\partial s_t}{\partial \delta_t^\top}$ is nonsingular by Remark 8.17, so the implicit function theorem applies and yields (8.59). The derivative with respect to δ was computed in the proof of Corollary 8.16. For σ_k, note that $\mu_{ijt} = \sum_k \tilde{x}_{jtk}(\sigma_k \nu_{ik} + \sum_d \pi_{kd} D_{id})$, so $\frac{\partial \mu_{ijt}}{\partial \sigma_k} = \tilde{x}_{jtk}\nu_{ik}$. From $\ln s_{ijt} = \delta_{jt} + \mu_{ijt} - \ln(1 + \sum_m e^{\delta_{mt}+\mu_{imt}})$,

$$\frac{\partial \ln s_{ijt}}{\partial \sigma_k} = \tilde{x}_{jtk}\nu_{ik} - \sum_m s_{imt}\tilde{x}_{mtk}\nu_{ik},$$

and multiplying by s_{ijt} and integrating gives (8.60). The derivative with respect to π_{kd} replaces ν_{ik} by D_{id}. For the gradient, write $Q_N(\theta_1, \theta_2)$ as in (8.56), so $Q_N^c(\theta_2) = Q_N(\hat{\theta}_1(\theta_2), \theta_2)$. By the chain rule,

$$\nabla Q_N^c = \frac{\partial Q_N}{\partial \theta_2} + \Big(\frac{\partial \hat{\theta}_1}{\partial \theta_2^\top}\Big)^\top \frac{\partial Q_N}{\partial \theta_1}.$$

The second term vanishes because $\frac{\partial Q_N}{\partial \theta_1} = 0$ at $\hat{\theta}_1(\theta_2)$. This is the envelope theorem. Holding θ_1 fixed, $\frac{\partial \xi}{\partial \theta_2^\top} = \frac{\partial \delta}{\partial \theta_2^\top}$, which gives (8.61). □

With simulation, every integral in the proposition is replaced by the average over the n_s fixed draws. The gradient then costs about as much as one more share evaluation plus the solution of a $J_t \times J_t$ linear system in each market. The matrix $\frac{\partial \delta}{\partial \theta_2^\top}$ also reappears in the asymptotic variance below and in the optimal instruments of Section 8.6.3.

8.5.6 Weighting, efficiency and clustering

The efficient weighting matrix is the inverse of the variance of the moments. With independent observations the second-step matrix is

$$W_2 = \Big[\frac{1}{N}\sum_{t}\sum_{j\in\mathcal{J}_t} z_{jt}^{\top}\,\hat{\xi}_{jt}^{2}\,z_{jt}\Big]^{-1},$$

where $\hat{\xi}_{jt}$ are the residuals at the first-step estimate. Nevo (2001, p. 319) follows this two-step procedure. He also iterated further and found that "the estimated parameters changed only slightly beyond the second iteration."

Errors are often correlated within groups of observations. Berry et al. (1995, pp. 862–863) follow car models over the years they are sold, and the unobservables of one model are more alike across years than across models. They sum the moments of each model over its years,

$$g_m(\theta) = \sum_{t}\big[f_{mt}(\mathcal{Z})^{\top}\otimes I_2\big]\begin{pmatrix}\xi_{mt}(\theta)\\ \omega_{mt}(\theta)\end{pmatrix},$$

where $f_{mt}(\mathcal{Z})$ is the vector of instrument functions for model m in year t and $\otimes$ is the Kronecker product. They then minimize a quadratic form in the average of g_m over models. The resulting standard errors allow arbitrary correlation across years for a given model and arbitrary heteroskedasticity across models. The corresponding efficient weighting matrix is the inverse of $\frac{1}{M}\sum_m g_m(\hat{\theta})g_m(\hat{\theta})^{\top}$, with M the number of models. The same construction applies with cities, markets or brands as clusters (Appendix A).

With the efficient weighting matrix, $N\,Q_N(\hat{\theta})$ is the *Hansen J statistic*. Under correct specification it converges in distribution to a χ^2 with $L-K_1-K_2$ degrees of freedom. A rejection signals that some instruments are invalid or that the model is misspecified. With tens of thousands of observations the test rejects almost any model, as Nevo (2001, p. 325, n. 23) notes.

8.5.7 Asymptotic distribution and simulation error*

The estimator departs from textbook GMM in two ways. The moments are computed from sampled shares, and the share integral is simulated. Berry et al. (1995, Section 5) account for both. Their setting is a single cross section of J products, with asymptotics as J grows. Let s^0 be the population shares, s^n the shares observed in a sample of n consumers, P_0 the distribution of consumer attributes, and P_{n_s} the empirical distribution of n_s simulation draws. BLP standardize the two unobservables by a 2×2 matrix $T(z_j)$ with $T(z_j)^{\top}T(z_j) = \Upsilon(z_j)^{-1}$, where $\Upsilon(z_j) = \mathbb{E}[(\xi_j,\omega_j)^{\top}(\xi_j,\omega_j)\mid z_j]$ (their eqs. 5.1–5.2). BLP write Ω for this covariance matrix. We write Υ because Ω is the ownership matrix in this book. They interact the standardized errors with an $L\times 2$ instrument matrix $H_j(\mathcal{Z})$ and form

$$G_J(\theta;s,P) = \frac{1}{J}\sum_{j=1}^{J} H_j(\mathcal{Z})\,T(z_j)\begin{pmatrix}\xi_j(\theta,s,P)\\ \omega_j(\theta,s,P)\end{pmatrix}$$

(eq. 5.4). The estimator minimizes $\|G_J(\theta;s^n,P_{n_s})\|$ with $\|y\| = y^{\top}y$ (eq. 5.5).

The computed moments differ from the ideal ones $G_J(\theta_0; s^0, P_0)$ in two ways. Adding and subtracting gives the decomposition

$$G_J(\theta_0; s^n, P_{n_s}) = \underbrace{G_J(\theta_0; s^0, P_0)}_{\text{product draws}} + \underbrace{\left[G_J(\theta_0; s^n, P_0) - G_J(\theta_0; s^0, P_0)\right]}_{\text{consumer sampling}} + \underbrace{\left[G_J(\theta_0; s^n, P_{n_s}) - G_J(\theta_0; s^n, P_0)\right]}_{\text{simulation}}.$$

The three terms come from three independent random processes: the draws of the product characteristics (x, w, ξ, ω), the sampling of consumers, and the simulation draws. Their variances, scaled by J, converge to

$$V_1 = \lim_{J\to\infty} \mathbb{E}_{\mathcal{Z}}\left[H_j T(z_j) \begin{pmatrix}\xi_j \\ \omega_j\end{pmatrix}\begin{pmatrix}\xi_j \\ \omega_j\end{pmatrix}^{\top} T(z_j)^{\top} H_j^{\top}\right],$$

$$V_2 = \lim_{J\to\infty} \frac{J}{n}\,\mathbb{E}\Big(n\left[G_J(\theta_0; s^0, P_0) - G_J(\theta_0; s^n, P_0)\right]\left[\,\cdot\,\right]^{\top}\Big),$$

$$V_3 = \lim_{J\to\infty} \frac{J}{n_s}\,\mathbb{E}\Big(n_s\left[G_J(\theta_0; s^n, P_{n_s}) - G_J(\theta_0; s^n, P_0)\right]\left[\,\cdot\,\right]^{\top}\,\Big|\, s^n\Big),$$

where $[\cdot]$ repeats the preceding bracket. The usual GMM linearization then applies. The first-order condition $\hat{G}^{\top} G_J(\hat{\theta}) = 0$, with $\hat{G}$ the Jacobian of the moments, and a mean value expansion $G_J(\hat{\theta}) \approx G_J(\theta_0) + G(\hat{\theta} - \theta_0)$ give $\sqrt{J}(\hat{\theta} - \theta_0) \approx -(G^{\top}G)^{-1}G^{\top}\sqrt{J}\,G_J(\theta_0)$. Hence the asymptotic variance is

$$(G^{\top}G)^{-1}G^{\top}(V_1 + V_2 + V_3)\,G\,(G^{\top}G)^{-1}, \qquad G = \lim_{J\to\infty} \frac{\partial \mathbb{E}[G_J(\theta, s^0, P_0)]}{\partial \theta^{\top}}\bigg|_{\theta=\theta_0}, \tag{8.62}$$

which is equation (5.6) of Berry et al. (1995), who write Γ for G. With a general weighting matrix the formula becomes $(G^{\top}WG)^{-1}G^{\top}W(V_1 + V_2 + V_3)WG(G^{\top}WG)^{-1}$.

The scale factors explain which terms matter. V_2 carries the factor $\frac{J}{n}$, and BLP note that n, the number of U.S. households, "is on the order of 100 million," so V_2 is negligible (Berry et al., 1995, p. 859). V_3 carries the factor $\frac{J}{n_s}$, and with a feasible number of draws it is not negligible. The limit theory requires n and n_s to grow "on the order of J^3" (p. 859). The "in process" paper that BLP cite for these results was published as Berry et al. (2004b). Its theorems need the number of draws to grow only at rate J^2 in logit-style models, a weaker condition than the rate BLP quote (Section 8.9.4). BLP estimate V_1 by its sample analog at $\hat{\theta}$. They estimate V_3 by drawing new sets of simulation draws, recomputing the moments at $\hat{\theta}$ for each set, and taking the empirical variance. The correction "increases our reported standard errors . . . by about 5–20% (with the exception of one parameter, whose reported standard error doubles)" (p. 859).

The sampling scheme behind V_1 deserves a word. BLP do not assume that products are independent draws. They assume that the vectors $y_j = (\xi_j, \omega_j, z_j)$ are *exchangeable*: their joint density is unchanged by any permutation of the product labels (Berry et al., 1995, p. 856, n. 14). This allows characteristics chosen by firms to be related across products and allows common shocks to many products.

In data with many markets and a fixed set of products, as in Nevo (2001), the asymptotics run over markets instead. The moments are averages of independent market-level terms, and the usual cluster-robust GMM formulas apply. Nevo (2001, p. 319) corrects for simulation error

by accounting for the fact that the draws are common to all observations in a market. One caveat carries over from Section 8.3. The log of a simulated share is biased (Proposition 8.13), so the inverted δ carries a bias of order $\frac{1}{n_s}$ that does not average out across markets. Consistency therefore requires n_s to grow with the sample, and in practice n_s should be large enough that the bias is small relative to the standard errors.

Two practical points complete the picture. First, the standard errors must be computed for the full parameter vector $\theta = (\theta_1, \theta_2)$. The moment Jacobian is

$$G = \frac{1}{N} \boldsymbol{Z}^\top \Big[-\boldsymbol{X},\ \frac{\partial \delta}{\partial \theta_2^\top} \Big],$$

with the second block from Proposition 8.22. Treating the second-stage regression (8.57) as ordinary 2SLS with δ as data ignores the estimation of θ_2 and understates the uncertainty in $\hat{\theta}_1$. Second, objects such as elasticities, markups and welfare are nonlinear functions $\varphi(\theta)$. Their uncertainty can be computed by the delta method, $\widehat{\mathrm{Var}}(\varphi(\hat{\theta})) = \nabla\varphi^\top \widehat{\mathrm{Var}}(\hat{\theta}) \nabla\varphi$, or by a parametric bootstrap. The bootstrap draws $\theta^{(r)}$ from the estimated asymptotic distribution of $\hat{\theta}$, computes $\varphi(\theta^{(r)})$ for each draw, and reads off percentiles. Nevo (2001, pp. 319, 333) uses the bootstrap, with 1,500 draws for the margins of his Table VIII (Section 8.13).

8.5.8 MPEC: estimation as constrained optimization*

Su and Judd (2012) propose to estimate structural models by *mathematical programming with equilibrium constraints* (MPEC), and Dubé et al. (2012) apply the idea to BLP. Instead of solving the share equations for every trial value of θ_2, MPEC treats the mean utilities as additional unknowns and imposes the share equations as constraints:

$$\min_{\theta_1, \theta_2, \delta, \eta} \ \eta^\top W \eta \quad \text{subject to} \quad s_t(\delta_t; \theta_2) = s_t^{\text{obs}} \ \ (t = 1, \dots, T), \qquad \eta = \frac{1}{N} \boldsymbol{Z}^\top (\delta - \boldsymbol{X}\theta_1). \tag{8.63}$$

The auxiliary vector $\eta \in \mathbb{R}^L$ holds the sample moments.

Proposition 8.23 (Equivalence of MPEC and NFXP)**.** *Suppose the conditions of Theorem 8.14 hold for every θ_2 in the parameter space. Then $(\hat{\theta}_1, \hat{\theta}_2)$ minimizes the GMM objective (8.56) if and only if there exist $\hat{\delta}$ and $\hat{\eta}$ such that $(\hat{\theta}_1, \hat{\theta}_2, \hat{\delta}, \hat{\eta})$ solves (8.63). In that case $\hat{\delta} = \delta(\hat{\theta}_2)$ and $\hat{\eta} = g_N(\hat{\theta})$.*

Proof. By Theorem 8.14, for each θ_2 the share constraints have exactly one solution, $\delta(\theta_2)$. The second constraint then determines η. The feasible set of (8.63) is therefore

$$\Big\{ \big(\theta_1, \theta_2, \delta(\theta_2), \frac{1}{N} \boldsymbol{Z}^\top (\delta(\theta_2) - \boldsymbol{X}\theta_1)\big) : (\theta_1, \theta_2) \text{ in the parameter space} \Big\}.$$

On this set the objective equals $g_N(\theta)^\top W g_N(\theta) = Q_N(\theta)$. Minimizing over the feasible set is the same as minimizing Q_N over θ, and the minimizers correspond one to one. The map $\theta_2 \mapsto \delta(\theta_2)$ is continuous by Proposition 8.22, so local minimizers also correspond. □

The two formulations have the same solutions and different computational properties. MPEC has no inner loop, so there is no inner tolerance and no propagation of inversion error into the objective. The share constraints need hold only at the solution, so the solver does not spend effort on precise inversions at trial values far from the optimum. The constraint Jacobian is sparse, because s_t depends only on δ_t and θ_2. Derivatives can be supplied by automatic differentiation. Against this, the problem has $K_1 + K_2 + N + L$ unknowns, N nonlinear share

constraints and L linear moment constraints. It requires a large-scale constrained solver and careful scaling, and the solver may stop at an infeasible point. Dubé et al. (2012, Section 7) find MPEC faster than NFXP when the contraction is slow. By Corollary 8.16, this happens when outside shares are small. With an outside share of 0.35 in their experiments, MPEC is about 24 times faster (their Table III). Conlon and Gortmaker (2020, Sections 3 and 5) instead use the nested fixed point. They prefer an inner tolerance between 10^{-14} and 10^{-12}. They find SQUAREM the fastest and most reliable way to accelerate the contraction. The choice between the two is a matter of implementation. The statistical properties of the estimator are the same.

Other estimators trade exactness for speed. Lee and Seo (2015, Section 5) linearize the log share function around the current mean utilities and invert this approximation analytically at each trial value. After each minimization they update the point of approximation by one Newton step. The share equations therefore hold exactly only at the optimum. Salanié and Wolak (2019, Sections 2 and 3) expand the inverse share function to second order around zero random coefficients. The resulting approximate model is linear in the mean coefficients and in the variances and covariances of the random coefficients. Two-stage least squares therefore estimates it. These estimates can serve as starting values for the exact estimator. Proposition 8.24 below derives the leading term of such an expansion.

8.6 Instruments and identification

The estimator of Section 8.5 is only as good as its instruments. This section first explains why prices need instruments, how many instruments are needed and which roles they play. It then derives the efficient instruments and reviews the instrument families used in practice. It closes with brand fixed effects and with nonparametric identification.

8.6.1 Price endogeneity

Firms observe ξ_{jt} when they set prices. In a Nash-Bertrand equilibrium the price is marginal cost plus a markup (Chapter 4), and the markup depends on demand, hence on ξ_t. Nevo (2001, eq. 8) writes

$$p_{jt} = mc_{jt} + f(\xi_{jt}, \dots) = (mc_j + f_j) + \big(mc_{jt} - mc_j + f_{jt} - f_j\big),$$

where mc_j and f_j are brand means and the second bracket is the deviation of the market from them. With brand dummies the brand means are absorbed, but the market-specific deviation of the markup still moves with the market-specific deviation of ξ (Nevo, 2001, p. 320).

A single-product logit firm makes the sign transparent. Its first-order condition gives the markup $m_j = p_j - mc_j = \frac{1}{\alpha(1-s_j)}$ (Chapter 7). Hold rivals' prices fixed and define

$$G(m_j, \xi_j) = m_j - \frac{1}{\alpha\big(1 - s_j(m_j, \xi_j)\big)},$$

where s_j is the logit share at price $mc_j + m_j$. The optimal markup solves $G(m_j, \xi_j) = 0$. The logit derivatives are $\frac{\partial s_j}{\partial m_j} = -\alpha s_j(1 - s_j)$ and $\frac{\partial s_j}{\partial \xi_j} = s_j(1 - s_j)$. By the chain rule,

$$\frac{\partial}{\partial m_j}\frac{1}{\alpha(1-s_j)} = \frac{1}{\alpha(1-s_j)^2}\frac{\partial s_j}{\partial m_j} = -\frac{s_j}{1-s_j},$$
$$\frac{\partial}{\partial \xi_j}\frac{1}{\alpha(1-s_j)} = \frac{1}{\alpha(1-s_j)^2}\frac{\partial s_j}{\partial \xi_j} = \frac{s_j}{\alpha(1-s_j)}.$$

Hence

$$\frac{\partial G}{\partial m_j} = 1 + \frac{s_j}{1 - s_j} = \frac{1}{1 - s_j}, \qquad \frac{\partial G}{\partial \xi_j} = -\frac{s_j}{\alpha(1 - s_j)}.$$

The implicit function theorem then gives the response of the best-response markup to unobserved quality,

$$\frac{\partial m_j}{\partial \xi_j} = -\frac{\partial G}{\partial \xi_j}\left(\frac{\partial G}{\partial m_j}\right)^{-1} = \frac{s_j}{\alpha(1 - s_j)}(1 - s_j) = \frac{s_j}{\alpha} > 0.$$

A better unobserved product sells more and carries a higher markup. This comparative static holds marginal cost fixed, so the sign of $\mathrm{Cov}(p_{jt}, \xi_{jt})$ also depends on how costs move with ξ_{jt}. In this logit example the covariance is positive when marginal cost is independent of ξ_{jt} or increases with it, as when better products cost more to make. If cost falls with unobserved quality fast enough, the covariance can be zero or negative.

Consider the logit estimating equation $\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$ and let $\tilde{p}_{jt}$ be the residual from projecting p_{jt} on x_{jt}. By the Frisch-Waugh theorem the OLS coefficient on price satisfies

$$\operatorname{plim} \widehat{(-\alpha)}_{OLS} = -\alpha + \frac{\mathrm{Cov}(\tilde{p}_{jt}, \xi_{jt})}{\mathrm{Var}(\tilde{p}_{jt})}.$$

When x_{jt} is uncorrelated with ξ_{jt}, $\mathrm{Cov}(\tilde{p}_{jt}, \xi_{jt}) = \mathrm{Cov}(p_{jt}, \xi_{jt})$. If this covariance is positive, the estimated price coefficient is biased toward zero, and demand looks too inelastic. Random coefficients do not remove the problem, since ξ_{jt} enters δ_{jt} in the same way.

The cost condition matters. Take one product per market, $\alpha = 1$, no characteristics other than a constant, ξ_j uniform on $[-0.2, 0.2]$ and marginal cost $mc_j = 1 - \xi_j - e^{2\xi_j - 2}$, which is positive on this range. The pricing condition then gives $p_j = 2 - \xi_j$, with markup $1 + e^{2\xi_j - 2}$. Hence $\mathrm{Cov}(p_j, \xi_j) = -\mathrm{Var}(\xi_j)$, and the OLS price coefficient converges to -2 instead of -1. Least squares now overstates price sensitivity. The case for instruments does not depend on the sign. Equilibrium prices respond to ξ_{jt}, and OLS is inconsistent whenever the covariance is nonzero.

In the leading applications the evidence points to a positive covariance. In the automobile data of Berry et al. (1995, Table III), the OLS logit price coefficient is -0.089 (0.004). It implies that 1,494 of the 2,217 models have inelastic demand, which is inconsistent with profit maximization. With instruments the coefficient becomes -0.216 (0.123), and only 22 models have inelastic demand (pp. 873–874). In the cereal data of Nevo (2001, Table V), the OLS logit coefficient with brand dummies is -7.26 (0.16). The same specification instrumented with prices in other cities gives -17.57 (0.50) (columns ii and v). Sections 8.11 and 8.13 present these tables in full.

8.6.2 How many instruments, and what they must do

The order condition of Section 8.5.2 counts the instruments. The exogenous characteristics in x_{jt} serve as their own instruments. The remaining instruments must be at least as many as the endogenous variables in the mean utility (usually price alone) plus the number of nonlinear parameters. A model with one random coefficient per characteristic and on price needs $K + 2$ excluded instruments, where K is the number of characteristics: one for price and $K + 1$ for Σ.

The instruments play two distinct roles. Some must shift prices, as in any demand system. Others must shift what Berry and Haile (2014, Section 7) call "quantities," the market shares that enter the inverse demand function. Berry and Haile (2024, p. 1136, n. 2) note that instruments for quantities are what the applied literature informally calls instruments for the "nonlinear

parameters." The next result shows concretely why the nonlinear parameters need their own source of variation.

Proposition 8.24 (Small-σ expansion of the inverse)**.** *Suppose there is a single random coefficient, $\mu_{ijt} = \sigma \nu_i x_{jt}$, with ν_i symmetric about zero, $\mathbb{E}[\nu_i^2] = 1$ and $\mathbb{E}[e^{c|\nu_i|}] < \infty$ for all $c > 0$, as for the standard normal. Normalize $x_{0t} = 0$ for the outside good and let $\bar{x}_t = \sum_{m=0}^{J_t} s_{mt} x_{mt}$ be the share-weighted mean of the characteristic. Then the inverted mean utility satisfies*

$$\delta_{jt}(s_t; \sigma) = \ln \frac{s_{jt}}{s_{0t}} - \frac{\sigma^2}{2} x_{jt}\big(x_{jt} - 2\bar{x}_t\big) + O(\sigma^4).$$

Proof. Drop t. Let $K(\tau) = \ln \sum_{m=0}^{J} e^{\delta_m + \tau x_m}$ with $\delta_0 = 0$. For a consumer with $\tau = \sigma \nu_i$, $\ln s_{ij} = \delta_j + \tau x_j - K(\tau)$. The function K is the cumulant generating function of x under the logit probabilities $s_m^L(\delta) = e^{\delta_m - K(0)}$. Hence $K'(0) = \sum_m s_m^L x_m \equiv \bar{x}^L$ and $K''(0) = \sum_m s_m^L x_m^2 - (\bar{x}^L)^2 \equiv V^L$. A second-order expansion gives

$$\ln s_{ij} - \ln s_j^L = \tau(x_j - \bar{x}^L) - \frac{\tau^2}{2} V^L + O(\tau^3).$$

Exponentiating,

$$\frac{s_{ij}}{s_j^L} = 1 + \tau(x_j - \bar{x}^L) + \frac{\tau^2}{2}\big[(x_j - \bar{x}^L)^2 - V^L\big] + c_j \tau^3 + R_{ij},$$

for a constant c_j and a remainder bounded by $C\tau^4 e^{C|\tau|}$ for some constant C. Integrating over ν_i removes the linear and cubic terms, because ν_i is symmetric, and $\mathbb{E}[\tau^2] = \sigma^2$. The moment condition on ν_i makes the expected remainder of order σ^4. So

$$\ln s_j = \ln s_j^L + \frac{\sigma^2}{2}\big[(x_j - \bar{x}^L)^2 - V^L\big] + O(\sigma^4), \qquad j = 0, 1, \dots, J.$$

Subtract the equation for $j = 0$, where $x_0 = 0$, and use $\ln s_j^L - \ln s_0^L = \delta_j$:

$$\ln \frac{s_j}{s_0} = \delta_j + \frac{\sigma^2}{2}\big[(x_j - \bar{x}^L)^2 - (\bar{x}^L)^2\big] + O(\sigma^4) = \delta_j + \frac{\sigma^2}{2} x_j (x_j - 2\bar{x}^L) + O(\sigma^4).$$

Finally, the logit shares differ from the true shares by $O(\sigma^2)$, so replacing $\bar{x}^L$ by $\bar{x}$ changes the right-hand side by $O(\sigma^4)$. Solving for δ_j gives the result. □

We checked the expansion numerically in a market with four products. Their shares are 0.20, 0.15, 0.10 and 0.05, and their characteristic values are 0.5, 1.0, 1.5 and 2.5. At $\sigma = 0.1$ the exact inverse differs from the logit inversion by up to 1.8×10^{-2}. It differs from the approximation by at most 8.3×10^{-5}. The ratio of this error to σ^4 stays near 0.8 as σ falls from 0.4 to 0.05.

Substituting the expansion into (8.55) gives, to second order,

$$\xi_{jt}(\theta) \approx \ln \frac{s_{jt}}{s_{0t}} - x_{jt}\beta + \alpha p_{jt} - \frac{\sigma^2}{2} x_{jt}\big(x_{jt} - 2\bar{x}_t\big).$$

The parameter σ^2 multiplies a constructed regressor that depends on the shares through $\bar{x}_t$. Shares respond to ξ, so this regressor is endogenous, and estimating σ requires an instrument that predicts it, and predicts it separately from price. A cost shifter can do this in principle,

because it moves shares and hence $\bar{x}_t$. In practice its variation in the constructed regressor is often weak relative to its variation in price, so identification of σ through cost shifters alone tends to be fragile. Natural candidates are functions of the characteristics of the other products in the market, which shift $\bar{x}_t$ directly. The regressor also involves the squared distance of x_{jt} from the market average. This is the logic behind the differentiation instruments of Section 8.6.4.

Nevo (2000a, pp. 529–530) gives the economic intuition. Suppose products A and B have similar characteristics, products B and C have equal shares, and the price of A rises. The logit predicts equal share gains for B and C, while the random coefficients model allows B to gain more. The observed relative change in the shares of B and C distinguishes the models, and its size identifies the parameters of the taste distribution. Data from more markets help, especially when products enter, exit or change characteristics. Choice-set variation of this kind helps identify the variance of the random tastes. Nevo (2000a, p. 541) and Nevo (2001, p. 330, n. 27) point to its absence in their data to explain imprecise estimates of Σ. Identifying the coefficients on demographics, Π, requires markets with different distributions of demographics (Nevo, 2000a, p. 529).

Berry et al. (1995, p. 877) explain why the mean and the variance of a taste are separately identified. A high mean taste for horsepower and a high variance both raise the share of powerful cars. The two explanations differ in substitution. With zero variance, consumers who leave a powerful car after a price increase do not favor other powerful cars. With a large variance, the consumers who leave are those who value horsepower most, and they move disproportionately to other powerful cars. BLP add that they "had much more difficulty estimating separate mean and variance terms from a single cross section" than from the panel (n. 30).

8.6.3 Optimal instruments

The conditional moment restriction (8.53) makes every function of $\mathcal{Z}_t$ a valid instrument. Some functions are more informative than others. Chamberlain (1987) characterizes the best choice.[4] Consider a scalar residual with $\mathbb{E}[\xi(\theta_0) \mid \mathcal{Z}] = 0$ and conditional variance $\varkappa^2(\mathcal{Z})$, and let

$$\mathcal{D}(\mathcal{Z}) = \mathbb{E}\left[\frac{\partial \xi(\theta_0)}{\partial \theta} \,\middle|\, \mathcal{Z}\right]$$

be the expected derivative of the residual, a column vector of dimension $\dim \theta$.

Proposition 8.25 (Optimal instruments)**.** *Consider GMM estimators based on exactly identifying moments $\mathbb{E}[h(\mathcal{Z})\xi(\theta)] = 0$, where h has dimension $\dim \theta$. Their asymptotic variance is*

$$\left(\mathbb{E}[h\mathcal{D}^\top]\right)^{-1} \mathbb{E}[hh^\top \varkappa^2] \left(\mathbb{E}[\mathcal{D}h^\top]\right)^{-1}.$$

It is minimized by $h^*(\mathcal{Z}) = \frac{\mathcal{D}(\mathcal{Z})}{\varkappa^2(\mathcal{Z})}$, and the minimal variance is $\left(\mathbb{E}[\mathcal{D}\mathcal{D}^\top \varkappa^{-2}]\right)^{-1}$.

Proof. Define $u = h\varkappa$ and $v = \frac{\mathcal{D}}{\varkappa}$. Then $\mathbb{E}[h\mathcal{D}^\top] = \mathbb{E}[uv^\top]$ and $\mathbb{E}[hh^\top \varkappa^2] = \mathbb{E}[uu^\top]$. We must show

$$\mathbb{E}[uv^\top]^{-1}\mathbb{E}[uu^\top]\mathbb{E}[vu^\top]^{-1} - \mathbb{E}[vv^\top]^{-1} \geq 0.$$

This is equivalent to $\mathbb{E}[vv^\top] - \mathbb{E}[vu^\top]\mathbb{E}[uu^\top]^{-1}\mathbb{E}[uv^\top] \geq 0$, by taking inverses of both sides of the inequality between positive definite matrices. Let $\Gamma = \mathbb{E}[vu^\top]\mathbb{E}[uu^\top]^{-1}$. The left side

[4] Berry et al. (1995) cite this paper as Chamberlain (1986), *Journal of Econometrics* 33. It appeared in volume 34 in 1987.

equals $\mathbb{E}[(v - \Gamma u)(v - \Gamma u)^\top]$, the second moment of a projection residual, which is positive semidefinite. Equality holds when u is proportional to v, that is, when $h \propto \frac{\mathcal{D}}{\kappa^2}$. □

For BLP, let

$$\mathcal{D}_j(\mathcal{Z}) = \mathbb{E}\Big[\frac{\partial \xi_j(\theta_0, s^0, P_0)}{\partial \theta}, \; \frac{\partial \omega_j(\theta_0, s^0, P_0)}{\partial \theta} \Big| \mathcal{Z} \Big]$$

be the dim $\theta \times 2$ matrix of expected derivatives. The standardized errors $r_j = T(z_j)(\xi_j, \omega_j)^\top$ have identity conditional variance, and their expected derivative matrix is $\mathcal{D}_j(\mathcal{Z})T(z_j)^\top$. The optimal instruments for the standardized errors are therefore

$$H_j(\mathcal{Z}) = \mathcal{D}_j(\mathcal{Z})\, T(z_j)^\top, \qquad \text{so that} \qquad H_j r_j = \mathcal{D}_j(\mathcal{Z})\, \Upsilon(z_j)^{-1} \begin{pmatrix} \xi_j \\ \omega_j \end{pmatrix},$$

with asymptotic variance $\{\mathbb{E}_{\mathcal{Z}}[\mathcal{D}_j(\mathcal{Z})\Upsilon(z_j)^{-1}\mathcal{D}_j(\mathcal{Z})^\top]\}^{-1}$. Berry et al. (1995, eq. 5.7) print $\mathcal{D}_j T(z_j)$ without the transpose. The two coincide when T is the symmetric inverse square root $\Upsilon(z_j)^{-\frac{1}{2}}$, which we adopt whenever a choice of T matters. The formula gives more weight to observations whose computed unobservables are sensitive to θ. For the demand error alone, $\frac{\partial \xi_{jt}}{\partial \beta} = -x_{jt}$, $\frac{\partial \xi_{jt}}{\partial \alpha} = p_{jt}$ and $\frac{\partial \xi_{jt}}{\partial \theta_2} = \frac{\partial \delta_{jt}}{\partial \theta_2}$ from Proposition 8.22. The optimal instrument for α is the expected equilibrium price given the exogenous variables. The optimal instruments for θ_2 are the expected derivatives of the inverted mean utilities.

These objects are hard to compute (Berry et al., 1995, p. 860). One would have to solve for the equilibrium prices for many draws of (ξ, ω), differentiate at the equilibrium, and integrate. This requires a rule for selecting among multiple equilibria and knowledge of the joint distribution of (ξ, ω). Newey (1990) shows that a nonparametric first-stage estimate of $\mathcal{D}_j$, for example a polynomial series, attains the efficiency bound. Here the arguments of $\mathcal{D}_j$ include the characteristics of all J products. An unrestricted series of fixed order then has a number of terms that grows polynomially in J, which is also the dimension along which the sample grows (Berry et al., 1995, p. 860).

Berry et al. (1995, pp. 860–861) use exchangeability to break this curse of dimensionality, following Pakes (1994). The demand and cost functions of product j do not depend on the order in which the other products are listed. A firm's pricing function does change if we swap one of its own products with a rival's. A unique Nash equilibrium is still *partially exchangeable*. The functions ξ_j and ω_j are unchanged when we permute the order of the competing firms, the order of a given competitor's products, or the order of the firm's own other products. Theorem 32 of Pakes (1994) shows that the dimension of a polynomial basis of given order with these symmetries does not depend on the number of products. For the k-th characteristic of product j of firm f, the first-order basis functions are

$$z_{jk}, \qquad \sum_{r \neq j,\; r \in \mathcal{J}_f} z_{rk}, \qquad \sum_{r \notin \mathcal{J}_f} z_{rk}, \tag{8.64}$$

which is equation (5.8) of Berry et al. (1995). The first-order basis has $3K$ terms instead of JK. Because one characteristic is the constant, the numbers of own-firm and rival products are among the instruments.

Berry et al. (1995, p. 862) do not project $\mathcal{D}_j$ on the basis, as Newey's method would suggest. They enter the basis functions directly as instruments in GMM with the efficient weighting matrix. When $\mathcal{D}_j$ is linear in the basis and T is constant, the two procedures have the same limiting distribution, and the GMM version is easier to compute. Higher-order terms were nearly collinear with the first-order terms, and even the first-order matrix was close to singular (p. 861).

A feasible approximation

Berry et al. (1999, Appendix, p. 429) propose an approximation to the optimal instruments. Berry (1994, p. 258) already notes that such approximations were developed in the working-paper version of Berry et al. (1995). Berry and Pakes (2007, Section 5.3.1, n. 17) tried the approximation of the 1999 paper in their Monte Carlo work and found that it had little effect on their results. The approximation evaluates the derivatives at the expectation of the unobservables, $\xi = \omega = 0$. Reynaert and Verboven (2014, Section 2.4) and Conlon and Gortmaker (2020, Section 4, Algorithm 2) study and implement this approach. The steps are as follows.

(i) Estimate $\hat{\theta}$ with simple instruments such as (8.64).

(ii) Construct exogenous prices $\hat{p}_{jt}$. One option solves for the equilibrium prices implied by $\hat{\theta}$ with $\xi = \omega = 0$, which requires a supply model. Another option uses the fitted values of a regression of prices on exogenous variables.

(iii) Set $\hat{\delta}_{jt} = x_{jt}\hat{\beta} - \hat{\alpha}\hat{p}_{jt}$, the mean utility with $\xi = 0$, and compute $\frac{\partial \delta_{jt}}{\partial \theta_2}$ by Proposition 8.22 at $(\hat{\delta}_t, \hat{p}_t)$.

(iv) Use $\left(x_{jt}, \hat{p}_{jt}, \frac{\partial \hat{\delta}_{jt}}{\partial \theta_2^{\top}}\right)$ as the instrument vector, one instrument per parameter, and re-estimate.

The approximation ignores the nonlinearity of the expectation in ξ, but it captures how the derivatives depend on the configuration of products. In Monte Carlo experiments, Reynaert and Verboven (2014, Sections 4 and 5) find that such instruments reduce bias and greatly improve precision relative to sums of rival characteristics. They also improve stability. In their baseline design about 15 percent of the estimates of σ lie near zero with standard instruments. This spike almost disappears with the approximate optimal instruments. In their application to European car demand with three random coefficients, the standard errors of the estimated σ fall by a factor of 5 to 7 (their Section 7).

8.6.4 Instrument families

This subsection reviews the instruments used in practice. For each family we state what it assumes and what can go wrong. No family is valid everywhere. Nevo (2000a, p. 536) concludes that validity "is an empirical issue" to be resolved by comparing instrument sets, adding data, and using knowledge of the industry.

Cost shifters

Variables that shift marginal cost and are excluded from utility are the textbook instruments. Product-level cost data are rarely available (Nevo, 2000a, p. 534). In BLP, miles per gallon and a time trend enter cost but not utility, and miles per dollar enters utility but not cost. The cost-only variables were nearly collinear with the other instruments, so BLP left them out of the demand-side list and used 15 demand-side instruments. On the cost side, the three terms of (8.64) for each of the six cost characteristics plus miles per dollar give 19 instruments. The total is 34 moments (Berry et al., 1995, p. 862). Nevo (2001, p. 321) proxies city-level distribution costs by region dummies for transport costs, city density for the cost of space, and supermarket-sector earnings from the CPS Monthly Earnings Files.

Characteristics of other products

The *BLP instruments* are the sums (8.64) over the firm's other products and over rival products. Their logic is that a product with close substitutes has a low markup, and the characteristics of own-firm and rival products affect markups differently (Berry et al., 1995, p. 855). They vary across products, and they vary over time as products enter and exit (Berry et al., 1995, p. 861). Their validity requires $\mathbb{E}[\xi_{jt} \mid x_t] = 0$. This is questionable whenever firms choose characteristics knowing ξ. A firm that knows its product has an appealing unobserved feature may also give it more horsepower, and rivals may position near successful products. Choosing characteristics before prices does not help, since the firm already knows ξ when it designs the product. The assumption also makes counterfactuals short-run, because they hold characteristics fixed while firms would reposition in the long run. The instruments are also inefficient. Any function of x_t is valid under the assumption, and ad hoc sums do not reproduce the optimal instruments of Section 8.6.3.

Brand fixed effects remove most of the variation in these instruments. Suppose each brand's characteristics are fixed and the choice set does not change across markets. Then the sum of rivals' characteristics for product j is the same in every market, and it is collinear with the brand dummy. Nevo (2001, p. 320) reports that the instrument matrix is then "essentially singular," except that one product was missing in some quarters. He uses the brand dummies themselves as instruments in a specification without brand effects, "a nonparametric way to use all the information contained in the characteristics." The price coefficient is −8.17 (0.11), close to the OLS value with brand dummies (Nevo, 2001, Table V, col. iv). In a panel with a fixed set of brands, these moments require the brand mean of ξ to be zero for every brand.

The strength of BLP instruments is also a concern. In a logit market with single-product firms the markup $\frac{1}{\alpha(1-s_j)}$ converges to $\frac{1}{\alpha}$ as the number of products grows and shares shrink. Rival characteristics then have a vanishing effect on prices. Holding prices fixed, $\frac{\partial s_j}{\partial x_{rk}} = -s_j s_r \beta_k$, which is of order $\frac{1}{J^2}$, so the sum over J rivals moves s_j, and hence the markup, by order $\frac{1}{J}$. Armstrong (2016, Section 3) formalizes this point with asymptotics in the number of products. If markups converge to a constant faster than the rate $\frac{1}{\sqrt{J}}$, estimates based on BLP instruments are inconsistent. This happens in the logit and random coefficients logit models with single-product firms and no random coefficient on price. Cost shifters move prices directly and keep their power. Armstrong also finds cases in which BLP instruments remain informative, for example logit demand with a fixed number of asymmetric multiproduct firms. First-stage diagnostics for weak instruments (Appendix A) should be reported.

Prices in other markets

Hausman et al. (1994) and Hausman (1997) use the panel structure of scanner data, in the multi-level demand systems of Chapters 5 and 10. Their model of the price of brand j in city n and period t is

$$\ln p_{jnt} = \lambda_j \ln c_{jt} + a_{jn} + e_{jnt},$$

(Hausman et al., 1994, p. 164, eq. 4). Here c_{jt} is a cost common to all cities, a_{jn} is a city-specific brand differential, and e_{jnt} is a local shock such as a promotion. After brand and city effects are removed, prices in different cities move together because of the common cost. If the local shocks are independent across cities, the price in one city is a valid instrument for the price in another (p. 165). To see the conditions, let $z_{jnt} = \frac{1}{C-1} \sum_{n' \neq n} \ln p_{jn't}$ be the average log price in

the other $C-1$ cities. Then

$$\operatorname{Cov}(z_{jnt}, \xi_{jnt}) = \lambda_j \operatorname{Cov}(\ln c_{jt}, \xi_{jnt}) + \frac{1}{C-1} \sum_{n' \neq n} \operatorname{Cov}(e_{jn't}, \xi_{jnt}),$$

which is zero if costs are uncorrelated with local demand shocks and the local price shocks of other cities are uncorrelated with the demand shock of city n. Relevance comes from the common cost, since $\operatorname{Cov}(z_{jnt}, \ln p_{jnt})$ contains $\lambda_j^2 \operatorname{Var}(\ln c_{jt})$. The *Hausman instruments* of Nevo (2001, pp. 320–321) are regional quarterly average prices of the brand, excluding the city being instrumented, in all twenty quarters. He makes no claim that they are optimal (n. 18).

The identifying assumption fails under common demand shocks. A national discovery that fiber reduces the risk of cancer would raise the valuation of fiber-rich cereals in all cities, and prices everywhere would respond (Nevo, 2001, p. 321). Advertising or promotions coordinated across city borders would correlate local shocks within a region. Nevo (2001, p. 321) offers mitigations: well-established brands with less systematic shocks, time dummies for aggregate shocks, the large size of the IRI cities and Census regions, and controls for demographics and heterogeneity. He compares the estimates with those from his cost proxies and finds them similar. Prices in other markets are proxies for costs, which is how Berry and Haile (2014, p. 1761) classify them.

Market-level demographics

When the distribution of consumer demographics differs across markets, equilibrium markups differ too. A market with many high-income consumers supports higher markups on luxury goods. Berry and Haile (2024, Section 5.3) call market-level observables that alter equilibrium markups *Waldfogel instruments*, after Waldfogel (2003). They are excluded from demand when individual demographics enter utility directly, which is most credible with consumer-level data (Section 8.8).

Differentiation instruments

Gandhi and Houde (2019, Section 2.3) propose instruments built from the differences $x_{rk} - x_{jk}$ between a product and its rivals in characteristic space. Examples are the sum of squared differences $\sum_{r \neq j} (x_{rk} - x_{jk})^2$ and the number of rivals within a threshold distance of x_{jk}, such as one standard deviation of characteristic k. Suppose the demand shocks are exchangeable and the characteristics are exogenous. Their Proposition 2 then writes the reduced form as a symmetric function of these differences plus a market-specific constant. With endogenous prices, they extend this logic to differences in predicted prices through a heuristic approximation. Proposition 8.24 gives a simple version of this logic, since the constructed regressor involves the squared distance of x_{jt} from the market mean. Differentiation instruments rely on the same exogeneity of characteristics as BLP instruments.

8.6.5 Brand fixed effects and minimum distance

With several markets one can include a dummy for each brand. Nevo (2000a, pp. 536–538) and Nevo (2001, pp. 322–323) argue that brand effects should be used whenever possible. Suppose the characteristics x_j of brand j are fixed across markets. Decompose the unobservable as

$$\xi_{jt} = \xi_j + \xi_t + \tilde{\xi}_{jt},$$

a brand mean, a market (or time) effect and a market-specific deviation. The mean utility becomes

$$\delta_{jt} = d_j + \xi_t - \alpha p_{jt} + \tilde{\xi}_{jt}, \qquad d_j = x_j\beta + \xi_j.$$

The brand effect d_j absorbs both the mean valuation of the observed characteristics and the brand mean of unobserved quality. The correlation between prices and ξ_j "is fully accounted for and does not require an instrument" (Nevo, 2001, p. 322). Instruments are still needed for the correlation between prices and $\tilde{\xi}_{jt}$, as Section 8.6.1 explained. The brand effects improve the fit of the mean utility, while substitution patterns are still driven by the observed characteristics in μ_{ijt}.

Two objections arise (Nevo, 2000a, p. 537). The first is that brand dummies reintroduce the dimensionality problem that discrete choice models were meant to solve. They do not, since the number of parameters grows with J and not with J^2, and the dummies are linear parameters that Proposition 8.20 handles at almost no cost. The second objection is that β seems unidentified once the dummies absorb $x_j\beta$. Nevo recovers β by *minimum distance* (Chamberlain, 1982). Stack the J brand effects as $d = (d_1, \dots, d_J)^\top$, the characteristics as the $J \times K$ matrix $\boldsymbol{X}_b$ with $K < J$, and the brand means of unobserved quality as $\xi_b = (\xi_1, \dots, \xi_J)^\top$. Then

$$d = \boldsymbol{X}_b\beta + \xi_b.$$

Assume $\mathbb{E}[\xi_b \mid \boldsymbol{X}_b] = 0$ and let $\hat{d}$ be the estimated brand effects with estimated covariance matrix V_d. The minimum distance estimator solves

$$\min_\beta (\hat{d} - \boldsymbol{X}_b\beta)^\top V_d^{-1} (\hat{d} - \boldsymbol{X}_b\beta).$$

The first-order condition $\boldsymbol{X}_b^\top V_d^{-1}(\hat{d} - \boldsymbol{X}_b\beta) = 0$ gives

$$\hat{\beta} = (\boldsymbol{X}_b^\top V_d^{-1} \boldsymbol{X}_b)^{-1} \boldsymbol{X}_b^\top V_d^{-1} \hat{d}, \qquad \hat{\xi}_b = \hat{d} - \boldsymbol{X}_b\hat{\beta}, \tag{8.65}$$

as in Nevo (2000a, p. 537) and Nevo (2001, p. 322). This is a GLS regression with J "observations," one per brand, weighted by the covariance of the estimated brand effects. Under the restricted model with $\xi_b = 0$, the minimized value $(\hat{d} - \boldsymbol{X}_b\hat{\beta})^\top V_d^{-1}(\hat{d} - \boldsymbol{X}_b\hat{\beta})$ is the chi-square statistic of Chamberlain (1982) with $J - K$ degrees of freedom.

Three features of this step deserve emphasis. First, the assumption $\mathbb{E}[\xi_b \mid \boldsymbol{X}_b] = 0$ is the one that justifies characteristics as instruments, but here it is used only to recover the taste parameters. It does not affect the estimate of price sensitivity (Nevo, 2001, p. 322, n. 19). Second, the chi-square test of $\xi_b = 0$ asks whether the characteristics explain the brand effects completely. It is typically rejected, which only confirms that unobserved quality matters. Third, when $\xi_b \neq 0$ the weight V_d reflects only the estimation error in $\hat{d}$ and ignores $\mathrm{Var}(\xi_b)$. The estimator of β remains consistent as the number of brands grows. Its precision is governed by the number of brands, whatever the number of markets, and standard errors based on V_d alone understate the uncertainty.

8.6.6 Nonparametric identification with market data*

The previous subsections relied on parametric assumptions. Berry and Haile (2014) ask whether those assumptions are essential for identification, or whether they play only their usual roles of approximation and extrapolation. They show that the primary requirement is the availability of suitable instruments, and they clarify which instruments are needed. Their analysis formalizes the informal argument of Berry et al. (1995, p. 855, n. 13), who note that they "use identification in an informal sense."

The model

Each consumer i in market t chooses one good from $\mathcal{J} = \{0, 1, \dots, J\}$. A market is described by $\chi_t = (x_t, p_t, \xi_t)$: observed exogenous characteristics $x_{jt} \in \mathbb{R}^K$, a scalar unobservable ξ_{jt} for each product, and a scalar endogenous characteristic p_{jt}, called price. Consumer utilities $(v_{i1t}, \dots, v_{iJt})$, normalized by $v_{i0t} = 0$, are drawn from a distribution $F_v(\cdot \mid \chi_t)$, independently across consumers and markets. The demand function is

$$s_j(\chi_t) = \mathbb{P}\Big(\arg\max_{k \in \mathcal{J}} v_{ikt} = j \,\Big|\, \chi_t \Big), \qquad j = 0, \dots, J,$$

as in equation (1) of Berry and Haile (2014), with $s_j(\chi_t) > 0$ for all j. Nothing so far restricts how χ_t affects utilities, apart from the restriction to one unobservable per product.

The key restriction is an index. Partition $x_{jt} = (x_{jt}^{(1)}, x_{jt}^{(2)})$ with $x_{jt}^{(1)} \in \mathbb{R}$ and define the linear indices

$$\delta_{jt} = x_{jt}^{(1)} \beta_j + \xi_{jt}, \qquad j = 1, \dots, J,$$

which is their equation (2). The index differs from the BLP mean utility, since it contains only the one characteristic that is a perfect substitute for ξ_{jt}.

Assumption 8.26 (Index, Berry and Haile, 2014, Assumption 1)**.** $F_v(\cdot \mid \chi_t) = F_v(\cdot \mid \delta_t, x_t^{(2)}, p_t)$.

The assumption says that $x_{jt}^{(1)}$ and ξ_{jt} affect utilities only through δ_{jt}. The marginal rate of substitution between the two is constant. Prices and the other characteristics may enter in any way. The linear random coefficients model $v_{ijt} = x_{jt}\beta_{it} - \alpha_{it} p_{jt} + \xi_{jt} + \epsilon_{ijt}$ satisfies the assumption whenever one characteristic has a degenerate (nonrandom) coefficient, as is common in applications (their Example 1). The model generalizes BLP by allowing any distribution of the random coefficients, any correlation among them, and even utilities that depend on other products' characteristics. Because ξ_{jt} has no natural location or scale, we normalize $\beta_j = 1$, so that $\delta_{jt} = x_{jt} + \xi_{jt}$ with x_{jt} now denoting $x_{jt}^{(1)}$, and later $\mathbb{E}[\xi_{jt}] = 0$. We hold $x_t^{(2)}$ fixed and suppress it, and write $s_j(\delta_t, p_t)$.

The second assumption ensures that demand can be inverted.

Definition 8.27 (Connected substitutes, Berry et al., 2013)**.** Let λ_t denote either $-p_t$ or δ_t. Goods $0, 1, \dots, J$ are *connected substitutes* in λ_t if both of the following hold.

(i) For all $j > 0$ and $k \neq j$, $s_k(\delta_t, p_t)$ is nonincreasing in λ_{jt}.

(ii) Take any (δ_t, p_t) in the support and any nonempty $\mathcal{K} \subseteq \{1, \dots, J\}$. There exist $k \in \mathcal{K}$ and $\ell \notin \mathcal{K}$ such that $s_\ell(\delta_t, p_t)$ is strictly decreasing in λ_{kt}.

Assumption 8.28 (Berry and Haile, 2014, Assumption 2)**.** Goods $0, 1, \dots, J$ are connected substitutes in $-p_t$ and in δ_t.

Part (i) requires weak gross substitutes. Part (ii) requires enough strict substitution that no strict subset of inside goods substitutes only within itself. It holds if each v_{ijt} is strictly increasing in δ_{jt} and in $-p_{jt}$ and is unaffected by other products' indices and prices. The assumption allows an increase in δ_{jt} to lower the utility of some consumers, so x_{jt} and ξ_{jt} need not be vertical characteristics (their n. 17).

Lemma 8.29 (Berry and Haile, 2014, Lemma 1)**.** *Consider any price vector p and any share vector s with $s_j > 0$ for all j and $\sum_{j=1}^J s_j < 1$. Under Assumptions 8.26 and 8.28, there is at most one vector δ such that $s_j(\delta, p) = s_j$ for all j.*

The lemma, proved by Berry et al. (2013), generalizes Theorem 8.14 far beyond the logit family. For any (s_t, p_t) in the support we can write $\delta_{jt} = s_j^{-1}(s_t, p_t)$, or

$$x_{jt} + \xi_{jt} = s_j^{-1}(s_t, p_t), \qquad j = 1, \dots, J, \tag{8.66}$$

which is their equation (6).

Identification of demand

Equation (8.66) resembles a nonparametric regression with endogenous regressors, but with a twist. In the standard model of Newey and Powell (2003) the dependent variable is endogenous and an unknown function of other endogenous variables is subtracted. Here all endogenous variables (s_t, p_t) sit inside the unknown function s_j^{-1}, and the exogenous x_{jt} enters with a known coefficient. Let z_t denote instruments excluded from demand, such as cost shifters or prices in other markets.

Assumption 8.30 (Exclusion, Berry and Haile, 2014, Assumption 3)**.** For all $j = 1, \dots, J$, $\mathbb{E}[\xi_{jt} \mid z_t, x_t] = 0$ almost surely.

Assumption 8.31 (Completeness, Berry and Haile, 2014, Assumption 4)**.** For all functions $B(s_t, p_t)$ with finite expectation, if $\mathbb{E}[B(s_t, p_t) \mid z_t, x_t] = 0$ almost surely, then $B(s_t, p_t) = 0$ almost surely.

Completeness is the nonparametric analog of the rank condition. It requires the instruments to move the endogenous variables (s_t, p_t) enough that any function of them can be distinguished from any other through the exogenous variation. Both z_t and x_t are needed. The vector x_t has only J elements, while (s_t, p_t) has $2J$, and z_t can affect shares only through prices (Berry and Haile, 2014, p. 1762).

Theorem 8.32 (Berry and Haile, 2014, Theorem 1)**.** *Suppose Assumptions 8.26, 8.28, 8.30 and 8.31 hold. Then for all j, (i) ξ_{jt} is identified with probability one for all t. (ii) The demand function $s_j(\chi_t)$ is identified on the support of χ_t.*

Proof. Take expectations of (8.66) conditional on (z_t, x_t):

$$\mathbb{E}[\xi_{jt} \mid z_t, x_t] = \mathbb{E}\left[s_j^{-1}(s_t, p_t) \mid z_t, x_t\right] - x_{jt}.$$

By Assumption 8.30, $\mathbb{E}[s_j^{-1}(s_t, p_t) \mid z_t, x_t] - x_{jt} = 0$ almost surely. Suppose another function $\tilde{s}_j^{-1}$ satisfies the same equation. Let $B(s_t, p_t) = s_j^{-1}(s_t, p_t) - \tilde{s}_j^{-1}(s_t, p_t)$. Subtracting the two equations gives $\mathbb{E}[B(s_t, p_t) \mid z_t, x_t] = 0$ almost surely. Assumption 8.31 then forces $B = 0$ almost surely, so s_j^{-1} is identified. Repeating for each j, (8.66) determines each ξ_{jt}, which proves (i). Since shares are observed and all arguments of $s_j(\chi_t)$ are now known, (ii) follows. □

The argument of Newey and Powell (2003) carries over once we note that x_{jt} plays the role of a known regressor. Berry and Haile (2014, Appendix B) also replace the linear index by a nonseparable index $\delta_{jt} = \delta_j(x_{jt}, \xi_{jt})$ that is strictly increasing in ξ_{jt}. This extension uses the stronger instrumental variable conditions of Chernozhukov and Hansen (2005).

Welfare

In general, changes in individual welfare are not identified from market data. Aggregate consumer surplus is identified under quasilinear preferences. In our notation, Berry and Haile (2014, Assumption 5) require $v_{ijt} = r_{ijt} - p_{jt}$, where the reservation prices $r_{it} = (r_{i1t}, \ldots, r_{iJt})$ are independent of p_t conditional on (x_t, ξ_t). Prices may still be correlated with (x_t, ξ_t) in any way. The change in expected consumer surplus per consumer when prices move from p^0 to p^1 is the line integral

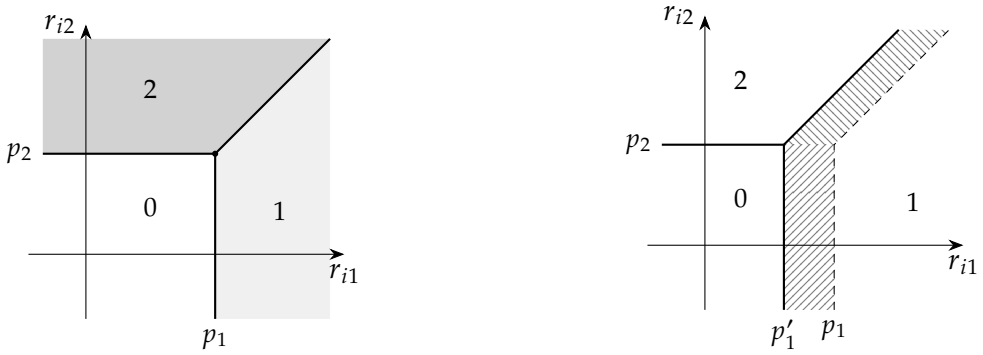
$$\Delta CS = -\int_a^b s\big(\delta_t, \gamma(\tau)\big) \cdot \gamma'(\tau)\, \mathrm{d}\tau,$$

along any piecewise smooth path γ from $\gamma(a) = p^0$ to $\gamma(b) = p^1$. Identification of demand therefore identifies the welfare effect of any price change within a path-connected part of the support of prices. Welfare effects of changes in characteristics require price variation large enough to integrate under the whole left tail of demand.

The distribution of reservation prices satisfies $s_0(\delta_t, p_t) = F_r(p_t \mid \delta_t)$, because a consumer chooses the outside good exactly when $r_{ijt} < p_{jt}$ for every j (their eq. 7). With large support of prices, this equation alone identifies F_r. With limited support, each demand function contributes information about a region of reservation prices. With $J = 2$ and a density f_r, differentiating $s_0 = F_r(p_1, p_2 \mid \delta_t)$ twice gives

$$f_r(p_1, p_2 \mid \delta_t) = \frac{\partial^2 s_0(\delta_t, p)}{\partial p_1\, \partial p_2}.$$

Figure 8.5 shows the choice regions and how a price cut moves them.



(a) Choice regions at prices (p_1, p_2)

(b) After the price of good 1 falls to p_1'

Figure 8.5: Choice regions in the space of reservation prices (r_{i1}, r_{i2}) with two inside goods and quasilinear utility $v_{ij} = r_{ij} - p_j$. A consumer chooses good 1 when $r_{i1} - p_1$ exceeds both zero and $r_{i2} - p_2$. In panel (b), solid lines are the new boundaries and dashed lines the old ones. Consumers in the hatched vertical strip switch from the outside good to good 1. Consumers in the hatched diagonal band switch from good 2 to good 1. Redrawn after Berry and Haile (2014, Figure 1).

Marginal costs and cost functions

Given demand, a supply model identifies marginal costs through the firms' first-order conditions. Let $\mathcal{D}(\chi_t)$ denote the $J \times J$ matrix with (j, k) element $\frac{\partial s_j(\chi_t)}{\partial p_k}$. Berry and Haile (2014, Assumption 6) require the demand functions to be continuously differentiable in prices, with

a strict version of part (ii) of connected substitutes in prices. Their high-level condition is as follows.

Assumption 8.33 (Berry and Haile, 2014, Assumption 7a)**.** For each j there is a known function ψ_j such that $mc_{jt} = \psi_j\big(s_t, M_t, \mathcal{D}(\chi_t), p_t\big)$ for all (M_t, χ_t, s_t) in the support.

The function ψ_j is a generalized residual marginal revenue. Their Remark 1 shows that it exists under marginal cost pricing, monopoly or joint profit maximization, Nash equilibrium in prices, and Nash equilibrium in quantities, with single- or multi-product firms. For multi-product Bertrand pricing with ownership matrix Ω, the first-order conditions of Chapter 4 give $\psi(s_t, \mathcal{D}, p_t) = p_t + \left[(\Omega \odot \mathcal{D})^\top\right]^{-1} s_t$, where $\mathcal{D}_{jk} = \frac{\partial s_j}{\partial p_k}$ plays the role of Δ in our notation.

Theorem 8.34 (Berry and Haile, 2014, Theorem 2)**.** *Under Assumptions 1 to 4, 6 and 7a of Berry and Haile (2014), mc_{jt} is identified for all j and t.*

The proof is immediate. Theorem 8.32 identifies demand, hence $\mathcal{D}(\chi_t)$, and Assumption 8.33 maps it into marginal costs. Marginal costs and markups are thus identified with no new exclusion restriction and no restriction on the cost function. To identify the marginal cost function, write $mc_{jt} = c_j(Q_{jt}, w_{jt}) + \omega_{jt}$, where Q_{jt} collects the quantities of the firm's products and w_{jt} are observed cost shifters (their eq. 11). Since mc_{jt} is known, this is a standard nonparametric regression with endogenous Q_{jt}. With instruments y_{jt} excluded from cost, a mean independence condition and a completeness condition (their Assumptions 8 and 9), Theorem 3 identifies c_j by the Newey and Powell (2003) argument. Many instruments are available. Demand shifters of all products move every quantity through the choice problem and the equilibrium, and market size moves quantities directly (pp. 1767–1768).

Berry and Haile (2014, Section 4.4) also identify the cost shocks without specifying the supply model, under a cost index restriction and exclusion of the demand shifters from marginal cost (their Theorem 4). They note that suitable instruments exist in many applications. In BLP, miles per dollar enters demand but not cost, which depends on miles per gallon. Other examples are interactions of product characteristics with market characteristics, product-specific advertising, firm locations, and local offerings of complementary products (p. 1771). Section 5 of their paper replaces the completeness conditions by a simultaneous equations argument with more transparent support or density conditions.

Discriminating between models of conduct

Berry and Haile (2014, Section 6) formalize the intuition of Bresnahan (1982) that demand variation can distinguish models of conduct (Chapter 3). Suppose cost shocks are identified without a supply model. Each candidate model of conduct implies its own function ψ_j. If two observations have the same cost function arguments, they must have the same marginal cost. Let κ_{jt} denote the cost index. Their Theorem 8 states the testable restriction. Whenever $(Q_{jt}, \kappa_{jt}) = (Q_{j't'}, \kappa_{j't'})$ for products with the same cost function,

$$\psi_j\big(s_t, \tilde{\mathcal{D}}(s_t, p_t), p_t\big) = \psi_{j'}\big(s_{t'}, \tilde{\mathcal{D}}(s_{t'}, p_{t'}), p_{t'}\big),$$

where $\tilde{\mathcal{D}}(s_t, p_t)$ is the derivative matrix written as a function of shares and prices through Lemma 8.29. A false model generally violates this equality. In the simplest example a monopolist faces a change in demand that rotates its marginal revenue curve around the observed quantity. Under the true model of monopoly, the implied marginal cost is unchanged.

Under the false model of marginal cost pricing, the implied marginal cost changes, although neither the cost index nor the quantity changed. The result requires no rotations of demand, allows product differentiation and heterogeneous firms, and does not rely on conjectural variations. Without the cost index, their Theorem 9 gives a weaker restriction on conditional expectations.

Functional form versus instruments

Berry and Haile (2014, Section 7) draw the practical lessons. Inverting demand gives one equation per product,

$$\xi_{jt} = s_j^{-1}(s_t, p_t) - x_{jt}, \qquad j = 1, \ldots, J, \tag{8.67}$$

but each equation depends on the $2J$ endogenous variables (s_t, p_t). The exogenous x_t supplies J of the $2J$ instruments, because each x_{jt} enters with a known coefficient. The remaining J must come from elsewhere, for example product-specific cost shifters. Parametric models need fewer instruments because their inverse demand depends on (s_t, p_t) in restricted ways. Table 8.5 compares the cases. Every parametric case has the form $\xi_{jt} = s_j^{-1}(s_t, p_t; \theta) - x_{jt}$ (their eq. 34). The instruments needed grow with the number of parameters that interact with the endogenous variables.

Table 8.5: Inverse demand and the instruments it requires

Model	Inverse demand	Instruments needed beyond x_{jt}
Logit	$\xi_{jt} = \ln \frac{s_{jt}}{s_{0t}} + \alpha p_{jt} - x_{jt}\beta$	One excluded instrument for price: a cost shifter or rivals' characteristics x_{-jt}
Nested logit	$\xi_{jt} = \ln \frac{s_{jt}}{s_{0t}} - \sigma \ln s_{j\|g,t} + \alpha p_{jt} - x_{jt}\beta$	One more, for $\ln s_{j\|g,t}$, which x_{-jt} can supply
BLP	$\xi_{jt} = \delta_j(s_t, p_t; \Sigma) + \alpha p_{jt} - x_{jt}\beta$	One for price plus enough to identify Σ (BLP instruments or others)
Price only in index	$\xi_{jt} = s_j^{-1}(s_t) + \alpha p_{jt} - x_{jt}$	A single instrument, for example a market-level cost shifter
Nonparametric	$\xi_{jt} = s_j^{-1}(s_t, p_t) - x_{jt}$	J excluded instruments, such as product-specific cost shifters, together with all of x_t
Exogenous prices	$\xi_{jt} = s_j^{-1}(s_t) - x_{jt}$	None beyond x_t, which supplies all J needed

Notes: Based on equations (29)–(34) and the discussion in Section 7 of Berry and Haile (2014). The coefficient on x_{jt} is normalized to one in the nonparametric rows. In the BLP row, $\delta_j(\cdot)$ maps shares into mean utilities given the random coefficient parameters Σ.

Two cases in the table carry lessons beyond the parametric examples. Suppose first that price enters only through the index, $\delta_{jt} = x_{jt} - \alpha p_{jt} + \xi_{jt}$, as in many applications. Then the unknown function depends on shares alone and a single instrument beyond x_t suffices, for example a market-level cost shifter (Berry and Haile, 2014, p. 1785). Suppose next that prices are exogenous. One might think that no exclusion restriction is then needed. This is

wrong, because each share still depends on the whole vector ξ_t, so the inverse $s_j^{-1}(s_t)$ has J endogenous arguments. Cost shifters do not help, since they move shares only through prices. Identification is possible only because the index restriction makes x_t available as instruments (Berry and Haile, 2014, pp. 1785–1786). This shows the necessity of the BLP instruments and the role of the index restriction in making them valid. The characteristics of rival products x_{-jt} can be excluded from the inverse demand of product j only because they enter utility through their own indices.

The conclusion is reassuring for applied work. Strong functional forms are not necessary for identification. They serve to smooth, to extrapolate, and to compensate for the gap between the exogenous variation needed to distinguish all nonparametric models and the variation available in practice (Berry and Haile, 2014, p. 1786). The qualification is that the instruments must exist. With consumer-level data the requirements fall further, as Berry and Haile (2024) show and Section 8.8 explains.

8.6.7 Summary: what identifies what

Table 8.6 collects the identification arguments of this chapter. For each object it lists the variation that identifies it and the instruments that deliver that variation.

Table 8.6: Sources of identification in random coefficients demand models

Object	Identifying variation	Typical instruments or data	Discussion
Mean tastes β	Variation in characteristics across products, given $\mathbb{E}[\xi \mid x] = 0$	Own characteristics. With brand effects, minimum distance on $\hat{d}$	Section 8.6.5
Mean price coefficient α	Price variation unrelated to ξ, across or within markets	Cost shifters, prices in other markets, market demographics, rivals' characteristics	Sections 8.6.1 and 8.6.4
Taste dispersion Σ	Changes in the set and characteristics of competing products that alter substitution, holding ξ fixed	Sums of rivals' characteristics, differentiation instruments, choice-set variation, second-choice data	Sections 8.6.2 and 8.8
Demographic interactions Π	Cross-market variation in the distribution of demographics. Within-market covariances in micro data	Market demographics interacted with characteristics, micro moments	Section 8.8
Marginal costs mc_{jt}	None beyond demand, given a model of conduct	First-order conditions	Sections 8.6.6 and 8.7
Cost function c_j	Quantity variation unrelated to cost shocks	Demand shifters of own and rival products, market size	Sections 8.6.6 and 8.7
Conduct	Variation that moves the implied marginal revenue but not marginal cost	Demand shifters excluded from cost	Section 8.6.6, Chapter 3

Notes: "Rivals' characteristics" are the BLP instruments of equation (8.64). Their validity requires exogenous characteristics. Micro data change the requirements, as Section 8.8 explains.

8.7 The supply side and joint estimation

The demand model of Sections 8.1, 8.5 and 8.6 can be estimated without any assumption about how firms set prices. The instruments must be uncorrelated with the demand unobservable, and nothing more is required of the supply side. A model of pricing nevertheless does three things for us. It turns the demand estimates into marginal costs and markups without any cost data. It adds moment conditions that can sharpen the demand estimates. And it lets us compute the prices that would prevail after a merger, a tax or the entry of a product.

The template is the pair of equations that recurs through the rest of the book. Demand is $q = f(p, x, \xi; \theta_d)$, estimated with instruments. Supply is the multiproduct pricing condition $p = mc + b(p, x, \xi; \theta_d)$, where b is a vector of markups and marginal cost is $mc_j = w_j\gamma + \omega_j$ or its logarithm. Counterfactuals change the ownership structure or the product set and solve for new prices. This section develops the supply side for the random coefficients logit, then shows how to estimate it jointly with demand and how to compute counterfactual equilibria.

8.7.1 Multiproduct Bertrand-Nash pricing

We study one market and drop the index t. There are F firms, and firm f sells the products in $\mathcal{J}_f$. The following assumption collects the standard supply side of Berry et al. (1995, Section 3).

Assumption 8.35 (Static multiproduct pricing)**.** (i) Marginal cost mc_j is constant in output. It depends on observed cost shifters w_j and an unobserved cost component ω_j, either as $\ln mc_j = w_j\gamma + \omega_j$ or as $mc_j = w_j\gamma + \omega_j$. (ii) Firms observe (x, ξ, ω) and the demand parameters. (iii) Each firm chooses the prices of its products to maximize its total profit, taking rivals' prices as given. (iv) A Nash equilibrium in prices exists, and the equilibrium prices are interior.

The profit of firm f is

$$\Pi_f = \sum_{j \in \mathcal{J}_f} (p_j - mc_j)\, M s_j(p, x, \xi; \theta) - C_f, \tag{8.68}$$

where M is market size, s_j is the share function of Section 8.1 and C_f is a fixed cost (Berry et al., 1995, eq. 3.2). Differentiating with respect to p_j for $j \in \mathcal{J}_f$ gives the first-order condition

$$s_j(p, x, \xi; \theta) + \sum_{r \in \mathcal{J}_f} (p_r - mc_r) \frac{\partial s_r(p, x, \xi; \theta)}{\partial p_j} = 0 \tag{8.69}$$

(Berry et al., 1995, eq. 3.3). Market size multiplies every term and drops out. The first term is the revenue gained on inframarginal units when p_j rises. The sum is the profit lost on all of the firm's products whose sales respond to p_j. It includes the products that p_j diverts toward, so a multiproduct firm internalizes part of the substitution among its own products.

We write the J conditions in matrix form. Let Δ be the $J \times J$ matrix of share derivatives with (j, k) element $\frac{\partial s_j}{\partial p_k}$. Let Ω be the ownership matrix, with $\Omega_{jr} = 1$ when j and r have the same owner (Chapter 4). The derivative in (8.69) is $\frac{\partial s_r}{\partial p_j} = \Delta_{rj} = (\Delta^\top)_{jr}$, and the sum runs over the products with $\Omega_{jr} = 1$. Hence

$$\begin{aligned} s_j + \sum_{r=1}^{J} \Omega_{jr}(\Delta^\top)_{jr}(p_r - mc_r) = 0, \qquad j = 1, \ldots, J, \\ s + (\Omega \odot \Delta^\top)(p - mc) = 0. \end{aligned} \tag{8.70}$$

Because Ω is symmetric, $\Omega \odot \Delta^\top = (\Omega \odot \Delta)^\top$. Solving for the price-cost margins gives the markup vector

$$p - mc = b(p, x, \xi; \theta) \equiv -\left[(\Omega \odot \Delta)^\top\right]^{-1} s. \tag{8.71}$$

Berry et al. (1995) write the same object with a different matrix. Their $J \times J$ matrix has (j, r) element $-\frac{\partial s_r}{\partial p_j}$ when r and j have the same owner and zero otherwise (their eq. 3.4). In our notation this matrix is $-(\Omega \odot \Delta)^\top$, so their markup formula $b = [-(\Omega \odot \Delta)^\top]^{-1} s$ (their eq. 3.5) is (8.71). We use (8.71) throughout the book. Substituting the logarithmic cost function gives the pricing equation that Berry et al. (1995, eq. 3.6) take to the data,

$$\ln\left(p_j - b_j(p, x, \xi; \theta)\right) = w_j \gamma + \omega_j. \tag{8.72}$$

With a linear cost function the pricing equation is

$$p_j = w_j \gamma + b_j(p, x, \xi; \theta) + \omega_j, \tag{8.73}$$

the form used by Berry et al. (2004a, eqs. 16–17).

Three features of (8.71) matter for estimation. First, the markups depend only on the demand parameters and on equilibrium prices and shares. Marginal costs are then recovered as $mc = p - b$, with no cost data. Second, the markup is endogenous in the pricing equation. Prices respond to ω, so $b(p, x, \xi; \theta)$ is a function of ω, and the correlation between ξ and ω adds a second channel (Berry et al., 1995, p. 854). The pricing equation must therefore be estimated with instruments, just as the demand equation is. Third, the markup formula requires the matrix $(\Omega \odot \Delta)^\top$ to be invertible. The next lemma shows that the random coefficients logit always satisfies this condition when every consumer dislikes higher prices.

Lemma 8.36 (The markup is well defined)**.** *Let demand be random coefficients logit with individual price coefficients $-\alpha_i$, where $\alpha_i > 0$ with probability one, and let the outside good have positive choice probability for every consumer. Then $\Omega \odot \Delta$ is nonsingular for every ownership matrix Ω, and (8.71) defines a unique markup vector.*

Proof. By Proposition 8.4, $\Delta_{jk} = \int \alpha_i s_{ij}(s_{ik} - \mathbf{1}\{j = k\})\, \mathrm{d}F$. The diagonal element is $\Delta_{jj} = -\int \alpha_i s_{ij}(1 - s_{ij})\, \mathrm{d}F < 0$. The off-diagonal elements of row j are positive, and their sum is

$$\begin{aligned}
\sum_{k \neq j} \Delta_{jk} &= \int \alpha_i s_{ij} \sum_{k \neq j} s_{ik}\, \mathrm{d}F \\
&= \int \alpha_i s_{ij}(1 - s_{ij} - s_{i0})\, \mathrm{d}F \\
&< \int \alpha_i s_{ij}(1 - s_{ij})\, \mathrm{d}F = |\Delta_{jj}|,
\end{aligned}$$

where the second line uses $\sum_{k=0}^{J} s_{ik} = 1$ and the strict inequality uses $\alpha_i s_{ij} s_{i0} > 0$. Each row of Δ is therefore strictly diagonally dominant. After reordering the products by owner, $\Omega \odot \Delta$ is block diagonal, and each block is a principal submatrix of Δ. A principal submatrix of a strictly diagonally dominant matrix is strictly diagonally dominant. A strictly diagonally dominant matrix is nonsingular (the Levy-Desplanques theorem). The blocks are nonsingular, so $\Omega \odot \Delta$ and its transpose are nonsingular. □

Two special cases connect (8.71) to earlier chapters. The first is the logit, which we use repeatedly in the case studies.

Proposition 8.37 (Logit markups of a multiproduct firm)**.** *Suppose demand is logit with price coefficient α, firm f sells the set $\mathcal{J}_f$, and $S_f = \sum_{r \in \mathcal{J}_f} s_r$ is its combined share. In any interior Bertrand-Nash equilibrium, every product of firm f carries the same dollar markup,*

$$p_j - mc_j = \frac{1}{\alpha(1 - S_f)} \qquad \text{for all } j \in \mathcal{J}_f. \tag{8.74}$$

The same formula holds for any set of products priced jointly, with S_f replaced by the combined share of the set.

Proof. Write $m_r = p_r - mc_r$. The logit derivatives are $\Delta_{jj} = -\alpha s_j(1 - s_j)$ and $\Delta_{rj} = \alpha s_r s_j$ for $r \neq j$. Substituting into (8.69) gives

$$s_j - m_j\, \alpha s_j(1 - s_j) + \sum_{r \in \mathcal{J}_f,\, r \neq j} m_r\, \alpha s_r s_j = 0.$$

Dividing by αs_j and collecting the terms in $m_j s_j$ gives

$$m_j = \frac{1}{\alpha} + \sum_{r \in \mathcal{J}_f} m_r s_r.$$

The right side does not depend on j, so all products of the firm share one markup m_f. Substituting $m_r = m_f$ gives $m_f = \frac{1}{\alpha} + m_f S_f$, and solving yields (8.74). The argument uses only the set of jointly priced products, which proves the last claim. □

A single-product firm has $m_j = \frac{1}{\alpha(1 - s_j)}$, as in (8.24) and Chapter 7. In the logit, markups depend on the firm's total share and on nothing else. Two firms with equal shares have equal markups, whatever their characteristics. Sections 8.11 and 8.13 show how this restriction distorts estimated markups and tests of conduct.

With random coefficients the markup depends on the whole distribution of price sensitivities through $\Delta_{jk} = \int \alpha_i s_{ij}(s_{ik} - \mathbf{1}\{j = k\})\, \mathrm{d}F$. A product bought mostly by consumers with low α_i has a small own-price derivative relative to its share, and hence a high markup. The markup is therefore a function of (α, θ_2) and of the data, and the pricing equation carries information about the demand parameters. This is the source of the efficiency gains from joint estimation.

8.7.2 Joint estimation of demand and supply

Joint estimation stacks the demand and pricing equations. For a trial parameter vector $\theta = (\beta, \alpha, \theta_2, \gamma)$, which adds the cost parameters γ to the demand parameters, we compute two unobservables for every product and market. The demand unobservable comes from the inversion of Section 8.4,

$$\xi_{jt}(\theta) = \delta_{jt}(s_t^{\text{obs}}; \theta_2) - x_{jt}\beta + \alpha p_{jt}. \tag{8.75}$$

The cost unobservable comes from the pricing equation,

$$\omega_{jt}(\theta) = \ln\big(p_{jt} - b_{jt}(\alpha, \theta_2)\big) - w_{jt}\gamma \quad \text{or} \quad \omega_{jt}(\theta) = p_{jt} - b_{jt}(\alpha, \theta_2) - w_{jt}\gamma. \tag{8.76}$$

The markup b_{jt} is evaluated at the observed prices and shares. It depends on θ_2 through δ_t and μ_{ijt}, and on the mean price coefficient α through α_i. It does not depend on β, because the inversion fixes δ_t at the value that reproduces the observed shares.

The identifying assumption of Berry et al. (1995, eq. 4.1) is that both unobservables are mean independent of the exogenous variables,

$$\mathbb{E}[\xi_{jt} \mid z_t] = \mathbb{E}[\omega_{jt} \mid z_t] = 0. \tag{8.77}$$

Here z_t collects the characteristics and cost shifters of all products in the market. Price and quantity are excluded from the conditioning set because the model determines them jointly with ξ and ω. With demand instruments z^d_{jt} and supply instruments z^s_{jt}, both functions of z_t, the sample moments are

$$\bar g(\theta) = \frac{1}{N}\sum_{t=1}^{T}\sum_{j\in\mathcal{J}_t}\begin{pmatrix} z^{d\top}_{jt}\,\xi_{jt}(\theta) \\ z^{s\top}_{jt}\,\omega_{jt}(\theta)\end{pmatrix}, \qquad \hat\theta = \arg\min_{\theta}\ \bar g(\theta)^\top W \bar g(\theta). \tag{8.78}$$

The linear parameters (β, γ) can be concentrated out exactly as in Proposition 8.20. Fix (α, θ_2) and define the two dependent variables $y^d_{jt} = \delta_{jt}(\theta_2) + \alpha p_{jt}$ and $y^s_{jt} = \ln(p_{jt} - b_{jt}(\alpha, \theta_2))$. Stack them over products as $\bar y = (y^{d\top}, y^{s\top})^\top$, and define

$$\bar X = \begin{pmatrix} X^d & 0 \\ 0 & X^s\end{pmatrix}, \qquad \bar Z = \begin{pmatrix} Z^d & 0 \\ 0 & Z^s\end{pmatrix}, \qquad \begin{pmatrix}\xi \\ \omega\end{pmatrix} = \bar y - \bar X\begin{pmatrix}\beta \\ \gamma\end{pmatrix},$$

where X^d and X^s stack the rows x_{jt} and w_{jt}, and Z^d and Z^s stack the rows z^d_{jt} and z^s_{jt}. The objective is quadratic in (β, γ), and its first-order condition $\bar X^\top \bar Z W \bar Z^\top(\bar y - \bar X(\beta^\top, \gamma^\top)^\top) = 0$ gives

$$\begin{pmatrix}\hat\beta(\alpha,\theta_2) \\ \hat\gamma(\alpha,\theta_2)\end{pmatrix} = \left(\bar X^\top \bar Z W \bar Z^\top \bar X\right)^{-1} \bar X^\top \bar Z W \bar Z^\top \bar y. \tag{8.79}$$

With a block-diagonal W this is two separate instrumental variables regressions. With the efficient weighting matrix the blocks are linked whenever ξ and ω are correlated. Either way the outer search runs over (α, θ_2) only. Berry et al. (1995, Section 6.5) concentrate out β and γ in this way and search over the price coefficient and the standard deviations with the Nelder-Mead simplex method. Note that α moves from the linear to the nonlinear block once the supply side is added, because it enters the markup nonlinearly.

Berry et al. (1995, p. 851) state the case for joint estimation. Since the pricing rule depends in equilibrium on the true demand parameters, "joint estimation of the pricing and demand equations should increase efficiency as long as the model is correctly specified." Nevo (2000a, Section 5.1) adds that the extra programming effort is small for static supply models, and that the gain in efficiency comes at the cost of more structure. The cost is real. If the assumed conduct or cost function is wrong, the supply moments are invalid, and the error spreads to the demand parameters through the joint objective. Nevo (2001, p. 318) therefore identifies demand "without specifying a functional form for the supply side." His goal is to compare models of conduct, so the demand estimates must not presume one of them (Section 8.13).

Joint estimation is most valuable, and sometimes necessary, in four situations.

1. The demand moments identify the price coefficient or θ_2 only weakly. In the single cross section of Berry et al. (2004a, p. 93), the demand-only instrumental variables estimate of the mean price coefficient had a standard error ten times the point estimate (25 against 2.5). Adding the pricing equation gave -3.58 with a standard error of 0.22 (Section 8.14).
2. The unobservables ξ and ω are correlated. The efficient weighting matrix then uses the supply moments to sharpen the demand parameters even when the instrument sets coincide.

3. Conduct or the shape of the cost function is itself estimated, as with returns to scale below.

4. We need correct standard errors for the cost parameters γ. These depend on the demand estimates through the markup, a dependence that a second-step regression ignores.

The last point deserves a formula, because the two-step procedure is common in practice. In the first step we estimate the demand parameters $\hat{\theta}_d$. In the second step we regress $y^s_{jt}(\hat{\theta}_d) = \ln(p_{jt} - b_{jt}(\hat{\theta}_d))$ on w_{jt}. The dependent variable is a *generated regressand*, a variable built from estimated parameters. To see its effect, write the second-step moment as $\bar{g}_s(\theta_d, \gamma) = \frac{1}{N}\sum_{j,t} w^\top_{jt}(y^s_{jt}(\theta_d) - w_{jt}\gamma)$ and expand it around the true values:

$$0 = \bar{g}_s(\hat{\theta}_d, \hat{\gamma}) \approx \bar{g}_s(\theta_{d0}, \gamma_0) + G_{sd}(\hat{\theta}_d - \theta_{d0}) + G_{s\gamma}(\hat{\gamma} - \gamma_0),$$
$$\hat{\gamma} - \gamma_0 \approx -G_{s\gamma}^{-1}\left[\bar{g}_s(\theta_{d0}, \gamma_0) + G_{sd}(\hat{\theta}_d - \theta_{d0})\right],$$

with $G_{s\gamma} = -\frac{1}{N}\sum w^\top_{jt} w_{jt}$ and $G_{sd} = \frac{1}{N}\sum w^\top_{jt}\frac{\partial y^s_{jt}}{\partial \theta_d^\top}$. The variance of $\hat{\gamma}$ therefore has three parts: the variance of $\bar{g}_s$, the term $G_{sd}\,\mathrm{Var}(\hat{\theta}_d)G_{sd}^\top$, and the covariances between the two. The naive regression standard error keeps only the first. The full variance follows from stacking both steps into one GMM problem, or from a bootstrap that resamples markets and re-estimates demand in every replication (Appendix A). In the simulated market of Section 8.10, demand uncertainty moves all markups together and loads almost entirely on the cost intercept.

The markup also needs instruments of its own in (8.73). Berry et al. (2004a, p. 92) use predicted markups,

$$\hat{b}_j = b_j\big(x, \hat{p}, \hat{\delta};\ \hat{\beta}_p, \hat{\Pi}, \hat{\Sigma}\big), \tag{8.80}$$

(their eq. 18). Here $\hat{\delta}$ and $\hat{p}$ are projections of the estimated mean utilities and the observed prices on the exogenous characteristics. The coefficient $\hat{\beta}_p$ is a preliminary instrumental variables estimate of the price coefficient. The predicted markup is a function of exogenous variables and parameter estimates only, so it is a valid instrument. It is relevant because it tracks the equilibrium markup. The authors iterate: each new estimate of the price coefficient produces a new $\hat{b}$ and a new estimate, until convergence (their fn. 17).

8.7.3 Marginal costs, markups and returns to scale

Once demand is estimated, (8.71) delivers the markup of every product, and $mc_{jt} = p_{jt} - b_{jt}$ delivers its marginal cost. Neither step uses cost data. Standard errors for markups and marginal costs follow from the delta method or from simulating the estimated asymptotic distribution of the demand parameters (Section 8.5). Accounting data, when they exist, become a check on the model instead of an input (Section 8.13).

The constant-marginal-cost assumption can be relaxed. Berry et al. (1995, p. 877) add the log of output to the cost function,

$$\ln mc_j = w_j\gamma_w + \gamma_q \ln q_j + \omega_j. \tag{8.81}$$

The first-order condition (8.69) is unchanged, because mc_j is now the marginal cost at the equilibrium output. Output is endogenous in (8.81), and the authors use the same instruments as before. Their estimate is $\hat{\gamma}_q = -0.387$ with a standard error of 0.029 (Berry et al., 1995, Table IV). The elasticity of marginal cost with respect to output is -0.387. A 10 percent increase in output would multiply marginal cost by $1.1^{-0.387} \approx 0.964$, a fall of about 3.6 percent (our

calculation). The authors judge these implied returns to scale "implausibly high." Adding higher-order terms in $\ln q$ reduces the problem, but they hesitate to push further because model-level production data are inaccurate for about a fifth of the sample (mostly foreign cars). The motivation for the exercise was the negative coefficient on fuel efficiency in the constant-returns specification. The best-selling cars had high fuel efficiency, and constant returns may force them to have low estimated marginal cost (Berry et al., 1995, pp. 876–877, and Section 8.11).

8.7.4 Existence and uniqueness of equilibrium

Estimation and counterfactuals need different equilibrium properties. The moment conditions use only the first-order conditions at the observed prices, which hold at any interior equilibrium. Berry et al. (1995, fn. 12) note that "none of the properties of the estimates require uniqueness of equilibrium." Counterfactuals are another matter. Without uniqueness, "it is not clear how to use our estimates to examine the effects of policy and environmental changes."

General results are scarce. Caplin and Nalebuff (1991) give conditions for existence of a price equilibrium with single-product firms, based on log-concavity of the density of consumer types (Chapter 4). Their theorems do not extend easily to multiproduct firms (Berry et al., 1995, fn. 12). In practice we check numerically. We verify that the estimated demand and costs support an equilibrium at the observed prices, and we search for other equilibria from many starting points when we compute a counterfactual. The simulated market of Section 8.10 illustrates the check.

8.7.5 Computing counterfactual equilibria

A counterfactual fixes demand, marginal costs and the unobservables (ξ, ω), changes one primitive, and solves (8.70) for the new prices. In a merger simulation the primitive is the ownership matrix (Chapter 11). Three solution methods are common. A Newton or quasi-Newton method solves the J equations (8.70) directly. The *markup iteration* updates $p \leftarrow mc + b(p)$ with b from (8.71). The third method, due to Morrow and Skerlos (2011), rewrites the first-order conditions by splitting the share derivatives into two parts.

Proposition 8.38 (Morrow-Skerlos decomposition)**.** *Let demand be random coefficients logit with $\alpha_i > 0$ with probability one. Define the diagonal matrix $\Lambda(p)$ and the symmetric matrix $\Gamma(p)$ by*

$$\Lambda_{jj}(p) = \int \alpha_i s_{ij}(p)\, \mathrm{d}F, \qquad \Gamma_{jk}(p) = \int \alpha_i s_{ij}(p)\, s_{ik}(p)\, \mathrm{d}F. \tag{8.82}$$

Then $\Delta(p) = -\Lambda(p) + \Gamma(p)$, and a price vector p satisfies the first-order conditions (8.70) if and only if

$$p - mc = \zeta(p) \equiv \Lambda(p)^{-1}\big[s(p) + (\Omega \odot \Gamma(p))(p - mc)\big]. \tag{8.83}$$

Proof. By Proposition 8.4, $\Delta_{jk} = \int \alpha_i s_{ij}(s_{ik} - \mathbf{1}\{j = k\})\, \mathrm{d}F$. Splitting the integrand gives

$$\Delta_{jk} = \int \alpha_i s_{ij} s_{ik}\, \mathrm{d}F - \mathbf{1}\{j = k\} \int \alpha_i s_{ij}\, \mathrm{d}F = \Gamma_{jk} - \mathbf{1}\{j = k\}\Lambda_{jj},$$

so $\Delta = -\Lambda + \Gamma$, and Γ is symmetric by construction. Because Λ is diagonal and Ω has ones on its diagonal, $\Omega \odot \Lambda = \Lambda$. Hence

$$(\Omega \odot \Delta)^{\top} = (-\Lambda + \Omega \odot \Gamma)^{\top} = -\Lambda + \Omega \odot \Gamma,$$

where the last step uses the symmetry of Ω and Γ. Substituting into (8.70),

$$s - \Lambda(p - mc) + (\Omega \odot \Gamma)(p - mc) = 0$$
$$\Lambda(p - mc) = s + (\Omega \odot \Gamma)(p - mc).$$

Every diagonal element of Λ is positive because $\alpha_i > 0$ and $s_{ij} > 0$, so Λ is invertible. Multiplying by Λ^{-1} gives (8.83). Each step is reversible, which proves the equivalence. □

The decomposition has a clear economic reading. The ratio $\frac{\Lambda_{jj}}{s_j} = \int \alpha_i \frac{s_{ij}}{s_j}\, dF$ is the average price sensitivity of product j's buyers, each consumer weighted by her probability of buying j. Write it as $\bar{\alpha}_j$. Because $\alpha_i > 0$, every entry satisfies $\Gamma_{jk} \le (\sup_i s_{ik})\Lambda_{jj}$. For a product j of firm f, summing over the firm's products gives $\sum_{k \in \mathcal{J}_f} \Gamma_{jk} \le (\sup_i \sum_{k \in \mathcal{J}_f} s_{ik})\Lambda_{jj}$. When each consumer's combined probability of buying the products of firm f is uniformly small, the Γ term is therefore small relative to Λ, and (8.83) gives

$$p_j - mc_j \approx \frac{s_j}{\Lambda_{jj}} = \frac{1}{\bar{\alpha}_j}. \tag{8.84}$$

The markup is the inverse of the buyers' average price sensitivity, the discrete choice version of the inverse semi-elasticity rule. Small aggregate shares do not justify (8.84). Suppose a single-product firm faces consumers with $\alpha_i = 1$, of whom 1% buy j with probability 0.99 and 99% with probability 10^{-6}. Then $s_j \approx 0.0099$, yet $\Gamma_{jj} \approx 0.99\,\Lambda_{jj}$. The exact markup $\frac{s_j}{\Lambda_{jj} - \Gamma_{jj}}$ is about 99, while $\frac{1}{\bar{\alpha}_j} = 1$. The Γ term adds two corrections. Its off-diagonal own-firm entries capture cannibalization among the firm's products. Its diagonal entry restores the factor $1 - s_{ij}$ in each consumer's own-price derivative $-\alpha_i s_{ij}(1 - s_{ij})$, which matters only when individual choice probabilities are large. In the logit, $\alpha_i = \alpha$ gives $\Lambda_{jj} = \alpha s_j$ and $\Gamma_{jk} = \alpha s_j s_k$, so (8.83) becomes $m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k$. This is the logit fixed point solved in Proposition 8.37. It shows that small probabilities for each product are not enough. A firm with 20 products of share 0.02 has $m_j = \frac{1}{0.6\,\alpha}$, about $\frac{1.67}{\alpha}$, although every individual choice probability is 0.02 and (8.84) gives $\frac{1}{\alpha}$.

Proposition 8.38 suggests the iteration

$$p^{(n+1)} = mc + \zeta\big(p^{(n)}\big), \qquad n = 0, 1, 2, \ldots, \tag{8.85}$$

started at $p^{(0)} = mc$ or at observed prices, and stopped when $\|p^{(n+1)} - p^{(n)}\|_\infty$ falls below a tight tolerance. At convergence we verify the first-order conditions directly. A residual measured in price units, $\|\zeta(p) - (p - mc)\|_\infty$, is more informative than the residual of (8.70) in share units. The reason is that every share, and with it every term of (8.70), tends to zero as prices rise without bound. A root finder applied to the share-unit conditions can therefore stall at very high prices, where the residual is small although no equilibrium is near. The map ζ divides by Λ, which tends to zero at the same rate as the shares, and it stays informative at high prices. Morrow and Skerlos (2011) call (8.83) the ζ-markup equation and study the fixed-point iteration built on it. Conlon and Gortmaker (2020, n. 65) instead terminate on the share-unit residual $\|\Lambda(p)(p - mc - \zeta(p))\|$, which Morrow and Skerlos (2011, Section 2.3) call the simultaneous stationarity condition. The iteration (8.85) is not guaranteed to be a contraction, so convergence must be checked in each application.

The simulated market of Section 8.10 shows the three methods at work. The iteration (8.85), started at marginal cost, converges in 10 to 13 iterations in each of 100 markets. Started from 20

random price vectors per market, drawn uniformly on $[0, 4]$, it converges to the same prices in all 2,000 runs. The markup iteration also converges in all 2,000 runs in this design, where the own-firm entries of Γ are small relative to Λ. A Newton-type root finder applied to the share-unit conditions, started at the same random points, reaches the equilibrium in only 13 of the 2,000 runs.

Merger simulation applies the same machinery with a new ownership matrix Ω^{post}. We keep the estimated demand parameters, the recovered marginal costs and the unobservables, and we solve (8.83) with Ω^{post} in place of Ω. Chapter 11 develops the method and its applications, including the random coefficients nested logit, for which the inversion needs the dampened contraction of Grigolon and Verboven (2014) (Section 8.4).

8.7.6 Conduct

Every formula above assumes multiproduct Nash pricing under the actual ownership structure. Other forms of conduct change the matrix Ω. Joint profit maximization by all firms sets every element of Ω to one. Pricing by independent brand managers sets Ω to the identity matrix. For each candidate $\Omega^{(m)}$, (8.71) gives a predicted margin $\frac{p_j - mc_j^{(m)}}{p_j}$, where $mc^{(m)} = p + [(\Omega^{(m)} \odot \Delta)^\top]^{-1} s$. Nevo (2001) compares these predictions with accounting margins in the cereal industry. Current multiproduct ownership fits the data, and joint ownership of the brands in his sample predicts margins far above the observed ones (Section 8.13). Formal identification of conduct from the demand system is studied by Berry and Haile (2014, Section 6), who extend the logic of Bresnahan (1982) without requiring demand rotations (Section 8.6 and Chapter 3). Backus et al. (2021a) use the demand elasticities to discriminate between alternative models of firm conduct in the same cereal industry, including pricing under common ownership. Berry and Haile (2024, p. 1140) cite their work, with Berry and Haile (2014), as an example of this use of the demand system.

8.8 Micro data and micro moments

So far the data have been market shares, prices and characteristics. Many studies also observe individual consumers: the attributes of a household and the product it bought. Goldberg (1995) matches households to their car purchases (Section 8.15). Petrin (2002) uses the average demographics of buyers of each type of vehicle. Berry et al. (2004a) use a survey of new-car buyers that records their second choices. This section asks what such data add. The short answer has three parts. Micro data identify the interactions between consumer attributes and product characteristics from variation within a market. They reduce, but do not remove, the need for instruments. And they leave the level of price elasticities to cross-market variation or outside information.

8.8.1 What consumer-level data identify

We write the model with observed attributes D_i and unobserved tastes ν_i as

$$u_{ijt} = \delta_{jt} + \sum_k \tilde{x}_{jtk}\left(\pi_k^\top D_i + \sigma_k \nu_{ik}\right) + \epsilon_{ijt}, \qquad \delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \tag{8.86}$$

where $\pi_k^\top$ is row k of Π and σ_k is the k-th diagonal element of Σ. This is Berry et al. (2004a, eqs. 3–4) in our notation. Their observed-taste coefficients β^o are our Π, and their unobserved-taste

coefficients β^u are our Σ. Conditional on (D_i, ν_i) the choice probability is logit,

$$P_{ijt}(\delta_t, \Pi, \Sigma) = \frac{\exp\left(\delta_{jt} + \sum_k \tilde{x}_{jtk}(\pi_k^\top D_i + \sigma_k \nu_{ik})\right)}{1 + \sum_{q \in \mathcal{J}_t} \exp\left(\delta_{qt} + \sum_k \tilde{x}_{qtk}(\pi_k^\top D_i + \sigma_k \nu_{ik})\right)} \tag{8.87}$$

(Berry et al., 2004a, eq. 6). Integrating over ν_i gives the probability that a consumer with attributes D_i buys j.

Equation (8.86) shows what can be learned from consumers within one market. The vector δ_t is a set of product-market fixed effects. It absorbs $x_{jt}\beta$, p_{jt} and ξ_{jt}, which are common to all consumers in the market. The remaining parameters (Π, Σ) govern how choices vary across consumers facing the same products. Given parametric assumptions on (ν, ϵ), the micro data identify (δ_t, Π, Σ) without any assumption on the joint distribution of (ξ, x) (Berry et al., 2004a, pp. 72–73). The interaction $\pi_{k\ell}$ between characteristic k and attribute ℓ is identified by the covariance of the attribute with the characteristic of the chosen product. If large families buy large cars more often than small families, the interaction of size with family size is positive. The unobserved tastes Σ need more. They are identified by the correlation between the characteristics of successive choices by the same consumer, through second-choice data or panels, or by variation in choice sets. Panels of repeated choices can also reveal persistent differences across consumers in the valuation of the unobserved quality ξ_{jt}. Our specification rules these out, because every consumer values ξ_{jt} equally. Das et al. (1994) allow a distribution of such valuations (Section 8.12.2).

This answers the question of why micro data reduce the worry about price endogeneity. The endogeneity problem comes from ξ_{jt}, and ξ_{jt} is constant within a market. Within-market comparisons across consumers are free of it, just as a within estimator is free of a fixed effect. The interactions of price with demographics, the elements of Π in the price row, are identified this way.

It also answers why the worry does not disappear. Own- and cross-price elasticities depend on the mean price coefficient α, and α enters only through δ_{jt}. Recovering it requires the regression

$$\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \tag{8.88}$$

which has one observation per product and market, and in which p_{jt} is correlated with ξ_{jt} for the reasons of Section 8.6. Berry et al. (2004a, p. 73) make the point directly. The number of observations available to estimate β "equals the number of products," so β cannot be identified "without some assumption on the joint distribution of (ξ, x)." Instruments are still needed for the mean price coefficient.

Two practical facts temper the appeal of product-level fixed effects. Berry et al. (1995, p. 852) note that their automobile data contain on average more than 100 products per year, against about 500 new-car purchases a year in the Consumer Expenditure Survey. With so few buyers per product, product dummies are estimated imprecisely, and earlier micro studies of car demand aggregated the products into a few classes. Nevo (2000a, Section 5.2) observes that most consumer-level studies ignore the correlation between prices and unobserved quality. He gives two reasons why it can persist. Consumers take prices as given, but their optimal choices from a menu can still create econometric endogeneity (Kennan, 1989). And unless the controls are rich enough, the common unobservable ξ_{jt} remains in the error and biases the estimates.

8.8.2 Two-step estimation with product-market effects

When the micro sample is large in every market, a two-step estimator follows directly from the argument above (Nevo, 2000a, p. 544). In the first step we maximize the simulated log likelihood of the observed choices,

$$\ell(\delta, \Pi, \Sigma) = \sum_{t=1}^{T} \sum_{i \in \mathcal{I}_t} \sum_{j=0}^{J_t} \mathbf{1}\{y_i = j\} \, \ln\Big(\frac{1}{n_s} \sum_{r=1}^{n_s} P_{ijt}(\delta_t, \Pi, \Sigma; D_i, \nu_r) \Big). \tag{8.89}$$

Here $\mathcal{I}_t$ is the set of sampled consumers in market t, and y_i is the product chosen by consumer i. The estimated mean utilities $\hat{\delta}_{jt}$ then play the role of the inverted mean utilities of the aggregate model. In the second step we estimate (8.88) by instrumental variables with $\hat{\delta}_{jt}$ as the dependent variable. The error of the second step is $\xi_{jt} + (\hat{\delta}_{jt} - \delta_{jt})$. The first-step estimation error adds to its variance and must enter the standard errors. With 2SLS, regressors $\boldsymbol{X}$ and instruments $\boldsymbol{Z}$, the variance of $\hat{\theta}_1$ is approximately

$$\operatorname{Var}(\hat{\theta}_1) \approx A \, \boldsymbol{Z}^{\top} \big(\operatorname{Var}(\xi) + V_{\hat{\delta}} \big) \boldsymbol{Z} \, A^{\top}, \qquad A = \big(\boldsymbol{X}^{\top} \boldsymbol{Z} (\boldsymbol{Z}^{\top}\boldsymbol{Z})^{-1} \boldsymbol{Z}^{\top} \boldsymbol{X} \big)^{-1} \boldsymbol{X}^{\top} \boldsymbol{Z} (\boldsymbol{Z}^{\top}\boldsymbol{Z})^{-1}, \tag{8.90}$$

where $\operatorname{Var}(\xi)$ is the covariance matrix of ξ and $V_{\hat{\delta}}$ is the first-step covariance matrix of $\hat{\delta}$. When aggregate shares are also available, a better first step uses them to pin down δ_t exactly, as the next subsections show.

8.8.3 Micro moments

Often the micro information comes as summary statistics. Petrin (2002) combines aggregate shares of automobiles with survey estimates of purchase probabilities for groups of households (Chapter 10). An example is the probability that a household in a given income group buys a new vehicle. Nevo (2000a, Section 5.2) describes the idea as forcing the estimated purchase probabilities to predict the observed ones, much like observing the same product in different markets. A typical *micro moment* matches the model's prediction of the mean attribute of the buyers of product j to its survey counterpart.

The model's prediction follows from Bayes' rule. Let F_D be the population distribution of attributes and F_ν the distribution of unobserved tastes, independent of D. Then

$$\begin{aligned} \mathbb{E}[D \mid y = j; \theta] &= \int D \, \mathrm{d}F(D \mid y = j) = \int D \, \frac{\mathbb{P}(y = j \mid D; \theta)}{\mathbb{P}(y = j; \theta)} \, \mathrm{d}F_D(D) \\ &= \frac{\iint D \, P_{ij}(\delta, \Pi, \Sigma; D, \nu) \, \mathrm{d}F_D(D) \, \mathrm{d}F_\nu(\nu)}{s_j(\delta, \theta_2)} \end{aligned} \tag{8.91}$$

(Berry et al., 2004a, eq. 9). The first equality defines the conditional mean. The second applies Bayes' rule to the conditional density of D given the choice. The third writes $\mathbb{P}(y = j \mid D) = \int P_{ij} \, \mathrm{d}F_\nu$ and $\mathbb{P}(y = j) = s_j$. When δ is chosen so that model shares match observed shares, the denominator equals the observed share s_j^{obs}. The numerator is simulated with draws (D_r, ν_r), $r = 1, \dots, n_s$, with D_r drawn from a household survey such as the Current Population Survey:

$$\hat{\mathbb{E}}[D \mid y = j; \theta] = \frac{\frac{1}{n_s} \sum_{r=1}^{n_s} D_r \, P_{rj}(\delta, \Pi, \Sigma; D_r, \nu_r)}{s_j^{\text{obs}}} \tag{8.92}$$

(Berry et al., 2004a, eq. 10). The micro moment is the difference between the survey mean of D among buyers of j and (8.92). Its sampling variance is the variance of D among buyers of j divided by the number of sampled buyers, plus the simulation variance of (8.92). Group purchase probabilities work the same way. The probability that a household in group g buys some product in a set $\mathcal{A}$ is $\frac{1}{\mathbb{P}(D \in g)} \iint \mathbf{1}\{D \in g\} \sum_{j \in \mathcal{A}} P_{ij} \, \mathrm{d}F_D \, \mathrm{d}F_\nu$.

8.8.4 The micro BLP estimator

Berry et al. (2004a) combine three kinds of information in one method of moments estimator. The data consist of aggregate shares s_j^N for the population of N households (over 100 million), and a choice-based sample from new-vehicle registrations. In the sample, n_j buyers of vehicle j report their attributes D_i and their second choice $j_i^{(2)}$, the vehicle they would have bought had their first choice $j_i^{(1)}$ been unavailable. The three sets of moments are as follows (Berry et al., 2004a, pp. 74–79).

1. The first set matches aggregate shares. The model must reproduce s_j^N, so for each value of $\theta_2 = (\Pi, \Sigma)$ the contraction mapping gives $\delta^{n_s,N}(\theta_2)$ solving

$$s_j^N - \frac{1}{n_s} \sum_{r=1}^{n_s} \mathbb{P}\big(j^{(1)} = j \mid D_r, \nu_r, \theta_2, \delta^{n_s,N}(\theta_2)\big) = 0 \tag{8.93}$$

   (their eq. 7). The sampling variance of s^N is of order $\frac{1}{N}$ and negligible, so the efficient estimator sets model shares equal to observed shares. This step concentrates out the more than 200 elements of δ, and the search runs over θ_2 only.

2. The second set consists of first-choice moments. Each interaction of a characteristic k with an attribute gets one moment. It compares the sample average attribute of buyers of j with (8.92), weighted by x_{kj} and by the sampling weights:

$$G^1(\theta_2) \approx \sum_j \frac{n_j}{n} x_{kj} \Big\{ \frac{1}{n_j} \sum_{i:\, j_i^{(1)} = j} D_i - \mathbb{E}\big[D \mid j^{(1)} = j, \theta_2\big] \Big\} \tag{8.94}$$

   (their eq. 8). These moments mainly identify Π. A separate moment for the mean attributes of buyers helps identify the utility of the outside good, because the sampling rates are roughly proportional to shares.

3. The third set consists of second-choice moments. Among buyers whose first choice is j, the average characteristic k of the reported second choices is compared with its model prediction, and the difference is interacted with x_{kj} (their eqs. 11–12). These moments identify Σ.

The model prediction for second choices rests on a property of the type-I extreme value distribution.

Lemma 8.39 (Second choices in the logit)**.** *Let $U_l = V_l + \epsilon_l$, $l \in C$, with ϵ_l independent and identically distributed type-I extreme value. For distinct $j, q \in C$,*

$$\mathbb{P}\Big(U_j > U_q > \max_{l \in C \setminus \{j,q\}} U_l\Big) = \frac{e^{V_j}}{\sum_{l \in C} e^{V_l}} \cdot \frac{e^{V_q}}{\sum_{l \in C \setminus \{j\}} e^{V_l}}. \tag{8.95}$$

Hence $\mathbb{P}(q \text{ second} \mid j \text{ first}) = \frac{e^{V_q}}{\sum_{l \in C \setminus \{j\}} e^{V_l}}$. *Conditioning also on the second choice being an inside good removes the outside good from the denominator.*

Proof. Let $R = C \setminus \{j, q\}$ and $M = \max_{l \in R} U_l$. By the max-stability of the extreme value distribution (Chapter 6), M is extreme value with location $V_R = \ln \sum_{l \in R} e^{V_l}$, and it is independent of U_j and U_q. For three independent extreme value variables, the logit formula gives the probability that each is the largest. The event $\{U_j > U_q > M\}$ equals $\{U_q > M\}$ minus $\{U_q > \max(U_j, M)\}$, and the second event is contained in the first. Therefore

$$\begin{aligned}
\mathbb{P}(U_j > U_q > M) &= \frac{e^{V_q}}{e^{V_q} + e^{V_R}} - \frac{e^{V_q}}{e^{V_j} + e^{V_q} + e^{V_R}} \\
&= \frac{e^{V_q}\left[(e^{V_j} + e^{V_q} + e^{V_R}) - (e^{V_q} + e^{V_R})\right]}{(e^{V_q} + e^{V_R})(e^{V_j} + e^{V_q} + e^{V_R})} \\
&= \frac{e^{V_j}}{e^{V_j} + e^{V_q} + e^{V_R}} \cdot \frac{e^{V_q}}{e^{V_q} + e^{V_R}}.
\end{aligned}$$

Since $e^{V_R} = \sum_{l \in R} e^{V_l}$, this is (8.95). Dividing by $\mathbb{P}(U_j \text{ largest})$ gives the conditional probability. Conditioning on $q \neq 0$ divides by $1 - \mathbb{P}(0 \text{ second} \mid j \text{ first})$, which removes e^{V_0} from the denominator. □

Fix (D, ν) and write $V_q = \delta_q + \sum_k \tilde{x}_{qk}(\pi_k^\top D + \sigma_k \nu_k)$. A second choice is a vehicle, so by Lemma 8.39 the second-choice probability is a logit over the inside goods other than j. The denominator drops both the outside good and j. This is the logit form "modified to take both vehicle j and the outside alternative out of the choice set" (Berry et al., 2004a, p. 79). It is also the "exploded" or rank-ordered logit of Beggs et al. (1981).

The aggregate prediction then weights consumer types by their probability of choosing j first. By Bayes' rule,

$$\mathbb{P}\big(j^{(2)} = q \mid j^{(1)} = j\big) = \frac{1}{s_j} \iint P_{ij}(D, \nu) \, \frac{e^{V_q(D,\nu)}}{\sum_{m \notin \{0,j\}} e^{V_m(D,\nu)}} \, \mathrm{d}F_D \, \mathrm{d}F_\nu. \tag{8.96}$$

Equation (8.96) shows why second choices identify Σ. Buyers of j are disproportionately consumers whose tastes (D, ν) favor j's characteristics. Their second choices inherit those tastes and fall on products with similar characteristics. With $\Sigma = 0$ the posterior tilt operates only through the observed attributes. With no heterogeneity at all, (8.96) becomes $\frac{e^{\delta_q}}{\sum_{m \notin \{0,j\}} e^{\delta_m}}$, which is proportional to the share of q. The plain logit predicts that the most popular vehicle is everyone's most likely second choice, whatever the first choice was.

The estimator stacks the first- and second-choice moments and applies two-step GMM (Hansen, 1982). The draws are held fixed, which brings the estimator under the limit theorems of Pakes and Pollard (1989). The asymptotic theory lets the sample size n grow with $\frac{N}{n} \to \infty$ and $\frac{n_s}{n}$ tending to a positive constant, so the variance includes simulation error. The covariance of the moments has two independent parts, sampling error in the survey means and simulation error. The second is estimated by recomputing the moments with many independent sets of draws, solving the contraction anew for each set (Berry et al., 2004a, Appendix and fn. 24). The authors report that somewhat less than half of the variance of their estimates is due to simulation (their fn. 15). The derivative matrix of the moments must include the effect of θ_2 on $\delta(\theta_2)$, as in Proposition 8.22.

Two findings of the application belong here, because they concern identification. The authors could not estimate the full model from first-choice data alone. Very different parameter values gave essentially the same value of the objective, and only the second-choice data allowed precise estimates (Berry et al., 2004a, p. 90). Their single cross section has no variation in choice sets. In other data, they note, such variation might identify the random coefficients instead. And the micro data leave the mean price coefficient to the product-level regression (8.88). Section 8.14 reports how they resolve it with the pricing equation and with outside information.

8.8.5 Nonparametric identification with micro data: Berry and Haile (2024)*

Question. Berry and Haile (2024) ask in what precise sense micro data help to identify demand. Their earlier work showed that with market-level data, nonparametric identification requires instruments for all prices and all quantities (Berry and Haile, 2014). The characteristics of rival products serve as the instruments for quantities (Section 8.6). The question matters because instruments are the scarcest input of demand estimation. Their main message is that "micro data has a high marginal value over market-level data alone" (p. 1136). With rich enough micro data, the only essential instruments are those for prices. This "cuts the number of required instruments in half and avoids the necessary reliance on BLP instruments" (p. 1136).

Setting. There are J goods and an outside good, consumers i and markets t. A market is defined by a price vector P_t, other observables X_t, a vector of unobservables $\xi_t = (\xi_{1t}, \dots, \xi_{Jt})$, and a distribution of consumer observables $D_{it} \in \mathbb{R}^J$. We write D_{it} for what the authors call Z_{it}, to avoid a clash with our instrument matrix. The *choice environment* of consumer i is $C_{it} = (D_{it}, P_t, X_t, \xi_t)$. With discrete choice, behavior is summarized by the structural choice probabilities

$$\mathbf{s}(C_{it}) = \mathbb{E}[Q_{it} \mid C_{it}], \tag{8.97}$$

where $Q_{it} \in \{0,1\}^J$ records the purchase (their eq. 1). The authors also define the *conditional demand* of market t, $\tilde{\mathbf{s}}(D, P; t) = \mathbf{s}(D, P, x_t, \xi_t)$, the demand function with (X_t, ξ_t) held at their realized values. It answers ceteris paribus questions about prices. It determines all own- and cross-price elasticities in market t, markups and marginal costs under a model of supply, diversion ratios, and equilibrium responses to taxes or mergers. It cannot answer questions about changes in X_t.

Model and assumptions. Beyond the dimension requirement on D_{it}, the model rests on an index structure. We write the assumptions in our notation.

Assumption 8.40 (Berry-Haile index structure)**.** (1) *Index*. $\mathbf{s}(C_{it}) = \varrho(\psi(D_{it}, X_t, \xi_t), P_t, X_t)$, where $\psi = (\psi_1, \dots, \psi_J)$ and $\psi_j(D_{it}, X_t, \xi_t) = \phi_j(D_{it}, X_t) + \xi_{jt}$. (2) *Invertible demand*. For all (p, x), $\varrho(\cdot, p, x)$ is injective on the support of the index. (3) *Injective index*. For all (x, ξ), $\psi(\cdot, x, \xi)$ is injective on the support $\mathcal{D}(x)$ of D_{it}. (4) *Support*. $\mathcal{D}(x)$ is open and connected. (5) *Nondegeneracy*. For each x there is a price vector p such that the support of ξ_t given $(P_t, X_t) = (p, x)$ is open and connected. (6) Smoothness and nonsingular Jacobians of the index with respect to D and of ϱ with respect to the index.

These are Assumptions 1 to 6 of Berry and Haile (2024, pp. 1141–1143). The index assumption is the key functional form restriction. Prices are excluded from the index, and each demand shock ξ_{jt} enters only the j-th component, additively. A unit change in $\phi_j(D_{it}, X_t)$ thus has the same effect on demand as a unit change in ξ_{jt}. Invertibility follows from Berry (1994)

under standard distributional assumptions, or from the connected-substitutes conditions of Berry et al. (2013). Nondegeneracy rules out cases in which (P_t, X_t) pins down ξ_t. It holds in standard supply models, where cost shifters let the same prices arise under different demand shocks.

The authors absorb the conditional mean of ξ_t into the index. Define

$$g(D_{it}, X_t) = \phi(D_{it}, X_t) + \mathbb{E}[\xi_t \mid X_t], \qquad h(X_t, \xi_t) = \xi_t - \mathbb{E}[\xi_t \mid X_t], \tag{8.98}$$

so that $\psi = g + h$ and $\mathbb{E}[h(X_t, \xi_t) \mid X_t] = 0$ by construction (their eqs. 2–4). Demand and conditional demand become

$$\mathbf{s}(C_{it}) = \varrho\big(g(D_{it}, X_t) + h(X_t, \xi_t), P_t, X_t\big), \qquad \tilde{\mathbf{s}}(D_{it}, P_t; t) = \varrho\big(g(D_{it}, x_t) + h(x_t, \xi_t), P_t, x_t\big). \tag{8.99}$$

Two normalizations fix the representation. The location of ξ is free, so $\mathbb{E}[\xi_t] = 0$. Any injective affine transformation of the index can be undone by redefining ϱ, so the authors pick a point $d^0(x)$ in the support and set $g(d^0(x), x) = 0$ and $\frac{\partial g(d,x)}{\partial d}\big|_{d=d^0(x)} = I$ (their eqs. 9–10).

The standard random coefficients model is a special case (Berry and Haile, 2024, Section 3). Take

$$u_{ijt} = x_{jt}\beta_{ijt} - \alpha_{it}p_{jt} + \xi_{jt} + \epsilon_{ijt}, \qquad u_{i0t} = \epsilon_{i0t},$$

with $\alpha_{it} = \exp(\alpha_0 + \alpha_y y_{it} + \alpha_\nu \nu_{it}^{(0)})$, where y_{it} is income, and $\beta_{ijt}^{(k)} = \beta_{0j}^{(k)} + \sum_{\ell=1}^{L} \beta_{zj}^{(k,\ell)} D_{i\ell t} + \beta_{\nu j}^{(k)} \nu_{it}^{(k)}$ (their eqs. 11–13). Collecting terms gives $u_{ijt} = g_j(D_{it}, x_t) + \xi_{jt} + \mu_{ijt}$, with

$$g_j(D_{it}, x_t) = \sum_k x_{jt}^{(k)} \sum_{\ell=1}^{L} \beta_{zj}^{(k,\ell)} D_{i\ell t} \tag{8.100}$$

and μ_{ijt} collecting the remaining terms (their eqs. 14–16). All effects of D_{it} and ξ_t run through the indices $g_j + \xi_{jt}$, so the index assumption holds. The injective-index assumption requires the linear map g to be invertible in a J-dimensional subvector of D_{it}, hence $L \geq J$. The example has no consumer attribute that shifts the utility of one good exclusively. Nor does it make the composite error $\xi_{jt} + \mu_{ijt}$ independent of the observables. Both features are often required in earlier identification results for micro data.

Identification argument. The observables are $(Q_{it}, D_{it}, P_t, X_t)$ and instruments z_t. They reveal $s_t(d)$, the choice probabilities in market t conditional on $D_{it} = d$. The argument proceeds in three steps.

The first step uses within-market variation to identify g. By the two injectivity assumptions, for each choice probability vector s in market t there is a unique consumer type $d_t^*(s)$ who chooses with probabilities s. This type is observed even though ξ_t is not. Inverting ϱ gives

$$g\big(d_t^*(s), x\big) + h(x, \xi_t) = \varrho^{-1}(s; p, x) \tag{8.101}$$

(their eq. 19). Take two markets t and t' with the same (p, x) but different demand shocks. Suppose the same probability vector $\hat{s}$ arises at $d = d_t^*(\hat{s})$ in market t and at $d' = d_{t'}^*(\hat{s})$ in market t'. Differentiating (8.101) with respect to s in each market gives

$$\frac{\partial g(d, x)}{\partial d}\frac{\partial d_t^*(\hat{s})}{\partial s} = \frac{\partial \varrho^{-1}(\hat{s}; p, x)}{\partial s} = \frac{\partial g(d', x)}{\partial d}\frac{\partial d_{t'}^*(\hat{s})}{\partial s},$$

and therefore

$$\left[\frac{\partial g(d', x)}{\partial d}\right]^{-1}\frac{\partial g(d, x)}{\partial d} = \frac{\partial d_{t'}^*(\hat{s})}{\partial s}\left[\frac{\partial d_t^*(\hat{s})}{\partial s}\right]^{-1}.$$

The right side is observed, so the left side is identified (their Lemma 2). Nondegeneracy guarantees that such pairs of markets exist for all nearby d and d' (their Lemma 1). Chaining overlapping neighborhoods from $d^0(x)$, using the normalization of the Jacobian at $d^0(x)$ and integrating along paths, identifies $g(\cdot, x)$ everywhere on $\mathcal{D}(x)$ (their Lemma 3). It follows that $\frac{\partial \varrho^{-1}}{\partial s}$ is identified, and so is the difference $A(p, x, s^1, s^0) = \varrho^{-1}(s^1; p, x) - \varrho^{-1}(s^0; p, x)$ between any two probability vectors that occur at (p, x) (their Corollary 1, where the difference is called Ω).

The second step uses instruments for prices to recover the demand shocks. The authors assume

$$\text{(i) } \mathbb{E}[h_j(X_t, \xi_{jt}) \mid X_t, z_t] = 0 \text{ for all } j, \qquad \text{(ii) } \mathbb{E}[\Psi(X_t, P_t) \mid X_t, z_t] = 0 \implies \Psi(X_t, P_t) = 0 \text{ a.s.} \tag{8.102}$$

for all functions Ψ with finite expectation (their Assumption 7). Part (i) is the exclusion restriction, and part (ii) is the completeness condition of nonparametric instrumental variables. Fix an arbitrary consumer type $\tilde{d}_{it}$ in market t and an arbitrary reference vector $s^0(p, x)$. Rearranging (8.101) gives, for each good j,

$$\tilde{y}_{jt} = f_j(x_t, p_t) - e_{jt}, \tag{8.103}$$

with

$$\tilde{y}_{jt} = g_j(\tilde{d}_{it}, x_t) - A_j\big(p_t, x_t, s_t(\tilde{d}_{it}), s^0(p_t, x_t)\big),$$
$$f_j(x, p) = \varrho_j^{-1}\big(s^0(p, x); p, x\big), \qquad e_{jt} = h_j(x_t, \xi_{jt})$$

(their eqs. 26–27). The left side is known from the first step. Equation (8.103) is a separable nonparametric regression with endogenous regressors (X_t, P_t), an unknown function f_j and errors satisfying $\mathbb{E}[e_{jt} \mid X_t, z_t] = 0$. By Newey and Powell (2003, Proposition 2.1), completeness identifies f_j, and hence every $e_{jt} = h_j(x_t, \xi_{jt})$ (their Lemma 4). Once $h(x_t, \xi_t)$ is known in every market, conditional demand is a conditional expectation of observables:

$$\tilde{\mathbf{s}}(D_{it}, P_t; t) = \mathbb{E}\big[Q_{it} \mid D_{it}, P_t, x_t, h(x_t, \xi_t)\big].$$

This is their Theorem 1. Conditional demand is identified in every market without assuming that X_t is exogenous.

The third step adds exogeneity of the other observables, $\mathbb{E}[\xi_t \mid X_t] = 0$ (their Assumption 8). Then $h(X_t, \xi_t) = \xi_t$, the demand shocks themselves are identified, and so is the full demand function $\mathbf{s}$ (their Theorem 2). The instruments required are excluded instruments for prices only. Quantities, the choice probabilities, never appear as regressors in (8.103), because the adjustment terms A_j remove them. This is the source of the halving of instrument requirements. Table 8.7 summarizes the contrast with market-level data.

Lessons for applied work. Section 5 of the paper draws four lessons. First, the marginal value of micro data is high. Within-market variation in consumer observables identifies g, and with it the derivatives of demand with respect to the index, without any instrument. This variation is free of confounding demand shocks because ξ_t does not vary within a market. The consumer observables are not assumed exogenous. The logic is that of within estimation in panel data with fixed effects.

Second, cross-market variation remains essential. Lemma 2 needs markets with the same prices and different demand shocks. More fundamentally, demand depends on (X_t, P_t, ξ_t),

Table 8.7: What nonparametric identification of demand requires with market-level data and with micro data.

	Market-level data (Berry and Haile, 2014)	Micro data (Berry and Haile, 2024)
Index restriction	on product characteristics $x_{jt}^{(1)}$, one per good	on consumer observables D_{it}, of dimension J
Excluded instruments	for all J prices and all J quantities	for the J prices only
Role of rival characteristics	essential instruments for quantities	not needed (usable for prices only under extra restrictions)
Exogeneity of X_t	required	not required for conditional demand (elasticities, markups)
Source of substitution patterns	cross-market variation with instruments	within-market variation across consumers
Cross-market variation	essential	still essential

Notes: Summary of Berry and Haile (2024, Sections 1, 4 and 5). Both columns also require completeness conditions and continuous support for the instruments.

which do not vary within a market. Data from one market therefore reveal nothing about the effects of prices without additional restrictions. The authors give an example (their fn. 31). With one market, set $\xi = 0$, assume X has no effect, and posit a multinomial logit with money-metric utilities $g_j(d) - p_j$. Choosing $g(d) = \varrho_{MNL}^{-1}(s(d)) + p$ fits the observed choice probabilities perfectly. The implied price effects then reflect only the a priori assumptions.

Third, the focus shifts to instruments for prices. Candidates include cost shifters, the prices of the same product in other markets (Hausman instruments, Section 8.6), and exogenous shifters of market structure. Micro data add the Waldfogel instruments of Section 8.6.4, market-level demographics that shift equilibrium markups (Waldfogel, 2003). With micro data, individual demographics enter demand directly, so the market average can plausibly be excluded. When X_t is endogenous, conditioning on it can make a valid instrument invalid, or the reverse. The authors' Appendix A uses causal graphs to examine these cases. Rival characteristics, the BLP instruments, are not needed to shift quantities. To use them for prices requires both their exogeneity and a restriction on how they enter demand.

Fourth, the results do not license ignoring functional forms. The authors describe their sufficient conditions as "an ideal," a "point of reference" for judging the available evidence (p. 1154). With large choice sets it is hard to find J excluded instruments and J-dimensional consumer observables. Their Supplemental Appendix studies trade-offs, including semiparametric models in which a single binary consumer characteristic and a single excluded price instrument suffice.

Interpretation and critiques. The paper explains why empirical work with micro data, such as Petrin (2002) and Berry et al. (2004a), obtains much more precise estimates than work with market data alone. It also clarifies a division of labor that Section 8.8.1 derived in the parametric model. Within-market variation identifies substitution patterns, while the level of price effects needs cross-market variation and price instruments. The limits are equally clear. The requirement of J continuous consumer observables is demanding when J is large. The index restriction allows a random coefficient on each index $\phi_j + \xi_{jt}$ but rules out random coefficients on ξ_{jt} or on terms involving D_{it} (their fn. 19). Completeness conditions cannot be tested. The contribution is a nonparametric foundation for the micro-data branch of the

literature, and a precise statement of what micro data can and cannot replace.

8.9 Estimation in practice and the limits of the model

The estimator of Section 8.5 is a nonlinear GMM problem with an inner fixed point, simulated integrals and instruments of uncertain strength. Each of these features can produce estimates that reflect the algorithm more than the data. This section collects the practical lessons of the literature, proves the sign normalization of the standard deviations, and then turns to the limits of the model itself.

8.9.1 A practical checklist

The following list summarizes recommendations from Nevo (2000a), Dubé et al. (2012), Knittel and Metaxoglou (2014) and Conlon and Gortmaker (2020), together with lessons from the simulated market of Section 8.10.

1. Search from many starting values and compare the minima. The GMM objective can have several local minima, and optimizers can stop at points that are not minima. Knittel and Metaxoglou (2014, p. 34) show that estimates, and the merger predictions built on them, can change with the optimization algorithm and the starting values. Across their runs, price elasticities and the welfare effects of hypothetical mergers vary by a factor of 2 to 5.
2. Set the inner tolerance much tighter than the outer one, for example 10^{-12} to 10^{-14} for the contraction. A loose inner tolerance makes the objective numerically non-smooth, and the optimizer may stop at a false minimum (Dubé et al., 2012, and Proposition 8.18).
3. Supply analytic gradients (Proposition 8.22). At the reported minimum, check that the gradient is close to zero and that the Hessian is positive definite. Report the smallest eigenvalue of $G^\top W G$, which signals weak identification when it is close to zero.
4. Scale the characteristics to comparable magnitudes. The standard deviations are then comparable, and the optimizer works on a better conditioned problem.
5. Evaluate exponentials safely. Subtract $\max\{0, \max_k V_{ik}\}$ from all utilities of draw i, including the zero utility of the outside good, before exponentiating.
6. Choose the number and type of draws with care and hold them fixed across evaluations of the objective. Use different draws in different markets, or quadrature and quasi-random rules (Section 8.3). The number of draws must grow with the number of products (Berry et al., 2004b).
7. Report standard errors that include simulation error, estimated by recomputing the moments with new draws (Section 8.5).
8. Impose the sign normalization of Proposition 8.41 below, and do not start the search at $\sigma_k = 0$.
9. Check the economic output. All own-price elasticities should be negative and all markups and marginal costs positive. Diversion to the outside good should be plausible, and markups should be compared with accounting data when these exist. When the price coefficient has a random component, report the share of consumers with a positive price coefficient. Nevo (2001, p. 329) reports 0.7 percent for his main specification, against as much as 13 percent in specifications without demographic interactions.

10. Check sensitivity to the definition of market size, which determines the outside share (Section 8.1).
11. Treat zero shares explicitly. The model predicts a positive share for every product, so an observed zero cannot be inverted, and dropping zeros selects the sample. Gandhi et al. (2023) propose an estimator for data with zeros.
12. Examine instrument strength. Near collinearity among rival sums of characteristics is common. Differentiation instruments (Gandhi and Houde, 2019) and approximate optimal instruments (Reynaert and Verboven, 2014) often help (Section 8.6).
13. Use tested software where possible. The `pyblp` package of Conlon and Gortmaker (2020, Sections 3 and 4) implements many of these recommendations, including approximate optimal instruments, accelerated fixed-point iteration and quadrature rules.

8.9.2 The sign of the standard deviations*

The standard deviations in Σ are identified only up to sign. The reason is the symmetry of the taste distribution.

Proposition 8.41 (Sign normalization of Σ)**.** *Let R_k be the diagonal matrix that flips the sign of the k-th component of a vector. Suppose that ν_i has the same distribution as $R_k\nu_i$ and is independent of D_i. This holds, for example, for $\nu_i \sim N(0, I)$. Let Σ' equal Σ with its k-th column multiplied by -1. Then for every market and every δ_t,*

$$s_t(\delta_t; \Pi, \Sigma') = s_t(\delta_t; \Pi, \Sigma). \tag{8.104}$$

Consequently $\delta_t(s_t^{obs}; \Pi, \Sigma') = \delta_t(s_t^{obs}; \Pi, \Sigma)$, the GMM objective takes the same value at Σ and Σ', and the sign of column k of Σ is not identified. If the objective is differentiable, its derivative with respect to σ_k is zero at $\sigma_k = 0$ when Σ is diagonal.

Proof. Column k of Σ enters utility through $\tilde{x}_{jt}\Sigma\nu_i = \sum_m \tilde{x}_{jt}\Sigma_{\cdot m}\nu_{im}$. Since $\Sigma' = \Sigma R_k$, we have $\tilde{x}_{jt}\Sigma'\nu_i = \tilde{x}_{jt}\Sigma(R_k\nu_i)$. Write $\tilde{\nu}_i = R_k\nu_i$. The share of product j under Σ' is

$$\begin{aligned} s_{jt}(\delta_t; \Pi, \Sigma') &= \iint \frac{\exp(\delta_{jt} + \tilde{x}_{jt}(\Pi D + \Sigma R_k \nu))}{1 + \sum_q \exp(\delta_{qt} + \tilde{x}_{qt}(\Pi D + \Sigma R_k \nu))} \, \mathrm{d}F_\nu(\nu) \, \mathrm{d}F_D(D) \\ &= \iint \frac{\exp(\delta_{jt} + \tilde{x}_{jt}(\Pi D + \Sigma \tilde{\nu}))}{1 + \sum_q \exp(\delta_{qt} + \tilde{x}_{qt}(\Pi D + \Sigma \tilde{\nu}))} \, \mathrm{d}F_\nu(\tilde{\nu}) \, \mathrm{d}F_D(D) = s_{jt}(\delta_t; \Pi, \Sigma), \end{aligned}$$

where the second equality changes variables from ν to $\tilde{\nu}$, which has the same distribution and is independent of D. This proves (8.104). The inversion is unique (Section 8.4), so equal share functions give equal inverses, equal $\xi(\theta)$ and equal moments. With Σ diagonal, flipping column k is the same as replacing σ_k by $-\sigma_k$. The objective is then an even function of σ_k, and the derivative of a differentiable even function is zero at the origin. □

The proposition has three practical consequences. We restrict $\sigma_k \geq 0$, or estimate without restriction and report $|\hat{\sigma}_k|$. We never start the search at $\sigma_k = 0$, because the gradient in that direction is zero there and a gradient-based optimizer will not move. And tests of $\sigma_k = 0$ are nonstandard, because the restricted value lies on the boundary of the parameter space. The usual t test is not valid there. The same argument would apply to a column of Π only if the distribution of the corresponding demographic were symmetric about zero, which is rare. Income, for example, is skewed. With a full matrix Σ in Cholesky form, the analogous normalization is a nonnegative diagonal.

8.9.3 The too-many-characteristics problem

The idiosyncratic shock ϵ_{ijt} is what makes the logit family tractable. It is also the source of the model's main limitation. Every product brings its own dimension of taste, ϵ_{ij}, and with it a set of consumers who like that product for no observable reason. Berry and Pakes (2007, Section 2) describe models of this kind as having "tastes for products," as opposed to tastes for characteristics. The dimension of the implied characteristic space grows with the number of products, which leads to four problems.

The first is substitution between near-identical products. Suppose a commuter chooses between a car and a red bus with equal mean utility δ, and there is no outside good. Logit shares are $\frac{1}{2}$ each. Add a blue bus, identical to the red bus. The logit share of each alternative becomes

$$\frac{e^{\delta}}{e^{\delta}+e^{\delta}+e^{\delta}}=\frac{1}{3},$$

because the ratio of the car's share to the red bus's share must stay at one. Common sense predicts $\frac{1}{2}$ for the car and $\frac{1}{4}$ for each bus. Random coefficients help. Give the two buses a common random coefficient $\sigma\nu_i$ on a bus dummy, with $\nu_i \sim N(0,1)$. Conditional on ν_i the car's choice probability is $\frac{1}{1+2e^{\sigma\nu_i}}$. As $\sigma \to \infty$ this tends to one for $\nu_i < 0$ and to zero for $\nu_i > 0$, so the car's share tends to $\frac{1}{2}$ and each bus gets $\frac{1}{4}$. The two buses still differ in their ϵ draws, however, and that difference drives the remaining problems.

The second problem concerns markups. With J symmetric single-product firms, logit demand and an outside good, each share is $s=\frac{e^{\delta}}{1+Je^{\delta}}$, and (8.24) gives the markup

$$p-mc=\frac{1}{\alpha(1-s)}\;\longrightarrow\;\frac{1}{\alpha}\qquad\text{as } J\to\infty.$$

The markup never falls below $\frac{1}{\alpha}$, however crowded the market. Every product keeps consumers with high ϵ_{ij} who would pay a premium for it. Berry and Pakes (2007, Section 2) make this point for any model with an i.i.d. taste for each product, and they note that Anderson et al. (1992) make a similar point for the logit. They draw two implications: there is always a further incentive to develop products, and outcomes do not approach competition as products multiply. Random coefficients do not remove the floor, because each product keeps its own ϵ. In the pure characteristics model of Section 8.9.4, by contrast, products become ever closer substitutes as the product space fills up, and prices approach marginal cost (Berry and Pakes, 2007, Section 2).

The third problem concerns welfare. Logit consumer surplus is $\frac{1}{\alpha}\ln(1+\sum_k e^{\delta_k})$ up to a constant (Chapter 7). Adding a clone of product j, with the same δ_j, raises it by

$$\frac{1}{\alpha}\left[\ln\left(1+\sum_k e^{\delta_k}+e^{\delta_j}\right)-\ln\left(1+\sum_k e^{\delta_k}\right)\right]=\frac{1}{\alpha}\ln\left(1+\frac{e^{\delta_j}}{1+\sum_k e^{\delta_k}}\right)>0,$$

although nothing new is offered. With J identical products, surplus is $\frac{1}{\alpha}\ln(1+Je^{\delta})$, which grows like $\frac{1}{\alpha}(\ln J+\delta)$ without bound. In the bus example with $\sigma\to\infty$, the bus lovers gain $\ln 2$ in expected maximum utility when the blue bus arrives, for the same reason. The model is therefore likely to overstate the welfare gains from new products (Chapter 10). In a model with a finite set of characteristics, by contrast, the gain from an additional product declines to zero as the product space fills up (Berry and Pakes, 2007, Section 2).

The fourth problem is the mirror image. The model predicts a positive share for every product at every parameter value, so it cannot use the information in products with zero sales. The inversion $\ln s_j$ is undefined at $s_j = 0$.

8.9.4 The pure characteristics model

Berry and Pakes (2007) propose to drop the idiosyncratic shock. Their *pure characteristics model* has utility

$$u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j, \qquad u_{i0} = 0, \tag{8.105}$$

with $\beta_{ik} = \beta_k + \sigma_k \nu_{ik}$ and $\alpha_i > 0$ (Berry and Pakes, 2007, eqs. 10–11). The model assumes a single unobserved characteristic, and that it is *vertical*: every consumer values more ξ. Utility is normalized by subtracting the outside option's utility and dividing by the coefficient on ξ, and the mean of α_i is set to one to fix units. The model is the random coefficients logit without ϵ. It is also related to the ideal-point models of the theory of product differentiation (Chapter 6). In those models consumers care about the distance between their own location and the product's location in characteristic space.

The obvious way to nest the two models fails. Scale the logit shock by λ and divide utility by λ. The choice probability becomes

$$\mathbb{P}(i \text{ chooses } j) = \int \frac{\exp\left(\varsigma[f_{ij} + \sum_k \nu_{ik} x_{jk}]\right)}{\sum_q \exp\left(\varsigma[f_{iq} + \sum_k \nu_{ik} x_{qk}]\right)} \, \mathrm{d}F(\nu), \qquad \varsigma = \frac{1}{\lambda},$$

which tends to the pure characteristics probability as $\varsigma \to \infty$ (Berry and Pakes, 2007, eqs. 7–9). The authors give three reasons why this "modified BLP" model need not mimic the pure characteristics model. Standard consistency proofs fail, because the limit lies at the boundary $\lambda = 0$ where the shares are undefined. Computers cannot evaluate $\exp(\varsigma \cdot)$ when ς is large. And an estimator that knows $\lambda = 0$ should be more precise.

Shares in the pure characteristics model are computed from the vertical model. Fix all random coefficients except α_i, so that $\delta_j(\nu) = x_j\beta_i + \xi_j$ is the quality of product j for this consumer type. Order the products by price, with the outside good first ($p_0 = 0$, $\delta_0 = 0$). A consumer prefers j to a cheaper product k if and only if $\alpha_i(p_j - p_k) < \delta_j - \delta_k$, and to a more expensive product k if and only if $\alpha_i(p_k - p_j) > \delta_k - \delta_j$. She buys j if and only if

$$\underline{\Delta}_j(\nu) \equiv \max_{k>j} \frac{\delta_k - \delta_j}{p_k - p_j} < \alpha_i < \min_{k<j} \frac{\delta_j - \delta_k}{p_j - p_k} \equiv \bar{\Delta}_j(\nu) \tag{8.106}$$

(Berry and Pakes, 2007, eq. 15). With $F(\cdot \mid \nu)$ the distribution of α_i, the share is the mixture over ν of vertical-model shares,

$$s_j = \int \left[F(\bar{\Delta}_j(\nu) \mid \nu) - F(\underline{\Delta}_j(\nu) \mid \nu)\right] \mathbf{1}\{\bar{\Delta}_j(\nu) > \underline{\Delta}_j(\nu)\} \, \mathrm{d}G(\nu) \tag{8.107}$$

(their eq. 18), simulated with draws from G. If F has a density, the simulated shares are continuous and piecewise smooth in the parameters, with kinks where the binding neighbor in (8.106) changes. A product whose quality is too low for its price has zero share for that consumer type, so the model can generate zero and very small shares.

The inversion is harder. The authors prove that a unique δ reproduces any interior share vector under three conditions (their Theorem 1). Shares must be monotone in own and rival δ. They must not change when the same constant is added to every δ. And every product must be a strict substitute with some other good. The proof shows that the *element-by-element inverse*, which solves each share equation for its own δ_j holding the others fixed, is a weak contraction with modulus at most one. The authors could not prove that the modulus is below one. They therefore combine three methods. The first is the modified BLP contraction with a large ς.

The second is the element-by-element inverse with occasional Newton steps. The third is a homotopy,

$$\delta(t) = (1 - t)\,\delta^0 + t\,r\big(s, \delta(t)\big), \qquad t \in [0, 1), \tag{8.108}$$

where r is the element-by-element inverse and δ^0 a starting guess (their eqs. 32–34). For $t < 1$ the map in (8.108) is a contraction with modulus at most t. As t approaches one, the solution approaches the true inverse and convergence slows.

Simulation error works in the other direction. In the logit, $\frac{\partial \delta_j}{\partial s_j} = \frac{1}{s_j} + \frac{1}{s_0}$ with the other inside shares held fixed. This is close to $\frac{1}{s_j}$ for a small product, so small shares make δ very sensitive to error in the shares. In the vertical model competition becomes local and fierce as products multiply, and δ is much less sensitive. Berry and Pakes (2007, Section 4.4) report the results of Berry et al. (2004b). The number of draws must grow at rate J in the vertical model, against J^2 in logit-style models. In their Monte Carlo work, fifty draws suffice for the vertical model with up to two hundred products, while the logit model with one hundred products needs over two thousand draws.

The Monte Carlo evidence of Berry and Pakes (2007, Section 5) shapes the practical advice. Their two sample designs differ mainly in the number of products. The first has 20 markets, each with a number of products drawn with equal probability from two to ten. The second has 100 products per market but only three markets. The homotopy is slow in this design, so the authors experiment less with it. Both designs use 5,000 simulated consumers to construct predicted shares (Section 5.3). Consider first the design with few products per market. With the scale ς fixed at a large value, the modified BLP contraction estimates the parameters about as well as the homotopy. When ς is estimated instead, the results are noticeably worse, and large values of ς often cause numerical errors. The functional form used to compute elasticities matters as well. Derivatives computed from the pure characteristics share equations reproduce the true substitution patterns much better than those computed from the modified BLP formulas, even at the modified BLP parameter estimates. With many products (about 100 per market, patterned on the personal computer market), the differences are large. The modified BLP model drives the constant down to fit the tiny shares, and only the homotopy captures the level of the elasticities. A hybrid works well. It keeps the modified BLP estimates of the taste distribution, recomputes δ by the homotopy, and then computes elasticities.

8.9.5 The hedonic approach

Bajari and Benkard (2005) revive the two-step hedonic approach of Rosen (1974) and allow for one unobserved characteristic. We cite their 2004 working paper version. A product is a vector (x_j, ξ_j) with scalar ξ_j, and consumer i chooses a product and a composite good c to maximize $u_i(x_j, \xi_j, c)$ subject to $p_{jt} + c \le y_i$. There is no idiosyncratic shock.

The first result needs only consumer optimization. Suppose utility is strictly increasing in c with a marginal utility bounded away from zero, Lipschitz in (x, ξ), and strictly increasing in ξ. Then, among products with positive demand, equal characteristics imply equal prices and higher ξ implies a higher price. Prices are also Lipschitz in characteristics (their Theorem 1). Hence $p_{jt} = \mathbf{p}_t(x_j, \xi_j)$ for a market-specific *hedonic price function*. The function is an equilibrium object that holds for any supply model, and it changes whenever a primitive changes.

The first stage recovers $\mathbf{p}_t$ and the ξ_j. The authors give four sets of sufficient conditions. In the leading case ξ is independent of x and $\mathbf{p}_t(x, \cdot)$ is strictly increasing. Normalize ξ to be

uniform on $[0,1]$. Then

$$F_{p_t|x=x_j}(p_{jt}) = \mathbb{P}\big(\mathbf{p}_t(x,\xi) \le p_{jt} \mid x = x_j\big) = \mathbb{P}\big(\xi \le \mathbf{p}_t^{-1}(x_j, p_{jt})\big) \\ = \mathbf{p}_t^{-1}(x_j, p_{jt}) = \xi_j,$$

so ξ_j is the conditional quantile rank of product j's price among products with the same observed characteristics, following Matzkin (2003). The other cases use models sold with options packages that share the model's ξ, a market in which prices depend on ξ alone, or nonparametric instruments.

The second stage recovers tastes from each consumer's choice. With a continuum of products, the chosen bundle satisfies first-order conditions that equate marginal rates of substitution to the slopes of the price function. With utility $u_{ij} = \sum_k \beta_{ik} \ln x_{jk} + \beta_{i\xi} \ln \xi_j + c$, the conditions $\frac{\beta_{ik}}{x_{jk}} = \frac{\partial \mathbf{p}_t}{\partial x_{jk}}$ give

$$\beta_{ik} = x_{jk} \frac{\partial \mathbf{p}_t(x_j, \xi_j)}{\partial x_{jk}}, \qquad \beta_{i\xi} = \xi_j \frac{\partial \mathbf{p}_t(x_j, \xi_j)}{\partial \xi_j} \tag{8.109}$$

(their eqs. 6–10). One observed choice recovers the consumer's whole taste vector, and the distribution of tastes follows nonparametrically. In general, one choice identifies at most as many random coefficients as there are continuous characteristics (their Theorem 5). With a finite set of products, revealed preference only places each consumer's taste vector in a set. The authors use these sets to bound the taste distribution, or to estimate it by Gibbs sampling.

The motivation for the unobserved characteristic is striking. In their personal computer data, 357 of 695 products are dominated: another product is better in every observed characteristic and cheaper (their Section 1). A hedonic model with fully observed characteristics cannot rationalize positive demand for such products, while an unobserved ξ can. In the application the authors estimate a 20-dimensional taste distribution for desktop computers. They find tastes for the characteristics highly positively correlated and rising quickly over time. The main cost of the approach is its data requirement. The first stage needs many products, and the second stage needs a dense product space for the first-order conditions to be informative. Compared with the random coefficients logit, the hedonic model imposes no particular shape on demand curves, and the two models can differ most in predictions outside the range of the data.

8.10 A simulated market: estimation step by step

This section estimates the random coefficients logit on data that we generate ourselves. Because we know the true parameters, we can see what each step of the method recovers and what it does not. Appendix C poses the same market as a problem and solves its first five steps in full (Sections C.4, C.6 and C.7). These steps run from the simulation of the data to instrumental variables with the taste dispersion Σ known. The appendix also adds the vertical model of Chapter 6. Here we summarize what each of those five steps teaches and refer to the appendix for their tables. Steps 6 and 7 go further. They estimate the taste dispersion itself and trace the consequences for substitution patterns. Every number below comes from a single Python script with fixed random seeds, `worked_example.py` in the folder `figures/ch08/src`, so the reader can reproduce all of them.

8.10.1 Design

Think of the market for yogurt in 100 metropolitan areas, which we treat as independent markets. Ten products exist in total, and four firms own them. Each market offers between 4 and 9 of them, 6.54 on average, which gives 654 product-market observations. A product has three characteristics: a constant, its sugar content and an indicator for organic production. Products 2, 4 and 9 are organic. Marginal cost also depends on a cost shifter w_j, the price of milk used in production. The characteristics and the cost shifter are fixed by product across markets, and Table C.14 lists them. Across markets, only the set of products offered, the unobservables (ξ_{jt}, ω_{jt}) and the market size vary.

Consumer i in market t has utility

$$u_{ijt} = x_j\beta - \alpha p_{jt} + \xi_{jt} + \tilde{x}_{jt}\Sigma\nu_i + \epsilon_{ijt}, \qquad u_{i0t} = \epsilon_{i0t}, \tag{8.110}$$

where $x_j = (1, \text{sugar}_j, \text{organic}_j)$, $\tilde{x}_{jt} = (x_j, p_{jt})$, $\nu_i \sim N(0, I_4)$ and ϵ_{ijt} is type-I extreme value. The true parameters are $\beta = (-1, 0.2, 0.15)$, $\alpha = 3$ and $\Sigma = \text{diag}(0.5, 0.2, 0.3, 0.5)$. Price carries a random coefficient, so consumer i's price sensitivity is $\alpha_i = 3 - 0.5\,\nu_{i4}$. It is negative only when $\nu_{i4} > 6$, an event of probability about 10^{-9}. Marginal cost is

$$mc_{jt} = x_j\gamma_1 + \gamma_2 w_j + \omega_{jt}, \qquad \gamma_1 = (0.2, 0.25, 0.3), \quad \gamma_2 = 0.5. \tag{8.111}$$

The unobservables are drawn independently of each other and of the characteristics. Their sample standard deviations are 0.50 for ξ and 0.050 for ω, and their sample correlation is 0.004. Market sizes range from 9,756 to 10,223 consumers. The firms know all primitives. Each firm computes expected demand by averaging over 100 consumer types drawn once for each market. The econometrician observes characteristics, the cost shifter, ownership, market sizes, prices and realized shares.

8.10.2 Step 1: equilibrium prices

In each market the firms play the multiproduct pricing game of Section 8.7.1. The iteration (8.85), started at marginal cost, converges in every market in 10 to 13 iterations. Restarts from 2,000 random price vectors find no second equilibrium (Section 8.7.5). Markups range from 0.348 to 0.451, and the mean Lerner index is 0.334. Tables C.15 and C.16 report the details. The step teaches why markups are nearly equal across products. In market 0 the average price sensitivity of each product's buyers, $\bar{\alpha}_j = \frac{\Lambda_{jj}}{s_j}$, lies between 2.69 and 2.81. It is below the population mean $\alpha = 3$, because price-sensitive consumers buy less. Its inverse, between 0.356 and 0.372, approximates the markups within ten percent, as (8.84) predicts. The Γ term of (8.83) accounts for the difference.

8.10.3 Step 2: realized shares

At the equilibrium prices we simulate M_t consumers in each market, 999,870 in all. Each consumer receives fresh draws of ν_i and of the extreme value shocks and chooses the alternative with the highest utility. The resulting *realized shares*, the fractions of consumers who choose each product, play the role of the observed data. They differ from the firms' expected shares for two reasons. The finite number of consumers adds sampling error, with standard deviation close to $\sqrt{\frac{s_{jt}(1-s_{jt})}{M_t}}$. The firms' 100 draws add simulation error of similar size (Table C.15). Realized and expected shares have correlation 0.986. The outside share averages 0.879 and is never below

0.788. Observed shares therefore contain sampling error even before any simulation by the econometrician.

8.10.4 Step 3: logit demand

We first estimate the misspecified logit model. The inversion of Chapter 7 gives the linear equation

$$\ln s_{jt} - \ln s_{0t} = x_j\beta - \alpha p_{jt} + \xi_{jt}. \tag{8.112}$$

Price is correlated with ξ_{jt} because firms see ξ_{jt} when they set prices. We estimate (8.112) by OLS and by 2SLS with seven excluded instruments, and we cluster standard errors by market. The first instrument is the price of milk. The other six are the *competition instruments* of the BLP type. Four are the sums of sugar and of the organic indicator over the firm's other products and over rival products. Two are the numbers of the firm's other products and of rival products in the market.

OLS gives $\hat{\alpha} = 2.330$ and 2SLS gives 2.641, against the true mean price coefficient of 3 (columns (1) and (2) of Table 8.8). The first stage is strong, with a cluster-robust F statistic of 92.5, but the strength comes almost entirely from the cost shifter. The six competition instruments have a joint F statistic of only 2.32. They vary only through the choice set, and each sum of sugar is nearly collinear with the corresponding count of products (Table C.21). Hansen's test does not reject the overidentifying restrictions ($J = 8.82$, $p = 0.18$). The 2SLS estimate stays below the truth because the logit is misspecified, as Step 5 shows.

8.10.5 Step 4: the contraction with Σ known

Suppose for now that we know Σ. We draw $n_s = 1{,}000$ vectors ν_i for each market once, and keep them fixed for the rest of the estimation. Started from the logit inversion $\delta_{jt}^{(0)} = \ln s_{jt} - \ln s_{0t}$, the contraction of Section 8.4 reaches a tolerance of 10^{-12} in 13 to 21 iterations. Table C.26 reports the recovered mean utilities of market 0, and two facts stand out. First, every recovered δ_j lies below its logit start. A logit choice probability below one half is convex in own utility, and individual probabilities in this design stay below one half. By a Jensen-type argument the random terms then tend to raise the average choice probability for a given δ, so matching the observed shares requires lower mean utilities. The argument is heuristic. The random terms also shift the utilities of the other products, and the probability of j is concave in the utility of any product k whose probability is below one half. Second, the recovered values are close to the truth. Simulation error from the 1,000 draws is between 0.005 and 0.037. The rest of the gap is sampling error in the shares, which is largest for products with few buyers.

8.10.6 Step 5: instrumental variables on the recovered mean utilities

With Σ known, the recovered δ_{jt} satisfy the linear equation $\delta_{jt} = x_j\beta - \alpha p_{jt} + \xi_{jt}$. With the instruments of Step 3, 2SLS gives $\hat{\alpha} = 2.926$ (0.413), within 0.2 standard errors of the truth (column (3) of Table 8.8, and Table C.27). Hansen's test does not reject ($J = 8.16$, $p = 0.23$).

The comparison with Step 3 measures the bias that Remark 8.10 predicts. Define the gap between the two dependent variables, $r_{jt} = \ln \frac{s_{jt}}{s_{0t}} - \delta_{jt}$. The 2SLS estimator is linear in the dependent variable. The logit estimate of α therefore equals the random coefficients estimate minus the 2SLS coefficient on price in a regression of r_{jt} on the same regressors. That coefficient is 0.284, the difference between the unrounded estimates 2.9255 and 2.6411. The gap term has

correlation 0.888 with price. The random coefficient on price lets less price-sensitive consumers sort into expensive products. The logit can only absorb this sorting into ξ_{jt}, which is then larger for the more expensive products of a market. In this simulation the estimated bias of 0.284 is toward zero even with valid instruments (Section 8.2). Its sign depends on the model, the design and the instruments (Proposition C.28).

8.10.7 Step 6: estimating Σ by the nested fixed point

We now drop the assumption that Σ is known. We estimate all eight parameters, (β, α) and the four standard deviations, by the GMM estimator of Section 8.5. The implementation follows the checklist of Section 8.9.1.

1. The simulation uses the 1,000 draws per market of Step 4, held fixed throughout.
2. The inner loop is the contraction with tolerance 10^{-12}, started at the solution of the previous outer evaluation. It takes between 15 and 25 iterations on average, depending on the instrument set.
3. The linear parameters are concentrated out (Proposition 8.20).
4. The outer search is a quasi-Newton method (L-BFGS-B) with the analytic gradient of Proposition 8.22. Each σ_k is restricted to $[0, 5]$, following Proposition 8.41. The search starts from $(0.5, 0.5, 0.5, 0.5)$ and from five vectors drawn uniformly on $[0.05, 1.5]^4$.
5. The first step uses $W = (\frac{1}{N}\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}$. The second step uses the inverse of the market-clustered covariance matrix of the moments at the first-step estimate, and restarts from the first-step estimate and three of the starting vectors.
6. Standard errors use the sandwich formula with the Jacobian G of the moments with respect to all eight parameters. The covariance of the moments adds a simulation term V_3 to the clustered sampling term. We estimate V_3 from 30 independent sets of 1,000 draws per market, re-solving the contraction for each set at the estimate.

We compare three sets of instruments, each containing the constant, sugar, the organic indicator and the price of milk.

(a) The BLP instruments add the six competition instruments of Step 3, for ten instruments and two overidentifying restrictions.

(b) The differentiation instruments follow the idea of Gandhi and Houde (2019). For each product we add the sums, over the firm's other products and over rival products, of squared differences in sugar content. We add the numbers of the firm's other products and of rival products with the same organic status. And we add the sums, over own and rival products, of squared differences in an exogenous price prediction $\hat{p}_j$. This prediction is the fitted value of a regression of price on the characteristics and the price of milk, which has $R^2 = 0.922$. The set has ten instruments.

(c) The approximate optimal instruments follow Berry et al. (1999, Appendix), with the regression-based price prediction of Reynaert and Verboven (2014, Section 2.4). We replace price by its prediction from a regression on all the exogenous variables in (b), set $\xi = 0$, and compute $\frac{\partial \delta_{jt}}{\partial \sigma_k}$ by Proposition 8.22 at a preliminary value σ^0. The instruments are the constant, sugar, organic, predicted price and these four derivatives. The set has eight instruments, so the model is just identified.

The choice of σ^0 in (c) is not innocuous. The estimates under (b), reported below, put three of the four standard deviations at zero. By Proposition 8.41, the population derivative $\frac{\partial \delta_{jt}}{\partial \sigma_k}$ is zero at $\sigma_k = 0$, so an instrument evaluated there would be pure simulation noise. We therefore evaluate the instruments at the round value $\sigma^0 = (1, 1, 1, 1)$, with the linear parameters concentrated out at σ^0.

Table 8.8: Demand estimates in the simulated market.

	Logit		Random coefficients logit

Notes: Standard errors in parentheses, clustered by market (100 clusters). Columns (1) to (3) regress $\ln \frac{s_{jt}}{s_{0t}}$ or the recovered δ_{jt} on the characteristics and price. In column (3) the standard deviations are fixed at their true values. Columns (1) to (3) repeat the corresponding columns of Tables C.22 and C.27. Columns (4) to (6) are two-step GMM estimates of all eight parameters with BLP instruments, differentiation instruments and approximate optimal instruments. Their standard errors include simulation error. Standard errors of estimates at the boundary $\sigma_k = 0$ are not meaningful. $Q(\Sigma_0) - Q(\hat{\Sigma})$ is the increase in the second-step objective $N \bar{g}^\top W \bar{g}$ when the four standard deviations are set to their true values and the linear parameters are concentrated out. In column (6) the model is just identified, and the minimized objective is 1.83.

Table 8.8 reports the estimates in columns (4) to (6). The price coefficient and the coefficients on sugar and organic stay in a plausible range in columns (5) and (6). The standard deviations are a different story. Their standard errors are large multiples of the estimates, and several estimates sit at the boundary $\sigma_k = 0$. None of the three instrument sets recovers Σ.

Each set fails in its own way. With the BLP instruments, the estimate of σ on organic is 3.307 and the mean organic coefficient is −3.427, against true values of 0.3 and 0.15. A large random coefficient on a dummy variable acts like a nest (Section 8.9.3). The model treats the three organic products as close substitutes for one another, and the negative mean keeps their shares small. Hansen's test does not detect anything wrong ($p = 0.18$). The search also shows a

second local minimum. In the first step, one of the six starting values stops at a point with objective 1.630, against 0.954 for the other five. With the differentiation instruments, only the constant has a positive standard deviation (0.678), and Hansen's test rejects at the 5 percent level ($p = 0.03$). With the approximate optimal instruments, the estimates of σ on price (0.488) and of α (2.898) are close to the truth, but the standard deviations on sugar and organic are zero. The minimized objective is positive although the model is just identified. A just-identified nonlinear system need not have a root in the parameter space, which here restricts each σ_k to $[0, 5]$. The minimum lies on the boundary $\sigma_k = 0$ for sugar and organic. There the population moments are flat in σ_k (Proposition 8.41), and the Jacobian of the moments is close to singular.

The data cannot reject the true Σ under any of the three sets. Setting the four standard deviations to their true values raises the second-step objective by 4.65, 0.64 and 1.05. All three are below 9.49, the 0.95 quantile of the χ^2 distribution with four degrees of freedom. Under standard conditions this increase is a distance-metric test of the four restrictions. Weak identification can distort that test, so we read it as a description of the flatness of the objective. The smallest eigenvalues of $G^\top W G$, between 4.3×10^{-6} and 2.2×10^{-4} against largest eigenvalues between 13 and 19, tell the same story.

Figure 8.6 shows the flatness directly. It plots the second-step objective against σ_p, the standard deviation of the price coefficient, with the other standard deviations held at their estimates and the linear parameters concentrated out. For the BLP instruments it also plots the profile in which the other three standard deviations are re-optimized at each value of σ_p. The two curves almost coincide. Each curve stays within 3.84 of its minimum, the 0.95 quantile of the χ^2_1 distribution, over a wide range of σ_p. On the solid curves the range runs from zero to about 1.37 for the BLP instruments, to 1.04 for the differentiation instruments, and to 1.02 for the approximate optimal instruments. The re-optimized curve for the BLP instruments crosses the 3.84 cutoff between 1.3 and 1.4 on its coarser grid. Both the true value 0.5 and zero lie inside all of these ranges.

These ranges describe the flatness of the objective. They are not confidence intervals, for two reasons. First, a curve that holds the other standard deviations b at their estimates $\hat{b}$ lies weakly above the profile, because $Q(\sigma_p, \hat{b}) \geq \min_b Q(\sigma_p, b)$. Its cutoff can exclude values that the profile retains, and we have computed the profile only for the BLP instruments. Second, the χ^2_1 calibration of a profile requires strong identification and nuisance parameters in the interior of the parameter space. Neither condition holds here. The Jacobian of the moments is nearly singular, and several standard deviations sit at zero. At $\sigma_p = 0$ the population moments are flat in σ_p (Proposition 8.41), so first-order identification fails at that boundary value. The plotted curves still have nonzero slopes at zero, because the 1,000 simulation draws per market are not exactly sign-symmetric. An interval for σ_p would need all nuisance parameters re-optimized at each value and a procedure that is robust to weak identification and to the boundary. What the curves do show is that a wide range of values, zero included, fits the moments about equally well.

Why is Σ so hard to estimate here? Its identification needs variation that shifts substitution patterns (Section 8.6). In this design every product has the same characteristics and the same cost shifter in every market. The only sources of cross-market variation are the choice set and the prices, and the price of a given product varies little across markets. Its standard deviation across markets is between 0.045 and 0.061, against 0.189 for all prices together. The inside goods also take only 5 to 21 percent of each market, so most substitution is to the outside good. Changes in the choice set then move the shares of the remaining products by small amounts, which the demand shocks, with standard deviation 0.50, easily mask. The simulation

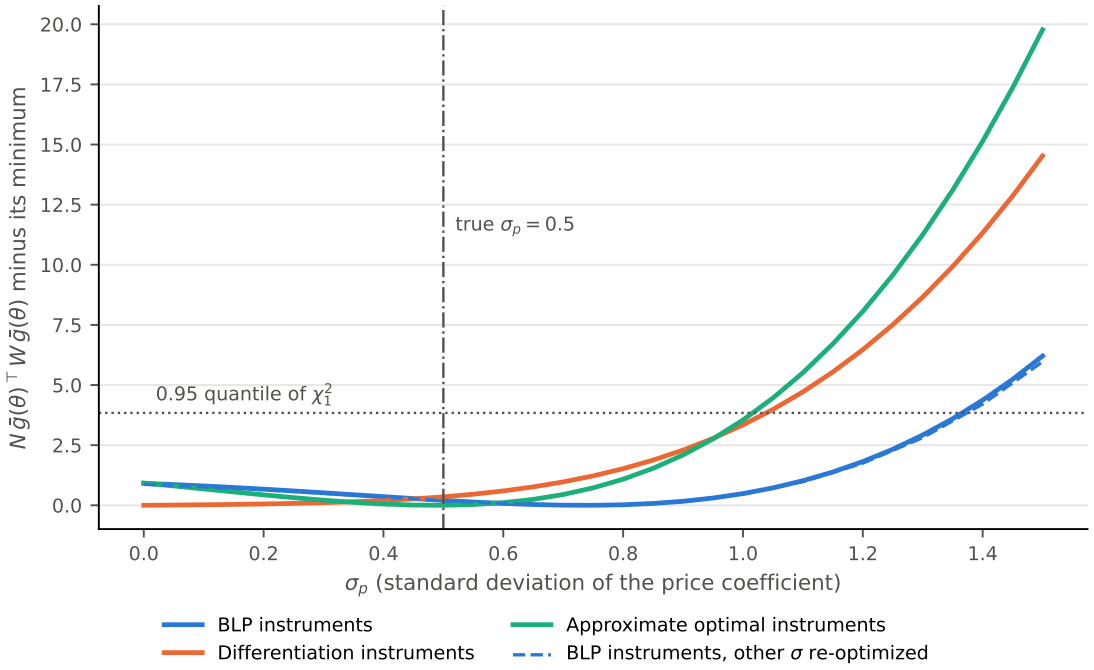

Figure 8.6: The GMM objective as a function of the standard deviation of the price coefficient in the simulated market. Each solid curve holds the other three standard deviations at the estimate of its instrument set, concentrates out the linear parameters and uses the second-step weighting matrix. The dashed curve re-optimizes the other three standard deviations for the BLP instruments. Curves are shifted so that their minimum is zero. The dotted line is the 0.95 quantile of the χ^2_1 distribution, and the dash-dotted line marks the true value $\sigma_p = 0.5$.

correction is small by comparison. It raises the standard errors by at most 6 percent with the BLP instruments and by less than 1 percent with the other two sets.

The lesson is general. The price coefficient is identified by the cost shifter in every specification, and its instrumental variables estimates range from 2.5 to 3.5. The standard deviations depend on much weaker variation. A good fit and an unrejected overidentification test do not certify them. Step 7 shows what is at stake for the substitution patterns.

8.10.8 Step 7: elasticities and diversion

We compute the price elasticities of market 0 under each model. Under the random coefficients models we use the 1,000 estimation draws and the recovered mean utilities of that market, and the derivatives of Proposition 8.4. The true elasticities use the true parameters and 200,000 draws, which approximates the population integral. Table 8.9 reports three objects: the own-price elasticities, the responses of all shares to the price of product 4, and the diversion ratio to the outside good, $-\frac{\partial s_0}{\partial p_k}\left(\frac{\partial s_k}{\partial p_k}\right)^{-1}$ (Proposition 8.5). Own elasticities are reported as positive numbers.

Table 8.9: Elasticities and diversion in market 0.

	Logit	Random coefficients logit			True
	2SLS	Σ known	GMM, approx. optimal IV	GMM, BLP IV	
A. Own-price elasticity $-\frac{\partial s_j}{\partial p_j}\frac{p_j}{s_j}$					
Product 2	3.47	3.45	3.45	3.78	3.58
Product 3	2.62	2.68	2.67	3.02	2.76
Product 4	3.70	3.63	3.64	3.42	3.77
Product 6	2.59	2.65	2.64	2.99	2.74
Product 8	2.80	2.79	2.81	3.12	2.89
Product 9	3.81	3.74	3.74	4.01	3.87
Product 10	2.44	2.51	2.51	2.85	2.59
B. Cross-price elasticity with respect to p_4, $\frac{\partial s_j}{\partial p_4}\frac{p_4}{s_j}$					
Product 2	0.047	0.078	0.063	0.988	0.069
Product 3	0.047	0.067	0.059	0.038	0.060
Product 6	0.047	0.066	0.059	0.038	0.059
Product 8	0.047	0.069	0.060	0.039	0.062
Product 9	0.047	0.079	0.064	0.978	0.070
Product 10	0.047	0.066	0.058	0.038	0.059
Outside good	0.047	0.043	0.044	0.032	0.040
C. Diversion to the outside good (percent)					
Product 2	85.9	79.5	82.1	55.5	80.3
Product 3	87.7	83.4	85.2	85.7	84.0
Product 4	86.6	80.1	82.6	64.1	80.8
Product 6	87.3	83.0	84.8	85.2	83.5
Product 8	90.6	86.7	88.4	88.9	87.2
Product 9	86.0	79.2	81.8	55.3	80.2
Product 10	87.2	83.1	85.0	85.5	83.8

Notes: Market 0, at observed prices and realized shares. The columns use the estimates of columns (2), (3), (6) and (4) of Table 8.8. The true values use the true parameters, the true mean utilities and 200,000 draws. Products 2, 4 and 9 are the organic products and the three most expensive.

The own elasticities differ little across the logit, the random coefficients model with Σ

known and the model estimated with approximate optimal instruments. All three are within 0.15 of the truth, and all are slightly too small because the estimated price coefficients are below 3. The three most expensive products are the most elastic in every column. With small shares the logit own elasticity is close to αp_j, so this ordering is mechanical in the logit. In the true model it also holds, because the standard deviation of the price coefficient is moderate.

The cross elasticities separate the models. In the logit, a rise in p_4 raises every share, including the outside share, by the same 0.047 percent per percent. This is the IIA property of Chapter 7. In the true model the organic products 2 and 9 gain most (0.069 and 0.070), the other products less (0.059 to 0.062), and the outside good least (0.040). The model with Σ known reproduces this pattern. The model estimated with approximate optimal instruments shows it only weakly (0.063 and 0.064 against 0.058 to 0.060). Its estimate of σ on organic is zero, so only the random coefficient on price separates the expensive organic products. The model estimated with BLP instruments gets the pattern badly wrong. Its large σ on organic makes products 2 and 9 nearly perfect substitutes for product 4, with cross elasticities of 0.988 and 0.978, about fourteen times the true values.

Diversion to the outside good tells the same story. The logit sends between 85.9 and 90.6 percent of a product's lost buyers to the outside good, the value $\frac{s_0}{1-s_k}$ of Chapter 7. The true model sends between 80.2 and 87.2 percent, and the models with Σ known and with approximate optimal instruments come close. Under the BLP instrument estimates, only 55 percent of the buyers lost by product 2 or 9 leave the market. Panel B suggests where the others go: to the other organic products. A merger between the firms that sell products 2 and 9 would look far more harmful under these estimates than under the true model (Chapter 11). Figure 8.7 summarizes the comparison.

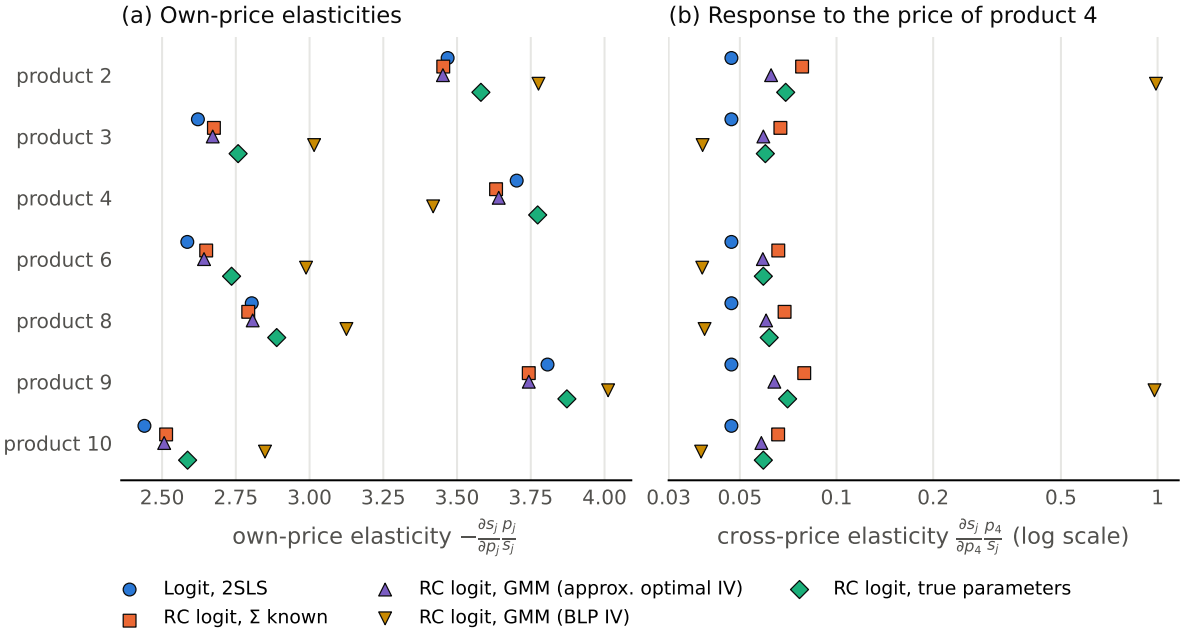

Figure 8.7: Elasticities in market 0 of the simulated market. Panel (a) shows own-price elasticities as positive numbers. Panel (b) shows the cross-price elasticity of each product's share with respect to the price of product 4, on a log scale. The random coefficients columns use the estimates of Table 8.8, and the true values use 200,000 draws.

8.10.9 What the simulated market teaches

Four lessons carry over to applications. First, the computational steps are fast and reliable when implemented carefully. The Morrow-Skerlos iteration finds the equilibrium in 10 to 13 iterations, and the contraction recovers the mean utilities to 10^{-12} in about 15 to 25 iterations. Second, a strong cost shifter identifies the mean price coefficient well. The logit estimate is biased toward zero by the sorting of less price-sensitive consumers into expensive products, and the random coefficients model removes most of the bias when Σ is right.

Third, Σ is the hard part. With market-level data its identification rests on variation in choice sets and in the characteristics of competing products. When that variation is weak, the estimates of Σ and the substitution patterns they imply can be far from the truth, even when the overidentification test passes. The diagnostics that reveal the problem are cheap: several starting values, the profile of the objective, the eigenvalues of $G^\top W G$, and comparisons across instrument sets.

Fourth, the remedies are the subjects of the preceding sections. Richer cross-market variation helps, as do approximate optimal instruments. Micro moments and second-choice data identify Σ from within-market variation (Section 8.8). A supply side adds moments that depend on Σ through the markups (Section 8.7). Where none of these is available, the appropriate report is the range of substitution patterns consistent with the data.

8.11 Case study: Berry, Levinsohn and Pakes (1995), U.S. automobiles

Berry et al. (1995), henceforth BLP, turned the random coefficients logit into a working tool for industrial organization. They estimate demand and marginal cost for essentially every car model sold in the United States from 1971 to 1990. They use only product-level data on prices, quantities and characteristics, together with the distribution of household income. The estimates come from a model in which consumers choose one car or none and multi-product firms set prices in a Nash equilibrium.

The general model, its computation and its identification occupy Sections 8.1 to 8.7. This section applies that machinery to the paper itself. We follow the order used for every deep case study in this book. We take up the question, the setting, the data, the model, and the estimator with its identification. Then come the results, robustness, interpretation, critiques and contribution. We reproduce the paper's Tables III, IV, V, VII, VIII and IX in full, Table I in condensed form, and an excerpt of Table VI. Several derived quantities in this section are our own calculations from the published tables, and we say so each time. Table 8.18 at the end of the section maps the study: its data, latent objects, identifying variation, maintained assumptions and counterfactuals.

8.11.1 The question and why it matters

The paper asks how to recover demand and cost parameters for a whole differentiated-products industry when only market-level data are available. The answers must be consistent with an oligopoly equilibrium. On the demand side BLP want own- and cross-price elasticities for every model, and elasticities of demand with respect to attributes such as fuel efficiency. On the cost side they want marginal cost as a function of product characteristics.

These objects are inputs to many policy questions. BLP list trade policy (import restrictions), merger policy, environmental policy (gas-guzzler and carbon taxes, emission standards and fuel economy standards) and the construction of price indices (Section 8.1 of the paper). The

automobile market was large, with sales above $150 billion in 1989 (p. 843). It was also at the center of trade and environmental debates.

The obvious alternative is a demand system written directly in product space. A constant-elasticity system for 100 products has 10,000 own- and cross-price elasticities (p. 842). Researchers therefore aggregate products into groups. BLP point out that a grouping that suits one question rarely suits another. Aggregating all foreign and all domestic cars may serve a tariff study, but it is useless for domestic competition or pollution taxes. Product-space systems also cannot predict demand for new goods, and they make it hard to use information on the distribution of consumers.

BLP work in characteristics space, following Lancaster (1971) and McFadden (1974). They identify two problems with the discrete-choice models available at the time. The first is the functional form of utility, which in logit-type models forces implausible substitution patterns. The second is the correlation between price and product characteristics that consumers see and the econometrician does not. BLP call this the differentiated-products analog of the classical simultaneity problem. They solve the aggregation problem by simulation, as in Pakes (1986). They solve the simultaneity problem by inverting the share equations, as in Berry (1994).

8.11.2 Setting and earlier approaches

Early work treated cars as a homogeneous product and estimated aggregate demand (Suits, 1958). Griliches (1971) introduced hedonic price regressions for cars, which work at the level of the individual model but do not model the production side. BLP call Bresnahan (1987) perhaps the first attempt to model and estimate demand and oligopoly pricing jointly (p. 844). He used a vertical differentiation model with a uniform density of consumers along the quality line (Chapter 6). Feenstra and Levinsohn (1995) allowed several dimensions of differentiation but kept the uniform density. Manski (1983) studied demand and a perfectly competitive supply side for the Israeli car market.

Micro-data studies of car demand had alternatives to BLP's solutions. They could interact consumer and product characteristics, or use nested logit, which BLP note is a restricted random coefficients model on group dummies (p. 851). Nested logit requires a priori knowledge of the order and content of the nests. Product-specific constants, which would absorb unobserved quality, are hard to estimate with micro data. There are on average more than 100 products per year in BLP's sample. The Consumer Expenditure Survey records only about 500 new-car purchases per year (p. 852). Even with product dummies, one still has to separate the effects of price, observed characteristics and unobserved quality, which requires the kind of instrumental-variable assumptions BLP make.

The vertical model restricts substitution severely. A product has nonzero cross-price elasticities only with its two neighbors on the price ladder. BLP give an example with a $24,998 station wagon, a $24,999 sports car and a $25,000 station wagon (p. 852). The vertical model makes the two wagons non-substitutes and the sports car a substitute for both. The logit model fails in the opposite way. If a cheap Yugo and an expensive Mercedes have the same share, a rise in the BMW's price must raise both of their sales by the same amount (p. 847). Two products with equal shares must also have equal own-price derivatives, and hence equal markups under single-product pricing (Section 8.2).

Finally, BLP stress the structural error ξ_{jt}. Without it, only sampling error separates the model's predicted shares from the data. With aggregate samples of millions of households, a chi-square test of the model's restrictions on the multinomial shares rejects with probability close to one (p. 850). The unobserved characteristic plays the role of the demand disturbance

in homogeneous-goods markets. Because firms know it when they set prices, prices respond to it and are in general correlated with it.

8.11.3 Data

The unit of observation is a car model in a year, and a market is the national market in a year. Product characteristics come from annual issues of the *Automotive News Market Data Book*, combined with a similar data set from Ernst Berndt (p. 868). The sample covers essentially all models sold from 1971 to 1990. Only "exotic" models with tiny shares, such as Ferrari and Rolls Royce, are excluded. The panel is unbalanced because models enter and exit. It has 2,217 model-years.

BLP need a rule that links model-years into models, because their standard errors allow correlation within a model over time. Two observations in adjacent years are the same model if they have the same name and their horsepower, width, length and wheelbase each change by at most ten percent. With this rule the 2,217 model-years represent 997 distinct models (p. 869).

The variables are as follows.

- *Price* is the list retail price of the base model, in thousands of 1983 dollars (deflated by the CPI). BLP would prefer transaction prices but could not find them.
- *Quantity* is U.S. sales by nameplate, in thousands. Fleet sales are not observed, so fleet buyers are treated as agents of households (footnote 23).
- *HPWT* is horsepower divided by weight, in horsepower per 10 pounds.
- *Air* equals one if air conditioning is standard equipment.
- *MP$* (miles per dollar) is the EPA miles-per-gallon rating divided by the real price of unleaded gasoline. It measures the cost of driving and enters utility. The production cost of fuel efficiency is captured instead by *MPG*, which enters the cost function.
- *Size* is length times width.
- *Reliability* is the Consumer Reports rating from 1 to 5, available for part of the sample and rescaled every year (footnote 24). It appears only in one robustness check.

The market size M_t is the number of U.S. households in year t, from the *Statistical Abstract*. The parameters of the household income distribution come from the March Current Population Survey (CPS) for each year. Divisions of one parent company form one firm, so Buick, Cadillac, Chevrolet, Oldsmobile and Pontiac all belong to General Motors. There are 22 firms (footnote 29). Each model is assigned the country of its producing firm.

Table 8.10 shows the main trends. The number of models rose from a low of 72 in 1974 to a high of 150 in 1988, while sales per model trended down. The sales-weighted list price stayed between about $7,500 and $8,000 during the 1970s. It then rose from $7,718 in 1980 to $10,337 in 1990, about a third.[5] The characteristics changed at the same time, so the price of a fixed bundle need not have risen. HPWT fell in the early 1970s and then trended up, mostly because cars became lighter. Fuel cost efficiency improved, from 18.50 miles per 1983 dollar of gasoline in 1971 to 28.52 in 1990. Air conditioning was standard on no car at the start and on

[5]The text of Berry et al. (1995, p. 870) says that the real sales-weighted list price "has risen almost 50 percent during the 1980's." Their Table I, which is already in 1983 dollars, implies an increase of $\frac{10.337}{7.718} - 1 = 34$ percent from 1980 to 1990. Measured from the 1979 value of 7.599, the increase is 36 percent. We follow the table.

Table 8.10: Descriptive statistics of the BLP (1995) data, selected years (condensed from their Table I)

Year	Models	Quantity	Price	Domestic	Japan	Europe	HPWT	Size	Air	MPG	MP$
1971	92	86.892	7.868	0.866	0.057	0.077	0.490	1.496	0.000	1.662	1.850
1973	86	92.785	7.535	0.932	0.040	0.028	0.364	1.529	0.022	1.589	1.819
1974	72	105.119	7.506	0.887	0.050	0.064	0.347	1.510	0.026	1.568	1.453
1975	93	84.775	7.821	0.853	0.083	0.064	0.337	1.479	0.054	1.584	1.503
1980	103	71.567	7.718	0.773	0.191	0.036	0.350	1.296	0.078	2.215	1.466
1985	136	78.143	8.938	0.761	0.191	0.048	0.372	1.265	0.140	2.261	2.024
1988	150	67.078	10.069	0.717	0.237	0.045	0.396	1.251	0.237	2.334	2.919
1990	131	66.377	10.337	0.682	0.276	0.043	0.419	1.270	0.308	2.270	2.852
All	2217	78.804	8.604	0.790	0.161	0.049	0.372	1.357	0.116	2.099	2.086

Notes: Source: Berry et al. (1995), Table I (p. 870), which reports all 20 years. "Models" is the number of models and "Quantity" is mean sales per model. The remaining nine columns are sales-weighted means. Quantity is in thousands of cars and price in thousands of 1983 dollars. HPWT is in horsepower per 10 pounds, MPG in tens of miles per gallon and MP$ in tens of miles per 1983 dollar of gasoline. Domestic, Japan and Europe are dummies for the location of the producing firm's headquarters.

30.8 percent at the end. The domestic share fell from a 1973 high of 93.2 percent to 68.2 percent in 1990, while the Japanese share rose from 4.0 to 27.6 percent.

BLP's Table II reports quartiles of the continuous variables and names the models at each quartile. The cheapest car is the 1990 Yugo at $3,393 (1983 dollars). The median price is $8,728 and the 75th percentile is $13,074. The most expensive car is a 1989 Porsche 911 Cabriolet at $68,597. Sales range from 49 cars to 577,313 cars (the 1971 Chevrolet Impala), with a median of 47,345. MPG ranges from 9 (1974 Cadillac Eldorado) to 53 (1989 Geo Metro). We use the price quartiles below to interpret the logit results.

The data also pin down the size of the outside good. Total 1990 sales are about $131 \times 66.377 \approx$ 8,695 thousand cars (Table 8.10). BLP describe the logit column of their Table VII as $\frac{s_0}{1-s_j}$, and its entries lie between 90.458 and 90.883 percent. Because $\frac{s_0}{1-s_j}$ exceeds s_0, the smallest entry bounds the outside share, $s_0 < 0.9046$. The entries do not rise with the shares as the formula requires (the best-selling Accord has the smallest entry), so we read them only as $s_0 \approx 0.90$. With s_0 near 0.90, $M_{1990} = \frac{8.695}{1-s_0}$ is roughly 90 million households (our calculation). Most households do not buy a new car in a given year, so the outside good is large.

8.11.4 The model

Utility. BLP nest random coefficients in the Cobb-Douglas utility (8.10) over the car's characteristics and spending on other goods (their eq. 2.6). Its logarithm gives the inside and outside utilities (8.11) and (8.12) (their eqs. 2.7a and 2.7b), which Section 8.1.3 derived. BLP write $\bar{\beta}$ for our β. The taste shocks ν_{ik} have mean zero and unit variance, so characteristic k has marginal utility $\beta_k + \sigma_k \nu_{ik}$, with mean β_k and variance σ_k^2. The term $\sigma_0 \nu_{i0}$ lets the outside option have more idiosyncratic variance than the inside goods. BLP motivate it by unobserved differences in access to public transport and in used-car holdings (p. 849).

BLP prefer this form to the plain random coefficients model $u_{ij} = x_j\beta - \alpha p_j + \xi_j + \sum_k \sigma_k x_{jk}\nu_{ik} + \epsilon_{ij}$ (their eq. 2.5) for two reasons (p. 848). They have outside information on the income distribution, and they have a theoretical rationale for the form of the interaction between income and price. The Cobb-Douglas form uses both.

The estimated form. The empirical model adds a year index t and makes income random.

Household income is lognormal, $y_{it} = e^{m_t + \sigma_y \nu_{iy}}$, with year-specific mean m_t and a common standard deviation σ_y, both estimated from the CPS. The utility functions are (8.15) and (8.16) (their eqs. 6.14a and 6.14b). The vector $(\nu_{iy}, \nu_{i0}, \nu_{i1}, \ldots, \nu_{iK})$ is standard multivariate normal, independent of everything else. BLP hold each simulated consumer's draws fixed over the 20 years of the panel. The idiosyncratic shocks ϵ_{ijt} are i.i.d. type-I extreme value. BLP did not estimate a separate σ_y for each year because those estimates were imprecise. They also tried drawing incomes directly from the CPS, which gave imprecise simulators, especially in the upper tail (footnote 21).

The characteristics in utility are $x_{jt} = (1, HPWT_{jt}, Air_{jt}, MP\$_{jt}, Size_{jt})$, so $K = 5$. Each has a mean β_k and a standard deviation σ_k. Price carries no separate random coefficient. Heterogeneity in price sensitivity comes entirely from income, as we now show.

Mean utility and individual deviations. Choice probabilities depend only on utility differences, so we subtract (8.16) from (8.15) and normalize $\xi_{0t} = 0$. The deterministic part of the difference is

$$u_{ijt} - u_{i0t} - (\epsilon_{ijt} - \epsilon_{i0t}) = \alpha\left[\ln(y_{it} - p_{jt}) - \ln y_{it}\right] + x_{jt}\beta + \xi_{jt} + \sum_k \sigma_k x_{jkt}\nu_{ik} - \sigma_0 \nu_{i0}$$

$$= \underbrace{x_{jt}\beta + \xi_{jt}}_{\delta_{jt}} + \underbrace{\alpha \ln\left(1 - \frac{p_{jt}}{y_{it}}\right) + \sum_k \sigma_k x_{jkt}\nu_{ik} - \sigma_0 \nu_{i0}}_{\mu_{ijt}}.$$

Three features of this decomposition matter for estimation. First, the mean utility

$$\delta_{jt} = x_{jt}\beta + \xi_{jt} \tag{8.113}$$

contains no price term. Price enters only through μ_{ijt}, so α is a nonlinear parameter. In the chapter's notation $\theta_1 = \beta$ and $\theta_2 = (\alpha, \sigma_1, \ldots, \sigma_5)$. Second, the constant is the first characteristic ($x_{j1t} = 1$), so the terms $\sigma_1 \nu_{i1} - \sigma_0 \nu_{i0}$ combine into one normal random variable with variance $\sigma_1^2 + \sigma_0^2$. A random coefficient on the inside-good constant and an extra shock on the outside good are therefore observationally equivalent, and only the combined variance is identified. This is why BLP's footnote 6 describes $\sigma_0 \nu_{i0}$ as a random coefficient on the constant. The reported standard deviation on the constant measures this combined dispersion. Third, μ_{ijt} is defined only when $y_{it} > p_{jt}$. A simulated household whose income draw is below a car's price cannot buy that car, and an implementation must remove the car from that household's choice set.

Market shares. Conditional on ν_i, integrating the extreme value shocks gives the logit form (8.18) (their eq. 6.6). The market share (8.19) integrates over the standard normal vector ν_i, with income determined by ν_{iy} (their eq. 6.7). The inner integral has a closed form and the outer one does not. BLP evaluate it by simulation (Section 8.3).

Price derivatives and elasticities. Differentiating μ_{ijt} gives the price sensitivity of household i for car j:

$$\frac{\partial \mu_{ijt}}{\partial p_{jt}} = -\frac{\alpha}{y_{it} - p_{jt}}.$$

This sensitivity falls with income. It also rises with the car's own price, because a dollar is worth more when less is left for other goods. A first-order expansion of the log for small $\frac{p_{jt}}{y_{it}}$ gives

$$\alpha \ln\left(1 - \frac{p_{jt}}{y_{it}}\right) \approx -\alpha \frac{p_{jt}}{y_{it}},$$

so household i behaves approximately as if its price coefficient were $\frac{\alpha}{y_{it}}$. Applying the general derivative formulas of Proposition 8.4 with this price sensitivity gives

$$\frac{\partial s_{jt}}{\partial p_{jt}} = -\int \frac{\alpha}{y_{it} - p_{jt}} s_{ijt}(1 - s_{ijt}) \, \mathrm{d}F(\nu_i), \tag{8.114}$$

$$\frac{\partial s_{jt}}{\partial p_{qt}} = \int \frac{\alpha}{y_{it} - p_{qt}} s_{ijt} s_{iqt} \, \mathrm{d}F(\nu_i), \qquad q \neq j \tag{8.115}$$

(their eqs. 6.9a and 6.9b). The derivative of the outside share is $\frac{\partial s_{0t}}{\partial p_{qt}} = \int \frac{\alpha}{y_{it} - p_{qt}} s_{i0t} s_{iqt} \, \mathrm{d}F(\nu_i)$.

BLP report *semi-elasticities*, which we denote

$$e_{jq} \equiv \frac{100}{s_j} \frac{\partial s_j}{\partial p_q}, \tag{8.116}$$

with prices in thousands of dollars. The entry e_{jq} is the percentage change in the share of j when the price of q rises by \$1,000. The elasticity follows by multiplying by $\frac{p_q}{100}$, so the own-price elasticity, written as a positive number, is $\varepsilon_j = -\frac{p_j}{100} e_{jj}$. The logit benchmark has $e_{jj} = -100 \, \alpha (1 - s_j)$ and $e_{jq} = 100 \, \alpha s_q$.

Costs and pricing. Firm f produces the set $\mathcal{J}_f$ of models. Marginal cost is constant in output and log-linear in observed cost characteristics w_j and an unobserved cost shock ω_j:

$$\ln mc_j = w_j \gamma + \omega_j \tag{8.117}$$

(their eq. 3.1). The cost characteristics are a constant, $\ln HPWT$, Air, $\ln MPG$, $\ln Size$ and a time trend. MPG replaces MP\$ because the production cost of fuel efficiency does not depend on the retail price of gasoline, at least in the short run. The trend captures technical change and regulation. Logs of the continuous attributes make the cost coefficients elasticities of marginal cost. BLP allow ω_j to be correlated with ξ_j, since cars with more unobserved quality may cost more to build.

Firm f's profit is (8.68) (their eq. 3.2), and each firm chooses its prices given rivals' prices. An interior Nash equilibrium satisfies the first-order conditions (8.69) (their eq. 3.3). Section 8.7.1 showed that BLP's markup formula (their eqs. 3.4 and 3.5) is our (8.71), and that substituting it into (8.117) gives the pricing equation (8.72) (their eq. 3.6). The markup depends on ω through the equilibrium prices, and on ξ directly. It therefore cannot be treated as exogenous in the pricing equation.

BLP assume that a Nash equilibrium exists with prices in the interior of the positive orthant (footnote 12). The existence results of Caplin and Nalebuff (1991) cover single-product firms and do not extend easily to multi-product firms. BLP instead check existence numerically at their estimates. None of the properties of the estimator requires a unique equilibrium. Without uniqueness, however, it is not clear how to use the estimates for policy counterfactuals.

8.11.5 Estimation and identification

Moment conditions. Let $z_j = (x_j, w_j)$ collect the demand and cost characteristics of product j, and let $z = (z_1, \ldots, z_J)$ collect them for all products in the market. BLP's identifying assumption is

$$\mathbb{E}[\xi_j \mid z] = \mathbb{E}[\omega_j \mid z] = 0 \tag{8.118}$$

(their eq. 4.1). Prices and quantities are excluded from the conditioning set because the model determines them partly through ξ and ω. Characteristics and cost shifters are treated as predetermined because the model does not explain how they are chosen.

BLP acknowledge that (8.118) holds only if the true process that chooses characteristics has special properties (p. 854). They mention an alternative for panel data. The pair (ξ, ω) of a model could follow a first-order Markov process whose innovations are independent of the model's initial characteristics. This assumption would also identify the model, but it would demand much more of the data, so BLP start from (8.118).

Why characteristics of other products are instruments. Under (8.118), any function of z is a valid instrument. The question is which functions carry information. BLP's answer comes from oligopoly pricing (p. 855). Products that face close substitutes have low markups, so the characteristics of rival products shift a product's price. Nash markups respond differently to products of the same firm and to products of rivals. The instruments should therefore distinguish the two. The demand for j depends on the characteristics of all products, so no characteristic is excluded from the demand of j in the usual sense. What identifies demand is the restriction that the utility of j depends only on the characteristics of j. The number of utility parameters then grows with the number of characteristics, and not with the number of products.

The instrument vector. The efficient instruments under conditional moment restrictions are infeasible here (Section 8.6.3). BLP instead use the first-order terms (8.64) of a partially exchangeable basis (their eq. 5.8). These are the own characteristic, its sum over the firm's other products and its sum over rival products. Section 8.6.3 derives this basis from the exchangeability of a unique Nash equilibrium (Pakes, 1994). The two sums vary across products because they exclude different own products, because firms offer different sets of products, and because the set of products changes over time. The constant is one of the characteristics, so the numbers of own-firm and rival products are instruments too.

Higher-order basis functions were nearly collinear with the first-order terms, and even the first-order terms were nearly of reduced rank. For the demand error BLP use the three terms of (8.64) for each of the five demand characteristics, giving 15 instruments. MPG and the trend enter cost and not demand, so they are excluded from demand. Adding them to the demand list caused numerical problems through near collinearity, and BLP left them out. For the cost error BLP use the three terms for each of the six cost characteristics, plus MP$, giving 19 instruments. The estimator therefore uses 15 + 19 = 34 moment conditions (p. 862). There are 17 parameters: five means β, five standard deviations σ, the income coefficient α and six cost parameters γ. Hence there are 17 overidentifying restrictions.

BLP enter the basis functions directly as GMM instruments, instead of first projecting the optimal instruments on them as Newey (1990) suggests (Section 8.6.3).

Clustering by model. Disturbances of the same model in different years are likely to be more similar than those of different models. BLP therefore treat the sum of a model's moments over the years it is sold as one draw from an exchangeable population of models. Let z^d_{mt} and z^s_{mt} be the 15 demand and 19 cost instruments of model m in year t, and let $\mathcal{T}_m$ be the years in which m is sold. The moment contribution of model m is

$$g_m(\theta) = \sum_{t \in \mathcal{T}_m} \begin{pmatrix} z^{d\top}_{mt}\, \xi_{mt}(\theta) \\ z^{s\top}_{mt}\, \omega_{mt}(\theta) \end{pmatrix} \in \mathbb{R}^{34}. \tag{8.119}$$

BLP write this as $\sum_t [f_{mt}(z)^\top \otimes I_2](\xi_{mt}, \omega_{mt})^\top$, with the instrument blocks restricted as described

above. The estimator minimizes

$$Q(\theta) = \bar{g}(\theta)^{\top} W \bar{g}(\theta), \qquad \bar{g}(\theta) = \frac{1}{997} \sum_{m=1}^{997} g_m(\theta), \tag{8.120}$$

with W a consistent estimate of the inverse covariance matrix of g_m. The resulting standard errors allow arbitrary correlation across years within a model and arbitrary heteroskedasticity across models. BLP note that this is probably not the most efficient way to use the panel.

Computing the objective. Each evaluation of the moments takes four steps for a given θ (p. 863).

1. Simulate the market shares $s_{jt}(\delta_t; \theta_2)$ implied by the model.
2. Solve for the mean utilities δ_t that equate simulated and observed shares, and set $\xi_{jt} = \delta_{jt} - x_{jt}\beta$.
3. Compute the markups b_{jt} from the simulated share derivatives and set $\omega_{jt} = \ln(p_{jt} - b_{jt}) - w_{jt}\gamma$.
4. Interact ξ and ω with the instruments to form (8.119).

The logit benchmark puts price in the mean utility, $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, and sets $\mu_{ijt} = 0$. Every step is then analytic. Shares are $s_{jt} = \frac{e^{\delta_{jt}}}{1 + \sum_q e^{\delta_{qt}}}$, the inversion is $\delta_{jt} = \ln s_{jt} - \ln s_{0t}$, and the demand error is $\xi_{jt} = \ln s_{jt} - \ln s_{0t} - x_{jt}\beta + \alpha p_{jt}$ (their eqs. 6.3 to 6.5). In the full model step 2 uses the contraction

$$\delta_{jt}^{h+1} = \delta_{jt}^{h} + \ln s_{jt}^{\text{obs}} - \ln s_{jt}\left(\delta_t^{h}; \theta_2\right)$$

(their eq. 6.8), whose convergence BLP prove in their Appendix I (Theorem 8.15).

Step 1 uses the importance sampler (8.45) of Section 8.3.4 (their eq. 6.13). BLP first obtain a preliminary estimate θ' with the plain smooth simulator. They then accept population draws of ν with probability $\bar{f}(\nu; \theta')$, the probability that a household with tastes ν buys some car, and reweight each accepted draw by $\frac{\bar{s}(\theta')}{\bar{f}(\nu;\theta')}$. The sampler oversamples households likely to buy a car, which is where the integrand is large. The same draws are used for every share. As Section 8.3.4 shows, this does not make the simulated shares of all $J + 1$ options sum to one. Their total is the sample mean of the weights, which is one only in expectation. The contraction still has a unique solution whenever the observed inside shares sum to less than that mean.

The first-order conditions of (8.120) are linear in β and γ given (α, σ). Both $\xi = \delta(\theta_2) - X\beta$ and $\omega = \ln(p - b(\theta_2)) - W_c\gamma$ are linear in the linear parameters, where W_c stacks the w_{jt}. The markup depends only on θ_2 because it is computed from the inverted δ and the share derivatives. BLP concentrate out β and γ as in Proposition 8.20 and search over the six elements of (α, σ) with the Nelder and Mead (1965) simplex method (p. 868).

Standard errors. The asymptotic variance is (8.62), the sandwich with the three variance pieces V_1 (product characteristics), V_2 (consumer sampling) and V_3 (simulation) derived in Section 8.5.7. With about 100 million U.S. households, V_2 is negligible and V_3 is not. BLP estimate V_3 by redrawing the simulation draws. The correction raises the standard errors in their Table IV by about 5 to 20 percent, except for one parameter whose standard error doubles (p. 859).

What identifies the parameters. Four sources of information identify the model. The cross-section of mean utilities, together with the characteristics instruments, identifies β and the overall

level of price sensitivity. The CPS income distribution fixes how price sensitivity varies across households, up to the single parameter α. The standard deviations σ_k are identified by how shares respond to the configuration of products in characteristics space. BLP explain the distinction between a mean and a variance with HPWT (p. 877). Cars with high HPWT can be popular because the mean taste for HPWT is high, or because the taste is dispersed and some consumers value HPWT a lot. Both raise the share of high-HPWT cars. They have different implications for substitution. With dispersed tastes, consumers who leave a high-HPWT car are those who value HPWT most, so they move disproportionately to other high-HPWT cars.

The panel helps here. BLP report that separating means from variances was much harder in a single cross section than in the panel, which was one reason to use twenty years of data (footnote 30). The supply side adds a fourth source. The markups in (8.71) depend on θ_2, so the cost moments carry information about demand (Section 8.7). BLP note that their use of "identification" is informal and that a formal argument would need further regularity conditions (footnote 13). Section 8.6 discusses what later work established.

8.11.6 Results I: logit benchmarks

BLP first estimate two logit models and a marginal-cost pricing regression. The logit models give a transparent reference point. They also isolate the effect of instrumenting for price, because the IV logit keeps the logit's substitution patterns. Table 8.11 reproduces their Table III.

Table 8.11: Logit demand and marginal-cost pricing, 2,217 observations (BLP 1995, Table III)

Variable	OLS logit demand	IV logit demand	OLS ln(price) on w
Constant	−10.068	−9.273	1.882
	(0.253)	(0.493)	(0.119)
HPWT*	−0.121	1.965	0.520
	(0.277)	(0.909)	(0.035)
Air	−0.035	1.289	0.680
	(0.073)	(0.248)	(0.019)
MP$	0.263	0.052	
	(0.043)	(0.086)	
MPG*			−0.471
			(0.049)
Size*	2.341	2.355	0.125
	(0.125)	(0.247)	(0.063)
Trend			0.013
			(0.002)
Price	−0.089	−0.216	
	(0.004)	(0.123)	
No. of inelastic demands	1494	22	n.a.
(at ±2 s.e.)	(1429–1617)	(7–101)	
R^2	0.387	n.a.	0.656

Notes: Source: Berry et al. (1995), Table III (p. 873). Standard errors in parentheses. The dependent variable in the demand columns is $\ln s_{jt} - \ln s_{0t}$. Starred continuous characteristics enter demand in levels and the price regression in logs. The IV logit uses the instruments of (8.64). Column 3 assumes marginal-cost pricing.

OLS logit. The first column regresses $\ln s_{jt} - \ln s_{0t}$ on the characteristics and price by OLS.

The coefficients on HPWT and Air are negative but imprecise, which BLP call anomalies.[6] The price coefficient of -0.089 implies that 1,494 of the 2,217 models have inelastic demand.

This count follows directly from the logit formula. The logit own elasticity is $\varepsilon_j = \alpha p_j(1-s_j)$, and inside shares are tiny, so demand is inelastic when

$$\alpha p_j(1-s_j) < 1 \iff p_j < \frac{1}{\alpha(1-s_j)} \approx \frac{1}{\alpha}.$$

With $\alpha = 0.089$ the cutoff is $\frac{1}{0.089} \approx 11.24$, or \$11,236. The median price in BLP's Table II is \$8,728 and the 75th percentile is \$13,074. Between half and three quarters of all model-years should therefore be inelastic, and the reported count is 1,494, or 67 percent. The same calculation at $\alpha \pm 2(0.004)$ gives cutoffs of \$10,309 and \$12,346, which bracket the reported range of 1,429 to 1,617 inelastic demands (our calculation).

Inelastic demand is inconsistent with profit maximization. A single-product firm sets $\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j}$, which is below one only if $\varepsilon_j > 1$. Proposition 8.42 below shows that the same requirement holds for multi-product firms. The OLS estimate is therefore implausible on economic grounds, and BLP show that its imprecision does not explain the problem.

IV logit. The second column instruments price with the characteristics-based instruments. Every characteristic now enters utility positively, and all but MP\$ are significant. The price coefficient more than doubles in absolute value, from -0.089 to -0.216. This is what the simultaneity story predicts: products with high unmeasured quality sell at high prices, so OLS attributes part of the quality to a weak price response. Only 22 models now have inelastic demand. The cutoff falls to $\frac{1}{0.216} \approx 4.63$, or \$4,630, and the cheapest car in the sample costs \$3,393, so few models can lie below it.[7]

The fit of the logit regression suggests that unobserved characteristics are large. The OLS logit has $R^2 = 0.387$, which BLP read as implying that 61 percent of the variance in mean utility levels is due to ξ_{jt} (p. 874). Strictly, $1 - 0.387 = 0.613$, so 61 percent of the variance of $\ln s_{jt} - \ln s_{0t}$ is unexplained by the OLS regressors. Price is correlated with ξ_{jt}, so the OLS residual is not ξ_{jt}. If the other characteristics are uncorrelated with ξ_{jt}, the population residual variance is below $\mathrm{Var}(\xi_{jt})$. The population value of $1 - R^2$, which the sample puts at 0.61, is then a lower bound on $\frac{\mathrm{Var}(\xi_{jt})}{\mathrm{Var}(\delta_{jt})}$ (Section 7.3.5).

The logit's markups. The logit cannot generate plausible markups. The IV logit implies that all 1990 models have markups between \$4,630 for the BMW and \$4,805 for the Chevrolet Cavalier (p. 874). GM, which sells the most models, has the highest markups, and BMW, which sells the fewest, has the lowest. Proposition 8.37 explains why. Under the logit every product of firm f has the dollar markup $\frac{1}{\alpha(1-S_f)}$, where S_f is the firm's combined share.

With $\alpha = 0.216$, a firm with a negligible combined share has markup $\frac{1}{0.216} \approx 4.630$ thousand dollars. This is exactly BMW's reported \$4,630. GM's \$4,805 implies $1 - S_{GM} = \frac{1}{0.216 \times 4.805}$, so GM's combined market share was about 3.6 percent of households in 1990 (our calculation). The logit therefore ties markups to the size of a firm's portfolio and to nothing else. A Yugo and a BMW sold by firms of equal size would have identical dollar markups. BLP report that

[6] The text on p. 872 names "air conditioning and size" as the variables with negative coefficients. In the printed table the negative coefficients are on HPWT and Air, while Size has a positive coefficient of 2.341. We follow the table.

[7] The reported range of 7 to 101 inelastic demands at ±2 standard errors cannot come from the printed standard error of 0.123 in the simple way used for the OLS column. That interval, 0.216 ± 0.246, includes zero and negative values. The paper does not explain the calculation, and we report the table as printed.

putting $\ln p$ in place of p in the logit makes markups more reasonable, but substitution remains unreasonable (footnote 26).

Marginal-cost pricing. The third column assumes $p = mc$ and regresses $\ln p_j$ on w_j, which is a hedonic price regression. All characteristics except MPG have positive and significant coefficients. A 10 percent increase in HPWT is associated with a 5.2 percent increase in price, and hence in marginal cost under this assumption. The R^2 of 0.656 is much higher than that of the logit demand equation. Simple functions of characteristics explain log prices far better than they explain mean utilities (p. 875).

8.11.7 Results II: parameters of the full model

Table 8.12 reproduces BLP's Table IV. The first pair of columns imposes constant returns to scale (CRTS). The second adds $\ln q_j$ to the cost function. The standard errors are corrected for simulation error and for correlation within models over time, but not for correlation across models (p. 875).

Table 8.12: Demand and pricing equations, BLP specification, 2,217 observations (BLP 1995, Table IV)

		Constant returns		With $\ln q$ in cost	
Parameters	Variable	Estimate	S.e.	Estimate	S.e.
Means (β)	Constant	−7.061	0.941	−7.304	0.746

	Trend	0.019	0.002	0.026	0.004
	$\ln q$			−0.387	0.029

Notes: Source: Berry et al. (1995), Table IV (p. 876). Joint GMM estimation of demand and pricing equations with 34 moments. Standard errors are corrected for simulation error and for arbitrary correlation within a model across years. The cost function is $\ln mc_j = w_j\gamma + \omega_j$ in the first pair of columns and $\ln mc_j = w_j\gamma_w + \gamma_q \ln q_j + \omega_j$ in the second (p. 877).

Cost side. In the CRTS columns, the coefficients on the constant, ln HPWT, Air and the trend are positive and significant. The coefficient on ln Size is not significant, and the coefficient on ln MPG is negative and significant, as in the hedonic regression.

BLP compare these cost coefficients with the hedonic coefficients of Table 8.11. The

comparison has a simple logic. Write the pricing equation (8.72) as

$$\ln p_j + \ln\left(1 - \frac{b_j}{p_j}\right) = w_j\gamma + \omega_j.$$

For a moderate percentage markup, $\ln(1 - \frac{b_j}{p_j}) \approx -\frac{b_j}{p_j}$, so

$$\ln p_j \approx w_j\gamma + \frac{b_j}{p_j} + \omega_j. \tag{8.121}$$

A regression of $\ln p_j$ on w_j that omits the percentage markup therefore estimates approximately $\gamma + \lambda$, where λ is the coefficient from projecting $\frac{b_j}{p_j}$ on w_j. This is the omitted-variable formula. The differences between the two sets of coefficients estimate λ. They are 0.93 for the constant (1.882 against 0.952) and 0.171 for ln Size (0.125 against −0.046). The other differences are small: 0.043 for ln HPWT, 0.061 for Air, −0.056 for ln MPG and −0.006 for the trend (our calculation). BLP conclude that the average percentage markup is positive and rises with size (p. 876).

The negative MPG coefficient may be an artifact of constant returns. Best-selling cars tend to have high MPG and are large, conditional on other attributes. If marginal cost falls with output, imposing constant returns attributes the low cost of high-volume cars to their MPG and size, and drives those coefficients down. Adding $\ln q_j$ tests this story. In the last two columns every cost shifter is positive and significant, including ln MPG (0.293) and ln Size (1.499). The coefficient on $\ln q$ is −0.387 with a standard error of 0.029, which BLP regard as implying implausibly large returns to scale. Higher-order terms in $\ln q$ reduce the problem. BLP hesitate to push this far because output is inaccurate for about a fifth of the sample (p. 877). U.S. sales proxy well for the production of domestic models but not for that of imported models.

The size of these returns to scale is easy to quantify. With $\ln mc = w\gamma_w + \gamma_q \ln q + \omega$, marginal cost is $mc(q) = A\, q^{\gamma_q}$ with $A = e^{w\gamma_w + \omega}$. Total variable cost and average variable cost are

$$TVC(q) = \int_0^q A\, x^{\gamma_q}\, \mathrm{d}x = \frac{A\, q^{1+\gamma_q}}{1+\gamma_q},$$
$$AVC(q) = \frac{TVC(q)}{q} = \frac{mc(q)}{1+\gamma_q}.$$

With $\gamma_q = -0.387$, average variable cost is $\frac{1}{0.613} \approx 1.63$ times marginal cost. We can combine this factor with the markups that BLP report for this specification (Table 8.17 below). For the Mazda 323, $mc = 5.049 - 1.616 = 3.433$ and $AVC \approx 5.600$ thousand dollars, above its price of $5,049. The price falls short of average variable cost for 10 of the 13 cars in the table (our calculation). This makes concrete BLP's remark that markups over average variable cost are implausibly low in this specification (p. 883).[8]

The cost unobservable is modest. The estimated variance of ω is about 22 percent of the variance of log marginal cost, so observed characteristics explain most cost differences. The correlation between ξ and ω is positive but only 0.17. Cars with more unmeasured quality

[8]The text on p. 883 attributes the higher markups over marginal cost to "decreasing returns to scale." A negative γ_q means that marginal cost falls with output, which is increasing returns, as p. 877 states. Increasing returns put marginal cost below average variable cost, which is why markups over marginal cost rise and markups over average variable cost fall.

cost somewhat more to build, but most of the large variance of ξ is unrelated to marginal cost (p. 877).

Demand side. We discuss the CRTS estimates, which BLP use for all later tables. The means of the taste distributions for Air and Size are positive, and BLP describe them as significant at traditional levels. The mean for the constant is negative and precise. The means for HPWT and MP$ are insignificant. The standard deviations for HPWT and MP$ are large and significant. Every characteristic therefore has a significant positive mean or a significant standard deviation, and Size has both (p. 878).

A positive standard deviation on the constant means that the outside good has more idiosyncratic variance than the extreme value shocks give the inside goods (footnote 28). The coefficient on $\ln(y - p)$ is 43.501 with a standard error of 6.427, so the income effect is precisely estimated. BLP also estimated the demand side alone, and a version with firm dummies on both sides, which adds 66 parameters for 22 firms. Neither changed the point estimates much, but both raised the standard errors substantially (footnote 29).

The coefficients themselves are hard to read. Their economic content appears in the elasticities and markups they imply, which we turn to next.

8.11.8 Results III: elasticities and substitution

Attribute and price elasticities. Table 8.13 reproduces BLP's Table V. For thirteen 1990 models it gives each attribute's value and the elasticity of the model's share with respect to that attribute. The last column gives the price and the own-price elasticity. The elasticity with respect to characteristic k follows from differentiating (8.19):

$$\frac{\partial s_j}{\partial x_{jk}} \frac{x_{jk}}{s_j} = \frac{x_{jk}}{s_j} \int (\beta_k + \sigma_k \nu_{ik})\, s_{ij}(1 - s_{ij})\, \mathrm{d}F(\nu_i). \tag{8.122}$$

Dividing the elasticity by x_{jk} therefore gives approximately the average marginal utility of characteristic k among consumers on the margin of buying j, with weights proportional to $s_{ij}(1 - s_{ij})$. Unlike the logit, this average differs from car to car.

The MP$ column shows why the mean and the dispersion of tastes both matter. The MP$ elasticity rises almost monotonically with the car's MP$ rating, from −0.016 for the BMW at 1.885 to 1.132 for the Escort at 4.022.[9] A 10 percent rise in MP$ raises the sales of the Mazda 323, Sentra and Escort by about 10 percent. For cars with low MP$ the elasticity is slightly negative. BLP conclude that buyers of high-mileage cars care a lot about fuel economy, while buyers of the BMW 735i or Lexus LS400 do not (p. 878). Applying (8.122), the weighted mean marginal utility of MP$ among marginal buyers is about $\frac{1.010}{3.645} \approx 0.28$ for the Mazda 323 and $\frac{-0.016}{1.885} \approx -0.008$ for the BMW 735i (our calculation). With $\beta = -0.122$ and $\sigma = 1.050$, these values place the Mazda's marginal buyers about 0.38 standard deviations above the mean taste and the BMW's about 0.11 above it.

The other attributes tell similar stories. The Size elasticity generally declines as cars get larger. The HPWT elasticity is about 0.45 for the three smallest cars and about 0.1 or less for the four largest cars (Town Car, Seville, LS400 and BMW). The relation with the HPWT value is not monotone among midsize cars. The sporty Maxima has an HPWT elasticity of 0.322, while the similar-sized but more sedate Taurus has 0.180.

[9] The text of Berry et al. (1995, p. 878) says that the elasticity "declines almost monotonically with the car's MP$ rating." Their Table V shows that it declines as the rating falls. We describe the table.

Table 8.13: Attribute values and demand elasticities for 1990 models, CRTS estimates (BLP 1995, Table V)

	HPWT		Air		MP$		Size		Price	
Model	value	elas.	value	elas.	value	elas.	value	elas.	value	elas.

Notes: Source: Berry et al. (1995), Table V (p. 879), based on the CRTS estimates of Table IV. "Value" is the attribute's level (price in thousands of 1983 dollars). "Elas." is the elasticity of the model's market share with respect to the attribute. The price elasticity is the own-price elasticity written as a positive number.

Own-price elasticities. BLP's estimates imply that the demand for every one of the 2,217 model-years is elastic. The most elastic demands are in the most crowded segments, the compact and subcompact cars. The Buick Century, at 6.755, is an exception among midsize cars. The elasticities run from 6.528 (Sentra) and 6.358 (Mazda 323) down to 3.515 for the $37,490 BMW and 3.085 for the $27,544 Lexus.[10]

Figure 8.8 plots these elasticities against price and adds the logit benchmarks. The logit elasticity is $\alpha p_j(1 - s_j) \approx \alpha p_j$, a ray through the origin. The OLS ray lies below one for every car under $11,236. The IV ray predicts elasticities of 1.1 for the Mazda and 8.1 for the BMW. BLP's elasticities fall with price instead. Expensive cars are bought by high-income households, whose price sensitivity $\frac{\alpha}{y_i - p_j}$ is small. This is the pattern that Section 8.2 predicted for random coefficients, here generated by income alone.

The price sensitivity of the marginal buyers can be read off the own semi-elasticities. Combining (8.114) and (8.116),

$$-\frac{e_{jj}}{100} = \frac{1}{s_j}\int \frac{\alpha}{y_i - p_j}\, s_{ij}(1 - s_{ij})\, \mathrm{d}F(\nu_i) \le \mathbb{E}\Big[\frac{\alpha}{y_i - p_j}\,\Big|\, i \text{ buys } j\Big],$$

because $0 < 1 - s_{ij} < 1$. The two sides are close when the buyers' individual choice probabilities s_{ij} are uniformly small. Small aggregate shares alone do not ensure this. The semi-elasticities in Table 8.14 below give $-\frac{e_{jj}}{100} = 1.26$ for the Mazda 323, 0.52 for the Accord and 0.094 for the BMW 735i. Dividing $\alpha = 43.501$ by these numbers gives an upper bound on the harmonic mean of residual income $y_i - p_j$ among buyers. The bound is about $35,000 for the Mazda, $84,000 for the Accord and $464,000 for the BMW, in 1983 dollars (our calculation). It approximates the harmonic mean itself only if the buyers' choice probabilities are small. Under that condition, the specification can make luxury-car demand inelastic enough only by placing its buyers far

[10] The text on p. 879 says that "the Sentra and Mazda 323 face demand elasticities of 6.4 and 6.5 respectively." Table V gives 6.528 for the Sentra and 6.358 for the Mazda, so the text reverses the order. The text also rounds the Lexus's 3.085 to 3.0. We use the table values.

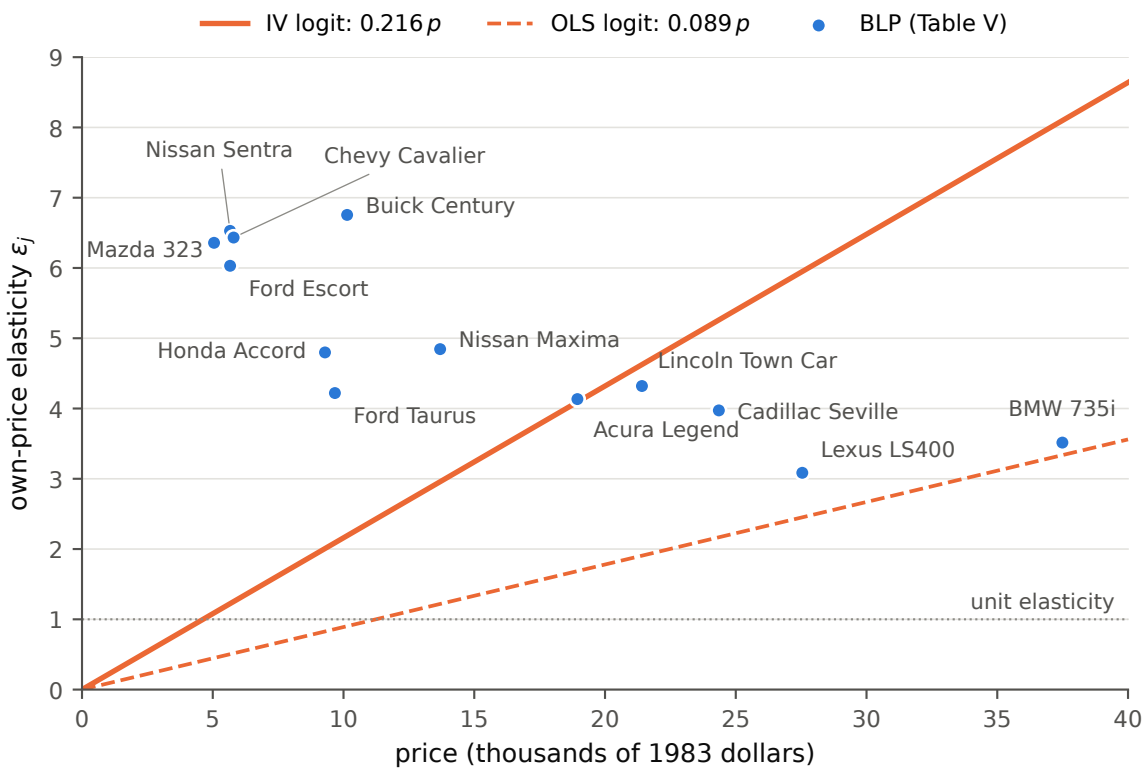

Figure 8.8: Own-price elasticities of thirteen 1990 models against price. Points are BLP's estimates (their Table V). The rays are the logit elasticities αp implied by the IV and OLS logit price coefficients of their Table III, ignoring the factor $1 - s_j \approx 1$. The dotted line marks unit elasticity. Redrawn from Berry et al. (1995), Tables III and V.

in the upper tail of the lognormal income distribution. This is one motivation for adding data on buyers' incomes, as Berry et al. (2004a) and Petrin (2002) later did (Sections 8.8 and 8.14).

Cross-price semi-elasticities. BLP's Table VI reports own- and cross-price semi-elasticities for the same thirteen models. Figure 8.9 displays the full matrix, and Table 8.14 reproduces two diagonal blocks. Entry (i, j) is the percentage change in the share of row car i when the price of column car j rises by \$1,000.

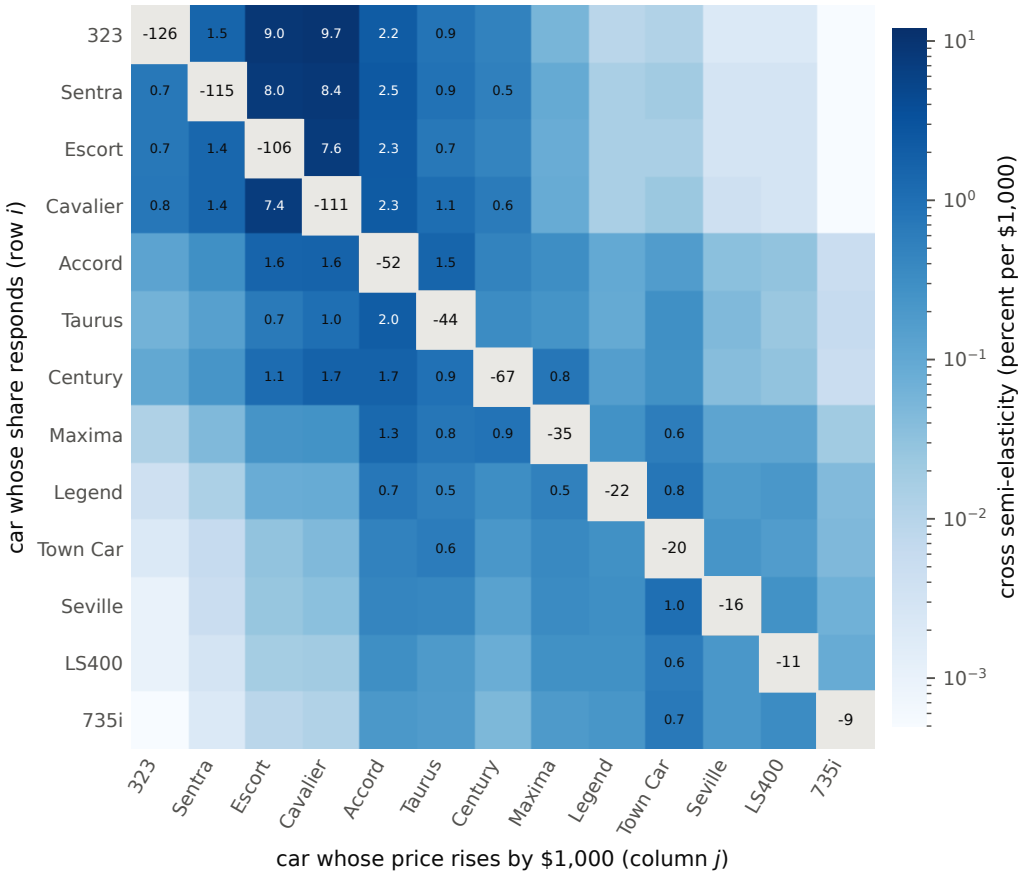

Figure 8.9: Own- and cross-price semi-elasticities for thirteen 1990 models. Cell (i, j) is the percentage change in the share of row car i for a \$1,000 increase in the price of column car j. Off-diagonal cells are shaded on a log scale, and entries of at least 0.5 are printed. Diagonal cells (gray) print the own semi-elasticity, which is negative. Entries printed as 0.000 in the source are shaded at the bottom of the scale. Redrawn from Berry et al. (1995), Table VI.

Three features stand out. First, own semi-elasticities fall sharply with price, from -125.9 for the Mazda 323 to -9.4 for the BMW 735i. Multiplying each by $-\frac{p_j}{100}$ reproduces every own-price elasticity in Table 8.13 to three decimals (our check). Under the IV logit every diagonal entry would be about $-100 \times 0.216 = -21.6$.

Second, cross effects are large among similar cars and close to zero across segments. A \$1,000 rise in the Mazda 323's price raises the Sentra's share by 0.705 percent but leaves the Town Car, Seville, Lexus and BMW almost unaffected. Under the logit the off-diagonal entries of a column would all equal $100\,\alpha s_j$, whatever the row car. In BLP's matrix the largest cross entry in the Escort column is about 1,000 times the smallest (8.954 against 0.009).

Table 8.14: Own- and cross-price semi-elasticities, two blocks of BLP (1995) Table VI

Panel A: small cars Share of ↓ / price of →	Mazda 323	Sentra	Escort	Cavalier
Mazda 323	−125.933	1.518	8.954	9.680
Sentra	0.705	−115.319	8.024	8.435
Escort	0.713	1.375	−106.497	7.570
Cavalier	0.754	1.414	7.406	−110.972
Panel B: luxury cars Share of ↓ / price of →	Town Car	Seville	LS400	BMW 735i
Town Car	−20.175	0.226	0.168	0.048
Seville	1.011	−16.313	0.263	0.068
LS400	0.606	0.212	−11.199	0.086
BMW 735i	0.685	0.215	0.336	−9.376
Panel C: small-car shares, luxury-car prices Share of ↓ / price of →	Town Car	Seville	LS400	BMW 735i
Mazda 323	0.012	0.002	0.002	0.000
Cavalier	0.023	0.004	0.003	0.000

Notes: Source: Berry et al. (1995), Table VI (p. 880), CRTS estimates. Entry (i, j) is $e_{ij} = \frac{100}{s_i}\frac{\partial s_i}{\partial p_j}$, the percentage change in the share of row car i for a \$1,000 increase in the price of column car j. The full 13×13 matrix is shown in Figure 8.9.

Third, the closest substitutes are intuitive. Measured down each column, the Lexus is the closest substitute for the BMW 735i, the Cadillac Seville for the Lincoln Town Car, and the Accord for the Taurus (p. 881). The effects of a \$1,000 increase are smaller for expensive cars because \$1,000 is a smaller fraction of their price. Converting to elasticities removes this scale effect. For example, the elasticity of the Seville's share with respect to the Town Car's price is $1.011 \times \frac{21.412}{100} \approx 0.22$.

Substitution to the outside good. BLP measure how much of the demand a car loses goes to the outside good. The statistic is

$$D_{j0} = 100 \times \frac{\frac{\partial s_0}{\partial p_j}}{\left|\frac{\partial s_j}{\partial p_j}\right|},$$

the number of consumers who switch from j to no car, as a percentage of all who leave j after a small price rise. This is the diversion ratio to the outside good. Under the logit, $\frac{\partial s_0}{\partial p_j} = \alpha s_0 s_j$ and $\left|\frac{\partial s_j}{\partial p_j}\right| = \alpha s_j(1 - s_j)$, so $D_{j0} = 100 \times \frac{s_0}{1-s_j}$. Under BLP, Proposition 8.5 gives

$$\frac{D_{j0}}{100} = \int \varpi_{ij} \frac{s_{i0}}{1 - s_{ij}} \, \mathrm{d}F(\nu_i), \qquad \varpi_{ij} = \frac{\frac{\alpha}{y_i - p_j} s_{ij}(1 - s_{ij})}{\int \frac{\alpha}{y_l - p_j} s_{lj}(1 - s_{lj}) \, \mathrm{d}F(\nu_l)},$$

a weighted average of individual diversions with weights concentrated on the price-sensitive marginal buyers of j.

Table 8.15 and Figure 8.10 report the results. Under the logit about 90 percent of those who leave any model choose no car, which is $\frac{s_0}{1-s_j} \approx s_0$. The logit column ranges from 90.458 to 90.883. Since $\frac{s_0}{1-s_j} > s_0$, this puts s_0 just below 0.905. The entries fall slightly with sales, which

Table 8.15: Substitution to the outside good after a price increase (BLP 1995, Table VII)

Model	Logit	BLP
Mazda 323	90.870	27.123
Nissan Sentra	90.843	26.133
Ford Escort	90.592	27.996
Chevy Cavalier	90.585	26.389
Honda Accord	90.458	21.839
Ford Taurus	90.566	25.214
Buick Century	90.777	25.402
Nissan Maxima	90.790	21.738
Acura Legend	90.838	20.786
Lincoln Town Car	90.739	20.309
Cadillac Seville	90.860	16.734
Lexus LS400	90.851	10.090
BMW 735i	90.883	10.101

Notes: Source: Berry et al. (1995), Table VII (p. 881). Entries are $D_{j0} = 100 \times \frac{\partial s_0}{\partial p_j} \left(\left| \frac{\partial s_j}{\partial p_j} \right| \right)^{-1}$, the percentage of consumers who leave car j after a small price increase and choose the outside good.

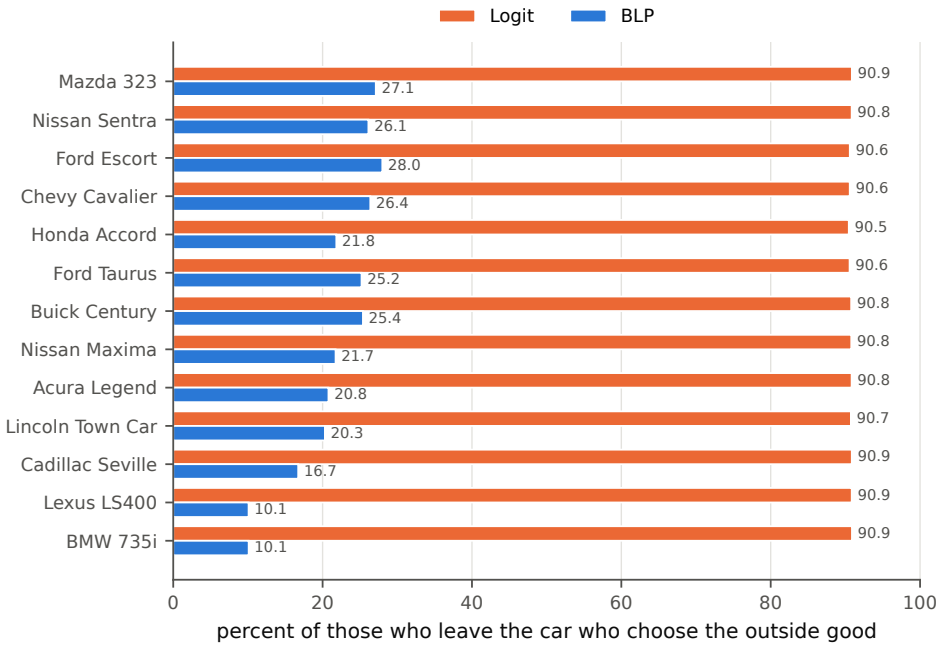

Figure 8.10: Diversion to the outside good after a small price increase, logit against BLP. Redrawn from Berry et al. (1995), Table VII.

$\frac{s_0}{1-s_j}$ does not allow, so the printed values match the formula only approximately. Under BLP's estimates the diversion ranges from 28.0 percent (Escort) to 10.1 percent (Lexus and BMW). It is lower for expensive cars. Buyers of luxury cars are rich and like cars, so for them s_{i0} is small and they move to other luxury cars. Buyers of cheap cars are closer to the margin of not buying. BLP still find their numbers "a bit large" and see this as a sign that the treatment of the outside good needs improvement (pp. 881–882). The outside good includes keeping an old car, and a dynamic model with a used-car market would treat it more realistically (Section 8.2 of the paper).

8.11.9 Results IV: markups and profits

Markups combine the demand and cost estimates. Table 8.16 reproduces BLP's Table VIII and adds four columns that we compute from it and from Table V.

Table 8.16: Markups and variable profits for 1990 models, CRTS estimates (BLP 1995, Table VIII, with derived columns)

		BLP Table VIII			Derived (our calculation)			
Model	Firm	Price	$p-mc$	$q(p-mc)$	$\frac{p-mc}{p}$	$\frac{1}{\varepsilon_j}$	Gap	Sales
Mazda 323	Mazda	5,049	801	18,407	0.159	0.157	0.001	22,980
Nissan Sentra	Nissan	5,661	880	43,554	0.155	0.153	0.002	49,493

Cadillac Seville	GM	24,353	7,500	249,195	0.308	0.252	0.056	33,226
Lexus LS400	Toyota	27,544	9,030	371,123	0.328	0.324	0.004	41,099
BMW 735i	BMW	37,490	10,975	114,802	0.293	0.284	0.008	10,460

Notes: Columns 3 to 5 are from Berry et al. (1995), Table VIII (p. 882), whose caption refers to "Table 6 (CRTS)" estimates, meaning those of Table IV. Price and markup are in 1983 dollars, and variable profits in thousands of 1983 dollars. "Firm" is the parent company. The last four columns are our calculations: the Lerner index, the inverse own-price elasticity from Table V, the gap between them, and implied unit sales $\frac{q(p-mc)}{p-mc}$.

Levels and pattern. In 1990 the average markup is \$3,753 and the average ratio of markup to price is 0.239 (p. 882). The lowest markups are those of the Mazda 323 (\$801), Sentra (\$880) and Escort (\$1,077). The Lexus and BMW have markups of \$9,030 and \$10,975. Markups rise almost monotonically with price, and the Lerner index rises from about 0.16 to about 0.3. Figure 8.11 contrasts this pattern with the IV logit, whose markups all lie in a band between \$4,630 and \$4,805. BLP note that the average level of markups is similar in the two models even though the pattern differs (footnote 31).

Profits. Large markups need not mean large profits, because some high-markup cars sell few units. BLP single out the Honda Accord and the Ford Taurus as the most profitable models in their table, by a factor of two relative to most others. Both were regarded as essential to their firms' finances (p. 882).[11] Dividing variable profits by markups recovers unit sales, which

[11] In the printed Table VIII the Lincoln Town Car's variable profit (\$832,082 thousand) is as large as the Accord's

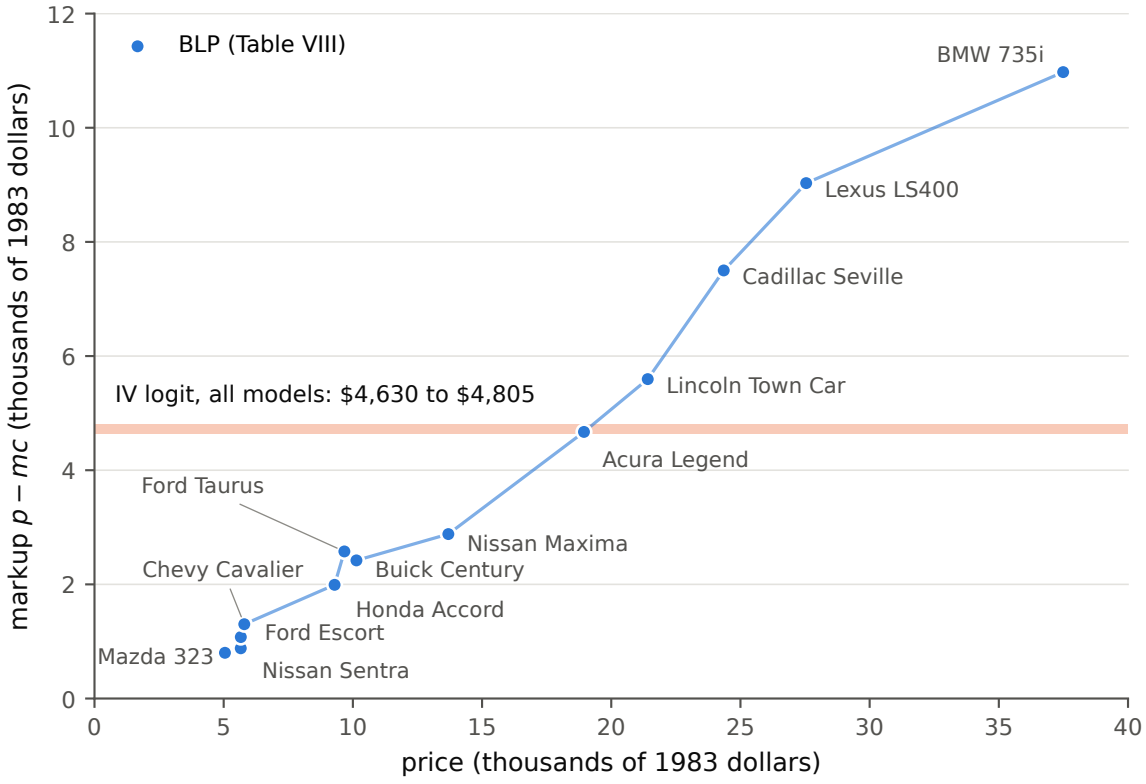

Figure 8.11: Price-cost markups of thirteen 1990 models against price. Points are BLP's estimates (their Table VIII). The shaded band is the range of markups implied by the IV logit for all 1990 models ($4,630 to $4,805, p. 874). Redrawn from Berry et al. (1995).

range from 10,460 BMW 735i's to 417,089 Accords.

Multi-product pricing in the markups. The derived columns of Table 8.16 reveal the role of multi-product ownership. The following decomposition holds in any Bertrand-Nash equilibrium.

Proposition 8.42 (Multi-product Lerner index)**.** *Let* $D_{jr} = \frac{\partial s_r}{\partial p_j}\left(\left|\frac{\partial s_j}{\partial p_j}\right|\right)^{-1}$ *be the diversion ratio from* j *to* r*. At an interior Bertrand-Nash equilibrium, every product* j *of firm* f *satisfies*

$$\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j} + \sum_{r \in \mathcal{J}_f, r \neq j} D_{jr}\,\frac{p_r - mc_r}{p_j}.$$

If the products are substitutes and markups are positive, the second term is nonnegative, so $\varepsilon_j > 1$ *whenever the Lerner index is below one.*

Proof. Move the own-product term of (8.69) to the left:

$$(p_j - mc_j)\Big(-\frac{\partial s_j}{\partial p_j}\Big) = s_j + \sum_{r \in \mathcal{J}_f, r \neq j} (p_r - mc_r)\frac{\partial s_r}{\partial p_j}.$$

Divide both sides by $p_j\left|\frac{\partial s_j}{\partial p_j}\right|$. The first term on the right becomes $\frac{s_j}{p_j}\left(\left|\frac{\partial s_j}{\partial p_j}\right|\right)^{-1} = \frac{1}{\varepsilon_j}$, and each term of the sum becomes $D_{jr}\frac{p_r - mc_r}{p_j}$. With substitutes $D_{jr} \geq 0$ and positive markups, so the sum is nonnegative. Then $\frac{1}{\varepsilon_j} \leq \frac{p_j - mc_j}{p_j} < 1$ gives $\varepsilon_j > 1$. □

The gap between the Lerner index and $\frac{1}{\varepsilon_j}$ measures the margins a firm recaptures on its other products. For the products of Mazda, Nissan, Honda, Toyota and BMW the gap is at most 0.008. Their 1990 portfolios contained few close substitutes for these models. For Ford's Escort, Taurus and Town Car the gap is 0.024 to 0.030. For GM's Cavalier, Century and Seville it is 0.056 to 0.091. GM's many divisions sell close substitutes for each of its models, so a price rise on the Century diverts many buyers to other GM cars. This portfolio effect, invisible in the logit except through S_f, is the mechanism that Nevo (2001) later used to separate multi-product pricing from collusion (Section 8.13).

8.11.10 Robustness*

The choice of characteristics in utility and cost is ad hoc, and computation limits the number of random coefficients. BLP report how markups change across six alternative specifications. They choose markups as the summary because markups combine demand and cost information and are easy to interpret. Table 8.17 reproduces their Table IX.

The pattern of markups survives every specification. In each column markups rise broadly with price, with a few reversals, and the correlation of each column with the base column is between 0.945 and 0.9997 (our calculation). Levels move more. Across the seven columns a car's highest markup is between 1.6 and 3.3 times its lowest.

The individual columns have specific explanations (pp. 883–885). Adding $\ln q$ in column (2) raises every markup above the base. It gives the highest markup in the table for six of the thirteen models, and column (6) gives the highest for the other seven.[12] BLP judge that even

($830,842 thousand) and the Taurus's ($807,212 thousand). The text's statement fits the other ten models.

[12] Berry et al. (1995, pp. 883–884) write that, of all the alternatives, this specification "yielded the highest price-marginal cost markups." Their Table IX supports this for six of the thirteen models only.

Table 8.17: Markups under alternative specifications, 1990 models, dollars (BLP 1995, Table IX)

	(1) Base (Table VIII)	(2) ln q in cost	(3) AT for Air	(4) Weight, HP for HPWT	(5) Cost interactions	(6) Regions, reliability	(7) Weight, interactions
Mazda 323	801	1,616	1,012	1,073	828	1,125	1,389
Nissan Sentra	880	1,769	1,153	1,271	912	1,308	1,487
Ford Escort	1,077	2,043	1,326	1,470	1,111	2,094	1,690
Chevy Cavalier	1,302	2,490	1,729	1,655	1,329	2,593	2,020
Honda Accord	1,992	3,059	2,629	2,703	2,059	3,839	2,327
Ford Taurus	2,577	3,721	2,528	3,344	2,585	4,094	2,898
Buick Century	2,420	4,162	3,161	2,939	2,405	4,030	3,321
Nissan Maxima	2,881	4,674	4,565	2,085	2,911	6,941	3,513
Acura Legend	4,671	7,105	6,563	3,059	4,661	8,305	5,081
Lincoln Town Car	5,596	8,029	6,778	4,765	5,508	7,114	6,518
Cadillac Seville	7,500	10,733	8,635	4,863	7,439	9,182	8,015
Lexus LS400	9,030	10,510	8,411	4,791	8,585	10,925	7,398
BMW 735i	10,975	13,646	9,122	7,605	10,713	12,153	12,202
Demand variables significant	5 of 5	4 of 5	4 of 5	6 of 6	4 of 5	8 of 8	4 of 6

Notes: Source: Berry et al. (1995), Table IX (p. 883). Price minus marginal cost in 1983 dollars. (2) adds ln q to the cost function (last columns of Table IV). (3) replaces Air with a dummy for standard automatic transmission. (4) replaces HPWT with horsepower and weight entered separately. (5) adds interactions of the continuous characteristics to the cost function. (6) replaces the constant in utility with U.S., Japan and Europe dummies and adds the reliability rating. (7) adds weight and cost-side interactions. The last row counts demand variables whose mean or standard deviation is significant at the 95 percent level.

these markups are not extraordinarily high. As shown above, the markups of column (2) over average variable cost are implausible. Using automatic transmission as the luxury proxy in column (3) raises markups slightly for cheap cars and lowers them slightly for expensive ones. Entering horsepower and weight separately in column (4) changes markups the most. It gives implausibly low markups for expensive cars, possibly because cost is not linear in horsepower and weight. Cost interactions in column (5) leave markups within a few percent of the base, although most interaction terms are significant. Region dummies with reliability in column (6) raise markups for several mid-priced models from different regions, for reasons BLP could not identify. Reliability is included there because region dummies may be correlated with reliability, which would otherwise sit in ξ and invalidate the instruments. Column (7) adds weight, which has an insignificant cost coefficient and a significant demand mean, and leaves markups close to the base.

8.11.11 Interpretation

BLP read Tables IV to VIII as evidence that flexible utility gives a more realistic picture of equilibrium in the industry. Three lessons stand out.

First, instrumenting for price matters even in the logit. It more than doubles the price coefficient and removes almost all inelastic demands (Table 8.11). Second, random coefficients and income effects change the economics, beyond the econometrics. Own elasticities fall with price, substitution runs between similar cars, and diversion to the outside good falls from about 90 percent to 10 to 28 percent. Each of these patterns is impossible in the logit. Third, the implied markups are plausible in level and pattern. They are consistent with standard multi-product pricing, in which GM's broad portfolio raises its margins above the inverse elasticity.

The results have clear implications for counterfactuals. A merger simulation built on the logit would predict uniform markups and diversion mostly to the outside good. It would therefore understate the price effects of merging close substitutes (Chapter 11). A tariff analysis would mispredict which domestic cars gain from higher import prices. A welfare calculation for a new model would depend on how much demand it takes from similar cars.

8.11.12 Limitations and critiques

Data. Prices are list prices of base models, so discounts and options are missing. Fleet sales are ignored. Output is poorly measured for imported models, which limits the cost function. Market size is the number of households, and every household is assumed to consider buying one new car each year.

Exogenous characteristics. The moment condition (8.118) treats observed characteristics as mean independent of ξ and ω. Firms choose characteristics, and they may choose them knowing ξ, so the instruments may be invalid. BLP raise this concern themselves and sketch a Markov alternative (Section 8.11.5). They also identify obtaining consistent estimates when observed and unobserved characteristics are correlated as the easier part of the dynamic problem. Endogenizing the choice of characteristics is the harder part (Section 8.2 of the paper).

Statics and the outside good. Cars are durable. A household's outside option is often its current car, and its timing of purchases responds to prices and expectations. A static model with an undifferentiated outside good cannot capture these choices, which may explain why diversion to the outside good still looks large.

Conditional counterfactuals. Policy analysis with the model holds characteristics and the product set fixed. Pakes et al. (1993) used the estimates to predict average MPG after the 1973 gasoline price shock. The model predicted 1974 and 1975 almost exactly, when characteristics changed little. From 1976 on, new small fuel-efficient models appeared and the predictions became markedly worse (pp. 885–886).

Functional form and the supply side. All heterogeneity in price sensitivity comes from income through $\alpha \ln(y_i - p_j)$, with one income dispersion parameter for all years. Our harmonic-mean bound suggests how far into the income tail the model places luxury-car buyers, provided their individual choice probabilities are small. The random coefficients are independent normals. Conduct is assumed to be Bertrand-Nash and is not tested. The constant-returns cost function produces a negative MPG coefficient, and the alternative with $\ln q$ implies implausible returns to scale.

Aggregate data only. BLP use no data that link households to the cars they buy. Their own conclusion points to consumer surveys and to plant-level cost data from the Census Longitudinal Research Database (Section 8.2 of the paper). Berry et al. (2004a) and Petrin (2002) later added consumer-level moments for cars (Sections 8.8 and 8.14), and Goldberg (1995) estimated car demand from household data (Section 8.15).

Numerical and instrument sensitivity. Later work re-examined the estimator. Knittel and Metaxoglou (2014, p. 35) used BLP's automobile data and the synthetic cereal data of Nevo (2000a). They found that BLP-type estimates and their implications can vary with the optimization algorithm and starting values. Dubé et al. (2012) showed that a loose tolerance in the contraction can produce false convergence (Sections 8.4 and 8.9). Armstrong (2016, Section 3) showed that the characteristics-based instruments can lose their power in markets

with many products. Equilibrium markups then vary little. Reynaert and Verboven (2014) and Conlon and Gortmaker (2020, Section 5) found in Monte Carlo experiments that approximations to the optimal instruments improve precision. These critiques concern implementation, and they leave the framework itself intact.

8.11.13 Contribution

BLP's contribution is a complete template for empirical work on differentiated products with market-level data. It combines five elements. Utility is defined over characteristics, with random coefficients and demographic information from outside the sample. Shares are aggregated by simulation. Mean utilities are recovered by inverting the share equations with a contraction. A GMM estimator built on structural errors handles price endogeneity, with instruments derived from oligopoly pricing and exchangeability. A multi-product Nash pricing equation recovers marginal costs and markups without cost data.

The same template now underlies most empirical work on differentiated-products markets. Applications include voluntary export restraints on Japanese cars (Berry et al., 1999), mergers (Nevo, 2000b, Chapter 11), the welfare gains from new goods (Petrin, 2002, Chapter 10), and airline hubs (Berry et al., 2006, Chapter 9). Nevo (2000a) wrote the guide that made the method accessible, and we turn to it next.

8.12 Case study: Nevo (2000a), the practitioner's guide and its application

Nevo (2000a) is a guide to the random coefficients logit for researchers who have not used it. It explains the model, the algorithm and the instruments with the stated aim of lowering the barriers to entry and increasing trust in the method among outsiders (p. 514). It ends with an application to a synthetic data set, and Nevo posted the data and his Matlab code. The model and algorithm of Sections 8.1 to 8.6 follow the guide's equations closely. This section covers the rest: the guide's framing, its specification choices and their implications, its practical advice, the application in full, and its list of extensions. Table 8.21 at the end of the section maps the application.

8.12.1 Purpose and framing

Nevo starts from two problems that make differentiated-products demand hard. The first is dimensionality. A log-log demand system for 100 products has 100 equations, each with 100 prices, which means at least 10,000 parameters (p. 514). Symmetry and adding up remove only part of these, and the number remains too large to estimate. More flexible substitution patterns make the problem worse. The second is heterogeneity. If all consumers were identical, markets would not show the variety of products we observe. A representative consumer exists under Gorman-form preferences (Gorman, 1959), but those assumptions are strong and often empirically false.

The logit model solves the dimensionality problem by projecting products onto a space of characteristics. The number of parameters then depends on the number of characteristics and not on the square of the number of products. The cost is the logit's treatment of heterogeneity, which makes substitution depend on market shares and not on how similar products are. Random coefficients keep the projection and model heterogeneity explicitly. Nevo lists three

Table 8.18: Identification and counterfactual map of Berry, Levinsohn and Pakes (1995)

Observed data	Prices, sales and characteristics of 2,217 U.S. car model-years (997 models), 1971–1990. The number of households and the CPS income distribution in each year. The ownership of models by 22 firms.
Latent objects	Unobserved quality ξ_{jt} and cost shocks ω_{jt}. Household tastes ν_i and incomes y_{it}. Marginal costs and markups.
Estimated parameters	Mean tastes β and standard deviations σ for five characteristics, the income coefficient α in $\alpha \ln(y_{it} - p_{jt})$, and six cost coefficients γ. There are 17 in all.
Identifying variation	The moments $\mathbb{E}[\xi_j \mid z] = \mathbb{E}[\omega_j \mid z] = 0$ with 34 instruments. They are own characteristics and their sums over the firm's other products and over rival products, which vary with product sets across firms and years. The CPS income distribution shapes price sensitivity, and the pricing equation adds cost moments.
Maintained assumptions	Characteristics are mean independent of (ξ, ω). Static multiproduct Bertrand-Nash pricing with an interior equilibrium. Constant marginal cost, log-linear in characteristics. Independent normal tastes, type-I extreme value errors, and a market size equal to the number of households.
Counterfactual and what it holds fixed	The paper solves for no new equilibrium. Elasticities, markups and variable profits are evaluated at observed prices. Policy uses of the estimates hold characteristics, the product set and conduct fixed (Section 8.11.12).
Conclusion	Own elasticities fall with price and substitution runs toward similar cars. Diversion to the outside good falls from about 90 percent in the logit to 10 to 28 percent, and markups rise with price. These findings rest on exogenous characteristics and Nash pricing.
One limitation	Firms choose characteristics and may know ξ when they do, so the instruments built from characteristics may be invalid.
Source and our additions	The tables are BLP's. The outside share and market size, the derived columns of Table 8.16, Proposition 8.42, the harmonic-mean income bound and the robustness correlations are our calculations.
Tools in the appendices	Sections A.5, A.7 and B.7.

advantages of the BLP method over earlier estimates of such models (p. 515). It needs only market-level price and quantity data, it deals with the endogeneity of prices, and it produces more realistic elasticities.

8.12.2 Specification choices and their implications

The guide's model. The guide's model is the one of Section 8.1.2. Indirect utility is (8.5) (his eq. 1), and tastes depend on demographics and unobserved characteristics as in (8.6) (his eq. 2). The unobserved tastes ν_i come from a parametric distribution, usually standard normal, and the demographics D_i from an empirical distribution such as CPS draws. The outside good is normalized as in Section 8.1.4. Combining the two equations gives the decomposition (8.8) (his eq. 3), and shares integrate over (D, ν, ϵ) with the factorization (8.4) (his eq. 4).

Assumptions and their implications. Nevo spells out three assumptions implicit in (8.5) and then discusses how (8.6) models heterogeneity (pp. 517–520).

1. *No wealth effects.* The form $\alpha_i(y_i - p_{jt})$ comes from quasilinear utility. This is reasonable for ready-to-eat cereal and unreasonable for cars. BLP's $\ln(y_i - p_j)$ is one alternative, and a flexible function $f(y_i - p_{jt})$ is another, as in Petrin (2002).

2. *A common valuation of ξ.* Every consumer values the unobserved characteristic equally. Because the price coefficient varies, this is consistent with theories of vertical differentiation. Das et al. (1994) model a distribution of valuations of ξ instead.

3. *Common prices and characteristics.* All consumers in a market face the same price. If they do not, a list or average price measures the relevant price with error. This is one more reason why price may be correlated with the error. The inversion method handles measurement error only if the mismeasured variable enters δ_{jt} alone (footnote 11, citing Berry, 1994).

4. *Observed and unobserved heterogeneity.* Demographics bring outside information into the model and reduce reliance on parametric assumptions. Nevo's example of an unobserved characteristic is whether a household owns a dog, which matters for choosing a car but appears in no survey (p. 519). The linear form ΠD_i is restrictive, especially for the price coefficient.

Where correlation in utility comes from. Nevo then explains why the logit fails and how to fix it (pp. 522–526), with the arguments and the cereal examples that Section 8.2.1 reproduced. The cure is correlation in utility across brands, which can enter through ϵ or through μ. Generalized extreme value models put it in ϵ. The nested logit groups brands into exhaustive and mutually exclusive nests fixed in advance. Within a nest, substitution is again proportional to shares. With nesting parameter σ and within-nest share $s_{j|g}$, the own elasticity becomes $\alpha p_j \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j\right]$. Nesting changes its level, yet it is still the price times a common coefficient times a function of shares. The nested logit therefore "does not help with the problem of own-price elasticities" (p. 524). Cardell (1997) shows the distributional assumptions under which a random coefficient on segment dummies reproduces the nested logit. With several layers of segmentation the order of the nests matters. Grouping computers first by brand and then by technology gives different substitution than the reverse order, even with the same groups (footnote 18). The principles-of-differentiation GEV model of Bresnahan et al. (1997) avoids ordering the nests. An unrestricted covariance matrix for ϵ reintroduces the dimensionality problem.

The random coefficients model puts the correlation in μ. Products with similar characteristics are correlated in utility, and consumers with similar demographics rank products similarly. The own-price derivative averages individual price sensitivities with weights given by individual purchase probabilities (Proposition 8.4). If the buyers of Kellogg's Corn Flakes are price sensitive, its own elasticity is high despite its low price (p. 526). Substitution is then driven by differences in price sensitivity across the buyers of different products, and not by the functional form.

8.12.3 Practical recommendations

The guide's Section 3 turns from the model to practice. Most of its advice is now part of the chapter's theory, and we list each item with the place where we develop it.

Data and market size. The data requirements and Nevo's four rules for choosing the market size are those of Section 8.1.9 (p. 527). Nevo strongly recommends several markets with variation in relative prices or in the products offered.

Two roles of characteristics. Characteristics explain mean utility δ and drive substitution through μ, and Nevo recommends keeping the two roles separate (pp. 527–528, Section 8.1.5). Substitution must come from characteristics, which should therefore guide what the researcher collects.

Identification. Nevo's informal argument starts from an ideal experiment that randomizes prices across consumers (pp. 528–530). Market data depart from it in two ways. Prices are set by firms that know ξ, which instruments address. More subtly, a discrete choice model can be estimated from one market. Each market is then an observation on the relative likelihood of buying J bundles of attributes, one of which is price. Identification improves with more markets that vary in product characteristics, choice sets and demographic distributions. His three-product example (A and B similar, B and C with equal shares) appears in Sections 8.2.6 and 8.6.2.

The estimator. The guide argues against matching shares by nonlinear least squares (his eq. 7) and builds the GMM residual from the inverted mean utilities (his eqs. 8 to 13). It notes that the logit and nested logit reduce to two-stage least squares. Section 8.5 develops all three points.

Instruments. Nevo reviews cost shifters, characteristics-based instruments and Hausman instruments with their caveats (pp. 534–536), as in Section 8.6.4. His footnote 23 makes the characteristics-based instruments concrete. Suppose there are two characteristics (horsepower and size) and two firms with three products each. The instruments for a product are then its two characteristics, their sums over the firm's other two products, and their sums over the rival's three products, six in all. Nevo stresses that validity must be argued case by case.

Brand dummies and minimum distance. Nevo believes brand fixed effects should be used whenever possible (p. 536). Section 8.6.5 develops his argument, his answers to the two objections and the minimum-distance estimator (8.65) of the taste parameters (pp. 537–538). The assumption $\mathbb{E}[\xi_b \mid \boldsymbol{X}_b] = 0$ is used only to recover β. A researcher unwilling to make it can still recover price sensitivity from the other instruments (footnote 24).

8.12.4 The application

Data. The data contain prices and quantities for 24 brands of a differentiated product in 47 cities over 2 quarters (p. 538). A market is a city-quarter, so there are 94 markets and

$24 \times 94 = 2{,}256$ observations. Every brand is sold in every market, so choice sets do not vary. The data were generated from the demand model of Section 2 and a multi-product Bertrand pricing model (footnote 25). The marginal costs and parameters were motivated by the cereal estimates of Nevo (2000b). Nevo warns that the data are not real and should not be used for analysis. Their purpose is to teach the method.

Products have two characteristics. *Sugar* measures sugar content, and *Mushy* equals one if the cereal gets soggy in milk. Demographics are drawn from the CPS: the log of income (*Income*), its square (*IncomeSq*), *Age*, and *Child*, a dummy for being under sixteen. The unobserved ν_i are standard normal, and each market uses $n_s = 20$ simulated individuals. All specifications include brand and time dummies. Section 4 does not describe the instruments used in the application.

Specification. The pattern of entries in Nevo's Table I reveals the estimated specification. Write $b_i^p = -\alpha_i$ for the price coefficient, which is what the table reports. Then

$$b_i^p = b^p + \pi_{p,1} Income_i + \pi_{p,2} IncomeSq_i + \pi_{p,3} Child_i + \sigma_p \nu_{ip},$$
$$\beta_i^k = \beta^k + \pi_{k,1} Income_i + \pi_{k,2} Age_i + \sigma_k \nu_{ik}, \qquad k \in \{\text{Constant}, \text{Sugar}, \text{Mushy}\}.$$

The nonlinear parameters are four standard deviations and nine demographic interactions, so θ_2 has 13 elements. The means of the constant, Sugar and Mushy are absorbed by the brand dummies and recovered by the minimum-distance step (8.65) with 24 brand effects.

Table 8.19: Results from the full model, synthetic cereal data (Nevo 2000a, Table I)

	Means	Std. dev.	Interactions with demographic variables			
Variable	β	σ	Income	IncomeSq	Age	Child
Price	−32.433	1.848	16.598	−0.659		11.625
	(7.743)	(1.075)	(172.334)	(8.955)		(5.207)
Constant	−1.841[a]	0.377	3.089		1.186	
	(0.258)	(0.129)	(1.213)		(1.016)	
Sugar	0.148[a]	0.004	−0.193		0.029	
	(0.258)	(0.012)	(0.005)		(0.036)	
Mushy	0.788[a]	0.081	1.468		−1.514	
	(0.013)	(0.205)	(0.697)		(1.103)	
GMM objective			14.9			
(Degrees of freedom)			(7)			

Notes: Source: Nevo (2000a), Table I (p. 539). Based on 2,256 observations. Except where noted, parameters are GMM estimates. All regressions include brand and time dummy variables. Asymptotically robust standard errors in parentheses. [a]Estimates from the minimum-distance procedure. Blank cells are interactions not included in the specification.

Results. Table 8.19 reproduces Nevo's Table I. The minimum-distance means say that the average consumer gains utility from more sugar (0.148) and from sogginess (0.788). The standard deviations capture unobserved heterogeneity. Nevo describes them as insignificant both economically and statistically, and he expects them to stay statistically insignificant even with more efficient estimation (footnote 26).[13]

[13]By the printed standard errors, the standard deviation on the constant (0.377, with standard error 0.129) has a t ratio near 2.9. The other three standard deviations are insignificant.

The demographic interactions have economically large point estimates, although most are imprecise. The valuation of sogginess falls with age (−1.514). Nevo says it also falls with income, while the printed income interaction is positive (1.468).[14] Figure 8.12(a) shows the implied distribution of the Mushy coefficient across consumers. Most consumers value sogginess positively, but about 31 percent prefer a crunchy cereal (p. 540). Sugar is valued less by richer consumers, and this interaction is very precisely estimated (−0.193, standard error 0.005).

The mean price coefficient is −32.433. Children are less price sensitive. Their price coefficient is higher by 11.625, which is 36 percent of the mean coefficient and 6.3 times the unobserved standard deviation $\sigma_p = 1.848$ (our calculation). Nevo also reports that above-average-income consumers are less price sensitive. The income terms are very imprecise, with a standard error of 172.334 on the linear term. Figure 8.12(b) shows the distribution of individual price coefficients. It is not normal, because it inherits the shape of the empirical distribution of demographics. Its mass lies between about −70 and −15, so no consumer has a positive price coefficient, although a linear specification allows one in principle (p. 540).

Demographics against unobserved tastes. The standard deviations are small relative to the demographic effects. Nevo computes the share of the variance of each estimated coefficient explained by demographics, and all these shares exceed 90 percent (p. 541). He reads this with care. It does not show that demographics explain all heterogeneity. It shows that the data reject the assumed normal distribution of unobserved tastes. Other work had found that purchase histories (Rossi et al., 1996) and second-choice data (Berry et al., 2004a) explain heterogeneity beyond demographics (footnote 27). A second explanation is the absence of choice-set variation across markets in these data, which BLP's data have. Such variation helps identify the variance of the random shocks (Section 8.12.3). Nevo notes that this explanation accounts for imprecision, but not for the low point estimates or for the significance of the demographic effects.

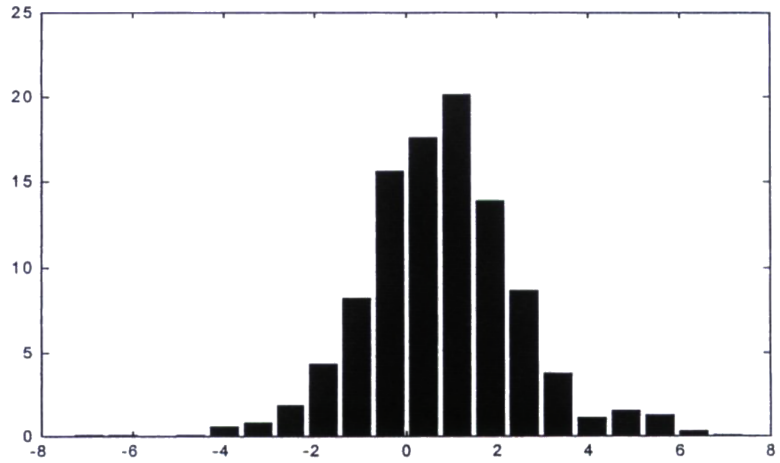
Specification tests. Nevo tests the logit against the full model by testing that all nonlinear parameters are jointly zero, and the hypothesis is easily rejected (footnote 28). The GMM objective is 14.9 with 7 degrees of freedom. If the objective is scaled as Hansen's J statistic, this value exceeds the 95th percentile of the $\chi^2(7)$ distribution, which is 14.07. The p-value is about 0.04 (our calculation), a marginal rejection of the overidentifying restrictions. Nevo does not discuss this statistic.

Elasticities. Table 8.20 reproduces Nevo's Table II. Its rows cover all 24 brands and the outside good, and its columns cover the prices of nine selected brands (1, 2, 3, 4, 5, 14, 15, 19 and 24). Each cell is the median over the 94 markets, and each brand row also lists the brand's sugar and mushy characteristics. Entry (i, j) is the percentage change in the share of row brand i for a one-percent change in the price of column brand j.

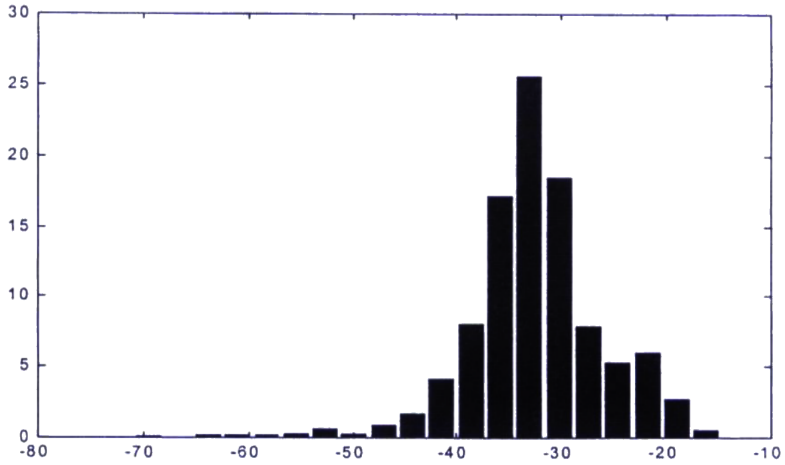
Reading Table II. Own elasticities among the printed columns range from −2.17 (brand 1) to −5.51 (brand 5). Cross elasticities within a column vary with characteristics, unlike the logit, which forces a constant column. Nevo summarizes this by the ratio of the largest to the smallest cross elasticity in a column, which he reports varies from 9 to 3 (p. 543).[15] A column with a

[14] The text on p. 540 states that "the marginal valuation of sogginess decreases with age and income." The income interaction in Table I is +1.468 with standard error 0.697. We report the table.

[15] Among the nine printed columns, the ratio ranges from 2.2 (brand 4) to 6.8 (brand 15) by our calculation. Nevo's range presumably covers all 24 columns, most of which are not printed.



(a) Taste for sogginess (Mushy coefficient)



(b) Price coefficient

Figure 8.12: Frequency distributions (in percent) of two individual coefficients implied by the estimates in Table 8.19. Panel (a) has mass below zero for consumers who prefer crunchy cereal. Panel (b) is skewed because the empirical distribution of demographics drives it. Source: Nevo (2000a), Figures 1 and 2.

Notes: Source: Nevo (2000a), Table II (p. 542). Entry (i, j) is the percentage change in the market share of row brand i for a one-percent change in the price of column brand j. Each entry is the median over the 94 markets. Only nine of the 24 columns are printed in the source.

ratio near one shows that the characteristics are too weak to break the logit pattern for that brand. Nevo suggests the diagnostic can guide which characteristics to add.

Brands with the same characteristics have nearly identical rows. Nevo points to brands 14 and 15, which both have Sugar 13 and Mushy 0. The table contains five more such groups: brands 3 and 12, 4 and 18, 5 and 23, 7 and 13, and 6, 9 and 21. The following result explains the pattern.

Proposition 8.43 (Products with identical heterogeneous utility)**.** *Suppose products j and j' have $\mu_{ij} = \mu_{ij'}$ for every consumer i. Then for every inside product $k \notin \{j, j'\}$, the elasticities of j and j' with respect to p_k are equal. Moreover, the diversion from k to j and to j' is in proportion to their shares, $\frac{D_{kj}}{D_{kj'}} = \frac{s_j}{s_{j'}}$.*

Proof. From (8.18), $\frac{s_{ij}}{s_{ij'}} = e^{\delta_j - \delta_{j'}} \equiv c$ for every i. Integrating gives $s_j = c\, s_{j'}$, so $\frac{s_{ij}}{s_j} = \frac{s_{ij'}}{s_{j'}}$ for every i. The cross elasticity with respect to p_k is

$$\varepsilon_{jk} = \frac{p_k}{s_j} \int \alpha_i s_{ij} s_{ik} \, \mathrm{d}F = p_k \int \alpha_i \frac{s_{ij}}{s_j} \, s_{ik} \, \mathrm{d}F,$$

and the last expression is the same for j and j'. For the diversion ratios, the common denominator $\left|\frac{\partial s_k}{\partial p_k}\right|$ cancels, so

$$\frac{D_{kj}}{D_{kj'}} = \frac{\int \alpha_i s_{ij} s_{ik} \, \mathrm{d}F}{\int \alpha_i s_{ij'} s_{ik} \, \mathrm{d}F} = c = \frac{s_j}{s_{j'}}.$$

□

In the application price carries a random coefficient, so μ_{ij} includes the price term. Two brands with the same Sugar and Mushy but different prices have slightly different μ. Their rows are therefore close but not identical, as in brands 14 and 15 (0.0834 against 0.0889 in column 1, 0.2697 against 0.2491 in column 5). The second part of the proposition shows that the random coefficients model keeps the IIA property among products that differ only in ξ. This is the clone problem of Section 8.9.

The outside-good row varies a lot, from 0.0303 for brand 1 to 0.3896 for brand 19. It rises with the brand's sugar content. Across the nine printed columns, its correlation with Sugar is 0.90 (our calculation). Table I suggests why. Richer consumers value inside goods more (the Constant-Income interaction is 3.089) and value sugar less (the Sugar-Income interaction is −0.193). Buyers of sugary brands are therefore poorer on average, closer to the margin of buying nothing, and they move to the outside good when prices rise.

8.12.5 Lessons, extensions and assessment

Lessons from the application. Nevo stresses economic significance over statistical significance, because most coefficients are imprecise. He attributes the imprecision to the simplifications made for teaching. More data, more simulation draws than $n_s = 20$, better simulation methods or a supply side would improve efficiency (p. 540). The application shows four things a user of the method should expect. Demographic interactions can carry most of the heterogeneity. Distributions of individual coefficients inherit the shape of the demographic distribution. Elasticity matrices depart clearly from the logit pattern but only as far as the characteristics allow. Without choice-set variation the standard deviations are hard to pin down.

Extensions. Nevo's Section 5 lists five directions.

- *Supply side.* In the guide the supply side only motivates the instruments. Specifying it adds moment conditions with little extra programming for standard static models (Section 8.7). It raises efficiency at the cost of more structure.
- *Consumer-level data.* With individual choices, models are usually estimated by maximum likelihood or simulated moments, as in Goldberg (1995), Rossi et al. (1996) and McFadden and Train (2000). The mean utilities can be estimated from the micro data and then treated like inverted mean utilities, with standard errors that account for their estimation. Endogeneity can persist with micro data, because optimal choice from a menu can create it (Kennan, 1989) and common unobserved characteristics remain. Combining micro and aggregate data adds moments, as in Petrin (2002) and Berry et al. (2004a) (Sections 8.8, 8.14 and 8.15).
- *Alternative methods.* Multi-level demand systems use separability to model a category, its segments and the brands within each segment, each with a flexible form such as the almost ideal demand system (Deaton and Muellbauer, 1980a; Hausman et al., 1994). They become impractical when segments contain more than a handful of brands (Chapter 5).
- *Dynamics.* The static demand model can feed dynamic models of firm behavior (Pakes and McGuire, 1994), and dynamic models could endogenize characteristics and supply new identifying conditions. Demand-side dynamics are better studied with consumer-level data (Erdem and Keane, 1996).
- *Instruments.* Nevo closes with a warning. Identification rests on adequate exogenous instruments, and researchers should not let the technical fireworks distract from this basic and difficult problem (p. 546).

Limitations and critiques. The application cannot answer any substantive question, because its data are synthetic. Its small number of draws makes simulation error a real concern (Section 8.3). The absence of choice-set variation weakens identification of Σ, as Nevo notes. The guide's code and data became a standard test case for later computational work. Dubé et al. (2012, Section 6.2) used the cereal data to show how a loose inner-loop tolerance distorts estimates. They also note that a loose outer-loop tolerance left the guide's reported estimates short of a local optimum. Knittel and Metaxoglou (2014, p. 39) adapted the guide's code to study how estimates on these data vary with optimizers and starting values. Conlon and Gortmaker (2020, Section 6) distribute the data with their software and replicate the guide's model on them. They find that tight optimization tolerances remove this dispersion (Section 8.9).

Contribution. The guide made the method usable. It translated BLP's estimator into explicit steps, explained the role of each assumption, and gave rules for market size, instruments and brand effects. The posted data and code let a generation of researchers reproduce every number before applying the method to their own markets. Its notation, with θ_1, θ_2, Π and Σ, is the notation of this chapter. Its most durable advice is that heterogeneity should be modeled with outside information wherever possible and that instruments deserve more attention than computation. Section 8.13 turns to Nevo's own application of the method to market power in ready-to-eat cereal.

8.13 Case study: Nevo (2001), market power in ready-to-eat cereal

Nevo (2001) applies the random coefficients logit model to a question the model was built to answer. Are the high price-cost margins of the ready-to-eat cereal industry the result of

Table 8.21: Identification and counterfactual map of the application in Nevo (2000a)

Observed data	Synthetic prices and shares of 24 cereal brands in 94 city-quarter markets, 2,256 observations generated from the model itself. The characteristics Sugar and Mushy, and CPS draws of income, age and a child dummy.
Latent objects	Market-specific deviations of unobserved quality, consumer tastes ν_i, and the brand effects that absorb mean quality.
Estimated parameters	Thirteen nonlinear parameters (four standard deviations and nine demographic interactions), brand and time effects, and three taste means recovered by minimum distance.
Identifying variation	Price variation across markets net of brand and time effects, with instruments that the application does not describe. Cross-market differences in the distribution of demographics identify the interactions.
Maintained assumptions	The data were generated by the estimated demand model and multiproduct Bertrand pricing, so the specification is correct by construction.
Counterfactual and what it holds fixed	None. The output is the matrix of median own- and cross-price elasticities at observed prices.
Conclusion	Demographics explain over 90 percent of the variance of each estimated taste coefficient, and cross elasticities vary with characteristics, unlike the logit. Nevo reads the high share as evidence against the assumed normal distribution of unobserved tastes.
One limitation	The choice set is the same in every market, so the standard deviations of the random coefficients are imprecise.
Source and our additions	Tables I and II and Figures 1 and 2 are Nevo's. The p-value of the GMM objective, the cross-elasticity ratios of the printed columns and Proposition 8.43 are ours.
Tools in the appendices	Sections A.5 and A.7.

collusion? The paper estimates brand-level demand for 25 cereals from city-level scanner data. It then computes the margins that the estimated demand implies under three models of conduct and compares them with accounting margins. The resulting decomposition of margins into a differentiation effect, a portfolio effect and a collusion effect is the paper's main methodological contribution. We follow the paper from its question to its contribution and reproduce all of its main tables. Table 8.30 at the end of the section maps the study. Page numbers refer to the journal article.[16]

8.13.1 The question

Ready-to-eat (RTE) cereal combines high concentration, high price-cost margins, heavy advertising and frequent introductions of new brands. These features made it a standard example of an oligopoly that avoids price competition and channels rivalry into advertising and new products. Nevo (p. 307, n. 2) quotes the verdict of Scherer (1982, p. 189). In Scherer's words, "the cereal industry's conduct fits well the model of price competition-avoiding, non-price competition-prone oligopoly." The inference ran from high margins to soft price competition. Nevo asks whether the inference survives once demand is measured with care.

The difficulty is that a high margin has three possible sources. The first is product differentiation. A brand with loyal consumers faces inelastic demand and earns a margin even when its owner sets its price alone. The second is the *portfolio effect*. A firm that owns several brands internalizes the substitution among them and prices each brand higher than separate owners would. The third is *price collusion*, the joint setting of prices across firms. Accounting data reveal at best the sum of the three. Nevo separates them by asking what margin each conduct model implies, given the estimated demand, and which model reproduces the observed margin. No cost data enter the computation of the predicted margins.

The answer is that multi-product Nash-Bertrand pricing at the current ownership structure matches the observed margins. Joint profit maximization over the 25 brands predicts margins far above them. Nevo concludes that prices are consistent with noncollusive conduct despite margins above 45% (p. 308). The margins come from the firms' portfolios of differentiated brands and from perceived quality built by advertising.

8.13.2 The industry

The industry began at the Battle Creek sanatorium of John Harvey Kellogg, who introduced ready-to-eat cereal as a health food. Entrants soon followed. They included Charles William Post, a former patient of Kellogg, and Quaker Oats, a company with origins in hot oatmeal. A Minneapolis milling company, later called General Mills, and the National Biscuit Company, now Nabisco, also entered (pp. 309–310). By the late 1940s the industry was one of the most concentrated in the United States. In 1997 the U.S. market consumed about three billion pounds of cereal, roughly $9 billion in sales (p. 310).

Table 8.22 reproduces the volume shares of the six main manufacturers from 1988 to 1992. The top three firms (Kellogg, General Mills, Post) held between 71.5% and 75.2% of pounds sold, and the top six held between 87.5% and 95.3%. Kellogg's share fell from 41.4% to 33.7% while General Mills rose from 22.0% to 26.8%. Private labels doubled their share, from 3.3% to

[16] Nevo writes the market-specific deviation of unobserved quality as $\Delta\xi_{jt}$ and the econometric error as ω_{jt}. We write $\tilde{\xi}_{jt}$ for both, because Δ is the matrix of share derivatives in this book (Section 8.1) and ω is the cost unobservable in Section 8.7. Nevo writes firm profits as Π_f and the GMM weighting matrix as A^{-1}. We write π_f and W, because Π is the matrix of demographic interactions.

7.6%. The leaders have also been very profitable. Nevo cites a ranking of Kellogg third among 1,285 U.S. nonfinancial corporations by profitability (p. 310, n. 6). The leaders earned after-tax returns on cereal assets of 19.8% over 1958–1970, and profits averaged about 17% of sales in the 1980s and early 1990s.

Table 8.22: Volume market shares of RTE cereal manufacturers, 1988–1992 (percent)

	88Q1	88Q4	89Q4	90Q4	91Q4	92Q4
Kellogg	41.39	39.91	38.49	37.86	37.48	33.70
General Mills	22.04	22.30	23.60	23.82	25.33	26.83
Post	11.80	10.30	9.45	10.96	11.37	11.31
Quaker Oats	9.93	9.00	8.29	7.66	7.00	7.40
Ralston	4.86	6.37	7.65	6.60	5.45	5.18
Nabisco	5.32	6.01	4.46	3.75	2.95	3.11
C3	75.23	72.51	71.54	72.64	74.18	71.84
C6	95.34	93.89	91.94	90.65	89.58	87.53
Private label	3.33	3.75	4.63	6.29	7.13	7.60

Notes: Shares of pounds sold. C3 and C6 are the combined shares of the three and six largest firms. Source: Nevo (2001), Table I, from the IRI Infoscan data base of the Food Marketing Policy Center, University of Connecticut.

Two features of the industry shape the analysis. The first is the number of brands. There were more than 200 brands, with national shares ranging from 5% (Kellogg's Corn Flakes, General Mills' Cheerios) to 1% for the 25th brand and below 0.1% for the 100th (p. 311). Only 80 new brands appeared between 1950 and 1972, while the top six producers introduced 67 major brands in the 1980s alone. Brand proliferation was the core of the Federal Trade Commission's "shared monopoly" complaint against Kellogg, General Mills and Post in the 1970s, whose economic argument Schmalensee (1978) laid out. The second feature is advertising. The advertising-to-sales ratio was about 13%, against 2–4% in other food industries, and about 18% for the established brands that Nevo studies (p. 311).

Production is less simple than it looks. There are five basic methods (granulation, flaking, shredding, puffing and extrusion), and extrusion in particular requires experience. A typical plant produces $400 million of output a year, employs 800 workers and costs $300 million to build (p. 311). Several brands are produced in one plant to exploit economies of scale in packaging.

Table 8.23 reproduces Nevo's two cost tables. Panel A uses the Annual Survey of Manufactures. The gross margin of price over average variable cost (materials, labor and energy) is 64.4% of the value of shipments for RTE cereal, against 26.5% for all food industries. Panel B reports accounting estimates of marginal cost per pound from a 1994 investment-bank report on Kellogg, as presented in testimony by Cotterill (1996). The manufacturer's gross margin is 57.5% of the manufacturer's price. It is about seven points below the Census figure, which Nevo attributes to the difference between marginal and average cost (p. 312). The last column expresses each item as a share of the retail price. The manufacturer's price is 80% of the retail price, so the retail margin is 20%, and the gross margin is $0.575 \times 0.80 = 46.0\%$ of the retail price. This 46.0% is the observed margin against which the conduct models are tested in Section 8.13.11.

Table 8.23: Production costs and margins in RTE cereal

Panel A. Aggregate estimates, Annual Survey of Manufactures, 1988–1992

	RTE cereal (SIC 2043)		All food (SIC 20)	
Item	M$	% of value	M$	% of value
Value of shipments	8,211	100.0	371,246	100.0
Materials	2,179	26.5	235,306	63.4
Labor	677	8.2	32,840	8.8
Energy	76	0.9	4,882	1.3
Gross margin		64.4		26.5

Panel B. Detailed estimates per pound

Item	$ per lb	% of mfr. price	% of retail price
Manufacturer price	2.40	100.0	80.0
Manufacturing cost	1.02	42.5	34.0
Grain	0.16	6.7	5.3
Other ingredients	0.20	8.3	6.7
Packaging	0.28	11.7	9.3
Labor	0.15	6.3	5.0
Manufacturing costs (net of capital costs)	0.23	9.6	7.6
Gross margin		57.5	46.0
Marketing expenses	0.90	37.5	30.0
Advertising	0.31	13.0	10.3
Consumer promotion (manufacturer coupons)	0.35	14.5	11.7
Trade promotion (retail in-store)	0.24	10.0	8.0
Operating profits	0.48	20.0	16.0

Notes: Panel A computes the gross margin as value of shipments minus materials, labor and energy, a price-average variable cost margin relative to the manufacturer's price. In Panel B capital costs were computed from Annual Survey of Manufactures data. The source is Cotterill (1996), who reports estimates from a CS First Boston report on the Kellogg Company (October 1994). Source: Nevo (2001), Tables II and III.

8.13.3 Supply: three models of conduct

The supply side is the multi-product Bertrand-Nash model of Section 8.7, applied market by market. There are F firms, and firm f produces the subset $\mathcal{J}_f$ of the J brands. Its profit in a market of size M is $\pi_f = \sum_{j \in \mathcal{J}_f} (p_j - mc_j) M s_j(p) - C_f$, with C_f the fixed cost. Nevo assumes that a pure-strategy Bertrand-Nash equilibrium exists with strictly positive prices. The first-order conditions are (8.69) (p. 313), and stacking them as in (8.70) gives

$$p - mc = -\left[(\Omega \odot \Delta)^\top\right]^{-1} s(p), \tag{8.123}$$

where Ω is the ownership matrix and Δ the matrix of share derivatives. This is Nevo's equation (1).[17] Given estimated demand, the right side is known at the observed prices and shares. The equation therefore delivers the markup of every brand, and with it the implied marginal cost $mc = p + [(\Omega \odot \Delta)^\top]^{-1} s$, without any cost data.

The key step is to evaluate Equation (8.123) under ownership matrices other than the true one. Nevo uses three.

1. *Single-product firms*, $\Omega = I_J$. Each brand is priced by an agent who considers only its own profit. The implied margins reflect product differentiation alone.
2. *Current ownership*, $\Omega = \Omega^{\text{co}}$, the actual ownership of the 25 brands by Kellogg, General Mills, Post, Quaker and Nabisco. The implied margins add the portfolio effect.
3. *Joint ownership*, $\Omega = \iota\iota^\top$ with ι a vector of ones. One agent prices all 25 brands, which corresponds to monopoly or perfect price collusion among them.

The margin under single-product pricing measures differentiation. The difference between the current-ownership and single-product margins measures the portfolio effect. The difference between the joint-ownership and current-ownership margins bounds the increase that collusion could produce (p. 313). Each row answers a counterfactual question about costs. If firms behaved according to conduct model k, what marginal costs would rationalize the observed prices? Each set of implied costs yields implied margins $L_j^k = \frac{p_j - mc_j^k}{p_j}$, and the test compares them with observed margins.

A rearrangement of the first-order condition shows what drives the differences between the three rows. Divide (8.69) by $-\frac{\partial s_j}{\partial p_j} > 0$ and use the diversion ratio $D_{jr} = -\left(\frac{\partial s_r}{\partial p_j}\right)\left(\frac{\partial s_j}{\partial p_j}\right)^{-1}$ of Proposition 8.5:

$$p_j - mc_j = \frac{s_j}{-\frac{\partial s_j}{\partial p_j}} + \sum_{r \in \mathcal{J}_f, r \neq j} D_{jr}\,(p_r - mc_r). \tag{8.124}$$

Dividing by p_j gives the multi-product Lerner decomposition of Proposition 8.42. The first term is the single-product markup. The second adds the markups of co-owned products, weighted by the fraction of j's lost sales that each of them captures. Enlarging the set of jointly priced products adds terms to the sum. The following proposition makes the ordering precise for any demand system with substitutes.

Proposition 8.44 (Ownership and implied markups)**.** *Fix prices and shares, and suppose that* $\frac{\partial s_j}{\partial p_j} < 0$, $\frac{\partial s_r}{\partial p_j} \geq 0$ *for* $r \neq j$, *and* $\sum_{r \neq j} D_{jr} < 1$ *for every* j, *where the sum runs over inside goods. For*

[17] Nevo defines $S_{jr} = -\frac{\partial s_r}{\partial p_j}$ and the matrix with elements $\Omega^*_{jr} S_{jr}$, which equals $-(\Omega \odot \Delta)^\top$. His equation (1), $p - mc = \Omega^{-1} s(p)$ in his notation, is therefore identical to Equation (8.123).

any ownership matrix Ω, the first-order conditions have a unique solution $m^{\Omega} = p - mc$. It satisfies $m_j^{\Omega} \geq s_j\big(-\frac{\partial s_j}{\partial p_j}\big)^{-1} > 0$ for every j. If $\Omega' \geq \Omega$ element by element, then $m^{\Omega'} \geq m^{\Omega}$ element by element.

Proof. Let $b_j = s_j\big(-\frac{\partial s_j}{\partial p_j}\big)^{-1} > 0$ and let $\mathbf{D}$ be the $J \times J$ matrix with zero diagonal and off-diagonal elements $D_{jr} \geq 0$. By Equation (8.124), the first-order conditions are

$$m = b + (\Omega \odot \mathbf{D})\, m.$$

Each row sum of $\Omega \odot \mathbf{D}$ is at most $\sum_{r \neq j} D_{jr} < 1$. Hence the sup-norm of $\Omega \odot \mathbf{D}$ is below one, its spectral radius is below one, and $I - \Omega \odot \mathbf{D}$ is invertible with

$$(I - \Omega \odot \mathbf{D})^{-1} = \sum_{n=0}^{\infty} (\Omega \odot \mathbf{D})^n.$$

Every term of the series is a nonnegative matrix, so $m^{\Omega} = \sum_{n \geq 0} (\Omega \odot \mathbf{D})^n b \geq b$, which proves the first two claims. If $\Omega' \geq \Omega$, then $\Omega' \odot \mathbf{D} \geq \Omega \odot \mathbf{D} \geq 0$ element by element. Products of nonnegative matrices are monotone in their factors, so $(\Omega' \odot \mathbf{D})^n \geq (\Omega \odot \mathbf{D})^n$ for every n, and summing gives $m^{\Omega'} \geq m^{\Omega}$. □

The condition $\sum_{r \neq j} D_{jr} < 1$ says that some of j's lost sales go to the outside good. It holds in every logit-type model with an outside option. The proposition implies that the three rows of Nevo's table are ordered for every brand. It also shows that the size of the portfolio and collusion effects depends on the diversion ratios among the jointly priced brands. The logit model restricts those ratios severely. In the logit, $D_{jr} = \frac{s_r}{1 - s_j}$, and Proposition 8.37 shows that if the products in a set $\mathcal{G}$ are priced jointly, every $j \in \mathcal{G}$ has the markup

$$p_j - mc_j = \frac{1}{\alpha\,(1 - S_{\mathcal{G}})}, \qquad S_{\mathcal{G}} = \sum_{r \in \mathcal{G}} s_r. \tag{8.125}$$

This formula explains why the logit cannot detect collusion in this market. Nevo defines the potential market as one serving per person per day, so the outside good has a large share and the 25 brands have a small combined share. By (8.125), the ratio of the joint-ownership to the single-product markup of brand j is $\frac{1 - s_j}{1 - S_{\mathcal{G}}}$, which is close to one when $S_{\mathcal{G}}$ is small. The logit spreads the sales that a brand loses over all brands in proportion to their shares, and most of them go to the outside good. Nevo anticipates this point when he writes that, under the logit, substitution to the inside goods "will on average be downward biased" because the outside share is large (p. 316).

8.13.4 Demand

A market t is a city-quarter. Consumer i in market t obtains from brand j the indirect utility (Nevo's equation (2), p. 314)

$$u_{ijt} = x_j \beta_i - \alpha_i p_{jt} + \xi_j + \tilde{\xi}_{jt} + \epsilon_{ijt}, \qquad i = 1, \ldots, I_t, \quad j = 1, \ldots, J_t, \quad t = 1, \ldots, T. \tag{8.126}$$

Here x_j is a K-dimensional row vector of observed characteristics, which do not vary across markets. The term ξ_j is the national mean valuation of unobserved characteristics, $\tilde{\xi}_{jt}$ is its city-quarter deviation and ϵ_{ijt} is a type-I extreme value shock. The unobserved characteristics

include a vertical component (at equal prices every consumer weakly prefers a national brand to its generic copy) and local merchandising other than national advertising. Firms and consumers observe all of them.

Tastes follow (8.6) with $\nu_i \sim N(0, I_{K+1})$ (Nevo's equation (3)). The demographics D_i are drawn from the empirical distribution in the consumer's city, and Σ is diagonal in the application. The specification combines observed demographics with a parametric distribution for the rest of the heterogeneity, and so relaxes the normality assumption on the distribution of tastes. The outside good gives $u_{i0t} = \xi_0 + \pi_0 D_i + \sigma_0 \nu_{i0} + \epsilon_{i0t}$. Its mean ξ_0 is normalized to zero. The terms π_0 and σ_0 cannot be separated from a demographic-varying intercept in (8.126), so they are set to zero (p. 315), as in Section 8.1.4.

Substituting the taste model into (8.126) exactly as in Section 8.1.2 gives $u_{ijt} = \delta_{jt} + \mu_{ijt} + \epsilon_{ijt}$, with

$$\delta_{jt} = x_j \beta - \alpha p_{jt} + \xi_j + \tilde{\xi}_{jt}, \qquad \mu_{ijt} = \tilde{x}_{jt}(\Pi D_i + \Sigma \nu_i), \tag{8.127}$$

Nevo's equation (4). Mean utility δ_{jt} collects the linear parameters $\theta_1 = (\alpha, \beta)$. The deviation μ_{ijt} depends on the nonlinear parameters $\theta_2 = (\Pi, \Sigma)$. Consumers buy one unit of the brand that gives the highest utility. Nevo defends the single-unit assumption by noting that most people eat one brand at a time even when households buy several (p. 315, n. 13). The market share is the integral (8.19) of the logit probabilities (8.18) over the distribution of (D_i, ν_i) (Nevo's equation (5)). By Proposition 8.4, the price elasticities, written with Nevo's sign convention, are

$$\eta_{jkt} = \frac{\partial s_{jt}}{\partial p_{kt}} \frac{p_{kt}}{s_{jt}} = \begin{cases} -\dfrac{p_{jt}}{s_{jt}} \displaystyle\int \alpha_i \, s_{ijt}(1 - s_{ijt}) \, \mathrm{d}P^*(D, \nu) & \text{if } j = k, \\ \dfrac{p_{kt}}{s_{jt}} \displaystyle\int \alpha_i \, s_{ijt} \, s_{ikt} \, \mathrm{d}P^*(D, \nu) & \text{otherwise,} \end{cases} \tag{8.128}$$

where s_{ijt} is the logit probability (8.18).

Nevo explains why the logit is inadequate for his purpose (p. 316). Its cross elasticities depend only on shares. Suppose that Quaker's Cap'n Crunch (a children's cereal) and Post's Grape Nuts (a simple-nutrition cereal) have similar shares. A rise in the price of General Mills' Lucky Charms (a children's cereal) then diverts equally to both. Intuition says it should divert more to the other children's cereal. Nested logit and the principles-of-differentiation GEV model of Bresnahan et al. (1997) relax this, but only through an a priori segmentation. The random coefficients model lets the composite error $\mu_{ijt} + \epsilon_{ijt}$ correlate with characteristics, so substitution follows characteristics. It also lets own elasticities reflect the price sensitivity of each brand's buyers. McFadden and Train (2000) show that such mixed logit models can approximate any random utility model arbitrarily well.

8.13.5 Data

Quantities and prices come from the IRI Infoscan data base held by the Food Marketing Policy Center at the University of Connecticut. IRI collects weekly scanner data from a random sample of supermarkets with annual sales above $2 million, which account for 82% of U.S. grocery sales (p. 337). The data are aggregated to the brand, city and quarter. They cover up to 65 cities, with the number rising over time, from 1988Q1 to 1992Q4. The sample consists of the 25 brands with the highest national shares in 1992Q4. Every brand except Post Honey Bunches of Oats appears in all 1,124 city-quarters. Honey Bunches of Oats enters in 1989Q1 (p. 317). The estimation sample has 27,862 brand-city-quarter observations. The 25 brands account for 43% to 62% of cereal volume in each city-quarter and for 55% to 60% nationally.

The variables are constructed as follows (Appendix A, pp. 337–338). Volume is converted to servings using the manufacturer's serving weight. The *potential market* is one serving per person per day. The share of brand j is servings sold divided by potential servings, and the outside share is one minus the sum of the inside shares. Price is dollar sales divided by servings, deflated by a regional urban consumer price index. It is therefore an average real transaction price per serving at the register, which does not net out manufacturers' coupons. Advertising is total national expenditure by brand and quarter across ten media, from the Leading National Advertisers data base. Characteristics were collected from cereal boxes. They are calories from fat, sugar, fiber, a dummy for cereal that gets soggy in milk (*mushy*), and segment dummies for all-family, kids, adults (taste-enhanced wholesome) and simple-health brands. Demographics are 40 draws per city and year from the March Current Population Survey (CPS). Income is household income divided by household size, and *Child* indicates age below 16.

Table 8.24 reproduces the summary statistics. The mean price is 19.4 cents per serving. Brand dummies account for 88.4% of the variance of prices and city dummies for a further 5.3%. Nevo concludes that, after controlling for brands, most price variation is across cities (p. 317). This cross-city variation, part exogenous and part correlated with demand shocks, is what identifies the price coefficient.

Table 8.24: Summary statistics for Nevo's cereal data

Panel A. Prices and market shares of the 25 brands

						Share of variance due to		
Variable	Mean	Median	Std	Min	Max	Brand	City	Quarter
Price (cents per serving)	19.4	18.9	4.8	7.6	40.9	88.4%	5.3%	1.6%
Advertising (M$ per quarter)	3.56	3.04	2.03	0	9.95	66.2%	n.a.	1.8%
Share within cereal market (%)	2.2	1.6	1.6	0.1	11.6	82.3%	0.5%	0%

Panel B. Characteristics and demographics

Variable	Mean	Median	Std	Min	Max
Calories	137.6	120	36.32	110	220
Fat calories (÷100)	0.124	0.100	0.139	0	0.60
Sodium (% RDA ÷100)	0.087	0.090	0.042	0	0.150
Fiber (% RDA ÷100)	0.095	0.050	0.094	0	0.310
Sugar (g ÷100)	0.084	0.070	0.060	0	0.200
Mushy (1 if soggy in milk)	0.35	n.a.	n.a.	0	1
Serving weight (g)	35.1	30	9.81	25	58
Income ($, per person)	13,083	10,475	11,182	14	275,372
Age (years)	29.99	28	23.14	1	90
Child (1 if age < 16)	0.23	n.a.	n.a.	0	1

Notes: Panel A covers 27,862 brand-city-quarter observations. The last three columns give the share of the variance explained by brand, city and quarter dummies. Advertising does not vary across cities, and the paper prints a dash for its city share. Panel B: characteristics from cereal boxes, demographics from CPS draws. Sources: Nevo (2001), Table IV (Panel A) and Table A(II) (Panel B).

8.13.6 Estimation

Nevo follows the BLP algorithm of Section 8.5 with three differences (p. 318). The instruments differ, and so does the identifying assumption behind them. Demand is identified without a functional form for supply, whereas BLP's identification uses their supply equation. Brand fixed effects control for unobserved product quality.

The estimator is the GMM estimator (8.56) based on the population moment $\mathbb{E}[Z^\top \tilde{\xi}(\theta^*)] = 0$, where Z stacks the instruments and θ^* is the true parameter (Nevo's equation (6)). The structural error is computed in two steps. First, for given θ_2, the share system (8.49) is inverted in each market (Nevo's equation (7)), with $S_{\cdot t}$ denoting the observed shares. The logit solution is $\delta_{jt} = \ln S_{jt} - \ln S_{0t}$. The random coefficients solution is computed by the contraction of Section 8.4. Second, the recovered mean utilities are regressed on the linear part of the model. With brand and quarter dummies, the estimating equation is

$$\delta_{jt}(S_{\cdot t}; \theta_2) = d_j + \tau_{q(t)} + \gamma\, a_{jt} - \alpha\, p_{jt} + \tilde{\xi}_{jt}, \tag{8.129}$$

where $d_j = x_j\beta + \xi_j$ is the brand effect, $\tau_{q(t)}$ is a quarter effect and a_{jt} is advertising. The error is the city-quarter deviation $\tilde{\xi}_{jt}$, because the brand effect absorbs both $x_j\beta$ and ξ_j. In the logit, Equation (8.129) with $\delta_{jt} = \ln S_{jt} - \ln S_{0t}$ is a linear regression. With $W = (Z^\top Z)^{-1}$, the GMM estimator is two-stage least squares (p. 319, n. 15).

The weighting matrix is computed in two steps (p. 319). The first step sets $W = (Z^\top Z)^{-1}$ and yields $\theta^{(1)}$. The second step uses the heteroskedasticity-robust matrix W_2 of Section 8.5.6, evaluated at the residuals $\tilde{\xi}_{jt}(\theta^{(1)})$. Further iterations changed the estimates only slightly. The nonlinear search is simplified in two ways. The first-order conditions are linear in θ_1, so θ_1 is concentrated out as in Proposition 8.20, and the search runs over θ_2 alone. The search uses a quasi-Newton method with an analytic gradient, which Nevo found much faster than the Nelder-Mead simplex used by BLP. Shares are simulated with the 40 CPS draws per city and year (200 per city over the five years) and independent normal draws of ν_i (p. 326, n. 25).

Standard errors use the usual GMM formulas (Hansen, 1982) with a correction for simulation error. The correction exploits the fact that the same simulation draws are used for all brands in a market (p. 319). Confidence intervals for nonlinear functions of the parameters, such as elasticities and margins, come from a parametric bootstrap. Nevo draws repeatedly from the estimated asymptotic distribution of the parameters and recomputes the function at each draw. Table VIII uses 1,500 draws.

8.13.7 Instruments and identification

Equation (8.123) shows why prices are endogenous. Prices equal marginal cost plus a markup, and the markup depends on the demand shocks. Nevo decomposes the price into a brand mean and a city-quarter deviation (his equation (8), p. 320):

$$p_{jt} = mc_{jt} + f(\tilde{\xi}_{jt}, \dots) = \left(\overline{mc}_j + \bar{f}_j\right) + \left(\widetilde{mc}_{jt} + \tilde{f}_{jt}\right). \tag{8.130}$$

Brand dummies absorb the first bracket. The error in Equation (8.129) is $\tilde{\xi}_{jt}$, and firms observe it when they set prices, so the markup deviation $\tilde{f}_{jt}$ is correlated with it. Unless the cost deviation $\widetilde{mc}_{jt}$ exactly cancels this correlation, prices are correlated with $\tilde{\xi}_{jt}$ and least squares, linear or nonlinear, is inconsistent. If the cost deviation $\widetilde{mc}_{jt}$ does not offset the markup response, prices covary positively with $\tilde{\xi}_{jt}$ and the estimate of α is biased toward zero (Section 8.6.1). The results confirm this direction.

Why characteristic-based instruments fail here. The usual instruments of Section 8.6 are functions of the characteristics of rival products. They assume that product locations are exogenous or predetermined, and they work because a brand's markup depends on the distance to its neighbors. Nevo points to a more basic problem in his data (p. 320). Each brand's characteristics are constant across cities and quarters, and the choice set is the same everywhere. Functions

of characteristics therefore vary only with the choice set, which barely varies. With brand dummies in the regression the instrument matrix is nearly singular. It is not exactly singular only because Honey Bunches of Oats is missing from some quarters (n. 17). The brand dummies themselves can serve as instruments when they are left out of the regression. This is a nonparametric way of using all the information in fixed characteristics, and column (iv) of Table 8.25 reports it.

Prices in other cities. The main instruments follow Hausman (1997). Write a market as $t = (c, q)$, city c in quarter q, and let $R(c)$ be the census region of city c. The instrument for brand j in city c averages the price of j over the other cities of the region,

$$z^H_{jcq'} = \frac{1}{|R(c)| - 1} \sum_{c' \in R(c),\, c' \neq c} p_{jc'q'},$$

and Nevo uses it for all 20 quarters q' (p. 321).[18] Two assumptions justify the instrument. The first is the identifying assumption itself. After brand effects, time effects and demographics, the city-specific valuations $\tilde{\xi}_{jcq}$ are independent across cities, though they may be correlated within a city. The second is a cost structure with a common regional component. Suppose that

$$mc_{jcq} = \bar{c}_j + \lambda_{jR(c)q} + e_{jcq},$$

with cost shocks independent of the demand shocks. By Equation (8.130), the price of j in another city c' is $p_{jc'q'} = mc_{jc'q'} + f_{jc'q'}$. Its markup depends on the demand shocks of city c', which are independent of $\tilde{\xi}_{jcq}$ by the first assumption. Its cost is independent of $\tilde{\xi}_{jcq}$ by the second. Hence $\mathrm{Cov}(z^H_{jcq'}, \tilde{\xi}_{jcq}) = 0$, which is the exclusion restriction. For $q' = q$, the prices p_{jcq} and $p_{jc'q}$ share the regional cost shock $\lambda_{jR(c)q}$, so the instrument is relevant. Distribution costs (transportation, shelf space and labor) are the plausible source of such common regional cost variation.

The independence assumption can fail in two ways (p. 321). A national or regional demand shock correlates valuations across cities. Nevo's example is the discovery that fiber reduces the risk of cancer, which would raise the valuation of every fiber-rich brand everywhere. He replies that the sample consists of established brands, which are less exposed to systematic shocks, and that time dummies absorb aggregate shocks to cereal. The second failure is local advertising or promotion coordinated across cities within a region. Nevo replies that IRI cities are mostly larger than metropolitan areas and census regions are large. Firms also plan their strategies on IRI's city-level geography.

Cost proxies. Because the plausibility of these assumptions is an empirical matter, Nevo also uses direct proxies for city-level marginal cost (pp. 321–322). Production and packaging costs vary little and are captured by the brand dummies. Distribution costs are proxied by region dummies (transportation), city density (the cost of space) and average earnings in the supermarket sector from the CPS Monthly Earnings Files (labor). A persistent regional taste difference beyond demographics, such as a western preference for natural cereals, would invalidate the region dummies. If both instrument sets give similar estimates, neither failure is likely to be large.

Identification of the nonlinear parameters. The price instruments identify α. The parameters in Π are identified mainly by cross-city variation in the distribution of demographics. Cities with

[18] Nevo notes that the results are essentially the same if only the regional average for the same quarter is used (p. 325, n. 21). He makes no claim that the instruments are optimal (n. 18).

more children or higher incomes should show different shares and different responses to price, in the directions that Π predicts. The standard deviations in Σ would be identified by changes in the choice set, but Nevo's choice set is almost fixed. He notes that this can explain their large standard errors, though not their small point estimates (p. 330, n. 27). Section 8.6 discusses this identification argument in general.

8.13.8 Brand fixed effects and the minimum-distance step

Brand dummies are Nevo's main departure from earlier work (pp. 322–323). They improve the fit of mean utility, while substitution patterns are still driven by characteristics through μ_{ijt}. They also remove the correlation between price and the national unobserved quality ξ_j, the main motivation of Berry (1994), without any instrument. Two objections arise. Brand dummies add parameters, but their number grows with J and not J^2, so the discrete-choice reduction of dimensionality survives. They are linear parameters, so they add no computational burden.

The price of brand dummies is that β is no longer estimated directly. Nevo recovers it by the minimum-distance procedure of Chamberlain (1982), the generalized least squares regression (8.65) of the estimated brand effects on the fixed characteristics derived in Section 8.6.5. Here the "observations" are the 25 brands. The restricted model, which sets $\xi_b = 0$, is tested by Chamberlain's statistic with $J - K$ degrees of freedom. The assumption $\mathbb{E}[\xi_b \mid \boldsymbol{X}_b] = 0$ is the one that justifies characteristic-based instruments. Here it serves only to recover the taste means and does not affect the price coefficient (p. 322, n. 19).

8.13.9 Results from the logit model

The logit is inadequate for measuring market power, but it is cheap and shows how much instruments matter. Table 8.25 reproduces Nevo's Table V. Every column regresses $\ln S_{jt} - \ln S_{0t}$ on price, advertising and quarter dummies.

OLS. Column (i) includes characteristics but no brand dummies, so its error contains ξ_j. The price coefficient is -4.96. Adding brand dummies in columns (ii) and (iii) raises it to -7.26 and -7.97, a large and significant change. The direction of the change indicates that, in these data, brands with high unobserved quality are both popular and expensive, which biases the column (i) coefficient toward zero. Even column (iii) implies a mean own elasticity of only -1.53 (median -1.50, standard deviation 0.39). Its implied demand is inelastic for 5.5% of observations (p. 323), which no profit-maximizing firm would choose. The coefficients on characteristics in column (i) are not reported in the table.[19]

Instrumental variables. Column (iv) uses brand dummies as instruments without brand dummies in the regression, which mimics characteristic-based identification. Its price coefficient, -8.17, nearly doubles that of column (i) but almost equals the OLS coefficient with brand dummies. Column (v) instruments with regional prices. The coefficient rises to -17.57, and every brand-city-quarter demand becomes elastic. The mean own elasticity is -3.38 (median -3.30, standard deviation 0.85, p. 325). Column (vi) uses the cost proxies instead and gives a similar -17.12. The two instrument sets rest on different assumptions and still agree.

Adding city-level demographics raises the price coefficient to between -22.56 and -23.77 in columns (vii) to (ix). Nevo reads this through the threat discussed above. If city valuations

[19] With standard errors in parentheses, they are constant -4.44 (0.04), fat calories 0.17 (0.04), sugar 2.7 (0.09), mushy -0.12 (0.011) and fiber 0.04 (0.06). The segment dummies are 0.53 (0.02) for all-family, 0.47 (0.02) for kids and 0.53 (0.02) for health (p. 323, n. 20).

Table 8.25: Logit demand for RTE cereal

	OLS			IV (2SLS)						
Variable	(i)	(ii)	(iii)	(iv)	(v)	(vi)	(vii)	(viii)	(ix)	(x)

Instruments				brand dummies	prices	cost	prices	cost	prices, cost	prices, cost
Brand dummies	no	yes	yes	no	yes	yes	yes	yes	yes	yes
City dummies	no	no	no	no	no	no	no	no	no	yes

Notes: Dependent variable $\ln S_{jt} - \ln S_{0t}$, 27,862 observations. All regressions include quarter dummies. Columns (i) and (iv) include the product characteristics (calories from fat, sugar, fiber, mushy and segment dummies). Asymptotically robust standard errors in parentheses. The fit row reports the adjusted R^2 for OLS and an overidentification test statistic for IV, with the 5% rejection threshold in parentheses. The thresholds are the 0.95 quantiles of χ^2 with 16, 19, 9 and 29 degrees of freedom. "Prices" are average regional prices of the brand in other cities, and "cost" are the cost proxies. Source: Nevo (2001), Table V.

depend on demographics that are correlated within regions, omitting demographics makes both instrument sets invalid. Adding them removes that omitted-variable bias and improves the overidentification statistic, from 168.5 to 83.96 for the price instruments. The value of cereal rises with income, while age and household size are insignificant. Column (x) adds city fixed effects and leaves the price coefficient at −23.07. With city effects, identification comes from variation over time within cities, so the results are not driven by cross-sectional differences alone (n. 22).

The overidentification test rejects in every IV column except (x). Nevo notes that with 27,862 observations a χ^2 test rejects almost any model (pp. 325–326). He also notes that the coefficients do not change from (ix) to (x), where city effects make the test pass. He concludes that the instruments are valid once demographics are controlled for in a rich enough way, which the full model does. The first-stage R^2 exceeds 0.88 and the first-stage F statistics range from 124 to 5,119, so the instruments are not weak in the usual sense.

Nevo's Table B(I) reports the first stages behind columns (v) to (x) (p. 339). Each includes the exogenous regressors of its column and region dummies. Both cost proxies enter with the expected positive sign and are precisely estimated. City density has coefficients of 0.152 (standard error 0.017) in column (vi), 0.146 (0.018) in (viii), 0.305 (0.019) in (ix) and 0.209 (0.010) in (x). Supermarket wages have coefficients of 0.172 (0.023), 0.196 (0.023), 0.182 (0.023) and 0.046 (0.018) in the same columns. The regional prices enter with one coefficient for each of the 20 quarters. These coefficients take both signs, from −0.477 to 0.536, and most are several standard errors from zero. With 20 such instruments, the F statistics measure their joint strength better than any single coefficient does.

Advertising is significant. Its coefficient falls from 0.158 to about 0.02 once brand dummies

are included, because popular brands with high ξ_j also advertise more. The implied mean advertising elasticity is about 0.06. Nevo calls this low, an order of magnitude below what a Dorfman-Steiner condition requires (p. 326).

The Dorfman-Steiner condition is the advertising analogue of the Lerner rule (Dorfman and Steiner, 1954). Consider a single-product firm with demand $q(p, A)$, where A is advertising expenditure, constant marginal cost c and profit $(p - c)\, q(p, A) - A$. The first-order condition for advertising is $(p - c)\frac{\partial q}{\partial A} = 1$. Multiplying both sides by $\frac{A}{pq}$ gives

$$\frac{A}{pq} = \frac{p - c}{p}\, \varepsilon_A, \qquad \varepsilon_A = \frac{\partial q}{\partial A}\, \frac{A}{q}.$$

The advertising-to-sales ratio equals the Lerner index times the advertising elasticity ε_A. Nevo does not report the inputs behind his comparison. Take advertising-to-sales ratios of 13% to 18% (p. 311), which we read as shares of manufacturer sales. On the same basis the margin bounds of Section 8.13.11 are about 39% (the 31% retail-price gap divided by 0.80) and 64.4%. The condition then requires ε_A between about 0.20 and 0.46, three to eight times the estimate (our calculation). The benchmark is static and treats each brand alone. Advertising that also raises demand in later quarters or for the firm's other brands changes the identity.

Nevo attributes the gap to measurement error in the advertising data (p. 326). He does not instrument for advertising. It varies by brand and quarter but not by city, and its coefficient does not move when price is instrumented, which suggests little feedback onto the price coefficient (n. 24).

8.13.10 Results from the random coefficients model

Table 8.26 reproduces Table VI, the preferred specification. The instruments are the regional prices for all quarters together with the cost proxies. Characteristics interact with four demographics: income, income squared, age and the child dummy. Income is household income per person (Table 8.24). The paper does not report how income and its square are transformed, scaled or centered in estimation, so the interaction coefficients cannot be converted into dollar terms. Brand and quarter dummies enter mean utility. The taste means for characteristics come from the minimum-distance step (8.65), while the price and advertising coefficients and all of θ_2 are GMM estimates. The model has 19 nonlinear parameters, nine standard deviations and ten demographic interactions.

Taste means. All minimum-distance estimates are significant and have the expected signs (p. 327). The minimum-distance statistic of 3472.3 rejects the restricted model in which characteristics explain the brand effects exactly. This is unsurprising, since the brand dummies are estimated very precisely from 27,862 observations.

Heterogeneity. The standard deviations are insignificant except for the kids segment (2.031, standard error 0.448), while most demographic interactions are significant (p. 328).[20] Sogginess is valued more by older and by richer consumers, whose Mushy interactions are 0.809 for age and 1.265 for income. Figure 8.13a shows the implied distribution of the Mushy coefficient. Most consumers dislike sogginess, but about 15% prefer a mushy cereal (p. 328). The interactions with price are significant. Nevo reads the income terms as making above-average-income

[20] Later in the text (p. 330), Nevo writes that "all the estimates of the standard deviations are statistically insignificant." Table VI and his own statement on p. 328 make an exception for the kids segment. We follow the table.

Table 8.26: The random coefficients model of cereal demand

	Means	Std. deviations	Interactions with demographic variables			
Variable	(β's)	(σ's)	Income	Income sq.	Age	Child
Price	−27.198	2.453	315.894	−18.200		7.634
	(5.248)	(2.978)	(110.385)	(5.914)		(2.238)
Advertising	0.020					
	(0.005)					
Constant	−3.592[b]	0.330	5.482		0.204

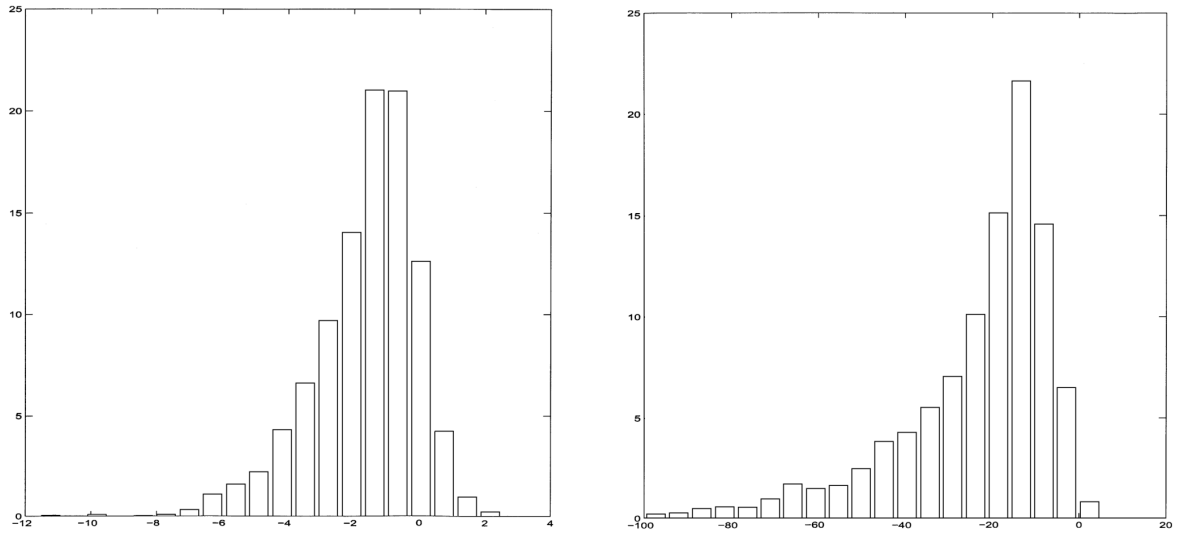
	(0.128)	(2.809)				
Sugar	5.742[b]	1.661	−24.931		5.105	
	(0.581)	(5.866)	(9.167)		(3.418)	
Mushy	−0.565[b]	0.244	1.265		0.809	
	(0.052)	(0.623)	(0.737)		(0.385)	
Fiber	1.627[b]	0.195				−0.110
	(0.263)	(3.541)				(0.0513)
All-family	0.781[b]	0.1330				
	(0.075)	(1.365)				
Kids	1.021[b]	2.031				
	(0.168)	(0.448)				
Adults	1.972[b]	0.247				
	(0.186)	(1.636)				
GMM objective (degrees of freedom)	5.05 (8)					
Minimum-distance χ^2	3472.3					
Percent of price coefficients > 0	0.7					

Notes: 27,862 observations. Parameters are GMM estimates except where marked [b], which are minimum-distance estimates from (8.65). All specifications include brand and quarter dummies. Asymptotically robust standard errors in parentheses. The price row gives coefficients on price in utility. Consumer i's price coefficient is $-27.198 + 2.453\,\nu_{ip} + 315.894\,\text{Inc}_i - 18.200\,\text{IncSq}_i + 7.634\,\text{Child}_i$, where Inc_i and IncSq_i are the income and income-squared variables as entered in estimation. The paper reports neither their units nor whether they are logged or centered, or whether IncSq_i squares a centered variable. Inserting the mean income of \$13,083 per person from Table 8.24 would give a coefficient of about −3.1 billion, so the formula holds only in these unreported units. The label "Means" on the first column suggests demographics with mean zero, which the paper does not state. The simulated cereal data of Nevo (2000a) use the log of income and its square. Source: Nevo (2001), Table VI.

consumers less price sensitive.[21] The standard deviation of the price coefficient, 2.453, is insignificant.

Figure 8.13b shows the distribution of individual price coefficients. It is far from normal, because it inherits the shape of the empirical distribution of demographics. Its tail could in principle cross zero, which would mean that utility rises with price. Only 0.7% of the simulated coefficients are positive. Specifications without the demographic interactions, reported in Nevo's dissertation, produce as many as 13% positive coefficients (p. 329). The flexible demographic terms are what keep the distribution on the right side of zero.



(a) Taste for sogginess (Mushy coefficient)

(b) Price coefficient

Figure 8.13: Frequency distributions of two individual coefficients implied by the estimates in Table 8.26. The horizontal axes give the value of the coefficient. The vertical axes, unlabeled in the original, give frequencies. The bars sum to about 100, so the heights are percentages of simulated consumers. Panel (a) puts about 15% of consumers at a positive taste for sogginess. Panel (b) is skewed to the left because it inherits the empirical distribution of demographics, and only 0.7% of its mass lies above zero. Source: Nevo (2001), Figures 1 and 2.

The insignificance of the standard deviations says that the included demographics explain most of the heterogeneity. The share of the variance of each coefficient explained by demographics exceeds 90% (p. 330). Appendix B of the paper re-estimates the model with the random shocks ν_i set to zero for the characteristics that have demographic interactions. The estimates and margins barely change (Table 8.29, column (i)). Nevo cautions against a stronger reading (p. 330, n. 26). The result says that the data reject the assumed normal distribution for the unobserved part of tastes. It does not say that information beyond demographics is useless. Purchase histories (Rossi et al., 1996) and second-choice data (the working-paper version of Berry et al., 2004a, Section 8.14) do reveal heterogeneity beyond demographics.

Elasticities. Table 8.27 reproduces Table VII. Because elasticities vary across markets, each entry is the median over the 1,124 markets of the elasticity of the row brand's share with respect to the column brand's price. The own elasticities on the diagonal run from −2.277 (Cap'n Crunch) to −4.252 (Shredded Wheat). They are not ordered by price as the logit would require.

[21] The text (p. 329) also says that older consumers are less price sensitive. Table VI has no interaction between price and age. The age-related price term is the interaction with Child, +7.634, which makes the price coefficient of

Table 8.27: Median own- and cross-price elasticities of cereal demand

#	Brand	Corn Flakes	Frosted Flakes	Rice Krispies	Froot Loops	Cheerios	Total	Lucky Charms	P Raisin Bran	CapN Crunch	Shredded Wheat

Notes: Entry (i, j) is the percent change in the share of row brand i for a one percent change in the price of column brand j, as in Equation (8.128). Each entry is the median over the 1,124 city-quarter markets. Own elasticities are negative numbers here, as in the paper. K, GM, P, Q and N denote Kellogg, General Mills, Post, Quaker and Nabisco. Source: Nevo (2001), Table VII.

The substitution patterns follow characteristics. Lucky Charms, a children's cereal, is most sensitive to the prices of other children's cereals (p. 330). It is least sensitive to the prices of Corn Flakes, Total and Wheaties, which serve different segments.[22] The logit forces every cross elasticity in a column to be equal. A summary of how far the estimates depart from that restriction is the ratio of the largest to the smallest cross elasticity in a column, which equals one in the logit. The ratio ranges from 21 for Corn Flakes to 3.5 for Shredded Wheat, with 95% confidence intervals of 11 to 260 and 3 to 52 (p. 330). A low ratio also flags brands whose observed characteristics do not differentiate them well. A formal test that all nonlinear parameters are zero, which is a specification test of the logit, is easily rejected (p. 332, n. 28).

The last row gives the elasticity of the outside good's share with respect to each price. It is larger for Corn Flakes (0.141) than for Froot Loops (0.022), in absolute terms and relative to the average cross elasticity in each column (p. 332). Generic versions of Corn Flakes have larger shares than generic versions of Froot Loops, and all generics belong to the outside good. A rise in the price of Corn Flakes therefore sends more consumers to the outside option. Comparisons across columns should use semi-elasticities, because a one percent price change differs in cents across brands (n. 29).

8.13.11 Price-cost margins and the test of conduct

Predicted margins. Table 8.28 reproduces Table VIII and Figure 8.14 plots it. Each entry is the median over the 27,862 observations of the margin implied by Equation (8.123) under one ownership matrix. Medians are used to limit the influence of outliers, and means with the 5% tails trimmed are essentially identical (p. 332, n. 30). For the logit the computation is analytical, using (8.125). For the full model the confidence intervals come from 1,500 parametric bootstrap draws.

Table 8.28: Median predicted price-cost margins under alternative conduct

	Logit (Table 8.25, col. ix)	Full model (Table 8.26)
Single-product firms	33.6% (31.8%, 35.6%)	35.8% (24.4%, 46.4%)
Current ownership of 25 brands	35.8% (33.9%, 38.0%)	42.2% (29.1%, 55.8%)
Joint ownership of 25 brands	41.9% (39.7%, 44.4%)	72.6% (62.2%, 97.2%)
Current ownership of all brands	37.2% (35.2%, 39.4%)	n.a.
Monopoly or perfect price collusion	54.0% (51.1%, 57.3%)	n.a.

Notes: Margins are $\frac{p-mc}{p}$, medians of the distribution over 27,862 brand-city-quarter observations. 95% confidence intervals for the medians in parentheses, based on the asymptotic distribution of the demand estimates. They are analytical for the logit and use 1,500 draws for the full model. The last two rows require the shares of brands outside the sample, which suffice only for the logit. Source: Nevo (2001), Table VIII.

children less negative. We follow the table.

[22] Nevo names Corn Pops and Froot Loops as the brands to whose prices Lucky Charms is most sensitive. Corn Pops and Wheaties are not among the ten columns printed in Table VII, so these statements refer to the full matrix. Among the printed columns, row 14 is largest for Cap'n Crunch (0.147), Frosted Flakes (0.131) and Froot Loops (0.124), and smallest for Corn Flakes (0.019).

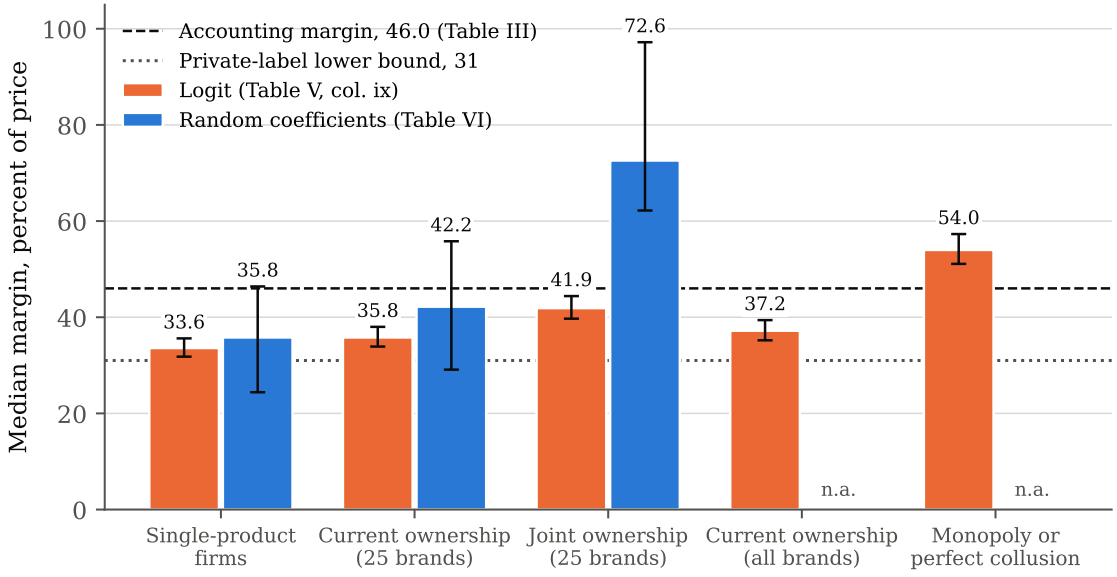

Figure 8.14: Median predicted margins under five conduct models, with 95% confidence intervals for the medians. The dashed line is the accounting gross margin of 46.0% of the retail price (Table 8.23). The dotted line is the lower bound of about 31% from the gap between national-brand and private-label prices (p. 333). The random coefficients model predicts a joint-ownership margin far above both lines, while its current-ownership interval covers them. The logit margins barely respond to ownership. Redrawn from Nevo (2001), Table VIII.

The logit price coefficient, -23.37, is close to the full model's price coefficient in the Means column, -27.198, yet their margins diverge as ownership widens. Under single-product pricing the medians are 33.6% and 35.8%. The portfolio effect adds 2.2 points in the logit and 6.4 points in the full model. Joint ownership of the 25 brands adds a further 6.1 points in the logit and 30.4 points in the full model. By Proposition 8.44, these increments are governed by the diversion ratios among co-owned brands. The full model concentrates diversion among similar cereals, so joint pricing internalizes much more substitution.

The logit increments match (8.125) closely. In the logit the ratio of the joint-ownership markup to the single-product markup of brand j is $\frac{1-s_j}{1-S_{\mathcal{G}}}$. A rough calculation with ratios of medians gives $\frac{41.9}{33.6} \approx 1.25$, which implies that the 25 brands hold about one fifth of the potential market. Similarly $\frac{54.0}{33.6} \approx 1.61$ implies that all brands together hold about 38%. The ratio of the two, about one half, is consistent with the 43% to 62% of cereal volume that the 25 brands account for.[23]

Observed margins. Testing requires a comparison with actual margins, which Nevo does not observe directly. He treats the retail margin as an additional cost to manufacturers, which is consistent with many models of manufacturer-retailer interaction (p. 333). The relevant observed margin is then the gross margin relative to the retail price, 46.0% from Table 8.23. This figure excludes promotional costs, some of which, such as coupon rebates, are arguably marginal. Excluding them makes the observed margin a generous one and the test conservative. Census data support the accounting figure. They are based on average variable cost and give

[23] These are our calculations. A ratio of medians is not the median of the ratios, and s_j is treated as negligible, so the implied shares are approximations.

an upper bound.[24] A lower bound comes from the gap between the prices of national brands and the corresponding private labels, about 31% according to Wongtrakool (1994). Private labels may carry a markup of their own and may have higher costs, so their price exceeds the national brands' marginal cost and the gap understates the margin (pp. 333–334). Nevo cautions that accounting margins are crude (Fisher and McGowan, 1983) and uses them only to discriminate between models.

The test. The predicted margins differ enough that even crude observed margins separate the models (p. 334). The joint-ownership interval for the full model, 62.2% to 97.2%, lies above both the typical margin of 46.0% and the lower bound of 31%. Joint profit maximization over the 25 brands is therefore rejected. The current-ownership interval, 29.1% to 55.8%, contains both figures, so multi-product Nash-Bertrand pricing is not rejected. The decomposition implied by the full model's medians attributes about 85% of the current-ownership margin to differentiation ($\frac{35.8}{42.2}$) and the remaining 6.4 points to the portfolio effect.

Two further arguments strengthen the conclusion. The first concerns the restriction to 25 brands (p. 334). The price coefficient should not be biased by the selection, and estimates on other samples confirm this. Brands outside the sample are probably more elastic, which would lower the single-product margins. Weighting by market shares, which is the likely effect of including small brands, offsets this. The share-weighted means are roughly 2 to 3 points above the medians in Table VIII. For the current-ownership and collusive models a second force operates. Moving products from the outside good into the inside set raises the predicted margins, and the effect grows with the number of jointly priced products. Adding brands would therefore move the Nash-Bertrand prediction closer to the observed margins and the collusive prediction further away. In this sense Table VIII is conservative.

The second argument concerns the logit. Applied to the logit column, the same test would not reject full collusion over all products (p. 335). The logit's collusive margins, 41.9% for the 25 brands and 54.0% for all brands, lie close to the observed margin of 46.0%. Nevo stresses that this result is driven entirely by the logit's restrictive substitution patterns and says nothing about conduct. It is the clearest demonstration in the paper of why flexible substitution patterns matter for questions of market power.

Why not a formal test. Nevo explains why he does not use two alternatives (pp. 334–335). One is to estimate a conduct parameter, as in homogeneous-goods industries (Bresnahan, 1989). Its interpretation is problematic (Corts, 1999), and its identification requirements are unlikely to be met with differentiated products (Nevo, 1998). The other is a non-nested test of fully specified models (Bresnahan, 1987; Gasmi et al., 1992). That requires the likelihood of each model, hence distributional assumptions on the errors and a complete supply equation, and there is no natural set of such assumptions. Chapter 3 and Section 8.7 discuss conduct testing more generally.

8.13.12 Robustness*

Appendix B of the paper reports four alternative specifications of the full model, reproduced in condensed form in Table 8.29. Column (i) drops the random shocks ν_i for the characteristics that interact with demographics. Its price coefficient (−25.595) and margins (36.1%, 41.9% and 67.4%) are close to the preferred ones, which supports the claim that demographics drive the heterogeneity. Columns (ii) and (iii) are nonlinear least squares without instruments,

[24] The Census margin of 64.4% is relative to the manufacturer's price. On the retail-price basis of Table 8.23, Panel B, it corresponds to $0.80 \times 64.4 \approx 51.5\%$. This conversion is ours.

without and with brand dummies. Their price coefficients are −4.291 and −7.407. The implied margins are absurd. They range from 67.6% to 84.5% under Nash-Bertrand pricing, and above 100% under collusion. Column (iv) uses brand dummies as instruments, the analogue of characteristic-based identification. Its estimates are imprecise and 22.4% of its price coefficients are positive. Nevo notes that it lacks the variance-reduction methods of BLP (p. 339).

Table 8.29: Alternative specifications of the full model

	(i) No ν_i on interacted chars.	(ii) NLLS, no brand dummies	(iii) NLLS, brand dummies	(iv) GMM, brand dummies as IVs
Mean price coefficient	−25.595	−4.291	−7.407	−9.856
	(2.673)	(0.143)	(0.164)	(3.039)
Price × income	311.101	34.565	8.552	21.575
	(61.797)	(1.455)	(0.974)	(96.912)
Percent of price coefficients > 0	0	16.1	0	22.4
Single-product margin	36.1%	67.6%	75.7%	48.2%
Multi-product margin	41.9%	75.6%	84.5%	54.0%
Collusive margin	67.4%	103.9%	117.6%	88.9%

Notes: Standard errors in parentheses. 27,862 observations. NLLS is nonlinear least squares, which does not instrument for price. Column (i) is the preferred specification without ν_i for the characteristics that have demographic interactions. The paper also reports all taste parameters, omitted here. The preferred specification gives 35.8%, 42.2% and 72.6% (Table 8.28). Source: Nevo (2001), Table B(II).

Other checks point the same way (pp. 327, 335–336). A specification with city fixed effects, the analogue of column (x) of Table 8.25, gives point estimates close to the preferred ones but very large standard errors. This is expected, since demographics barely change within a city over five years. A multi-stage budgeting demand system in the style of Hausman et al. (1994) and Hausman (1997), covered in Chapter 5, shows interesting differences in cross-price substitution but the same conclusions about conduct. Studies based on household data, a random coefficients model by Kiser (1996) and a nested logit by Shum (1999), use different data and different identifying assumptions. They produce very similar own- and cross-price elasticities.

8.13.13 Interpretation, limitations and contribution

Interpretation. If Nash-Bertrand pricing is the benchmark of noncollusive behavior, prices in RTE cereal are not collusive, even with margins above 45% (p. 336). High margins reflect consumers' willingness to pay for their favorite brands and firms' internalization of substitution within their portfolios. To the extent that the industry has market power, it lies in the ability to maintain a portfolio of differentiated brands and to shape perceived quality through advertising. Nevo relates this to the FTC case. The standard account of the complaint mentions cooperative pricing, but its core was brand proliferation as a barrier to entry (Schmalensee, 1978). In this sense the FTC focused on the dimensions of competition that Nevo finds important. His model, however, takes brands and advertising as given and cannot evaluate their competitive effects (p. 336).

Limitations. The test rules out only the extreme form of cooperation, joint maximization of profits over all 25 brands. Cooperation within a subset of products or firms, such as two raisin brans or two smaller producers, is not tested and would require more detailed cost data (p. 336).

The observed margin is a single accounting figure for a typical Kellogg brand, compared with medians over brands, cities and quarters. The Hausman instruments rest on independence of demand shocks across cities, which overidentification tests reject in the logit unless city effects are added. Advertising is treated as exogenous, and its implied elasticity is implausibly low. The model is static and uses quarterly averages of prices that include temporary promotions. The standard deviations of the random coefficients are imprecise because the choice set barely varies. The full model's margins have wide confidence intervals. The single-product interval runs from 24.4% to 46.4%. Finally, the definition of the potential market as one serving per person per day fixes the outside share, and with it the level of the implied markups (Section 8.1).

Contribution. The paper made four contributions that became standard. It combined brand fixed effects with the BLP estimator and recovered taste means by minimum distance, so that price endogeneity due to ξ_j needs no instrument. It used prices in other markets as instruments in a random coefficients model and checked them against cost proxies. It modeled heterogeneity with the empirical distribution of demographics. Above all, it turned the supply side into a tool for measuring conduct. Comparing margins implied by alternative ownership matrices with observed margins gives a transparent decomposition of market power. The same model and data underlie the merger simulations of Nevo (2000b), discussed in Chapter 11. Hausman's valuation of a new cereal brand, discussed in Chapter 10, depends on the same kind of assumption about price competition that Nevo tests. Later work uses the demand elasticities to discriminate between models of conduct in the same industry, including common-ownership pricing (Backus et al., 2021a).

Table 8.30: Identification and counterfactual map of Nevo (2001)

Observed data	IRI scanner prices and servings of 25 cereal brands in up to 65 cities, quarterly from 1988 to 1992 (27,862 brand-city-quarters). Brand characteristics, national advertising, CPS demographic draws, and accounting margins for a typical brand.
Latent objects	City-quarter quality deviations $\tilde{\xi}_{jt}$, consumer tastes ν_i, marginal costs and markups.
Estimated parameters	The price and advertising coefficients, brand and quarter effects, demographic interactions Π and standard deviations Σ. Taste means come from a minimum-distance step.
Identifying variation	Prices of the same brand in other cities of the region, checked against cost proxies. Brand effects absorb national quality, and cross-city differences in demographics identify Π.
Maintained assumptions	City demand shocks are independent across cities after brand, time and demographic controls, and costs share a regional component. Static pricing, exogenous advertising, and a potential market of one serving per person per day.
Counterfactual and what it holds fixed	Margins implied by (8.123) under single-product, current and joint ownership, at observed prices and shares. Demand is held at its estimates, and only the ownership matrix changes.
Conclusion	Current ownership predicts a median margin of 42.2 percent, whose interval contains the observed margins. Joint ownership of the 25 brands predicts 72.6 percent and is rejected. Margins come from differentiation and portfolios, given the Hausman instruments.
One limitation	Only joint profit maximization over all 25 brands is tested. Collusion within a subset of brands or firms is not.
Source and our additions	The tables are Nevo's. Proposition 8.44, the advertising benchmark and the logit share calculations behind the margin ratios are ours.
Tools in the appendices	Sections A.3, A.5 and A.9.

8.14 Case study: Berry, Levinsohn and Pakes (2004), micro and macro data

Berry et al. (2004a), henceforth BLP (2004), return to the automobile market with a new kind of data. A proprietary survey by General Motors covers a large sample of 1993 new-vehicle buyers. It records each buyer's demographics, the vehicle bought and the vehicle the buyer would have bought had the first choice been unavailable. The paper asks what such consumer-level data, and second choices in particular, add to the identification of substitution patterns. The answer has three parts. Second choices pin down the parameters that govern substitution. Unobserved heterogeneity in tastes is needed to match them, even with rich demographics. A single cross section still cannot determine the level of price elasticities. The general estimator was introduced in Section 8.8. Here we follow the paper in detail, and Table 8.39 at the end of the section maps it. Page numbers refer to the journal article.[25]

8.14.1 The question

We abbreviate Berry et al. (1995), the subject of Section 8.11, as BLP (1995). In that paper, substitution patterns are identified from changes across markets and years in the choice set and in the distribution of consumer attributes. The distribution of tastes, conditional on observed incomes, is assumed to be stable over time (pp. 69–70). Earlier discrete choice work, and Goldberg (1995) and Petrin (2002) in industrial organization, matched consumer attributes to choices. Such data identify substitution to the extent that observed attributes explain it. Section 8.15 discusses Goldberg's study.

Second-choice data offer a different source of identification (p. 70). They give a direct, data-based measure of substitution, so one can ask which models reproduce it. By requiring the parameters to match observed second choices, the econometrician gains identifying power that does not rely on exogenous changes in choice sets. The paper also stresses a limit. Second choices in a single cross section, with one price per vehicle, reveal the pattern of substitution but not the level of price elasticities. Outside information must fix the level. The paper closes with two out-of-sample predictions, the introduction of luxury sport utility vehicles and the closure of the Oldsmobile division of General Motors.

8.14.2 Data

The CAMIP survey. The consumer data come from a proprietary survey conducted for General Motors, here called CAMIP (pp. 79–80). It samples from the registrations of 1993 model-year vehicles of all manufacturers, not only GM. For each vehicle a given number of buyers is sampled, so the design is a random sample conditional on the vehicle purchased. A sample of this kind is called *choice-based*. The subsample used has 37,500 observations. The questionnaire asks about income, age of the household head, family size and place of residence, and each question is matched to a question in the CPS.

Table 8.31 compares CAMIP households with CPS households. CAMIP over-represents high incomes. Only 6.52% of CPS households earn $85,000 or more, against 25.13% of CAMIP households, and mean income is $72,270 in CAMIP against $34,170 in the CPS. New-vehicle

[25] BLP (2004) write observed household attributes as z_{ir}, the coefficients on their interactions with characteristics as β^o_{kr} ("observed") and the standard deviations of unobserved tastes as β^u_k ("unobserved"). We write D_{ir}, π_{kr} and σ_k, so that β^o and β^u correspond to the matrices Π and Σ of Section 8.1.

buyers are richer than the population. More surprisingly, CAMIP households are less urban (35% against 46%) and more rural (35% against 25%). Rural households buy a disproportionate number of vehicles, which helps explain the high share of trucks (p. 80).

Table 8.31: CPS and CAMIP household samples

Income range ($)	Percent in CPS	Percent in CAMIP	CPS group mean	CAMIP group mean
0–36,500	64.17	25.00	16.90	25.96
36,500–55,000	16.97	23.16	44.89	45.43
55,000–85,000	12.34	26.71	66.93	67.46
85,000 and above	6.52	25.13	114.25	148.19
All	100.00	100.00	34.17	72.27
Other demographics			CPS mean	CAMIP mean
Family size			2.36	2.65
Age of household head			46.80	46.18
Number of kids			0.66	0.58
Urban			0.46	0.35
Rural			0.25	0.35
Suburban			0.29	0.30

Notes: Group means of income in thousands of dollars. Source: Berry et al. (2004a), Table 1.

The choice set and product data. The vehicle list follows GM's sampling cells and has 203 vehicles: 147 cars, 25 sport utility vehicles (SUVs), 17 vans and 14 pickup trucks (p. 81). Early runs used 218 vehicles. The final runs aggregate 15 very expensive vehicles, with an average price of $74,000 and a combined share of 0.3% of vehicles sold, into one "super-luxury" model (n. 9). The survey records transaction prices. Characteristics are those of the modal vehicle in each cell, the most commonly purchased combination of options, and price is the average price of that modal vehicle. About 10.6 million vehicles were sold in 1993 at an average price of $18,500, for total sales of about $196 billion. The continuous characteristics are horsepower per weight (HP), number of passengers (Pass, a measure of size), city miles per gallon (MPG) and number of power accessories (Acc). They also include safety features (Safe, antilock brakes plus airbags) and the payload of light trucks. The dummies mark minivans, SUVs, pickups, full-size vans, sports cars and four- or all-wheel drive (Allw). The interactions PUPayl and SUVPayl multiply payload by the pickup and SUV dummies (Table 2).

Demographic patterns. Means of vehicle characteristics by demographic group reveal clear interactions (p. 81). Examples are kids with minivans, income with price, rural residence with pickups and four-wheel drive, and age with nearly everything. The authors used such tables to choose the interactions in utility. Table 8.32 condenses their Table 4. The mean price of the vehicle chosen rises from $16,600 in the lowest income group to $26,300 in the highest. Households with two or more children choose a minivan 18% of the time, against 3% for households without children. The mean of PUPayl, the pickup dummy times payload in thousands of pounds, is 0.31 among rural households, against 0.14 among urban and 0.10 among suburban households. Buyers over 50 choose vehicles that are more expensive and larger, with more accessories, and they rarely choose sports cars or SUVs (0.07 and 0.04).

Second choices. Table 8.33 reproduces the second-choice information for 17 representative vehicles. The 166 sampled buyers of the Ford Escort named the Ford Tempo most often (16 buyers), followed by the Ford Taurus. Together these two account for 18% of Escort buyers, who named 53 different second choices in all (p. 86). Second choices are more concentrated for

Table 8.32: Mean characteristics of the vehicles chosen by demographic group in the CAMIP data (condensed)

Group	Price	HP	Pass	Acc	Sport	MPG	Allw	Miniv	SUV	PUPayl
Age of household head										
30 or less	16.6	4.7	4.5	2.6	0.20	22.0	0.13	0.03	0.15	0.24
30–50	20.1	4.8	4.9	3.1	0.15	20.4	0.13	0.08	0.13	0.18

Suburban	21.7	5.0	4.9	3.4	0.15	20.3	0.10	0.06	0.10	0.10
Rural	19.2	4.7	4.9	3.0	0.11	20.2	0.12	0.06	0.11	0.31
Household income ($)										
37,000 or less	16.6	4.6	4.8	2.6	0.12	21.9	0.08	0.04	0.07	0.25
37,000–55,000	18.5	4.7	4.9	3.0	0.12	20.7	0.10	0.07	0.10	0.24
55,000–85,000	20.3	4.8	4.9	3.2	0.14	20.0	0.13	0.07	0.13	0.19
Over 85,000	26.3	5.2	4.9	3.7	0.14	19.1	0.11	0.05	0.12	0.08

Notes: Price in thousands of dollars. Sport, Allw, Miniv and SUV are shares of vehicles with the attribute. PUPayl is the pickup dummy times payload in thousands of pounds. The original table also reports safety features, the van dummy, SUV payload and rows by family size. Source: Berry et al. (2004a), Table 4 (p. 84).

light trucks and expensive cars. They are often made by the same company as the first choice, which supports pricing that maximizes the joint profits of each firm's products.

Second choices resemble first choices. Across households, the correlations between the characteristics of the first and the second choice are all positive and highly significant (p. 86). They are about 0.7 for price and the minivan dummy, about 0.6 for MPG, size and the other type dummies, and between 0.3 and 0.5 for the rest. The survey does not ask whether the household would have bought a vehicle at all. The data therefore say nothing directly about substitution to the outside good.

8.14.3 The model

Households i choose among vehicles $j = 1, \ldots, J$ and the outside option $j = 0$. Let k index observed characteristics, including price, and r index observed household attributes. Utility is linear in characteristics (BLP 2004, equations (1) and (2)):

$$u_{ij} = \sum_k x_{jk}\beta_{ik} + \xi_j + \epsilon_{ij}, \qquad \beta_{ik} = \bar{\beta}_k + \sum_r D_{ir}\pi_{kr} + \sigma_k \nu_{ik}. \tag{8.131}$$

The idiosyncratic shocks ϵ_{ij} are i.i.d. type-I extreme value, and the ν_{ik} are independent standard normals. Substituting the taste equation into utility gives (equations (3) and (4))

$$u_{ij} = \delta_j + \sum_{k,r} x_{jk} D_{ir} \pi_{kr} + \sum_k x_{jk}\nu_{ik}\sigma_k + \epsilon_{ij}, \qquad \delta_j = \sum_k x_{jk}\bar{\beta}_k + \xi_j. \tag{8.132}$$

The model has one unobserved product characteristic, valued equally by all households. The authors note that this simplifies computation but is not essential to their arguments (p. 71, n. 3).

Table 8.33: Examples of second choices in the CAMIP data

First choice	n_j	Modal second choice	Number choosing	Next second choice	(Modal + next) ÷ n_j	Different choices

Notes: n_j is the number of CAMIP buyers of the first-choice vehicle. The sixth column is the fraction of them whose second choice is either the modal or the next most common second choice. Source: Berry et al. (2004a), Table 5.

Price and income. Price receives special treatment (p. 87). The household-specific part of the price coefficient is $-e^{-W_i}$, where W_i is "effective wealth,"

$$W_i = \sum_r D_{ir}\pi_{wr} + \sigma_w \nu_{iw}. \tag{8.133}$$

The common part of the price coefficient, $\bar{\beta}_p$, sits in δ_j by Equation (8.132). Write $\bar{\alpha} = -\bar{\beta}_p$. Household i's price sensitivity is then

$$\alpha_i = \bar{\alpha} + e^{-W_i}. \tag{8.134}$$

Because $e^{-W_i} > 0$, no household with $\bar{\alpha} \geq 0$ prefers higher prices, which is the reason for the exponential form. The factor e^{-W_i} is lognormal given demographics. The attributes in W_i are a constant, family size and a spline in income. Preliminary runs allowed the slope of the spline to change at each quartile of the CAMIP income distribution, but only a change at the 75th percentile was needed. Higher income raises W_i and lowers price sensitivity.

The outside good. Little is known a priori about the value of not buying. Early runs let it depend linearly on all household attributes plus a normal disturbance. Only income, family size and sometimes the number of adults mattered (p. 87). The normal disturbance on the outside good plays the role of a random coefficient on the inside-good constant (Section 8.1).

What micro data identify. Equation (8.132) is a random coefficients discrete choice model with a separate constant δ_j for each product. Given parametric assumptions on (ν, ϵ), the micro data identify (δ, Π, Σ) without any assumption on the joint distribution of (ξ, x) (pp. 72–73). Some questions, such as ideal price indices, need only these parameters. Elasticities, however, also require the effect of price on δ_j, that is, $\bar{\beta}_p$. The equation $\delta_j = \sum_k x_{jk}\bar{\beta}_k + \xi_j$ has only J observations, and price is correlated with ξ_j. Identifying $\bar{\beta}$ therefore requires an assumption

on (ξ, x), the same identification problem as in BLP (1995). Micro data solve one part of the problem, the substitution parameters, and leave the other part untouched. Berry and Haile (2024), discussed in Section 8.8, generalize this division of labor nonparametrically.

Aggregate demand integrates over the distribution P_w of household attributes $w_i = (D_i, \nu_i, \epsilon_i)$ (equation (5)):

$$s_j(\delta, \Pi, \Sigma; x, P_w) = \int_{A_j(\delta,\Pi,\Sigma;x)} P_w(\mathrm{d}w), \qquad A_j = \Big\{ w : \max_{r=0,\dots,J} u_{ir}(w) = u_{ij} \Big\}.$$

Conditional on (D_i, ν_i), the logit form gives the choice probability (equation (6))

$$\mathbb{P}(j_i^{(1)} = j \mid D_i, \nu_i, \theta) = \frac{\exp\left(\delta_j + \sum_{k,r} x_{jk} D_{ir} \pi_{kr} + \sum_k x_{jk} \nu_{ik} \sigma_k\right)}{1 + \sum_q \exp\left(\delta_q + \sum_{k,r} x_{qk} D_{ir} \pi_{kr} + \sum_k x_{qk} \nu_{ik} \sigma_k\right)}, \tag{8.135}$$

where $\theta = (\delta, \Pi, \Sigma)$ and $j_i^{(1)}$ denotes household i's first choice.

8.14.4 The estimator

Maximum likelihood is efficient but was too burdensome, so the authors use a method of moments estimator (p. 74). It matches three sets of moments (p. 75).

1. *First-choice moments.* Covariances between the characteristics of the vehicle bought and the attributes of the household, for example family size and vehicle size. They identify Π. The means of household attributes among buyers identify the parameters of the outside good, because CAMIP samples vehicles roughly in proportion to their shares.
2. *Second-choice moments.* Covariances between the characteristics of the first and the second choice, one for each characteristic with a random coefficient. They identify Σ. If $\Sigma = 0$, the observed attributes alone determine both choices and hence their correlation. A predicted correlation far below the observed one signals that unobserved tastes matter.
3. *Market shares* of the J products, which identify δ.

A footnote makes the role of interactions precise (p. 75, n. 5). If $\Pi = 0$ and only first choices were used, aggregate shares would be sufficient statistics for the first-choice data. Matching individuals to their vehicles would then add no information.

Concentrating out the product constants. With over 200 vehicles, δ has over 200 elements and the full parameter vector about 250 (p. 77). The authors exploit the precision of the aggregate shares. The observed share vector s^N, computed from N households (over 100 million), is multinomial around the true $s(\delta_0, \beta_0)$ with variance of order N^{-1}. An efficient estimator therefore sets predicted shares equal to observed shares. Let $\theta_2 = (\Pi, \Sigma)$, which BLP (2004) call β. For each trial value of θ_2, the contraction of Section 8.4 finds the $\delta^{n_s,N}(\theta_2)$ that solves the simulated share equations (8.93) (their equation (7)). The pairs (D_r, ν_r) combine a CPS draw of demographics with a draw of ν. They are drawn once and held fixed, as Pakes and Pollard (1989) require. Importance sampling as in BLP (1995) reduces simulation variance (p. 77, n. 6). The micro moments are then evaluated at $(\theta_2, \delta^{n_s,N}(\theta_2))$, and the search runs over θ_2 alone.

First-choice moments and Bayes' rule. Because the sample is choice-based, the model's prediction to be matched is the expected attribute of a household that chose a given vehicle. Let n_j be the number of sampled buyers of j and $n = \sum_j n_j$. The first-choice moments (8.94) (their equation (8)) compare the sample mean attribute of j's buyers with its model counterpart, one moment

for each interaction in utility. The model counterpart is the Bayes formula (8.91) (their equation (9)). By construction of $\delta^{n_s,N}(\theta_2)$, its denominator equals s_j^N, and its numerator is simulated with the same draws as the shares, as in (8.92) (their equation (10)). The approach follows the literature on choice-based sampling (Manski and Lerman, 1977; Imbens and Lancaster, 1994). The same structure underlies the micro moments of Petrin (2002) in Chapter 10.

Second-choice probabilities. The second-choice moments require the probability that a household whose first choice is j names q as its second choice. The survey asks for a second vehicle, so both j and the outside good leave the choice set. By Lemma 8.39, conditional on (D_i, ν_i) the probability is again a logit with j and the outside good removed from the denominator (p. 79). It equals $\mathbb{P}(j_i^{(2)} = q \mid j_i^{(1)} = j, D_i, \nu_i, \theta_2) = \frac{\exp(V_{iq})}{\sum_{l \neq 0, j} \exp(V_{il})}$, where V_{il} is the deterministic utility in (8.135). The individual second choice satisfies IIA, but the aggregate one does not, because the integral over (D, ν) weights each household by its probability of having chosen j first, as in (8.96). Buyers of j have tastes favorable to j's characteristics and pick second choices with similar characteristics. The second-choice moment for characteristic k starts from the average x_k of the second choices named by j's buyers. It subtracts the model's prediction, interacts the difference with x_{kj} and averages over j with weights $\frac{n_j}{n}$ (their equations (11) and (12)). The prediction is

$$\mathbb{E}\Big[\sum_{q \neq j} x_{qk} \, \mathbf{1}\{j^{(2)} = q\} \,\Big|\, j^{(1)} = j, \theta_2 \Big] = \frac{\int\int \sum_{q \neq j} x_{qk} \mathbb{P}(q \mid j, D, \nu, \theta_2) \, \mathbb{P}(j \mid D, \nu, \theta_2) \, P(\mathrm{d}D, \mathrm{d}\nu)}{s_j^N},$$

where the posterior weighting mirrors (8.91). It is simulated with the same draws.

GMM and inference. The moments G^1 and G^2 are stacked, and θ_2 is estimated by two-step GMM (Hansen, 1982). The estimator is consistent if $n_s \to \infty$ and $N \to \infty$ as $n \to \infty$ (p. 79). Since N is much larger than n and n_s, the authors use the limit distribution with $\frac{N}{n} \to \infty$ and $\frac{n_s}{n}$ converging to a positive constant. The asymptotic variance then includes simulation error. The variance of the moments is the sum of a sampling part (from the CAMIP means) and a simulation part (from the draws), since the two errors are independent (Appendix, p. 103). The simulation part is estimated by recomputing the moments, including a new solution of (8.93), for many independent sets of draws. The derivative of the moments has two terms, a direct effect of θ_2 and an effect through $\delta(\theta_2)$. Typically somewhat less than half of the variance of the estimates comes from simulation (p. 90, n. 15).

8.14.5 Estimates of the interaction parameters

Table 8.34 reproduces Table 6, the estimates of Π, and Table 8.35 reproduces Table 7, the estimates of Σ. Each table compares the full model with restricted models. Two are logits with $\Sigma = 0$ but with product constants and observed interactions, estimated from first choices only and from first and second choices. The third sets $\Pi = 0$, like BLP (1995), and appears only in Table 7 (p. 87).

Observed interactions. All three price interactions are sharply estimated and have the expected signs (p. 90). Income raises effective wealth, with a steeper slope above the 75th percentile (0.714 and 1.17), and larger families have lower effective wealth (−0.565). Almost all other interactions also have the expected sign and are precise in all three specifications. Examples are minivans with kids (1.973), passengers with adults and with age, safety with age, and pickup payload with rural residence. The full model has one apparent anomaly, a positive

Table 8.34: Estimates of the interactions with observed household attributes (Π)

			Logit ($\Sigma = 0$)	
Characteristic	Household attribute	Full model	First choice	First and second
Price (W_i)	Constant	−2.18 (.142)	.092 (.0001)	.139 (.0003)
	Income, below 75th percentile	.714 (.044)	.299 (.002)	.344 (.001)
	Income, above 75th percentile	1.17 (.083)	.466 (.091)	.603 (.007)
	Family size	−.565 (.010)	−.144 (.001)	−.143 (.006)
Minivan	Kids (age ≤ 16)	1.973 (.242)	.765 (.098)	.771 (.323)
Pass	Adults (age > 16)	.203 (.095)	.018 (.0004)	−.067 (.009)
	Family size	.536 (.052)	−.055 (.003)	−.006 (.0002)
	Age of head	.019 (.003)	.002 (.00001)	.005 (.00001)
HP	Age	−.002 (.001)	−.010 (.0004)	−.012 (.0001)
Acc	Age	.0004 (.001)	.001 (.00001)	−.002 (.0001)
	Age^2	.0001 (.00001)	.000 (.00001)	.000 (.00001)
PUPayl	Age	.0174 (.002)	−.003 (.0001)	.000 (.00001)
	Rural	1.075 (.179)	.512 (.005)	.376 (.008)
Safe	Age	.013 (.0006)	.015 (.001)	.016 (.0004)
SUV	Age	−.219 (.010)	−.043 (.003)	−.043 (.004)
	Rural	.332 (.156)	.403 (.007)	−.016 (.002)
Allw	Rural	.278 (.247)	.142 (.005)	.734 (.246)
Outside good	Total income	5.151 (.228)	−.228 (.096)	−.305 (.063)
	Family size	−.007 (.002)	.532 (.057)	−.346 (.004)
	Adults	−.428 (.766)	.851 (.112)	1.953 (.148)

Notes: Standard errors in parentheses. The price rows are the coefficients of effective wealth W_i in Equation (8.133), so a positive coefficient lowers price sensitivity. The income rows give the slope of the income spline below and above the 75th percentile of CAMIP income. Source: Berry et al. (2004a), Table 6.

Table 8.35: Estimates of the standard deviations of unobserved tastes (Σ)

Parameter	Full model	$\Pi = 0$	Parameter	Full model	$\Pi = 0$
Price (σ_w)	.449 (.026)	.055 (.004)	SUVPayl	.356 (.072)	.015 (.013)
HP	.030 (.016)	.183 (.020)	Chrysler	1.689 (.058)	1.383 (.051)

Minivan	4.787 (.353)	6.641 (.113)	European	.454 (.084)	1.883 (.034)
SUV	3.076 (.292)	3.231 (.114)	Outside good	27.858 (1.004)	10.256 (.506)
Van	1.713 (.289)	6.888 (.266)			
PUPayl	2.160 (.092)	4.301 (.210)			

Notes: Standard errors in parentheses. Each entry is the standard deviation of the unobserved taste for the characteristic or firm dummy. The price entry is the standard deviation of ν_{iw} in Equation (8.133). The coefficients on the dummies for the European firms are constrained to be equal, and so are those for the smaller Asian producers. Source: Berry et al. (2004a), Table 7.

interaction between age and pickup payload. The first-choice logit has a negative interaction between passengers and family size. The logit with second choices adds a negative interaction between rural residence and SUVs. The outside-good coefficients of the full model imply that richer and smaller households value the outside option more, and the logits imply roughly the opposite. These coefficients are reduced-form and hard to interpret. The full model still predicts that richer households are more likely to buy, because the income-price interactions outweigh the outside-good effect (p. 90, n. 16). On these estimates alone, the logits look fine, and the cost of the full model is not obviously justified (p. 91).

Unobserved heterogeneity. Table 8.35 changes the verdict. The estimated standard deviations are large and precise. Nineteen of 22 are highly significant, 11 with t-values above 10, and two are marginally significant (p. 91). However many observed interactions the authors allowed, they needed unobserved interactions to fit the data. The CAMIP data contain most of the attributes available in large consumer surveys, so richer observables are unlikely to remove the need. Tastes for vehicles of U.S. firms are more dispersed than tastes for Japanese firms. The standard deviations are 1.689, 0.915 and 1.885 for Chrysler, Ford and GM, against 0.329, 0.506 and 0.169 for Honda, Nissan and Toyota. The model with $\Pi = 0$ estimates its standard deviations even more precisely, several with t-values above 50, because it has fewer parameters.

Fit. The comparison of fits is the paper's central evidence (p. 91). The full model fits the first-choice moments (8.94) about as well as the two logits, while the $\Pi = 0$ model cannot fit them at all. The $\Pi = 0$ model fits the first-second covariances about as well as the full model, while the logits' percentage errors on those moments are typically five to ten times larger. Logits therefore predict who buys what but not how consumers substitute. Only the full model fits both dimensions.

Second choices and convergence. The authors also tried the full model with first-choice data only. After substantial experimentation it would not converge, and very different parameter values produced essentially the same value of the objective (p. 90). The second-choice data are what let the estimator settle on precise values. With a single cross section there is no variation in the choice set. In other data sets, choice-set variation across markets or over time might identify the random coefficients instead, as in BLP (1995).

8.14.6 The level of price elasticities

The remaining demand parameters are the effects of characteristics on the product constants (equation (15)):

$$\delta_j = p_j \bar{\beta}_p + \sum_{k \neq p} x_{jk} \bar{\beta}_k + \xi_j. \tag{8.136}$$

This is a regression with $J = 203$ observations and an endogenous regressor. In BLP (1995), with 20 annual cross sections, demand-side estimates alone were too imprecise to be useful. The same problem appears here for $\bar{\beta}$ (p. 92). Using Equation (8.136) alone with instruments, the estimate of $\bar{\beta}_p$ has a standard error ten times the point estimate, 25 against 2.5 (p. 93).

Adding the supply side. The first remedy mimics BLP (1995). Marginal cost is linear in characteristics, $mc_j = \sum_k x_{jk}\gamma_k + \omega_j$, with ω_j mean independent of x. Nash pricing by multi-product firms then gives the pricing equation (equations (16) and (17))

$$p_j = \sum_k x_{jk}\gamma_k + b_j(x, p, \delta, \bar{\beta}_p, \Pi, \Sigma) + \omega_j, \tag{8.137}$$

where b_j is the multi-product markup of Section 8.7.[26] The markup depends on ξ, ω and p, so it must be instrumented. Besides x_j, the instruments are the predicted markups (8.80) of Section 8.7.2 (their equation (18)). There $\hat{\delta}$ and $\hat{p}$ are projections of the estimated constants and observed prices on x, and the price coefficient comes from an initial instrumental variables estimate of (8.136). The predicted markup is then a function of x and consistent estimates only. The authors iterate, recomputing $\hat{b}$ with each new estimate of $\bar{\beta}_p$ until convergence (n. 17). The two-equation estimate is $\bar{\beta}_p = -3.58$ with a standard error of 0.22 (p. 93). This identification relies on the pricing assumption and heavily on functional form, because each vehicle has only one price.

One restriction suffices. The authors observe that all price effects depend on (δ, Π, Σ) and on the single number $\bar{\beta}_p$ (p. 93). The following proposition makes the point precise.

Proposition 8.45 (Price effects are affine in $\bar{\beta}_p$)**.** *Fix (δ, Π, Σ) and the distribution of (D_i, ν_i). Every share derivative $\frac{\mathrm{d}s_j}{\mathrm{d}p_k}$, every price elasticity and every semi-elasticity is an affine function of $\bar{\beta}_p$. In particular,*

$$\frac{\mathrm{d}s_j}{\mathrm{d}p_k} = -\int \left(\bar{\alpha} + e^{-W_i}\right) s_{ij} \left(\mathbf{1}\{j = k\} - s_{ik}\right) \mathrm{d}P(D_i, \nu_i), \qquad \bar{\alpha} = -\bar{\beta}_p,$$

where s_{ij} is the conditional choice probability Equation (8.135).

Proof. Price enters utility in two places, through δ_k with coefficient $\bar{\beta}_p$ and through the household term $-e^{-W_i} p_k$. By the chain rule,

$$\frac{\mathrm{d}s_j}{\mathrm{d}p_k} = \frac{\partial s_j}{\partial \delta_k} \bar{\beta}_p + \frac{\partial s_j}{\partial p_k}\Big|_{\delta}.$$

The logit derivative of s_{ij} with respect to household i's utility of k is $s_{ij}(\mathbf{1}\{j = k\} - s_{ik})$. Hence $\frac{\partial s_j}{\partial \delta_k} = \int s_{ij}(\mathbf{1}\{j = k\} - s_{ik})\,\mathrm{d}P$ and $\frac{\partial s_j}{\partial p_k}\big|_{\delta} = -\int e^{-W_i} s_{ij}(\mathbf{1}\{j = k\} - s_{ik})\,\mathrm{d}P$. Both integrals depend only on (δ, Π, Σ), so the derivative is affine in $\bar{\beta}_p$. Substituting $\bar{\beta}_p = -\bar{\alpha}$ and combining the two integrals gives the displayed formula. Elasticities and semi-elasticities divide these derivatives by quantities that do not depend on $\bar{\beta}_p$, since shares and prices are held at their observed values. □

The proposition has two consequences. Any single outside fact that pins down one elasticity identifies $\bar{\beta}_p$, and with it every own and cross effect. GM's staff believed that the aggregate price elasticity of new-vehicle demand was near one. Setting the 1993 market elasticity to -1 gives $\bar{\beta}_p = -11$ (p. 93). The proposition also makes Table 8 easy to read. Table 8.36 reports, for $\bar{\beta}_p \in \{0, -3.58, -11\}$, the implied average semi-elasticity and the total market elasticity. The value 0 corresponds to studies that ignore the correlation between price and the product constants. Panel A is affine in $\bar{\beta}_p$, as the proposition predicts. The slope implied by the first two columns is $\frac{3.94 - 0.75}{3.58} \approx 0.89$, and extrapolating to $\bar{\beta}_p = -11$ gives $0.75 + 11 \times 0.89 \approx 10.6$, the reported 10.56. The slope is an average of $\frac{1}{s_j}\int s_{ij}(1 - s_{ij})\,\mathrm{d}P$, a number between zero and one.[27]

The level of the elasticities rises with $|\bar{\beta}_p|$, but their pattern is robust (p. 93). Semi-elasticities fall in magnitude with price. Given price, minivans, full-size vans, pickups, SUVs and to a

[26] The paper writes the markup's price-coefficient argument as $\bar{\beta}_1$. We write $\bar{\beta}_p$.

[27] The check is ours. The market elasticities are rounded to one decimal in the paper, so they cannot be checked the same way.

Table 8.36: Implications of alternative values of $\bar{\beta}_p$

	Value of $\bar{\beta}_p$		
	0	−3.58	−11
Panel A. Implied averages across vehicles

SUVPayl	−.107 (.101)	−.058 (.144)	−.400 (.416)

Notes: $\bar{\beta}_p = 0$ ignores the correlation of price with the product constants, −3.58 is the estimate from demand and pricing equations, and −11 calibrates the 1993 market elasticity to −1. Firm dummies are included in Panel B but not reported. Standard errors in parentheses. The paper's text reads negative Panel B coefficients as smaller elasticities, so the projected variable is evidently the magnitude of the semi-elasticity. Source: Berry et al. (2004a), Table 8.

lesser extent sports cars have noticeably smaller elasticities than other vehicles. This pattern accords with industry reports of high markups on these vehicles around 1993. The first feature is consistent with the income effects in the price coefficient, since expensive vehicles are bought by less price-sensitive households (Section 8.2).

8.14.7 Substitution patterns

The paper distinguishes two kinds of substitution (p. 94). A small price increase moves only the marginal buyers of a vehicle, who are its most price-sensitive buyers. Removing the vehicle from the choice set moves all of its buyers. The two patterns differ, and Proposition 8.5 shows why. Price-induced diversion weights households by $\alpha_i s_{ij}(1 - s_{ij})$, while deletion weights them by s_{ij}. Both patterns are virtually independent of $\bar{\beta}_p$, so the authors report them at $\bar{\beta}_p = -3.58$.

Table 8.37 condenses Table 9, the price substitutes predicted by the full model. Both best substitutes are almost always of the same type as the vehicle whose price rises, and they have similar prices and size. The fraction of switchers who leave the new-vehicle market ranges from 3.97% for the Taurus to 17.96% for the Metro, the cheapest vehicle in the list.

The restricted models fail this test (p. 96). The first-choice logit predicts the Dodge Caravan, a minivan, as the best price substitute for nine of the ten cars and for both pickups, both SUVs and the full-size van. The logit with first and second choices predicts the Ford full-size pickup for all ten cars. Observed household attributes do not capture enough of the variation in tastes, even with product constants. The $\Pi = 0$ model gives the same best substitute as the full model in 12 of 17 cases. For substitution patterns, interactions between unobserved tastes and characteristics matter far more than interactions with the observed attributes.

Table 8.37: Price substitutes predicted by the full model ($\bar{\beta}_p = -3.58$)

Vehicle	Price	Semi-elasticity	Best substitute	Movers (%)	Second best	Movers (%)	To outside (%)
Metro	7.84	−1.77	Tercel	14.96	Festiva	10.57	17.96
Cavalier	11.46	−4.08	Escort	8.62	Tempo	6.80	6.81

Trooper	22.78	−3.96	Explorer	17.53	Grand Cherokee	8.50	5.42
GMC FSP	16.76	−3.78	Chevy FSP	43.74	Ford FSP	13.56	6.03
Toyota pickup	13.77	−3.34	Ranger	20.53	Nissan pickup	11.93	9.35
Econovan	24.54	−2.86	Chevy van	12.90	Dodge van	9.73	5.38

Notes: Prices in thousands of dollars. "Movers" is the percentage of those who substitute away from the vehicle after a small price increase who choose the named vehicle. "To outside" is the percentage who leave the new-vehicle market. FSP denotes full-size pickup. The paper also reports the prices of the substitutes, omitted here. Source: Berry et al. (2004a), Table 9.

Second choices allow a direct comparison with the data (pp. 96–98). Table 8.38 reproduces Table 11. For each first choice it reports the most popular second choice predicted by each model and the rank of that vehicle among the second choices named by CAMIP buyers. The full model predicts the data's top second choice 9 times out of 17 and one of the top three 15 times.[28] It never predicts a vehicle that the data rank below tenth among more than 200 models. The $\Pi = 0$ model predicts the top second choice 12 times but picks two vehicles ranked below tenth. The logits predict the Ford full-size pickup as the second choice of every car. The best price substitutes and the best second choices differ for about half the cars and one of the light trucks, which illustrates the marginal-versus-average distinction above.

8.14.8 Prediction exercises

The paper ends with two out-of-sample predictions (pp. 98–102). Both hold the prices of other vehicles fixed and allow no further entry. In similar earlier exercises, the authors found induced price responses to be second-order for the response to gasoline prices (p. 100, n. 21). They were central for the voluntary export restraints studied by Berry et al. (1999). The paper does not state the units of the shares in its Tables 12 and 13. They behave as percentages of households, since dividing by the total of 9.711 reproduces the shares of vehicles quoted in the text.

Luxury SUVs. The new Mercedes and Toyota SUVs are given all the observed characteristics of the Ford Explorer, the best-selling SUV of 1993 (p. 100). The unobserved quality ξ of the Toyota is the mean ξ of Toyota's 1993 vehicles. Its price, \$30,240, comes from a hedonic regression of price on characteristics and company dummies, which avoids explicit cost and pricing assumptions. The Mercedes is treated the same way using the low end of Mercedes' 1993 range, priced at \$33,659. Both prices lie above that of every SUV sold in 1993. The Mercedes

[28] The text on p. 98 says 15. In the printed Table 11 (Table 8.38) the full model's prediction ranks third or better for 14 of the 17 vehicles. Corolla (6), Quest (7) and Legend (10) are the exceptions.

Table 8.38: Most popular predicted second choices compared with the data

	Full model		Logit, first		Logit, first and second		$\Pi = 0$	
First choice	Prediction	Rank	Prediction	Rank	Prediction	Rank	Prediction	Rank

Toyota pickup	Ranger	1	Chevy FSP	4	Chevy FSP	4	Ranger	1
Econovan	Chevy van	1	Ford FSP	6	Ford FSP	6	Chevy van	1

Notes: FSP denotes full-size pickup, MB Mercedes-Benz. "Rank" is the rank of the predicted vehicle among the second choices named by CAMIP buyers of the first-choice vehicle. Source: Berry et al. (2004a), Table 11.

SUV captures a share of 0.0762, about a third of the Explorer's 0.2518 (Table 12). Its sales come mainly from other SUVs. The Explorer falls by 0.0144, the Grand Cherokee by 0.010 and the Blazer by 0.0036. Luxury cars priced above $30,000 lose much less, 0.0045 in total. Total vehicle sales are unchanged at 9.711. The Toyota does less well at its predicted price, with a share of 0.05, and would need a price cut of $1,000 to match the Mercedes. The later success of the Mercedes M-Class is consistent with the prediction, though a precise comparison is impossible (p. 101).

Closing Oldsmobile. In 1993 Oldsmobile had about 2.44% of vehicles purchased and GM 32.2% (p. 102). Removing the six Oldsmobile models (Table 13) benefits most the family-sized GM cars, the Chevy Lumina (+0.0194), Buick LeSabre (+0.0120) and Pontiac GrandAm (+0.0119). High-selling family cars of other firms also gain, notably the Honda Accord (+0.0084), Ford Taurus (+0.0075) and Toyota Camry (+0.0072). Overall 43% of Oldsmobile car buyers switch to a non-GM vehicle, and GM's share falls to 31.1%. Total purchases fall only from 9.711 to 9.695. The profit consequences depend on the costs saved and on the markups of the GM cars that gain, which the model does not supply.

8.14.9 Lessons and critiques

The paper's lessons are three. First, unobserved heterogeneity in tastes for characteristics is needed to describe the tight substitution patterns in the data, even with the demographics available in large consumer surveys. This confirms, from a different angle, the emphasis on Σ in BLP (1995). It qualifies the finding of Nevo (2001) that demographics explain most of the heterogeneity in cereal. Nevo himself notes that his result concerns the normal distribution of the residual tastes, not the value of second-choice data (Section 8.13.10). Second, second-choice data identify the substitution parameters precisely without any variation in the choice set. Third, a single cross section cannot fix the level of price elasticities. Variation in choice sets

across markets, a supply side, or outside information must do so (p. 103). The nonparametric analysis of Berry and Haile (2024) formalizes the same division. Within-market micro variation identifies the interaction terms, and cross-market variation or instruments are needed for the effect of price on the product constants (Section 8.8).

Several limitations deserve mention. The CAMIP data are proprietary, so the results cannot be replicated. The survey omits the option of not buying as a second choice, so diversion to the outside good rests on functional form and on the outside-good parameters. The level of elasticities rests either on a pricing assumption with one price per vehicle or on a calibration to a market elasticity reported by GM's staff. The authors chose interactions after preliminary runs, which makes the standard errors suspect in the usual way (p. 87, n. 13). They also mention a referee's warning that random coefficients models have been unstable in related cross-sectional settings (p. 90, n. 14). The prediction exercises hold rivals' prices fixed and use 1993 data for events of the late 1990s. Despite these caveats, the paper set the template for combining micro and macro moments. Micro moments of the kind in (8.92) are now a standard part of demand estimation (Section 8.8).

Table 8.39: Identification and counterfactual map of Berry, Levinsohn and Pakes (2004)

Observed data	The CAMIP survey of 37,500 buyers of 1993 model-year vehicles, with their demographics, the vehicle bought and their second choice. Prices, characteristics and aggregate shares of 203 vehicles, and CPS demographics.
Latent objects	Product constants δ_j and the unobserved characteristic ξ_j. Household tastes ν_i and effective wealth W_i.
Estimated parameters	Interactions Π of household attributes with characteristics, standard deviations Σ, outside-good parameters and the 203 product constants. The common price coefficient $\bar{\beta}_p$ comes from a separate step.
Identifying variation	First-choice moments identify Π, second-choice moments identify Σ, and aggregate shares fix δ. The level $\bar{\beta}_p$ needs the pricing equation with predicted-markup instruments, or an outside estimate of one elasticity.
Maintained assumptions	Normal tastes and type-I extreme value errors. A choice-based sample handled through Bayes' rule. Multiproduct Nash pricing with marginal cost linear in characteristics, for the level of elasticities.
Counterfactual and what it holds fixed	Out-of-sample predictions for the launch of luxury sport utility vehicles and the closure of Oldsmobile. They hold the prices of other vehicles fixed and allow no further entry.
Conclusion	Unobserved taste dispersion is needed to match second choices, even with rich demographics. Second choices fix the pattern of substitution. A single cross section cannot fix the level of price elasticities.
One limitation	The survey omits not buying as a second choice, so diversion to the outside good rests on functional form.
Source and our additions	The tables are the paper's. Proposition 8.45 and the reading of the units of the paper's Tables 12 and 13 are ours.

8.15 Case study: Goldberg (1995), micro data, nested choice and trade policy

Goldberg (1995) appeared in the same issue of *Econometrica* as BLP (1995) and studies the same industry with a different strategy. Demand is a nested logit estimated on household data from the Consumer Expenditure Survey. Aggregate demand is the population-weighted sum of household choice probabilities. Supply is multi-product Bertrand-Nash pricing with a quota constraint for Japanese firms. The estimated model is used to evaluate the voluntary export restraint on Japanese cars and the weak response of import prices to exchange rates. Berry et al. (2004a, p. 70) cite it, with Petrin (2002), as recent work in industrial organization that uses data matching consumer attributes to their choices. It is also a structural application of differentiated-products oligopoly to trade policy, and Berry and Haile (2014, p. 1749, n. 2) list it among such applications. Table 8.48 at the end of the section maps the study. Page numbers refer to the journal article.[29]

8.15.1 Question and setting

Trade theory with imperfect competition implies that government intervention can shift rents toward domestic firms, and that optimal policy depends on market structure and conduct (pp. 891–892). Applied work was scarce and largely calibrated. The automobile industry is a natural test case. It is an oligopoly of a few firms with highly differentiated products, American and Japanese producers were rivals throughout the 1980s, and the industry was a major target of trade policy. Imported cars faced a tariff of 2.9% and compact trucks a tariff of 25%. From April 1981, Japanese sales were limited by a "voluntary export restraint" (VER).[30]

Goldberg identifies two shortcomings of earlier automobile studies (pp. 892–893). Studies based on household data, mostly logit models, allowed rich differentiation and avoided price endogeneity by treating prices as exogenous to a single household. They neglected supply and equilibrium, and so could not be used to predict policy outcomes in which prices respond. Studies based on aggregate data had to handle price endogeneity, and tractable reduced forms imposed implausible substitution patterns. Most studies also lacked an outside good, so a general price increase could not reduce total demand. The paper combines a disaggregate model of demand that includes the outside good with an aggregate oligopoly model. It then asks two questions. What were the effects of the VER on sales, prices and the quality mix over 1983–1987? Why did import prices respond so little to exchange rates?

8.15.2 Data

Demand is estimated from the Consumer Expenditure Survey (CES) of the Bureau of Labor Statistics (pp. 906–907). About 4,500 households are interviewed each quarter. Three quarters of them are re-interviewed the next quarter, and the rest are replaced. Since 1984 the survey records the make, model and purchase price of each car the household owns, the financing of

[29] Goldberg indexes households by h and vehicle models by m, and writes the stage coefficient vectors as $\alpha, \beta, \gamma, \delta, \zeta$. She writes the dissimilarity parameters as λ, the Lagrange multipliers as λ_{ft} and marginal cost as c. We write $i, j, \theta_B, \theta_N, \theta_C, \theta_O, \theta_M, \lambda, \psi_{ft}$ and mc. In the notation of Chapter 7, the nesting parameter of a nest with dissimilarity λ is $\sigma = 1 - \lambda$.

[30] The paper gives two figures for the original limit. Footnote 5 (p. 892) says 1.68 million cars a year, while Section 6.1 (p. 926) says 1,832,500 cars a year for April 1981 to March 1984. The limit was raised to 2,016,000 in April 1984, and from 1985 the Japanese government limited sales to 2.5 million a year.

new purchases, the disposal of old vehicles and many vehicle characteristics. Between 1983 and 1987 about 32,000 distinct households were interviewed. The sample is representative of the U.S. population in socioeconomic terms (Table A1), and its annual import shares correspond roughly to those reported by the industry press (Table A2).

Two features of the CES matter. Only about 9% of sample households buy a new vehicle in a year, against about 15% implied by total sales. Goldberg attributes the gap to fleet sales, which the household survey omits (p. 907, n. 29). Households in the sample buy about 400 new cars a year, while about 200 models are on the market. Infrequently bought models therefore appear rarely or never, which rules out model fixed effects. The CES is supplemented by product data on about 200 models a year for 1983–1987 from the *Automotive News Market Data Book*, provided by James Levinsohn. They include sales, list prices, size, performance, fuel efficiency and standard options. Models are assigned to nine market segments (subcompact, compact, intermediate, standard, luxury, sports, pickup trucks, vans and miscellaneous) and, within segments, to domestic and foreign origin. This gives 17 classes, since no foreign car is in the standard segment.

Consumers respond to transaction prices, which include transport costs, taxes and dealer discounts (p. 902). Transaction prices of alternatives not bought are unobserved, and a household's own price reflects its bargaining power. Goldberg therefore uses averages of the options-corrected transaction prices paid by CES households, by year and, where possible, region. Firms set wholesale prices. Goldberg approximates them with a rough rule of Bresnahan (1981a), based on average dealer markups reported by *Consumer Reports* (p. 902 and n. 23).[31] Wholesale prices are 75% of retail for intermediate, standard and luxury cars, 83% for subcompacts and 79% for others. Dealer markups are thus treated as exogenous.

8.15.3 Demand: a five-level nested logit

The horizon is one year, because most households buy no car in a given year and those that buy usually buy one (p. 894). Vehicles are indexed by the decision to buy (b), newness (n), market segment or class (c), origin (o) and model (j). Utility is additively separable into components that vary only with each level of this classification:

$$U_{i,bncoj} = \theta_B^\top B_{i,b} + \theta_N^\top N_{i,bn} + \theta_C^\top C_{i,bnc} + \theta_O^\top O_{i,bnco} + \theta_M^\top M_{i,bncoj} + \epsilon_{i,bncoj}. \tag{8.138}$$

The vectors B, N, C, O, M contain household characteristics, vehicle attributes and their interactions relevant at each level. The errors follow a generalized extreme value distribution that generates the nesting of Figure 8.15. A household decides whether to buy a car, then whether to buy a new or only a used car, then which of the nine classes, then foreign or domestic, then which model. The tree describes correlation in unobserved tastes, not a sequential decision process (p. 897, n. 12).

By the results of McFadden (1978, 1981), the conditional choice probability at each node is a multinomial logit (p. 896). McFadden (1984, pp. 1421–1425) gives a self-contained statement of these results. We derive them first for a tree with two levels of nests, in the GEV framework of Section 7.5.1, and then write Goldberg's version.

Multilevel nesting as a GEV model. Partition the alternatives into nests C, and partition each nest into subnests D. Alternative j has deterministic utility V_j, and we write $y_j = e^{V_j}$. Take

[31] Goldberg's text and reference list date this paper 1986. It appeared in the *Journal of Econometrics*, volume 17, in 1981.

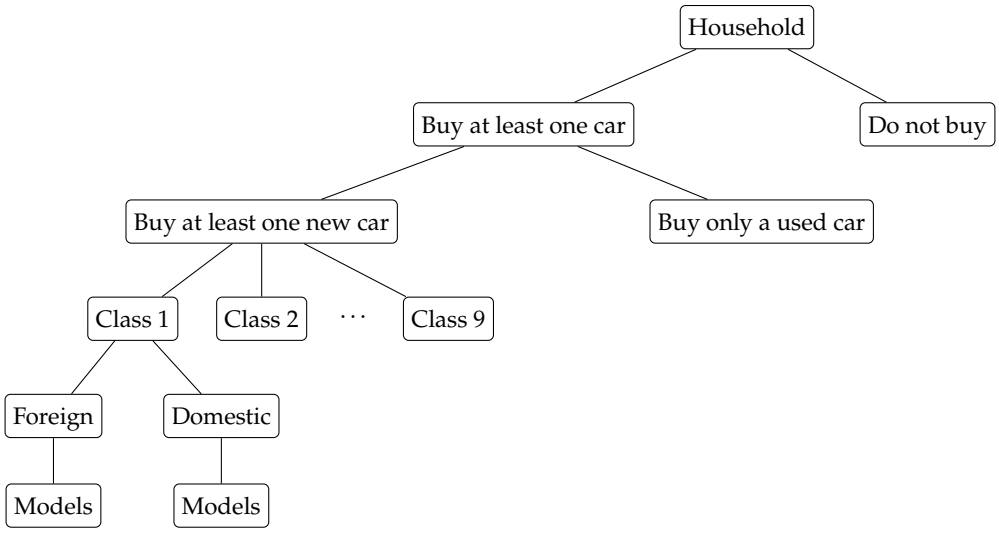

Figure 8.15: The nesting structure of Goldberg's automobile choice model. Each class has a foreign and a domestic branch, except the standard class, which has no foreign models. The final choice set at the bottom of the tree typically contains 10 to 30 models. Redrawn from Goldberg (1995), Figure 1.

positive weights a_C and b_{DC} and parameters $0 < \lambda_{DC} \le 1$ and $0 < \lambda_C \le 1$. The generating function of McFadden (1984, eq. 3.33) is

$$H(y) = \sum_C a_C \Big(\sum_{D \subseteq C} b_{DC} \Big[\sum_{j \in D} y_j^{\frac{1}{\lambda_{DC}\lambda_C}} \Big]^{\lambda_{DC}} \Big)^{\lambda_C}. \tag{8.139}$$

McFadden (1984, p. 1421) states that H is a GEV generating function (Definition 7.20) on this parameter range. We take this as given. Lemma 7.22 proves the case with one level of nests.

Proposition 8.46 (Conditional logits in a two-level tree)**.** *Let ϵ have the distribution generated by (8.139). For $j \in D \subseteq C$, the choice probability factors as $P_j = Q_C\, Q_{D|C}\, Q_{j|D}$, where*

$$Q_{j|D} = \frac{\exp\left(\frac{V_j}{\lambda_{DC}\lambda_C}\right)}{\sum_{k \in D} \exp\left(\frac{V_k}{\lambda_{DC}\lambda_C}\right)}, \qquad J_D = \ln \sum_{k \in D} \exp\left(\frac{V_k}{\lambda_{DC}\lambda_C}\right),$$

$$Q_{D|C} = \frac{b_{DC} \exp(\lambda_{DC} J_D)}{\sum_{D' \subseteq C} b_{D'C} \exp(\lambda_{D'C} J_{D'})}, \qquad I_C = \ln \sum_{D' \subseteq C} b_{D'C} \exp(\lambda_{D'C} J_{D'}),$$

$$Q_C = \frac{a_C \exp(\lambda_C I_C)}{\sum_{C'} a_{C'} \exp(\lambda_{C'} I_{C'})}.$$

Proof. By Proposition 7.21(ii), $P_j = \frac{\partial \ln H}{\partial V_j}$. Write $S_D = e^{J_D}$ and $T_C = e^{I_C}$. Then $S_D = \sum_{k \in D} y_k^{\frac{1}{\lambda_{DC}\lambda_C}}$, the bracket in (8.139) is $S_D^{\lambda_{DC}}$, the term in parentheses is T_C, and $H = \sum_C a_C T_C^{\lambda_C}$. Apply the chain rule from the inside out. The innermost derivative is

$$\frac{\partial S_D}{\partial V_j} = \frac{1}{\lambda_{DC}\lambda_C} \exp\left(\frac{V_j}{\lambda_{DC}\lambda_C}\right).$$

The next two are

$$\frac{\partial T_C}{\partial V_j} = b_{DC}\, \lambda_{DC}\, S_D^{\lambda_{DC}-1} \frac{\partial S_D}{\partial V_j}, \qquad \frac{\partial H}{\partial V_j} = a_C\, \lambda_C\, T_C^{\lambda_C - 1} \frac{\partial T_C}{\partial V_j}.$$

Substitute and note that the factors λ_C, λ_{DC} and $\frac{1}{\lambda_{DC}\lambda_C}$ cancel:

$$\frac{\partial H}{\partial V_j} = a_C T_C^{\lambda_C} \cdot \frac{b_{DC} S_D^{\lambda_{DC}}}{T_C} \cdot \frac{\exp\left(\frac{V_j}{\lambda_{DC}\lambda_C}\right)}{S_D}.$$

Divide by H. The first factor becomes $\frac{a_C T_C^{\lambda_C}}{H} = Q_C$. The second is $Q_{D|C}$, because $S_D^{\lambda_{DC}} = \exp(\lambda_{DC} I_D)$ and T_C is the denominator of $Q_{D|C}$. The third is $Q_{j|D}$. □

Following McFadden (1984, p. 1422), we call the log-sums I_D and I_C the *inclusive values* of subnest D and nest C. The proof shows that they are the logarithms of the denominators of $Q_{j|D}$ and $Q_{D|C}$.[32] Section 7.5.2 scales the inclusive value by the nest parameter, as in $I_g = (1-\sigma)\ln D_g$. With one level of nests, $\lambda_C = 1$ and $\lambda_{DC} = 1-\sigma$, so the term $\lambda_{DC} I_D$ equals that scaled inclusive value. Each stage is a logit whose index adds the inclusive value of the stage below, weighted by the parameter of that nest. McFadden (1984, p. 1422) reads λ_{DC} and λ_C as measures of the independence of the shocks within D and within C. Two limits make the reading precise. If every parameter equals one, then $H(y) = \sum_C \sum_{D\subseteq C} \sum_{j\in D} a_C b_{DC}\, y_j$, which is a multinomial logit with utilities $V_j + \ln a_C + \ln b_{DC}$. If instead $\lambda_{DC} \to 0$, write $t = \lambda_{DC}\lambda_C$ and $\bar{V}_D = \max_{k\in D} V_k$. The log-sum is squeezed between two bounds:

$$\bar{V}_D \;\le\; t \ln \sum_{k\in D} \exp\left(\frac{V_k}{t}\right) \;\le\; \bar{V}_D + t \ln |D|.$$

Since $\lambda_{DC} I_D = \frac{1}{\lambda_C}\, t \ln \sum_{k\in D} \exp(\frac{V_k}{t})$, it follows that

$$\lambda_{DC} I_D \;\longrightarrow\; \frac{\bar{V}_D}{\lambda_C} \qquad \text{as } \lambda_{DC} \to 0.$$

The subnest D then enters $Q_{D|C}$ and I_C as a single alternative whose utility is the best one in D. McFadden describes this limit in the same way (p. 1422). The shocks of the alternatives in D become perfectly correlated, so the alternatives differ only in V_k. The housing model of McFadden (1984, eqs. 3.40–3.48) applies the same two-level recursion (own or rent, then head or non-head, then dwelling unit). It drops the weights a_C and b_{DC} and puts the attributes common to a cluster into utility. There the coefficient of a dwelling attribute is scaled by $\kappa_{rh}\lambda_r$ and that of a subcluster attribute by λ_r (eq. 3.47). The stage logits (eqs. 3.41–3.43) then have unscaled coefficients, and the inclusive values enter them with coefficients κ_{rh} and λ_r.

Goldberg's tree. Goldberg's tree has four levels of nests below the root, for the buy, newness, class and origin decisions (Figure 8.15). Each level repeats the step of Proposition 8.46. Let a be an alternative at stage s inside the nest a^- chosen at stage $s-1$, with choice set C_{a^-}. Then

$$P_{i,a|a^-} = \frac{\exp\left(\frac{X_{ia}\theta_s}{\lambda_{a^-}} + \frac{\lambda_a}{\lambda_{a^-}} I_{ia}\right)}{\sum_{a'\in C_{a^-}} \exp\left(\frac{X_{ia'}\theta_s}{\lambda_{a^-}} + \frac{\lambda_{a'}}{\lambda_{a^-}} I_{ia'}\right)}, \qquad I_{ia} = \ln\Big[\sum_{a''\in C_a} \exp\left(\frac{X_{ia''}\theta_{s+1}}{\lambda_a} + \dots\right)\Big], \tag{8.140}$$

where the dots stand for the inclusive values of the next level down. The inclusive value I_{ia} measures the expected maximal utility within nest a. The coefficient $\frac{\lambda_a}{\lambda_{a^-}}$ measures the dissimilarity of the alternatives in nest a. Goldberg's λ_a is the product of McFadden's parameters

[32] The printed equation (3.38) of McFadden (1984, p. 1422) has λ_C in place of $\lambda_{D'C}$ in the exponent. With that exponent, Q_C would not equal the first factor in the proof. We follow the derivation.

along the path from the root to nest a. For a subnest D of a nest C, it is $\lambda_D = \lambda_{DC}\lambda_C$, and the ratio $\frac{\lambda_D}{\lambda_C}$ equals λ_{DC}. The index of $Q_{D|C}$ in Proposition 8.46 then takes the form (8.140), with $b_{DC} = \exp(\frac{X_{iD}\theta_s}{\lambda_C})$. The model is consistent with random utility maximization for all values of the regressors when these coefficients lie in the interval $(0, 1]$ (McFadden, 1984, pp. 1421, 1425). As they approach one, the model collapses to a multinomial logit. As they approach zero, the alternatives in the nest become perfect substitutes in unobservables. The unconditional probability of a model is the product of the conditional probabilities along its branch:

$$P_{i,bncoj} = P_{i,b} \cdot P_{i,n|b} \cdot P_{i,c|n,b} \cdot P_{i,o|c,n,b} \cdot P_{i,j|o,c,n,b}. \tag{8.141}$$

Price and income. Price enters at the bottom of the tree. The model component is written as $\theta_M^\top M_{i,bncoj} = \theta_{M1}^\top M1_{i,bncoj} + \zeta\,(INC_i - p_{bncoj})$, where INC_i is household income (p. 899). With a common ζ, income would cancel from all choice probabilities. Goldberg therefore lets the price coefficient vary with the household's income class (below or above \$75,000) and with whether the household has bought the model before. She also estimates it separately for small, large and luxury cars. Prices affect choices at higher nodes only through the inclusive values. These also provide consumer-specific price indices for classes of cars, which matter for policies that affect all foreign prices together. Vehicle attributes interact with household attributes, for instance car size with family size. Substitution within a nest therefore depends on the distribution of household attributes, so aggregate elasticities escape the logit restrictions even within a nest (pp. 898–899). Goldberg notes that the model resembles the random coefficients model of BLP, except that it has no unobserved dispersion in tastes for characteristics (p. 899, n. 17).

The nested structure determines the own-price response of a household's choice probability. The following lemma expresses it in terms of the coefficients estimated at each stage.

Lemma 8.47 (Own-price response in a multilevel nested logit)**.** *Let $\kappa_i < 0$ be the coefficient on price in the bottom-stage logit for household i. Let b_o, b_c, b_n, b_b be the inclusive-value coefficients $\frac{\lambda_a}{\lambda_{a^-}}$ of the nests on the branch of model j (origin, class, new, buy). Then*

$$\frac{\partial \ln P_{i,j}}{\partial p_j} = \kappa_i \Big[(1 - P_{i,j|o}) + b_o(1 - P_{i,o|c})P_{i,j|o} + b_o b_c (1 - P_{i,c|n})P_{i,oj|c} \\ + b_o b_c b_n (1 - P_{i,n|b})P_{i,coj|n} + b_o b_c b_n b_b (1 - P_{i,b})P_{i,ncoj|b} \Big],$$

where $P_{i,oj|c} = P_{i,o|c}P_{i,j|o}$ is the probability of model j given class c, and similarly for the other compound probabilities.

Proof. Write $\ln P_{i,j}$ as the sum of the logarithms of the five conditional probabilities in Equation (8.141). At the bottom, $P_{i,j|o}$ is a logit with price coefficient κ_i, so $\frac{\partial \ln P_{i,j|o}}{\partial p_j} = \kappa_i(1 - P_{i,j|o})$. Its inclusive value is the log-sum of the bottom-stage indices, so $\frac{\partial I_{i,o}}{\partial p_j} = \kappa_i P_{i,j|o}$. At the origin stage the inclusive value enters with coefficient b_o, so

$$\frac{\partial \ln P_{i,o|c}}{\partial p_j} = b_o(1 - P_{i,o|c})\frac{\partial I_{i,o}}{\partial p_j} = \kappa_i b_o (1 - P_{i,o|c})P_{i,j|o}.$$

The inclusive value of class c is the log-sum of the origin-stage indices, so $\frac{\partial I_{i,c}}{\partial p_j} = P_{i,o|c}\, b_o \frac{\partial I_{i,o}}{\partial p_j} = \kappa_i b_o P_{i,oj|c}$. Repeating the step at the class, newness and buy stages gives the remaining terms. Summing the five derivatives proves the formula. □

In the notation of Equation (8.140), $\kappa_i = -\frac{\zeta_i}{\lambda_o}$ and each product $\kappa_i b_o \cdots$ equals $-\frac{\zeta_i}{\lambda_{a^-}}$ for the parent nest of the relevant stage. For a single level of nests the lemma reduces to the nested logit derivative of Chapter 7. Aggregate demand derivatives are population-weighted sums of household derivatives, as described next. The lemma shows the role of the inclusive-value coefficients. A coefficient near zero at some stage shuts off substitution across the branches of that stage.

8.15.4 Aggregation and supply

Aggregate demand. The CES provides a weight w_i for each household that reflects its representativeness. The weights sum to the number of U.S. households (p. 901). Aggregate and expected demand for model j are

$$D_j = \sum_i P_{i,j}\, w_i + \sum_i \eta_{ij}\, w_i, \qquad \mathbb{E}D_j = \sum_i P_{i,j}\, w_i, \tag{8.142}$$

where η_{ij} is the difference between household i's purchase indicator and its probability, unobserved by both the econometrician and the firm. Aggregation needs no assumption about the shape of the aggregate demand curve. It preserves the household-level relations, so changes in demographics or policies that affect groups unevenly change the slope of aggregate demand. Price derivatives of expected demand are the weighted sums of the household derivatives in Lemma 8.47.

Costs. Firms play a one-shot pricing game with Nash conjectures and constant marginal costs (p. 903). Marginal cost is observed by firms but not by the econometrician, who models it as

$$mc_{jt} = c_0 + a\, Z_{jt} + u_{jt}, \tag{8.143}$$

with Z_{jt} product characteristics and u_{jt} an i.i.d. cost shock. Profits are expected profits because demand is random through η.

First-order conditions. Let p^w_{jt} be the dollar wholesale price and e_t the exchange rate in foreign currency per dollar. Foreign marginal costs are in the producer's currency, and foreign cars are invoiced in dollars. Firm f produces n_{ft} models. The first-order conditions are, for $j = 1, \ldots, n_{ft}$ (equations (1) to (3), p. 905):

$$\text{domestic firm:} \qquad \mathbb{E}_t D_{jt} + \sum_{k=1}^{n_{ft}} (p^w_{kt} - mc_{kt}) \frac{\partial \mathbb{E}_t D_{kt}}{\partial p^w_{jt}} = 0, \tag{8.144}$$

$$\text{foreign firm:} \qquad e_t \mathbb{E}_t D_{jt} + \sum_{k=1}^{n_{ft}} (e_t p^w_{kt} - mc_{kt}) \frac{\partial \mathbb{E}_t D_{kt}}{\partial p^w_{jt}} = 0, \tag{8.145}$$

$$\text{quota-constrained firm:} \qquad e_t \mathbb{E}_t D_{jt} + \sum_{k=1}^{n_{ft}} (e_t p^w_{kt} - mc_{kt}) \frac{\partial \mathbb{E}_t D_{kt}}{\partial p^w_{jt}} - \psi_{ft} \sum_{k \in V_f} \frac{\partial \mathbb{E}_t D_{kt}}{\partial p^w_{jt}} = 0, \tag{8.146}$$

with $\sum_{k \in V_f} \mathbb{E}_t D_{kt} \le Q_{ft}$, $\psi_{ft} \ge 0$ and complementary slackness. Here V_f is the set of the firm's models subject to the quota Q_{ft} (passenger cars) and ψ_{ft} is its Lagrange multiplier. Collecting terms in Equation (8.146) gives

$$e_t \mathbb{E}_t D_{jt} + \sum_{k=1}^{n_{ft}} \left(e_t p^w_{kt} - mc_{kt} - \psi_{ft} \mathbf{1}\{k \in V_f\} \right) \frac{\partial \mathbb{E}_t D_{kt}}{\partial p^w_{jt}} = 0.$$

A binding quota therefore acts exactly like an increase of ψ_{ft} in the marginal cost of every quota-constrained model. This equivalence drives both estimation and identification of the quota's shadow price.

Solving for equilibrium under a quota requires a rationing rule, which describes off-equilibrium behavior and cannot be estimated (p. 904). Goldberg assumes "no spillovers," meaning that excess demand for a Japanese car does not spill over to domestic demand. Without it a pure-strategy equilibrium need not exist (Krishna, 1989). Even with it, existence is assumed rather than proved, since the results of Caplin and Nalebuff (1991) cover only single-product firms.

Estimating costs. With N models in a year, Equations (8.144) and (8.145) form N linear equations in marginal costs, given demand estimates and observed wholesale prices (p. 906). Solving them gives the implied marginal cost of each model. Regressing implied costs on characteristics and year dummies estimates Equation (8.143). Costs are converted to producers' currencies at current exchange rates, and separate regressions are run for American, Japanese and other (mainly German) cars. By the equivalence above, the quota multipliers appear as year dummies for Japanese passenger cars (QUOT1 to QUOT5). They are identified because Japanese firms also sell trucks, vans and utility vehicles that are not subject to the VER. Honda sold only cars, so firm-specific multipliers are not identified. Goldberg imposes a common multiplier $\psi_{ft} = \psi_t$, which corresponds to a government allocation of quotas that equalizes their shadow price across firms (pp. 905–906).

8.15.5 Estimation and identification

Sequential maximum likelihood. The model has over 200 parameters, so full maximum likelihood was infeasible (p. 897). Goldberg estimates the tree from the bottom up in five stages, each a logit. Each stage uses the inclusive values computed from the estimates of the stage below. Sequential estimation is consistent but not efficient, and the naive standard errors are wrong. They are corrected with the recursive formulas of McFadden (1981). McFadden (1984, p. 1426) describes the same procedure. Each stage is a concave logit likelihood, and beyond the first stage the standard errors must account for the estimated coefficients inside the inclusive values. Data from 1983 to 1987 are pooled with year dummies.

Identification of the price coefficient. The main identifying assumption is that the regressors are uncorrelated with the household error (pp. 907–910). Two sets of regressors are suspect. Variables describing the existing stock of cars act like lagged dependent variables and are consistent only without serial correlation in the errors, which Goldberg assumes. Prices are the second set, and two arguments support treating them as exogenous.

The first argument rests on micro data. A household-level error contains an aggregate component only through macroeconomic shocks or through unobserved product characteristics valued alike by all consumers, the ξ_j of Berry (1994). Household income, employment and assets control for macroeconomic shocks. Unobserved product characteristics could in principle be absorbed by model fixed effects, but many models appear only once in the sample. Goldberg therefore decomposes

$$\xi_j = \xi_c + \xi_o + \xi_{br}, \tag{8.147}$$

into segment, origin and brand components, all estimated as fixed effects. Only model-specific quality beyond the brand remains in the error. Goldberg argues that reputation and reliability attach to brands and origins, not to individual models. Any remaining simultaneity would

show up as large gaps between predicted and actual model shares, which she does not find (pp. 909, 918).

The second argument rests on expected profit maximization (pp. 909–910). Firms set prices knowing their own costs but before the demand errors η are realized. From the econometrician's perspective, a firm's objective contains the cost shock u_{jt} and the expectation of demand. If u_{jt} is independent of the demand errors, the demand errors drop out of the pricing condition, and prices are uncorrelated with them by construction. Goldberg notes that independence fails if the same unobserved characteristics enter costs and demand (n. 35).

Assessment of the identification strategy. The two arguments differ in force. The second concerns the household error and the sampling error η, which firms indeed cannot observe. It does not address a product-level ξ_j known to firms when they set prices, which is the endogeneity problem of Section 8.6. The fixed effects in Equation (8.147) address ξ_j to the extent that it is common within segments, origins and brands. Within those cells, the price coefficient is identified from price differences across models. Model-level quality that is positively correlated with price would bias it toward zero. BLP (2004) make a general point here. Micro data identify the interactions between household attributes and characteristics without assumptions on ξ, but not the effect of price on the product constants (Section 8.14.3). In Goldberg's model the income and repeat-purchase variation in the price coefficient is of the first kind. Its level relies on the fixed-effect decomposition.

8.15.6 Results: demand, elasticities and markups

Choice model. The bottom stage is estimated separately for small cars (subcompacts and compacts), luxury and sports cars, and the remaining models. A likelihood ratio test rejects equal coefficients across the three equations. Imposing equality lowers the log-likelihood from -1267.2 to -1489.0 with 36 restrictions (p. 911), an LR statistic of $2 \times 221.8 = 443.6$. The final specification includes price interacted with income class and previous purchase, horsepower interacted with age, and size interacted with family size. It also includes fuel cost (gallons per mile times the regional gasoline price), options and many brand dummies. Table 8.40 reports the price coefficients and the inclusive-value coefficients.

Price sensitivity is highest for small cars and lowest for luxury and sports cars (p. 911). Within the first two equations it falls with income. The coefficients for first-time buyers are almost twice those for repeat buyers, and likelihood ratio tests reject their equality. Goldberg cautions that this pattern may reflect brand loyalty, switching costs or persistent unobserved heterogeneity, which cross-sectional data cannot separate (p. 912). In either case, current elasticities depend on past purchases.

The inclusive-value coefficients lie in the unit interval, so the nesting is consistent with random utility maximization (p. 912). They are high for small and large cars and lower for luxury and sports cars. Choice dummies account for much of the correlation in unobservables within classes (n. 38). At the new-versus-used node the coefficient is 0.011, and at the buy node the estimate was -0.01 and was set to zero (p. 913). By Lemma 8.47, these values nearly shut off two margins of substitution. A rise in new-car prices barely shifts households from new to used cars, and it does not change the decision to buy a car at all. Goldberg reads the first estimate as saying that new and used cars are poor substitutes. The model predicts 80% of all household choices correctly, 60% for households that bought a new car, and about 85% at each node conditional on the previous one (p. 914, n. 41).

Table 8.40: Price and inclusive-value coefficients in Goldberg's choice model

Panel A. Price coefficients in the model-choice logits

	Small cars	Big cars	Luxury and sports
First-time buyer, income < \$75,000	−4.747 (0.862)	−4.445 (0.602)	−1.223 (0.174)
First-time buyer, income > \$75,000	−4.501 (0.356)	−3.745 (0.332)	
Repeat buyer, income < \$75,000	−2.927 (0.328)	−3.076 (0.649)	−0.517 (0.220)
Repeat buyer, income > \$75,000	−2.755 (1.277)	−2.171 (0.396)	
Observations	707	980	185
Log-likelihood	−517.9	−414.5	−334.7

Panel B. Inclusive-value coefficients at higher nodes

Node (observations)	Coefficient
Foreign vs. domestic (1,867), small cars	0.891 (0.024)
Foreign vs. domestic, large cars	0.988 (0.023)
Foreign vs. domestic, luxury and sports cars	0.199 (0.100)
Class choice (1,992)	0.944 (0.024)
New vs. used (6,172)	0.011 (0.006)
Buy vs. not buy (20,571)	set to 0

Notes: Standard errors in parentheses, corrected for sequential estimation. "Repeat buyer" means the household has bought the model before. The luxury and sports equation has a single price coefficient for all incomes. Each Panel A equation also includes options, performance, fuel cost and 10 to 16 brand dummies. In Panel B the three foreign-versus-domestic coefficients are, in order, those of the inclusive values INCL1 to INCL3, which correspond to the small, large and luxury-and-sports equations of the bottom stage. The buy-versus-not-buy coefficient was estimated at −0.01 (t = 0.87) and then set to zero. Sources: Goldberg (1995), Tables B1 to B7 and p. 913.

Elasticities. Own-price elasticities of aggregate demand for individual models range from −1.00 to −10.13, with an unweighted average of −3.28 (p. 921). All demands are elastic. Table 8.41 reproduces the class averages. Intermediate and standard cars are the most elastic, with averages of −4.6 and −4.71 in the text, while luxury and sports cars are the least elastic (−2.02 and −1.35). First-time buyers average −4.1 against −2.1 for repeat buyers. These are elasticities with respect to transaction prices, which include dealer behavior (n. 50).

Cross-price effects are positive and are larger between models of the same class and origin (pp. 921–923). Goldberg reports them as semi-elasticities to avoid the illusion that expensive cars have large substitution effects. One pattern runs against the imposed tree. Cross effects between domestic and foreign models in the same segment are often smaller than those between foreign models in different segments. For example, the cross effect between the Honda Civic and the Chevrolet Chevette is smaller than that between the Civic and the Honda Accord or the Mazda 626. When foreign cars become more expensive, consumers tend to switch class rather than origin. Goldberg suggests that household characteristics such as income, education, age and region drive the choice of origin more than prices do.

Table 8.42 reproduces the corner of her Table III that contains these models. Her note describes entry (r, c) as the percent change in the demand for the column model c when the price of the row model r changes by one dollar (p. 922). The paper gives no formula for these semi-elasticities. Footnote 51 gives a formula only for elasticities, where the scale question does not arise. We therefore cannot tell whether the entries are scaled by 100. If they are unscaled log derivatives $\frac{\partial \ln q_c}{\partial p_r}$, with q_c the expected demand for model c, then an entry of 7.6×10^{-7} means 7.6×10^{-5} percent per dollar.

The comparisons do not depend on the scale. Along the Civic row, the entry for the

Table 8.41: Average own-price elasticities by class and origin

Class	Origin	All buyers	First-time buyers	Repeat buyers
Subcompacts	Domestic	−3.2857	−3.6245	−2.9816
	Foreign	−3.6797	−5.2531	−2.9488
Compacts	Domestic	−3.419	−4.8722	−3.1546
	Foreign	−4.0319	−5.7229	−3.3733
Intermediate	Domestic	−4.1799	−5.3153	−2.8420
	Foreign	−5.1524	−6.2232	−4.9274
Standard	Domestic	−4.7121	−5.932	−4.3730
Luxury	Domestic	−1.9121	−2.5981	−1.1137
	Foreign	−2.7448	−3.1272	−1.9959
Sports	Domestic	−1.0654	−2.3468	−1.3959
	Foreign	−1.5254	3.0211	−1.1429
Pick-ups	Domestic	−3.5259	−5.1391	−3.1647
	Foreign	−2.6883	−3.9822	−2.1483
Vans	Domestic	−4.3633	−5.4977	−3.9790
	Foreign	−4.6548	−4.8837	−2.4376
Other	Domestic	−4.0884	−4.3185	−3.5694
	Foreign	−3.0271	−3.3185	−2.3345

Notes: Averages of model-level own-price elasticities of expected aggregate demand with respect to transaction prices. The positive entry for first-time buyers of foreign sports cars is printed as such in the paper and is presumably a sign misprint. Source: Goldberg (1995), Table II.

Chevette is 7.6×10^{-7}, against 14.9×10^{-7} for the Accord and 21.8×10^{-7} for the Mazda 626. Down the Civic column, the entry for the Chevette's price is 49.1×10^{-7}, against 66.2×10^{-7} for the Accord and 50.1×10^{-7} for the Mazda 626. Both readings rank the Chevette, the domestic model in the Civic's own segment, last among the three.

Table 8.42: Cross-price semi-elasticities for six models in Goldberg's model (excerpt)

Price change of ↓	Demand for					
	Chevette	Civic	Tercel	Escort	Accord	Mazda 626
Chevette	−3.2	49.1	16.4	0.9	9.0	18.0
Civic	7.6	−3.4	35.5	0.8	14.9	21.8
Tercel	7.7	109.8	−3.4	0.8	11.6	20.7
Escort	6.3	34.6	11.3	−3.4	12.5	32.4
Accord	6.1	66.2	16.2	1.3	−3.4	140.9
Mazda 626	6.4	50.1	15.3	1.7	72.2	−3.4

Notes: Off-diagonal entries are cross-price semi-elasticities. Goldberg's note calls entry (i, j) the percent change in the demand for column model j when the price of row model i changes by \$1. The paper does not state whether the entries are scaled by 100. They are in units of 10^{-7}, and the paper prints, for example, 7.6E−07. Diagonal entries are own-price elasticities, which Goldberg reports in the same table (p. 921). The full table covers 15 models. Source: Goldberg (1995), Table III (p. 922).

Markups. Solving the first-order conditions for marginal costs gives markups $\frac{p^w - mc}{p^w}$ that average 38%, against about 15% in earlier studies (p. 923). Costs are positive, rise with vehicle size and are stable over time in producers' currencies, which Goldberg reads as support for the specification. Table 8.43 reproduces her 1986 estimates. Among the ten models shown, markups range from 10% for the Accord and 14% for the Civic to 56% for the Porsche 944 and 61% for the Ferrari. Across the 17 class and origin cells they range from 15% for domestic

models in the residual class to 69% for domestic sports cars. Foreign compacts (19%) and foreign vans (17%) also have low markups. Among the models, dollar markups range from $567 for the Accord to $12,018 for the Ferrari.

Table 8.43: Marginal costs and markups in Goldberg's model, 1986

Class	Origin	Cost ($)	Price ($)	Markup	Price − cost ($)
Panel A. Classes					
1 (subcompact)	Domestic	3906	6628	0.36	2722
	Foreign	5688	7840	0.27	2152
2 (compact)	Domestic	3213	6391	0.43	3178
	Foreign	5430	6610	0.19	1180
3 (intermediate)	Domestic	4773	7134	0.33	2361
	Foreign	9300	12781	0.30	3421

Jaguar		10768	19091	0.44	8323
Mercedes 300		13188	22662	0.42	9474
Porsche 944		5714	13136	0.56	7422
Ferrari		7679	19698	0.61	12018

Notes: The markup is $\frac{p^w - mc}{p^w}$, with p^w the wholesale price (p. 923). In Panel B it equals the last column divided by price, up to rounding. In Panel A it does not, presumably because the markup column averages model-level ratios. In four Panel A rows (foreign intermediate, both luxury rows and foreign pick-ups) the last column also differs from price minus cost, by between 9 and 270 dollars. We reproduce the printed values. Class names follow the numbering of Goldberg's Table A4. Source: Goldberg (1995), Table IV (p. 924).

Goldberg defends the level of the markups on three grounds (pp. 924–925). Data from the Annual Survey of Manufactures put labor and materials at about 85% of the value of shipments, consistent with the 15% figure. Part of payroll is fixed, however, and short-run marginal cost can be well below average cost when capacity is underused, as it was in the 1980s. Finally, Bresnahan and Reiss (1985) estimate a ratio of dealer to manufacturer markups of 0.71 and cannot reject 0.5. With dealer markups of 15% to 25% according to *Consumer Reports*, manufacturer margins between 22% and 50% follow.

Cost regressions find positive and significant effects of cylinders, horsepower and air conditioning (p. 925). The coefficients on QUOT1 to QUOT5, the average Lagrange multipliers, indicate that the quota bound throughout 1983–1987, with the strongest effects in the first three

years. Firm-specific multipliers, where identified, suggest that Toyota and Nissan were less constrained than average and Mazda more constrained in 1984 to 1986 (p. 926).

8.15.7 Specification tests*

Goldberg tests the tree against three alternatives that let domestic and foreign models compete at lower levels or reverse the order of the class and origin nodes (pp. 915–916). The first alternative omits the origin node. Its bottom-stage choice sets are broader, and it is tested by the Hausman-McFadden test of IIA (Hausman and McFadden, 1984). The model is estimated on the full choice set and on a random subset, and the statistic is

$$T = (\hat{\beta}_r - \hat{\beta}_u)^\top (\hat{V}_r - \hat{V}_u)^{-1} (\hat{\beta}_r - \hat{\beta}_u), \tag{8.148}$$

where u and r denote the unrestricted and restricted choice sets. Under IIA both estimators are consistent and the unrestricted one is efficient, so T is asymptotically χ^2. Without the origin node, IIA is rejected at the bottom for all three car groups (Table C1). The statistics are $\chi^2 = 49.82$ with 25 degrees of freedom for small cars, 66.75 with 26 for large cars and 126.74 with 20 for luxury cars. With the origin node, IIA is not rejected for small cars ($\chi^2 = 35.64$ with 25 degrees of freedom, $p = 0.077$) or luxury cars (8.63 with 20, $p = 0.986$) (Table C2). It is rejected at the 5% level for large cars, with $\chi^2 = 41.45$ (26 degrees of freedom, $p = 0.027$). That statistic is well below the value of 66.75 obtained without the origin node. Goldberg concludes that the origin node improves the specification, and that a finer classification might reduce the remaining violations (p. 916). This also rejects the second alternative, which omits the class node and has even broader choice sets. The third alternative reverses the class and origin nodes. Its inclusive-value coefficients above the bottom exceed one, for example 2.78 (standard error 0.086) at the origin node, so it is not globally consistent with utility maximization. McFadden (1984, pp. 1425–1426) notes that such estimates violate the ranking of cross elasticities implied by the tree and may signal a misspecified hierarchy. Goldberg's summary says that only the original tree is consistent with random utility maximization and free of IIA violations at each node (p. 916). Her Table C2 qualifies the second part. The original tree performs best among the trees considered, and its inclusive-value coefficients lie in the unit interval. IIA survives the test for small and luxury cars. For large cars it is still rejected at the 5% level.

The fit is mixed (pp. 916–920). Table 8.44 compares the population-weighted predictions with industry aggregates from the *Automotive News Market Data Book*. The model underpredicts total car sales in every year, for example 8,932,734 against 11,470,939 in 1986. It overpredicts the import share of cars, by as much as 35.1% against 23.4% in 1984 and 34.7% against 28.3% in 1986. Class shares are closer. In 1986 the predicted share of class 1 is 27.7% against 28.1%, and that of class 2 is 27.2% against 25.3%. Goldberg attributes the shortfall in sales to fleet sales, which the household survey omits (p. 917). From 1983 to 1987 about 7 million passenger cars were in fleets of ten or more vehicles. With a three-year turnover, this implies about 2.5 million fleet sales a year. Added to the predicted sales, this figure comes close to the actual totals (n. 45). Fleet sales consist mostly of domestic cars, which is consistent with the overprediction of import shares.

These gaps do not measure the fit of the estimation procedure. The model includes choice-specific dummies and time effects, so it predicts the unweighted CES sample shares at the higher nodes of the tree exactly (p. 918). Without the population weights, the predicted columns of Table 8.44 would coincide with the CES shares. The gaps therefore reflect the sampling of the CES and its omission of fleet buyers. For the same reason, Goldberg reads the close match of the class shares as evidence in favor of the sample itself (p. 917). She measures

Table 8.44: Predicted and actual aggregate sales and shares in Goldberg's model

	Predicted			Actual		
Year	Sales	Imports	% import	Sales	Imports	% import
Panel A. Passenger cars						
1983	8,219,423	2,383,633	29.0	9,181,530	2,386,064	25.9
1984	7,936,201	2,785,601	35.1	10,393,532	2,441,713	23.4
1985	9,298,155	2,436,117	26.2	11,046,243	2,839,226	25.7
1986	8,932,734	3,099,659	34.7	11,470,939	3,248,430	28.3
1987	9,938,719	3,627,632	36.5	10,225,304	3,144,042	31.0
Panel B. Trucks						
1983	2,004,378	348,762	17.4	3,129,000	471,000	15.0
1984	2,985,525	623,975	20.9	3,931,274	650,026	16.5
1985	3,672,620	569,256	15.5	4,517,668	805,822	17.8
1986	3,003,741	633,789	21.1	4,714,337	936,584	19.8
1987	3,633,452	832,060	22.9	4,962,938	870,041	17.5
Panel C. Car classes, 1986						
Class		Class share (%)	% import		Class share (%)	% import
1 (subcompact)		27.7	58.0		28.1	49.3
2 (compact)		27.2	40.3		25.3	41.1
3 (intermediate)		23.4	3.4		26.9	2.4
4 (standard)		9.3	0.0		8.7	0.0
5 (luxury)		9.0	28.3		10.8	30.9

Notes: Predicted values aggregate household choice probabilities with the CES population weights. Actual values are from the *Automotive News Market Data Book*. Goldberg reports class shares for 1986 only and says the other years are similar. Class names follow the numbering of her Table A4. Source: Goldberg (1995), Table I (p. 917).

fit by the gap between predicted and CES shares instead. At the bottom stage the model has brand dummies but no model dummies, so this gap is not zero by construction. Predicted shares of individual models deviate little from the CES shares, which she reads as evidence against serious simultaneity bias. Disaggregated χ^2 tests (Andrews, 1988) mostly reject the model unconditionally, but conditional tests at lower nodes do not. Out-of-sample predictions for 1989 and 1990 match segment and origin shares well and total new-car purchases poorly. Goldberg concludes that the weakness lies in the static treatment of the timing of purchases, while the composition of purchases, which matters for trade policy, is well predicted.

8.15.8 The voluntary export restraint

The policy experiments compare equilibria computed under alternative regimes, holding everything else fixed (pp. 926–927). Uniqueness of equilibrium is assumed, at least locally. The simulations concern only the new-car market and the price-setting stage, so they abstract from used-car prices, direct investment and product choices.

Whether the quota bound. The model is solved with and without the quota, and the multipliers ψ_t are computed as part of the equilibrium (p. 927). Table 8.45, Panel A, shows that the quota had a large effect in 1983 and 1984, lowering the Japanese import share from 0.314 to 0.271 and from 0.363 to 0.340. The effect was small in 1985, when Japan volunteered to extend the restraint, and again present in 1986 and 1987. Goldberg finds the 1987 result puzzling. She attributes it to treating models produced partly in the United States, such as the Accord and the Camry, as Japanese (p. 928, n. 60).

Table 8.45: Effects of the voluntary export restraint

Panel A. Import shares and Lagrange multipliers

Year	Import share, no quota	Import share, quota	Lagrange multiplier
1983	0.314	0.271	2155
1984	0.363	0.340	2018
1985	0.249	0.243	67
1986	0.339	0.328	402
1987	0.390	0.378	1961

Panel B. Equivalent tariffs

Year	Tariff on Japanese cars	General tariff on imports
1983	64%	65%
1984	62%	62%
1987	55%	57%

Panel C. Effects of the VER on sales (units, percent change in parentheses)

Year	Total	Passenger cars	American	Japanese	Other
1983	−33,478 (0.3%)	−90,899 (1.1%)	+209,990 (2.0%)	−340,321 (15.0%)	+39,432 (7.0%)
1984	−37,808 (0.3%)	−124,990 (1.6%)	+140,807 (1.5%)	−298,477 (9.4%)	+32,680 (6.4%)
1987	−29,991 (0.02%)	−106,632 (1.0%)	+57,510 (0.5%)	−185,843 (4.5%)	+21,702 (2.8%)

Notes: Panel A compares the Japanese import share in equilibria computed with and without the quota. Panel B gives the ad valorem tariffs that would limit Japanese passenger-car sales to the VER level. Panel C reports changes relative to free trade, with the percentage changes in absolute value as printed. Sources: Goldberg (1995), Tables V, VIII and VI.

Sales and prices. Goldberg analyzes 1983, 1984 and 1987, the years with the strongest effects

(pp. 928–929). The quota cut Japanese passenger-car sales by about 300,000 units a year in 1983 and 1984 (Table 8.45, Panel C). American producers captured on average only 54% of the lost Japanese sales. The figure matches the mean of the 1983 and 1984 ratios in Panel C, $\frac{209,990}{340,321} = 61.7\%$ and $\frac{140,807}{298,477} = 47.2\%$. The corresponding ratio for 1987 is 30.9%. Other imports, mainly European, rose by 18% on average, and total sales fell slightly[33] as some consumers switched to used cars. The households that switched to used cars were mostly in the lower income class and younger than 30. The small fall in total sales reflects the small inclusive-value coefficient at the new-versus-used node (p. 929, n. 62). Prices of Japanese passenger cars rose by about 14% a year in 1983 and 1984, while prices of domestic cars and other imports rose by 0.5% to 0.9%. The quota rents went to Japanese producers in the model, because dealer markups on Japanese cars are held fixed (n. 63).

Quality upgrading. Goldberg defines quality upgrading as a shift toward segments with more expensive cars (pp. 929–930). Table 8.46 reproduces her estimates for 1983. The quota lowered foreign subcompact sales by 18.0% and foreign compact sales by 15.3%, while foreign sales rose in the intermediate (7.5%), luxury (4.4%) and sports (7.6%) segments. Because Japanese firms dominate both small-car segments (p. 929), the larger fall in subcompacts raised the share of compacts in Japanese imports (p. 930). Foreign trucks, which the quota did not cover, rose most, by 10.1%. Domestic sales rose in every segment, by between 0.3% (vans) and 5.0% (trucks).

Table 8.46: Percent change in segment sales caused by the VER, 1983

Segment	Domestic	Foreign
Subcompact	1.9	−18.0
Compact	2.5	−15.3
Intermediate	4.2	7.5
Standard	3.3	n.a.
Luxury	3.0	4.4
Sports	4.2	7.6
Trucks	5.0	10.1
Vans	0.3	0.8
Other	3.1	4.0

Notes: Changes relative to the free-trade equilibrium. There are no foreign standard cars. Source: Goldberg (1995), Table VII (p. 930).

The share of higher-priced intermediate, standard and luxury cars rose for both American and foreign producers. The shift comes from demand. The households that leave the market are low-income buyers of small cars, and the quota changes relative prices across segments within each income group. Feenstra's hedonic studies, such as Feenstra (1988), found quality upgrading of Japanese imports by a different method.

Equivalent tariffs. The tariff that would limit Japanese sales to the VER level is between 55% and 65% (Table 8.45, Panel B). It is so high because pass-through of a tariff on Japanese cars is low. A 64% tariff raises Japanese import prices by only 22% (p. 931). A general tariff on all imports must be even higher. German pass-through is almost complete, so a general tariff raises German prices by 52% to 65% and removes the substitutes of buyers who prefer foreign cars. Under the 1983 general tariff imports would account for only 24% of sales, three points less than under the quota. Goldberg concludes that the VER had limited effects on domestic

[33]The 18% figure is Goldberg's statement on p. 929, and the paper does not say how it is computed. Panel C of Table 8.45 shows other imports rising by 7.0, 6.4 and 2.8 percent in the three years.

production and employment and large effects on prices, which probably benefited producers more than consumers (p. 932). As in competitive trade models, tariffs dominate quotas.

8.15.9 Exchange-rate pass-through

The 1980s saw large swings of the dollar that barely showed up in the dollar prices of imported cars (p. 933). Goldberg first isolates the static oligopoly mechanism. She holds characteristics at their 1983 values and simulates a 20% appreciation and depreciation of the dollar, with and without the quota. Table 8.47 reproduces the results.

Table 8.47: Percent change in dollar import prices after a 20% change in the value of the dollar

	Without quota		With quota	
	Dollar +20%	Dollar −20%	Dollar +20%	Dollar −20%
Japanese subcompact	−3.1	5.0	−0.3	0.2
Japanese compact	−3.6	6.0	−0.2	0.4
Japanese trucks	−3.9	4.9	−4.7	5.1
German intermediate	−14.0	24.2	−12.0	24.0
German luxury	−15.1	20.3	−11.2	22.2
German sports	−12.1	16.1	−12.0	21.3

Notes: Simulated changes in dollar prices, holding vehicle characteristics at 1983 values. A dollar appreciation (+20%) lowers dollar import prices. Source: Goldberg (1995), Table IX.

Three features stand out (p. 933). Pass-through is asymmetric, larger when the dollar depreciates and import prices rise. Pass-through for Japanese cars is small, between 15% and 30%, while German pass-through is about 65% for an appreciation and between 95% and 102% for a depreciation.[34] With the quota, Japanese car prices barely respond to exchange rates, while Japanese trucks, which the quota does not cover, still do. Firms in the model maximize profits myopically and have the same strategic behavior. The differences therefore come from the demand elasticities of the segments in which they sell (p. 934). The model implies that the elasticity of demand for Japanese imports rises with price at a decreasing rate, which dampens pass-through. For German cars the elasticity has an inverse U-shape around the equilibrium. It falls when prices fall, and it is fairly constant, or in some cases falling, when prices rise (p. 934). German producers sell mainly luxury cars, while Japanese producers dominate small cars. Small German cars such as the Volkswagen show the same pass-through as Japanese cars in the same segment.

Goldberg then lets quotas, exchange rates and quality upgrading interact over 1983–1987 (pp. 934–937). The model tracks the prices of domestic and Japanese cars, and of German cars in the first two years when the dollar was strong. After 1985 it predicts a large rise in German prices following the dollar's depreciation, while actual German prices stayed roughly constant. She concludes that pass-through cannot be studied without accounting for trade restrictions and quality change, and that the static model fails when the dollar depreciates. A likely reason is demand dynamics. Past purchases affect current choices, so producers facing a temporary depreciation have reasons not to raise prices fully.

[34] These coefficients are Goldberg's statements in the text (p. 933). The paper does not give the formula behind them, and they cannot all be recovered from Table 8.47. Dividing the German entries for a dollar depreciation without the quota by 20, for example, gives 81 to 121 percent.

8.15.10 Assessment

Goldberg's paper and BLP (1995) represent two solutions to the same problem. Both aggregate a discrete choice model to market demand, impose multi-product Bertrand-Nash pricing and recover marginal costs from first-order conditions. They differ in the source of identification. Goldberg uses household data, a nested logit with interactions between household and vehicle attributes, and fixed effects for segment, origin and brand. She treats prices as exogenous at the household level. BLP use aggregate data, random coefficients and instruments for price that are justified by an explicit product-level unobservable. The nested logit's correlation structure is imposed a priori, and the tests of IIA and of the inclusive-value bounds are used to choose among trees. In the random coefficients model, the correlation comes from estimated taste dispersion over characteristics.

Later work clarified the trade-off. BLP (2004) show that household attributes alone do not reproduce the tight substitution patterns revealed by second choices, and that unobserved dispersion in tastes is needed (Section 8.14.5). That is the element Goldberg's model lacks by her own description (p. 899, n. 17). The micro data identify interactions without assumptions on ξ, but the level of the price coefficient still requires an assumption about product-level unobservables (Section 8.14.3). The inclusive-value estimates near zero at the top of the tree make total new-car demand almost unresponsive to prices, so the outside good does little work in Goldberg's simulations. Her own tests point to the static treatment of purchase timing as the model's main weakness.

The paper's contribution is to show that a structural oligopoly model estimated from micro data can answer quantitative trade-policy questions. Its findings on the VER remain reference points. They are the limited gains for domestic producers, large price increases, quality upgrading and the superiority of tariffs. Its explanation of pass-through by the demand elasticities of each segment is a reference point as well. Berry et al. (1999) revisit the VER with the random coefficients model, and Goldberg and Verboven (2001) apply a related nested logit framework to price dispersion in the European car market. Nevo (2000a, p. 544) cites the paper as an example of consumer-level estimation by maximum likelihood, and Nevo (2000a, p. 524, n. 17) as an example of multiple levels of nesting.

8.16 Bibliographic notes

Random coefficients discrete choice models have roots in transportation economics. Boyd and Mellman (1980) and Cardell and Dunbar (1980) estimated mixed logit models of automobile demand. Hausman and Wise (1978) proposed the multinomial probit with correlated errors as a way around the independence of irrelevant alternatives. McFadden (1974, 1978, 1981) developed the conditional logit and the generalized extreme value family. McFadden (1984) surveys these models, including the multilevel nested logit and its sequential estimation, which Goldberg (1995) applies to automobile demand. Cardell (1997) showed how the nested logit arises from random coefficients on group dummies. McFadden and Train (2000) proved that mixed logits can approximate any random utility model. Train (2009) gives a textbook treatment of mixed logit and of simulation methods.

The methods that made the model estimable with market data came in a few steps. Pakes (1986) introduced aggregation by simulation, and Pakes and Pollard (1989) supplied the asymptotic theory of simulation estimators. Berry (1994) showed how to invert market shares and treat unobserved quality as a structural error. Berry et al. (1995) combined these ideas with a contraction mapping, characteristic-based instruments and a supply side, and Berry

Table 8.48: Identification and counterfactual map of Goldberg (1995)

Observed data	Consumer Expenditure Survey households, 1983–1987, with their vehicle purchases, demographics and transaction prices. About 200 models a year with list prices, sales and characteristics. Exchange rates and the quota levels.
Latent objects	Household taste shocks, model quality beyond the segment, origin and brand effects, marginal costs, and the shadow price ψ_t of the quota.
Estimated parameters	Coefficients and dissimilarity parameters of a five-level nested logit (buying, newness, segment, origin and model). Marginal-cost coefficients and yearly quota multipliers.
Identifying variation	Household-level differences in prices and attributes, within segment, origin and brand fixed effects. The quota multipliers are identified because Japanese firms also sell trucks and vans outside the quota.
Maintained assumptions	Prices are uncorrelated with household errors. Static multiproduct Bertrand-Nash pricing with constant marginal cost, a common quota multiplier across Japanese firms, no spillovers of rationed demand, and a unique equilibrium.
Counterfactual and what it holds fixed	Equilibria with and without the VER, equivalent tariffs, and a 20 percent rise or fall of the dollar. They hold characteristics, the product set and used-car prices fixed, and the pass-through runs at 1983 characteristics.
Conclusion	The VER lowered the Japanese import share in 1983 and 1984 and raised prices, with limited gains for domestic production. Tariffs dominate the quota. Low Japanese pass-through reflects the demand elasticities of the segments where Japanese firms sell.
One limitation	Price exogeneity rests on the fixed effects. Model-level quality correlated with price would bias the price coefficient toward zero.
Source and our additions	The tables are Goldberg's. Proposition 8.46 and Lemma 8.47 are derived in this book.
Tools in the appendices	Sections A.6 and B.5.

et al. (2004b) derived limit theorems as the number of products grows. Nevo (2000a) wrote the standard exposition, and Nevo (2001) showed how to use brand fixed effects, prices in other markets as instruments, and the empirical distribution of demographics. Berry et al. (2004a) and Petrin (2002) showed how micro data and micro moments sharpen the estimates.

A large literature studies computation. Dubé et al. (2012) examined the inner-loop tolerance and proposed the MPEC formulation of Su and Judd (2012). Knittel and Metaxoglou (2014) documented the sensitivity of estimates to optimizers and starting values. Skrainka and Judd (2011) and Heiss and Winschel (2008) studied quadrature rules, and Reynaerts et al. (2012) studied accelerated fixed point methods. Reynaert and Verboven (2014) showed the gains from approximate optimal instruments, and Conlon and Gortmaker (2020) collected best practices in the `pyblp` software. Lee and Seo (2015) and Salanié and Wolak (2019) proposed approximate estimators.

The identification of the model is now well understood. Berry et al. (2013) gave general conditions for the invertibility of demand. Berry and Haile (2014) showed that market-level data identify demand and marginal costs nonparametrically given suitable instruments, and Berry and Haile (2024) showed that micro data halve the instrument requirements. Berry and Haile (2021) survey this work. Armstrong (2016) showed that characteristic-based instruments can lose power in large markets, and Gandhi and Houde (2019) proposed differentiation instruments.

The model has been extended in many directions. Berry and Pakes (2007) drop the idiosyncratic shock in the pure characteristics model, and Bajari and Benkard (2005) develop a hedonic alternative. Grigolon and Verboven (2014) combine random coefficients with nested logit errors. Applications include mergers (Nevo, 2000b), trade policy (Goldberg, 1995; Berry et al., 1999), airline hubs (Berry et al., 2006), new goods (Petrin, 2002), tests of conduct (Backus et al., 2021a) and the long-run evolution of markups in the automobile industry (Grieco et al., 2024). Chapters 9 to 11 take up several of these applications.

8.17 Exercises

1. Use the linear random coefficients model of Section 8.1.2.

   (a) Proposition 8.4 covers the specification (8.15) of Berry et al. (1995) through $\alpha_{ij} = \frac{\alpha}{y_i - p_j}$. Write $\frac{\partial s_j}{\partial p_j}$ for this specification as an integral over income and the taste draws. Explain why an expensive car can have a lower own elasticity than a cheap car although every consumer has the same α.

   (b) Show that the formulas reduce to the logit derivatives when $\Pi = 0$ and $\Sigma = 0$.

   (c) Prove that the diversion ratios D_{jk}, $k \neq j$, sum to one when the outside good is included.

   (d) In the two-type market of Example 8.9, compute the diversion ratios D_{10} and D_{20} from the type-level probabilities in Table 8.1. Explain in words why random coefficients raise the outside diversion of the cheap good and lower that of the expensive good.

2. Consider two consumer types with equal population shares, price coefficients $\alpha_H > \alpha_L > 0$, two inside goods with prices $p_1 < p_2$, quality indices $q_1 < q_2$, and utilities $V_{rj} = q_j - \alpha_r p_j$.

   (a) Write the aggregate shares and the own-price elasticities ε_1 and ε_2 in closed form.

(b) Keep $\alpha_H = 4$ and the goods of Example 8.9, and let α_L rise from 1 toward 4. Compute ε_1 and ε_2 on a grid of values of α_L. At what value does the ranking of the two own elasticities reverse?

(c) Compute the single-product markups $\frac{p_j}{\varepsilon_j}$ along the same grid. Explain why the markup of the expensive good falls as the two types become more alike.

3. This exercise concerns the contraction of Section 8.4.

(a) Prove the row-sum formula (8.52) starting from the identity $\sum_k \frac{\partial s_{ij}}{\partial \delta_k} = s_{ij} s_{i0}$.

(b) Consider one inside good and two consumer types with equal weights and random utility terms $\mu_i \in \{-c, c\}$. Write the derivative of the map Φ at the solution as a function of δ and c. Show that it tends to one as $\delta \to \infty$, that is, as the outside share tends to zero.

(c) Use the bound $h \geq \frac{m \ln 10}{-\ln \kappa}$ of Section 8.4.3, with κ a uniform modulus on the path of the iterates, to compute how many iterations are needed to reduce the initial error by a factor of 10^{-12} when $\kappa = 0.5$, 0.9 and 0.99. Explain why the derivative from part (b) gives this count only near the solution.

(d) Explain how a warm start from the previous outer iteration and the SQUAREM extrapolation change these counts in practice.

4. Let $\delta(\theta_2)$ be the inverted mean utilities, $\boldsymbol{X}$ the matrix of linear regressors, $\boldsymbol{Z}$ the instruments and W a positive definite weighting matrix.

(a) Show that the matrix $\boldsymbol{M}$ of Proposition 8.20 satisfies $\boldsymbol{M}\boldsymbol{X} = 0$ and $\boldsymbol{M}^2 = \boldsymbol{M}$. Show also that $\boldsymbol{X}^\top \boldsymbol{Z} W \boldsymbol{Z}^\top \boldsymbol{M} = 0$, and interpret this identity as the first-order condition for θ_1.

(b) Show that in the logit model with $W = (\frac{1}{N}\boldsymbol{Z}^\top \boldsymbol{Z})^{-1}$ the estimator is two-stage least squares. Extend the argument to the nested logit.

(c) Derive $\frac{\partial \delta_t}{\partial \sigma_k}$ by the implicit function theorem for a model with a single random coefficient on one characteristic. Explain why the derivative is zero at $\sigma_k = 0$ when ν_i is symmetric (Proposition 8.41).

(d) Explain why the gradient of the profiled objective does not involve $\frac{\partial \hat{\theta}_1}{\partial \theta_2}$.

5. Suppose the individual purchase probability of a product equals 0.001 for 90 percent of consumers and 0.091 for the other 10 percent.

(a) Compute the market share s_j, the variance of s_{ij} and the coefficient of variation c_j of Proposition 8.13.

(b) Use the second-order approximation to compute the bias of the simulated log share with $n_s = 20$, 100 and 1,000 draws.

(c) Prove that $\mathbb{E}[\ln s_j^{n_s}] < \ln s_j$ for any nondegenerate distribution of s_{ij}.

(d) Explain the direction of the resulting error in the inverted mean utility, and why it does not average out as the number of markets grows.

6. A researcher has panel data on J brands in T markets with fixed characteristics and the same choice set in every market. Utility has K characteristics, a random coefficient on L of them and on price, and brand fixed effects.

(a) Count the minimum number of excluded instruments that the estimator needs.

(b) Show that the BLP instruments (8.64) are collinear with the brand dummies in this design.

(c) Use Proposition 8.24 to explain which functions of the other products' characteristics shift the constructed regressor that multiplies σ^2. Propose a differentiation instrument and state the assumption under which it is valid.

(d) Explain why prices of the same brand in other markets can serve as instruments here, and give one economic shock that would invalidate them.

7. Three products have logit demand with $\alpha = 2$ and shares $s = (0.10, 0.10, 0.20)$. Firm A owns products 1 and 2 and firm B owns product 3.

(a) Hold the shares at these values, as Nevo (2001) does when he computes implied margins. Use Proposition 8.37 to compute the dollar markups of all three products under single-product pricing, current ownership and joint ownership of all three products.

(b) Verify that the markups are ordered as Proposition 8.44 predicts.

(c) Show that, in the logit, the ratio of the joint-ownership markup to the single-product markup of product j is $\frac{1-s_j}{1-S}$, where S is the combined share of the three products. Explain why this ratio is close to one when the outside good is large.

(d) Use the answer to explain why the logit cannot detect collusion in the cereal data of Nevo (2001) (Table 8.28), while the random coefficients model can.

8. This exercise interprets the substitution results of Berry et al. (1995) and Berry et al. (2004a).

(a) Show that the logit diversion to the outside good is $\frac{s_0}{1-s_j}$. Use the logit column of Table 8.15 to bound the outside share in 1990.

(b) Use Corollary 8.6 to explain why random coefficients lower the outside diversion most for luxury cars.

(c) In the two-type market of Example 8.9, apply Lemma 8.39 type by type. Compute the probability that a buyer of good 1 names good 2 as her second choice, using the probabilities in Table 8.1. Compare it with the logit value $\frac{s_2}{1-s_1}$ and explain the difference.

(d) Explain which parameters the first-choice moments, the second-choice moments and the market shares identify. Why does none of them pin down the level of the price elasticities in a single cross section?

(e) In the nested logit of Goldberg (1995), the inclusive-value coefficient at the buy node is set to zero. Use Proposition 8.46 and Lemma 8.47 to show that a uniform rise in all new-car prices then changes the probability of buying a new car only through the new-versus-used inclusive value. Explain why the coefficient of 0.011 at that node (Table 8.40) makes total new-car sales almost insensitive to such a rise. Contrast this with the diversion to the outside good in the random coefficients model.

Chapter 9

Airlines: Hubs, Entry, and Market Power

9.1 Introduction

In 1985 an executive vice-president of USAir wrote an internal memo to the carrier's president and chief executive about its strategy in the northeastern United States. He argued that the carrier should control a major portion of the traffic at each city in the region. Such control, he wrote, "enables us to keep control of prices within our niche territory." The memo became an exhibit in the merger case of USAir and Piedmont in 1987, and Borenstein (1989, p. 344) opens his study of airline pricing with it.

The memo states the question of this chapter in the words of a practitioner. Do hubs, and the dominance of airports that comes with them, raise fares? If they do, is the fare premium market power? It might instead reflect lower costs, better service, or the scarcity of airport capacity. The answer matters for the evaluation of airline mergers and for the allocation of gates and slots. It also tests our understanding of how market structure shapes prices.

Airlines are a laboratory for industrial organization for four reasons. First, the deregulation of 1978 changed the rules of an entire industry at once. The years that followed show entry, exit and network design responding to new incentives. Second, a sharp theory was available. The theory of contestable markets predicted that the threat of entry would discipline fares even on routes served by a single carrier. Third, the data are unusually rich. The Department of Transportation compiles a 10% random sample of tickets, with fares, itineraries and carriers. Fourth, costs have a network structure. The cost of carrying a passenger depends on the traffic on each flight leg, which links markets across the network.

This chapter studies three papers that examine the same industry with the same public data source but with different methods. Borenstein (1989) regresses fares on measures of route and airport dominance, a reduced-form approach. Whinston and Collins (1992) measure how the stock market values of incumbent carriers respond when a low-fare carrier announces entry into their routes, an event study. Berry et al. (2006) estimate a structural model with two types of travelers, network costs and Nash pricing.[1] Comparing the three is the payoff of the chapter, because each identifies something that the others cannot. The pricing regressions measure how

[1]Their chapter was published in 2006. The text available to us is the earlier working paper (Berry et al., 1996), NBER Working Paper 5561, dated May 1996 with the running header "March 1996." Throughout the chapter, page, table, figure and footnote numbers for this study refer to the working paper. The published chapter may number them differently and may differ in detail.

fares move with dominance across thousands of routes. The event study bounds route-specific rents without a model of demand or costs. The structural model separates markups from costs and shows who pays the hub premium.

The chapter proceeds as follows. Section 9.2 describes the industry after deregulation, the data, and the devices that favor a carrier at an airport it dominates. Section 9.3 develops the theory of contestable markets, shows when its equilibrium fails to exist and why it is fragile, and states its testable predictions. It also shows what an incumbent's loss of value at an entry announcement reveals. Section 9.4 builds the pricing theory that the case studies use, from a conduct model that interprets fare regressions to a finite-mixture nested logit with network costs. Sections 9.5 to 9.7 study the three papers in depth, each in the same order: question, setting, data, model and estimating equations, identification, results, interpretation, critiques and contribution. Section 9.8 compares the three designs, assembles the evidence on the sources of hub premia and applies it to merger policy.

The chapter draws on much of the book. The structure-conduct-performance regressions and the efficiency critique of Demsetz (1973) come from Chapter 1 (Section 1.5.1). Cournot theory and free entry come from Chapter 2, and conduct parameters from Chapter 3. The demand models extend those of Chapters 7 and 8. The event-study and difference-in-differences methods are reviewed in Sections A.12 and A.13, and instrumental variables in Section A.3. The policy questions lead forward to the analysis of mergers in Chapter 11.

9.2 The U.S. airline industry after deregulation

The three studies at the center of this chapter use data on the U.S. airline industry between 1984 and 1987. That period followed the end of federal economic regulation of the industry. This section describes the institutions that a reader needs in order to interpret their regressions. We first explain how regulation worked and why economists argued for its removal. We then describe the changes that followed deregulation, the way the data define markets and products, and the devices that give a carrier an advantage at airports where it is large.

9.2.1 Regulation and the case for deregulation

Until 1978 a federal agency, the *Civil Aeronautics Board* (CAB), regulated interstate passenger air travel in the United States. The agency decided which carriers could serve which routes, whether a carrier could leave a route, and which fares it could charge. Berry et al. (2006, p. 1, n. 1) summarize the change in one sentence. Deregulation "removed restrictions on entry and exit and gave carriers the freedom to set fares." A carrier that wished to serve a new interstate route needed the agency's approval.

When the price is fixed above cost and entry is closed, rivalry moves to the dimensions that the regulator does not control. Flight frequency is the most important of them. A traveler values a schedule with many departures because it shortens the wait between the time she wants to leave and the next flight. Economists call this waiting cost *frequency delay*, a concept that Douglas and Miller (1974) defined and investigated (Borenstein, 1989, p. 350). Suppose every carrier on a route must charge the regulated fare $\bar{p}$, and a flight with S seats costs c_F to operate. At load factor LF, the share of seats filled, the cost per passenger is

$$\frac{c_F}{LF \cdot S}. \tag{9.1}$$

An extra flight attracts some new travelers and takes others from rival carriers. The carrier that adds the flight counts all the passengers it gains at the fare $\bar{p}$ and ignores the rivals' losses. Each carrier therefore adds flights beyond the number that maximizes the carriers' joint profit, and load factors fall. The margin between $\bar{p}$ and (9.1) shrinks as flights are added. Travelers recover part of it as shorter frequency delay, and the rest is spent on flying partly empty planes. The same business-stealing logic produces excess entry in the model of Mankiw and Whinston (1986) (Section 2.5).

Two empirical studies made the case that regulation raised fares. Levine (1965) compared fares on intrastate routes in California, which the CAB did not regulate, with fares on regulated interstate routes. The unregulated intrastate fares were much lower. Keeler (1972) estimated the costs of efficient carriers and found regulated fares far above them. Both studies shaped the policy debate, and Section 1.6.1 places them in the history of empirical industrial organization.

Economists also argued that deregulated airline markets would discipline themselves even when only one or two carriers served a route. An aircraft can fly a different route tomorrow at little cost, so most of an airline's capital is mobile across city pairs. Aircraft are often called "capital on wings" for this reason. If a carrier can enter a route, undercut the incumbent and leave without loss, the threat of entry alone keeps fares close to cost. This is the theory of contestable markets of Baumol et al. (1982), which Section 9.3 develops. Congress passed the Airline Deregulation Act in 1978 (Whinston and Collins, 1992, p. 445).

9.2.2 Deregulation, entry, and the rise of hubs

Whinston and Collins (1992, p. 445) summarize the first decade of deregulation. The Act, they write, "led to the entry of a large number of new carriers" and to "a dramatic change in existing carriers' route and fare structures." It also brought "a notable increase in the use of air transportation services." Three developments matter for this chapter. They are low-fare entry, the reorganization of networks around hubs, and a wave of mergers.

The emblematic new entrant was *People Express*, a low-fare carrier that operated mainly out of Newark airport in the New York area. Industry observers saw it as the embodiment of the innovations that deregulation made possible (Whinston and Collins, 1992, pp. 446–447). On the demand side, it introduced "low-frill" air travel. On the cost side, it used new operating procedures and paid lower labor costs than the formerly regulated carriers (their n. 3). Whinston and Collins add two caveats. Incumbents could perhaps have copied the procedures, and part of the labor-cost gap may reflect the quality or experience of the work force. In 1984 and 1985 People Express entered 24 new domestic nonstop markets in which takeoff and landing rights were not rationed, and 22 of them involved Newark (pp. 446, 450). Section 9.6 uses these entry events to test the theory of Section 9.3.

The largest change in the established carriers' operations was the move from point-to-point networks to hub-and-spoke networks. Berry et al. (2006, p. 1) call it "the almost complete shift in network organization." In a *point-to-point* network a carrier flies passengers nonstop between the cities they wish to travel between. In a *hub-and-spoke* network a carrier routes most passengers through one or a few *hub* airports, where they change planes. A *segment*, or *leg*, is a nonstop flight between two airports, and a *spoke* is a segment between a hub and another city. A passenger whose trip starts and ends at the two endpoints of a segment is a *local*, or *origin and destination* (O&D), passenger of that city pair. A passenger who changes planes at the hub is a *connecting* passenger there. A *through* passenger stays on board while the plane stops at an intermediate airport. Only local passengers count as passengers of the city-pair market defined by a segment's endpoints (Borenstein, 1989, p. 349, n. 21).

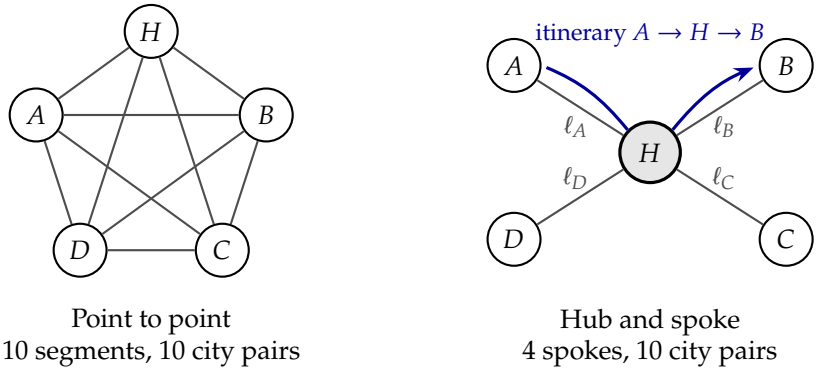
A short count shows why hubs economize on segments. Consider n outer cities and one hub city, $n + 1$ cities in all. The number of city pairs is

$$\binom{n+1}{2} = \frac{(n+1)n}{2}. \tag{9.2}$$

Nonstop service in every pair needs one segment per pair, so it needs $\frac{(n+1)n}{2}$ segments. A hub-and-spoke network needs only the n spokes. It serves the n hub markets nonstop and the remaining

$$\frac{(n+1)n}{2} - n = \frac{n(n-1)}{2}$$

city pairs with one change of plane at the hub. Each spoke carries its own hub market plus the $n - 1$ connecting markets that start or end at its outer city. Traffic from n city pairs therefore shares every spoke. Figure 9.1 draws the case $n = 4$. With $n = 30$ outer cities, 30 spokes serve 465 city pairs. This concentration of traffic on few segments lowers costs when the cost per passenger falls with the traffic on a segment (Example 9.41). The price of the concentration is a longer trip with a connection for most passengers.



Point to point
10 segments, 10 city pairs

Hub and spoke
4 spokes, 10 city pairs

Figure 9.1: Point-to-point and hub-and-spoke networks on the same five cities. Nonstop service in every city pair needs a segment for each of the $\binom{5}{2} = 10$ pairs. A hub H serves all $\frac{(n+1)n}{2} = 10$ pairs with $n = 4$ spokes $\ell_A, \ldots, \ell_D$. The four hub markets are served nonstop and the six other pairs with one connection, such as the itinerary $A \to H \to B$, which uses spokes ℓ_A and ℓ_B. Each spoke carries the traffic of $n = 4$ city pairs.

Observers disagree about what hubs do. One view holds that hub-and-spoke networks raise entry barriers and drive up fares for passengers whose trips begin at a hub (Borenstein, 1989, 1991). Critics also point to the extra connections and to congestion at hubs, where planes land and depart in bunches (Berry et al., 2006, p. 1, n. 2). A second view, held also by some airline executives, is that hubs reduce costs (Caves et al., 1984; Brueckner et al., 1992; Brueckner and Spiller, 1994). The success of carriers without hubs challenges the cost view. Berry et al. (2006, p. 1, n. 4) note that Southwest Airlines, which flies point to point, had been the only consistently profitable carrier since deregulation. The two views are not mutually exclusive, as Berry (1990) stressed. Hubs may raise markups over marginal cost and lower marginal cost at the same time. Separating the two effects is the aim of Berry et al. (2006), whom we study in Section 9.7.

Deregulation moved concentration in opposite directions at two levels of aggregation. Concentration within city-pair markets fell, and concentration at airports rose (Berry et al., 2006, pp. 3, 27), who cite Brueckner and Spiller (1994) for the airport facts. Berry et al. suggest,

without testing it, that hubs may explain both trends. Hubs give price and cost advantages that ease a carrier's entry into new city pairs out of the hub. A dominant hub carrier also draws business travelers away from its rivals at the hub, which leads them to cut service there (p. 27). A carrier can therefore face more rivals on its average route while it controls most of the departures at its hubs. Section 9.2.4 explains why dominance of an airport may raise fares even where route concentration does not.

In 1986 and 1987 a wave of mergers consolidated the industry. Carriers with modest national market shares proposed mergers that "led to substantial regional and route-specific increases in concentration" (Whinston and Collins, 1992, p. 446). The Department of Transportation reviewed the mergers of Texas Air and Eastern (1986), TWA and Ozark (1986), and USAir and Piedmont (1987) (Borenstein, 1989, p. 347, n. 14). The debates in these cases raised the questions of this chapter. Does the structure of a single route matter when each carrier operates a national network? Can the threat of entry discipline a carrier that dominates a route? Whinston and Collins (1992, p. 450) chose to study 1984 and 1985 partly because those years precede the merger wave.

9.2.3 Markets, products, and data

Empirical work on airlines defines a market as a directional trip from an origin to a destination. We index such markets by t, as elsewhere in the book, and call the origin and the destination the two *endpoints* $e \in \{1, 2\}$ of the market. Borenstein (1989, p. 362) and Whinston and Collins (1992) take the endpoints to be airports, so a market is an *airport pair*. Berry et al. (2006, p. 7) take them to be cities, so that New York's three airports (Newark, La Guardia and Kennedy) form one origin. In both cases direction matters. New York to Los Angeles is a different market from Los Angeles to New York. Directional markets let characteristics of the origin, such as whether it is the carrier's hub, shift demand. The choice between airport pairs and city pairs is substantive. It depends on whether flights from different airports in one city compete, a question we return to in Section 9.2.4.

Within a market, carriers sell many products. Berry et al. (2006, p. 7) define a *product* j as a unique combination of carrier, itinerary and fare. Three products in the New York to Los Angeles market might be a direct United flight at $399, a direct United flight at $299, and a United flight through Chicago at $299. Products with the same carrier and itinerary coexist at different fares because the tickets carry different restrictions. Typical restrictions are advance-purchase requirements, Saturday-night stay requirements and limits on the number of seats sold at a fare. The ticket data do not record them. This is one reason the demand models of Section 9.4 include an unobserved product characteristic ξ_{jt}. We write $\mathcal{J}_t$ for the set of products in market t, f for carriers, and q_{jt} for the number of passengers who buy product j in market t.

Itineraries differ in how they reach the destination. A *nonstop* itinerary uses one segment with no intermediate stop. A *direct* itinerary uses one plane but may stop on the way. A *connecting* itinerary requires a change of plane. Let ℓ index carrier segments, that is, nonstop flights between two airports operated by one carrier, and let $\mathcal{L}(j)$ be the set of segments in the itinerary of product j. The *density* of segment ℓ is the number of passengers on all itineraries that use it:

$$Q_\ell = \sum_t \sum_{j \in \mathcal{J}_t : \ell \in \mathcal{L}(j)} q_{jt}. \tag{9.3}$$

The outer sum runs over all markets. United's New York to Chicago spoke, for example, carries passengers to many destinations beyond Chicago (Berry et al., 2006, p. 8). Density links markets.

A change in the demand for one product changes the density, and possibly the cost, of every segment the product uses.

The data report several operating measures. An *enplanement* is one passenger boarding a plane at an airport, so enplanements count connecting passengers at every airport where they board. An *origination* is a passenger who begins a trip at the airport. A *seat-mile* is one seat flown one mile. A carrier's *available seat-miles* on a segment, ASM_ℓ, are the seats it offers times the segment's distance, summed over flights. Its *revenue passenger-miles*, RPM_ℓ, are the passengers it carries times the distance. The *load factor* of the segment is the share of seats filled,

$$LF_\ell = \frac{RPM_\ell}{ASM_\ell}. \tag{9.4}$$

Let d_t be the nonstop distance between the endpoints of market t. The *yield* of product j is its fare per mile, $\frac{p_{jt}}{d_t}$. The *circuity* of an itinerary is its total routing mileage divided by d_t, so a nonstop trip has circuity one. *Frequency* is the number of flights per period on a segment. A *slot* is the right to take off or land at an airport during a given time period. A *gate* is a physical facility, the building space and jetway through which passengers board (Borenstein, 1989, p. 347).

The empirical papers combine five sources.

- The *Origin and Destination Survey Databank 1A* (DB1A) of the U.S. Department of Transportation (DOT) is a random 10% sample of tickets, compiled quarterly. Each record gives the carrier, the itinerary and its direction, the dollar fare and the distance (Borenstein, 1989, p. 362). It also gives the number of sampled passengers who paid that fare in the quarter (Berry et al., 2006, p. 19). It is the source of fares and of passenger counts by market.

- The *Service Segment Data* are a census of the flights operated by the largest carriers of the regulated era. They count the passengers on board each flight, so they measure segment traffic more accurately than the 10% ticket sample (Borenstein, 1989, p. 363). Berry et al. (2006, p. 19) use the Service Segment Databank DB27R, which reports each carrier's total monthly traffic on every nonstop segment it serves. These data give densities, load factors, aircraft sizes and frequencies.

- The *Nonstop Market Data* are a similar census that covers all carriers. Borenstein (1989, p. 363) takes each carrier's enplanements at each airport from them.

- The *Official Airline Guide*, published every two weeks, lists every scheduled flight between two airports with its carrier and aircraft type. Whinston and Collins (1992, p. 450) convert its flight counts into the seats each incumbent offered when an entry announcement was made.

- Daily stock returns from the *Center for Research in Security Prices* (CRSP) supply the financial data for the event study of Section 9.6 (Whinston and Collins, 1992, p. 451).

Turning ticket records into market data requires conventions. Borenstein (1989, p. 362) splits each round-trip ticket into two directional trips and assigns each trip half of the round-trip fare. A one-way ticket is a single directional trip. The data vendor had already removed *open-jaw trips*, whose return starts or ends at a different city from the outbound trip, and *circle trips*, which visit several cities before returning. It had also removed tickets with more than one change of plane in either direction. Borenstein further drops tickets with a first-class segment and tickets that use more than one carrier on a directional trip, called *interline* tickets. He also

drops tickets that touch an airport outside the 200 largest U.S. airports, and fares below $10, which he presumes to be keypunch errors or frequent-flyer award trips. Berry et al. (2006, p. 19) keep only round-trip itineraries. They drop itineraries chosen by a single sampled passenger and very low and very high fares, all as likely coding errors.

Fares vary widely within a market, even for one carrier and one itinerary. In about half of the markets with more than one product, Berry et al. (2006, p. 19) find that fares lie within 20% of the market's mean fare. In 10% of these markets fares vary by more than 50% from the mean. Because of this dispersion, Borenstein (1989) studies three points of each carrier's fare distribution on a route: the 20th, 50th and 80th percentiles of the passenger-weighted distribution. He prefers the median to the mean because it is less sensitive to reporting errors (p. 348, n. 19). In his sample the mean 80th-percentile fare is $187, against $100 for the 20th percentile (his Table 4).

Berry et al. (2006, pp. 10–11, n. 10) report a fat upper tail in the distribution of fares per mile across tickets. Such a tail is inconsistent with a normal distribution. They suggest that the distribution may be a bimodal mixture and fit a mixture of two normal distributions to it. The fitted mixture puts weight 0.5987 on a component with mean 0.2375 and weight 0.4013 on a component with mean 0.5946. The means are in dollars per mile, the unit of the fare-per-mile row of their Table 6. The footnote writes the fit as $0.5987\,N(0.2375, 0.0781) + (1 - 0.5987)\,N(0.5946, 0.2752)$. It does not say whether the second argument of N is a standard deviation or a variance. Read as standard deviations, the fitted density has a shallow second mode near 0.59. Read as variances, it has a single mode. The mixture's adjusted R^2 is 0.999, against 0.972 for a single normal distribution. A population with two groups of travelers, one sensitive to price and one much less so, would generate this pattern. Section 9.4 builds the idea into a demand model with two consumer types.

9.2.4 Sources of airport dominance

A carrier that handles most of the passengers at an airport may enjoy an advantage on every route that touches the airport. Airline managers have said so openly, and they value dominance for the insulation from competition it may give (Borenstein, 1989, p. 345). The advantage can work in two ways. It can deter entry into the dominant carrier's routes, and it can weaken the rivals that do enter. A device that does the second also tends to do the first. Borenstein (1989, p. 345) separates advantages that arise naturally from those that airline institutions create. The main natural advantage is reputation. A carrier that offers most of the flights from a city becomes the carrier that local travelers know best. The institutional advantages are frequent-flyer programs, bonus programs for travel agents, computer reservation systems, and control of airport facilities. For each device we describe the mechanism and explain why it favors the carrier with the most flights at an airport.

A *frequent-flyer program* (FFP) gives a traveler a gift, usually free travel, after she has flown a given amount on the carrier. Carriers first offered such programs in 1980 (Borenstein, 1989, p. 346). Two features make FFPs effective tools of loyalty. The reward schedule is nonlinear, since the marginal bonus rises with the miles already accumulated. And the traveler often does not pay for her ticket, since her employer does. The first feature ties a traveler to a single program.

Lemma 9.1 (Nonlinear rewards concentrate purchases)**.** *Let $R : [0, \infty) \to \mathbb{R}$ be convex with $R(0) = 0$. Then $R(x) + R(y) \le R(x + y)$ for all $x, y \ge 0$. A traveler who flies M miles and divides them between two programs with the same reward schedule R therefore earns the largest total reward by*

putting all M miles in one program.

Proof. If $x + y = 0$ there is nothing to prove. Otherwise let $w = \frac{x}{x+y} \in [0, 1]$. Convexity and $R(0) = 0$ give

$$R(x) = R\big(w\,(x + y) + (1 - w) \cdot 0\big) \le w\,R(x + y) + (1 - w)\,R(0) = w\,R(x + y).$$

In the same way, $R(y) \le (1-w)\,R(x+y)$. Adding the two inequalities gives $R(x)+R(y) \le R(x+y)$. For the second claim, take any split $x = m$ and $y = M - m$ with $m \in [0, M]$. □

Which program does the traveler choose? She picks the carrier she expects to fly most in the future (Borenstein, 1989, p. 346). That carrier has the most service on her routes and the most routes from her home airport. The award also matters. The most common bonus is a free trip to a destination of the traveler's choice, which is worth more when the carrier serves more destinations with more direct service from her home. Both forces favor the carrier with the largest presence at the traveler's home airport. Small carriers can form affiliated programs, but the costs of transacting, bargaining and coordinating such arrangements are substantial. In their 1987 merger case, USAir and Piedmont argued that their small networks made their programs less attractive than those of larger carriers (p. 346).

The second feature turns FFPs into what observers call kickbacks to business travelers (Borenstein, 1989, p. 346). The employee chooses the carrier and collects the bonus, while the employer pays the fare. Write the employee's payoff from flying carrier f as $v_f + b_f - \varsigma\, p_f$. Here v_f is the value of the flight, b_f is the value of the bonus it earns, and $\varsigma \in [0, 1]$ is the share of the fare she bears herself. A business traveler has ς near zero. Her choice then responds weakly to fares and strongly to bonuses, which raises the effectiveness of the program. The bonus is also untaxed compensation. Borenstein notes that one can imagine an allocation of costs and benefits in which the only net loser is the government (p. 346 and n. 9). Large buyers of travel, such as IBM and General Motors, had not objected strongly to the programs. Low price sensitivity among business travelers is the ingredient that the two-type demand model of Section 9.4 formalizes.

A *travel agent commission override program* (TACO) pays a travel agent a bonus once the agent generates a given volume of revenue for the carrier (Borenstein, 1989, pp. 346–347). The bonus usually rises more than proportionally with revenue, so Lemma 9.1 applies to the agent. Bonuses take the form of higher commissions or of free travel that the agent can sell. A TACO works because the traveler cannot fully monitor the agent or judge the quality of the agent's advice. In a 1988 survey of travel agents, 24% said that such programs "usually" influence their choice of airline for a customer, and 27% said "sometimes" (p. 347). Another 13% answered "rarely" and 35% "never." As with FFPs, the carrier with the most flights from a city offers the most chances to earn bonuses and the most valued bonuses.

Computer reservation systems (CRSs) are the databases through which nearly all travel agents obtain schedules and fares. Several carriers owned one. Despite federal rules on displays, many observers thought that the owners biased the displays toward their own flights (Borenstein, 1989, p. 347). Local dominance reinforces the bias. In a city dominated by a carrier that owns a CRS, more agents choose that carrier's system. They do so because it carries more timely information about the dominant carrier's flights, and because their customers prefer that carrier for FFP and TACO reasons. The display bias then operates even for travelers who do not prefer the dominant carrier. A DOT study found a strong correlation between a system's share in a city and its owner's share of local traffic (p. 347, n. 13).

Serving an airport requires gates, and at some airports slots. A carrier that controls most of the gates can refuse to sell or lease them to entrants. It may also influence the airport operator, usually a local government, when the operator decides whether to expand the airport to accommodate entrants (Borenstein, 1989, p. 347). Where slots can be traded, a carrier that holds a dominant share of them can also inhibit profitable entry (p. 348). In the period we study, four airports allocated slots under federal rules (p. 351, n. 28, and Whinston and Collins, 1992, p. 450, n. 9). They were Chicago O'Hare, New York's Kennedy and La Guardia, and Washington National. Other congested airports operated under "flow control," which Borenstein describes as essentially allocation by queuing.

Scarce airport capacity creates a measurement problem. When gates or runways are scarce, fares at an airport can be high even if every carrier prices competitively. Such a premium is a *scarcity rent*, the competitive return to a scarce input. Borenstein insists that it must not be confused with market power (p. 348), and he proposes a way to tell the two apart. If the scarce input is allocated competitively, its shadow value is the same whichever carrier uses it. A carrier that uses a slot gives up the price at which it could sell or lease it. The scarcity rent therefore raises every carrier's fares at the airport by the same amount. Market power from dominance instead varies with each carrier's share of the airport's traffic. A pricing equation of the form

$$\ln p_{ft} = \ln mc_{ft} + \varrho_k + \phi_1 o_{fk} + (\text{other terms}) \tag{9.5}$$

separates the two. Here p_{ft} is carrier f's fare in market t and k is an endpoint airport of t. The term ϱ_k is a premium common to all carriers at k, and o_{fk} is carrier f's share of the passengers who originate at k. The airport effect ϱ_k is identified from the level of fares at k relative to other airports. The coefficient ϕ_1 is identified from differences in shares among carriers that serve the same airport. Borenstein adds a subtle point (p. 351, n. 27). Even the rents earned on inframarginal uses of a scarce input raise prices by the same amount in every use, if all uses are competitive. Rents then differ across uses only because production costs differ. Section 9.5 implements this idea with airport terms restricted to be equal across carriers.

The last question concerns the boundaries of markets. Do flights from Kennedy airport to Detroit discipline fares on flights from La Guardia to Detroit? Antitrust analyses usually answer with cross-elasticities of demand. Borenstein (1989, p. 348) argues that this ignores demand segmentation. Travelers with low values of time may switch readily between the two airports, while travelers with high values of time may not. If a carrier can sort the two groups, competition for the first group need not discipline the fares charged to the second. Restricted discount fares sort travelers by their time values. Competing airports in a city should therefore restrain discount fares more than the fares paid by business travelers. Borenstein treats flights from different airports as separate markets. Section 9.6 tests whether incumbents at other airports in the same city lose value when a low-fare carrier enters.

These mechanisms share a prediction. A carrier's presence at an endpoint airport, measured by its share of the passengers who begin their trips there, should raise its fares on routes from that airport. The effect should be strongest for fares paid by business travelers, who respond to FFPs and are least sensitive to price. The empirical work cannot separate the individual devices (Borenstein, 1989, p. 362). Borenstein (1989) measures dominance by route and airport shares (Section 9.5). Berry et al. (2006) measure it by the size of the carrier's hub network at the origin (Section 9.7). Ciliberto and Williams (2010) later measure the role of gate control directly (Section 9.8).

9.3 Contestability, entry, and incumbent profits

The theory of contestable markets gave the strongest argument that deregulated airline markets would perform well even when few carriers served them. It is also the benchmark that all three studies in this chapter reject. This section states the theory, proves its main results and shows that an equilibrium may fail to exist. It then explains why airlines seemed a natural application, why the theory is fragile, and what testable predictions it makes. The last subsection derives what an incumbent's loss of value at an entry announcement reveals, which is the logic of the event study in Section 9.6.

9.3.1 Contestable markets

The theory is due to Baumol et al. (1982) and Baumol (1982). We follow the single-product exposition of Tirole (1988, sec. 8.1.2), which states the first three definitions below in the same form. Tirole defines a perfectly contestable market as one in which any equilibrium configuration must be sustainable. This requirement is the last sentence of Definition 9.5. Conditions (i) to (iii) of that definition spell out the assumptions behind it. Tirole places (i) and (ii) in his setup and (iii) in his account of hit-and-run entry. The definitions extend to several products by treating outputs and prices as vectors. Market demand $Q(p)$ is continuous and strictly decreasing wherever it is positive. Every firm, active or potential, has the same cost function $C(q)$, with $C(0) = 0$. The condition $C(0) = 0$ means that a firm that produces nothing pays nothing, so no cost is sunk. A fixed cost is allowed, as in $C(q) = F + cq$ for $q > 0$, but it must be avoidable by shutting down.

Definition 9.2 (Industry configuration)**.** An *industry configuration* $(m; q_1, \ldots, q_m; p)$ is a number of active firms $m \geq 1$, their outputs $q_1, \ldots, q_m > 0$, and a common price p. The other firms are *potential entrants* and produce nothing.

Definition 9.3 (Feasible configuration)**.** A configuration is *feasible* if supply equals demand and no active firm loses money:

$$\sum_{i=1}^{m} q_i = Q(p) \qquad \text{and} \qquad p\, q_i - C(q_i) \geq 0 \quad \text{for } i = 1, \ldots, m.$$

Definition 9.4 (Sustainable configuration)**.** A feasible configuration is *sustainable* if no entry plan earns a positive profit at the incumbents' price. That is, there is no pair (p^e, q^e) with

$$p^e \leq p, \qquad 0 < q^e \leq Q(p^e), \qquad \text{and} \qquad p^e q^e - C(q^e) > 0.$$

The entry plan reflects the timing the theory assumes. An entrant that matches or undercuts the incumbents' price can sell any quantity up to the market demand at its own price. It evaluates its profit while incumbents keep their price unchanged.

Definition 9.5 (Perfectly contestable market)**.** A market is *perfectly contestable* if three conditions hold. (i) Entrants have the same cost function C as incumbents and face the same market demand. (ii) There are no sunk costs, so a firm that exits recovers every cost it incurred on entry. (iii) Consumers switch at once to a lower price, while incumbents change their prices only with a lag. An equilibrium of a perfectly contestable market is a sustainable configuration.

Conditions (ii) and (iii) together make *hit-and-run entry* possible. An entrant can come in, undercut the incumbents, earn profits until they respond, and leave without loss. Sustainability is the requirement that no such plan pays. Two results follow.

Proposition 9.6 (Zero profit)**.** *In a sustainable configuration, every active firm earns zero economic profit.*

Proof. Feasibility gives $\pi_i \equiv p\, q_i - C(q_i) \geq 0$ for every active firm. Suppose that $\pi_i > 0$ for some firm i. Consider the entry plan $(p^e, q^e) = (p - \epsilon, q_i)$ with $0 < \epsilon < \frac{\pi_i}{q_i}$. It satisfies $p^e \leq p$. Because demand is decreasing, $Q(p - \epsilon) \geq Q(p) \geq q_i$, so the plan satisfies $q^e \leq Q(p^e)$. Its profit is

$$(p - \epsilon)\, q_i - C(q_i) = \pi_i - \epsilon\, q_i > 0.$$

This contradicts sustainability. Hence $\pi_i = 0$. □

Proposition 9.7 (Marginal-cost pricing with two or more firms)**.** *Suppose C is differentiable at each active firm's output. In a sustainable configuration with $m \geq 2$ active firms, $p = C'(q_i)$ for every active firm i.*

Proof. By Proposition 9.6, $p\, q_i = C(q_i)$ for every active firm.

Suppose first that $p > C'(q_i)$ for some i. Because another firm is active, $Q(p) = \sum_k q_k > q_i$. Hence $q_i + h \leq Q(p)$ for every small $h > 0$, and the plan $(p, q_i + h)$ is admissible. Its profit is

$$\begin{aligned} p\,(q_i + h) - C(q_i + h) &= \big[p\, q_i - C(q_i)\big] + p\, h - \big[C(q_i + h) - C(q_i)\big] \\ &= 0 + p\, h - C'(q_i)\, h + o(h) \\ &= h\,\big(p - C'(q_i)\big) + o(h), \end{aligned}$$

which is positive for h small enough. This contradicts sustainability.

Suppose next that $p < C'(q_i)$. For small $h \in (0, q_i)$ the plan $(p, q_i - h)$ is admissible, since $q_i - h < Q(p)$. Its profit is

$$\begin{aligned} p\,(q_i - h) - C(q_i - h) &= \big[p\, q_i - C(q_i)\big] - p\, h + \big[C(q_i) - C(q_i - h)\big] \\ &= 0 - p\, h + C'(q_i)\, h + o(h) \\ &= h\,\big(C'(q_i) - p\big) + o(h), \end{aligned}$$

which is again positive for h small enough. Hence $p = C'(q_i)$. □

The second step of the proof does not use $m \geq 2$, so even a single active firm must price at or above marginal cost. The first step does use it. A lone incumbent sells the whole market demand at its price, so an entrant cannot sell more at the same price.

Corollary 9.8 (Efficient scale)**.** *In a sustainable configuration with $m \geq 2$ firms, each active firm produces where average cost $AC(q) = \frac{C(q)}{q}$ equals marginal cost. If AC is U-shaped and its derivative vanishes only at its minimum, each firm therefore produces at the bottom of its average cost curve and $p = \min_q AC(q)$.*

Proof. Proposition 9.6 gives $p = \frac{C(q_i)}{q_i} = AC(q_i)$, and Proposition 9.7 gives $p = C'(q_i)$. Hence $AC(q_i) = C'(q_i)$. Differentiating average cost,

$$AC'(q) = \frac{C'(q)\, q - C(q)}{q^2} = \frac{C'(q) - AC(q)}{q},$$

so $AC'(q_i) = 0$. Under the stated shape, the only such point is the minimum of AC. □

With a single firm the zero-profit condition becomes $p\,Q(p) = C(Q(p))$, so price equals average cost at the quantity demanded. The next proposition treats the natural monopoly case.

Proposition 9.9 (Sustainable natural monopoly)**.** *Suppose $AC(q)$ is strictly decreasing for $q > 0$. Let $P(q)$ be inverse demand, and suppose P and AC cross exactly twice, at $q_L < q_H$, with $P(q) > AC(q)$ for $q \in (q_L, q_H)$ and $P(q) < AC(q)$ for $q \notin [q_L, q_H]$. Let $p^c = P(q_H)$. Then the monopoly configuration $(1; q_H; p^c)$ is sustainable, and it is the only sustainable configuration. Among prices at which a firm serving the whole market breaks even, p^c is the lowest, so it maximizes consumer and total surplus.*

Proof. We first show that the configuration is sustainable. It is feasible because $p^c q_H = AC(q_H)\,q_H = C(q_H)$. Take any entry plan with $p^e \le p^c$ and $0 < q^e \le Q(p^e)$. Because $p^e \le p^c$, $Q(p^e) \ge q_H$. Because AC is decreasing and $q^e \le Q(p^e)$, $AC(q^e) \ge AC(Q(p^e))$. The plan's profit is therefore

$$q^e\big(p^e - AC(q^e)\big) \le q^e\big(p^e - AC(Q(p^e))\big) = q^e\big(P(Q(p^e)) - AC(Q(p^e))\big) \le 0,$$

where the last inequality holds because demand lies on or below average cost at quantities of at least q_H.

We next show uniqueness. Consider any sustainable configuration, and suppose it has $m \ge 2$ firms. By Proposition 9.6, $p = AC(q_i)$ for each firm, and $q_i < Q(p)$. Because AC is strictly decreasing, $AC(Q(p)) < AC(q_i) = p$. The plan $(p, Q(p))$ then earns $Q(p)\big(p - AC(Q(p))\big) > 0$, a contradiction. So $m = 1$ and $p = AC(Q(p))$, which means $p \in \{P(q_L), P(q_H)\}$. If $p = P(q_L)$, an entrant can choose any $q^e \in (q_L, q_H)$ at the price $P(q^e) < P(q_L)$ and earn $q^e\big(P(q^e) - AC(q^e)\big) > 0$. Hence $p = P(q_H) = p^c$.

Finally, a single firm serving the market breaks even exactly at the prices $P(q_L)$ and $P(q_H)$. Its profit is zero at both, so total surplus equals consumer surplus, which is decreasing in price. The lower price p^c therefore gives the larger surplus. □

The price p^c is the *second-best* price. A planner who cannot subsidize the firm, and who must therefore let it cover its costs, would choose it. Marginal-cost pricing would give more surplus. At the quantity q sold at that price, however, the firm would lose $C(q) - C'(q)\,q > 0$, because marginal cost lies below a falling average cost. The loss equals the fixed cost F when $C(q) = F + cq$.

Example 9.10 (A contestable natural monopoly)**.** Let $C(q) = F + cq$ for $q > 0$ with $C(0) = 0$, so the fixed cost F is avoidable. Then $AC(q) = c + \frac{F}{q}$ falls with q and marginal cost is c. Let demand be $Q(p) = 12 - p$, with $c = 2$ and $F = 8$. Setting $P(q) = AC(q)$ gives $12 - q = 2 + \frac{8}{q}$, or $q^2 - 10q + 8 = 0$. The roots are $q_L = 5 - \sqrt{17} \approx 0.88$ and $q_H = 5 + \sqrt{17} \approx 9.12$. The sustainable price is $p^c = 12 - q_H = 7 - \sqrt{17} \approx 2.88$. An unthreatened monopolist would set marginal revenue $12 - 2q$ equal to $c = 2$. It would sell 5 units at $p^m = 7$ and earn $5 \times 5 - 8 = 17$. Under perfect contestability, the same single firm charges 2.88 and earns zero. Figure 9.2 draws the example.

The same price solves the zero-profit condition in price form, $(p^c - c)\,Q(p^c) = F$ (Tirole, 1988, sec. 8.1.2). Substituting the example's values,

$$\begin{aligned}(p - 2)(12 - p) &= 8,\\ p^2 - 14p + 32 &= 0,\\ p &= 7 \pm \sqrt{17}.\end{aligned}$$

The larger root, $7 + \sqrt{17} \approx 11.12$, is the price $P(q_L)$ at the left crossing. The smaller root is p^c. For any cost function $C(q) = F + cq$ with a viable monopoly, Tirole draws three conclusions. (1) A single firm operates, so the fixed cost is not duplicated. (2) This firm earns zero profit. (3) Price equals average cost, and the allocation is *constrained efficient*. It is the best allocation that a planner can reach without subsidizing the firm. The first-best price c would make the firm lose F.

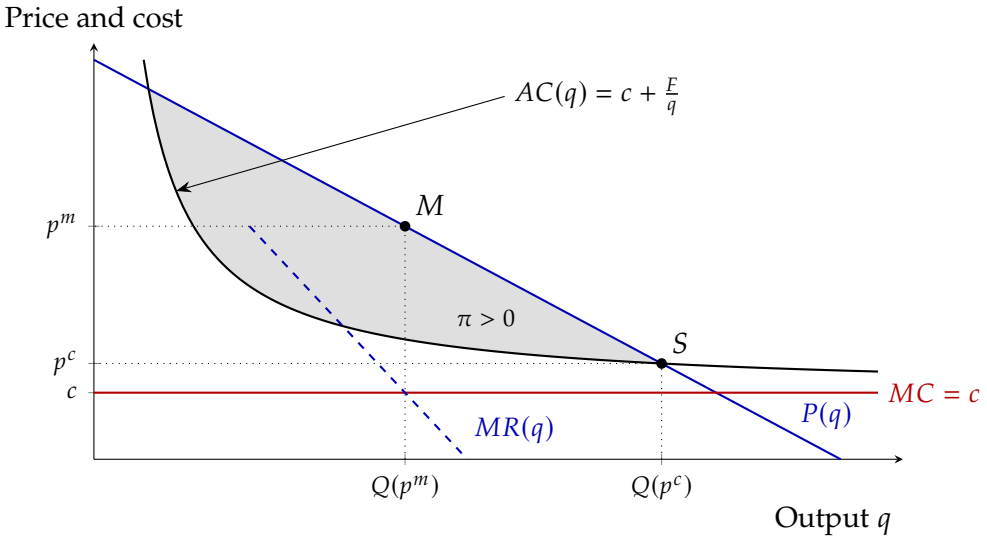


Figure 9.2: A contestable natural monopoly. Average cost $AC(q) = c + \frac{F}{q}$ lies above marginal cost c everywhere. An unthreatened monopolist would produce where marginal revenue $MR(q)$ equals c and charge p^m (point M). In the shaded region inverse demand $P(q)$ lies above average cost, so any price in it earns a positive profit $\pi = p\,Q(p) - C(Q(p))$ and invites hit-and-run entry. The only sustainable configuration is a single firm at S, where demand cuts average cost from above and $p^c = AC(Q(p^c))$. The curves use $c = 2$, $F = 8$ and $P(q) = 12 - q$, which give $p^m = 7$ and $p^c = 7 - \sqrt{17} \approx 2.88$.

Three features of the theory explain its appeal for policy, and a fourth limits it.

Remark 9.11 (Structure does not determine performance). In a perfectly contestable market, the price is pinned down by cost and demand alone. A monopoly and an industry of many firms can both price at average cost. Concentration therefore carries no information about market power, and the structure-conduct-performance regressions of Chapter 1 have no basis.

Remark 9.12 (Potential competition). Potential entrants discipline incumbents as well as actual rivals do. The incumbents need not face any active rival. They price at average cost because a price above it would invite entry.

Remark 9.13 (Efficiency). Sustainable configurations are efficient in the second-best sense. With two or more firms, price equals marginal cost and each firm produces at minimum average cost (Corollary 9.8). With one firm, price equals average cost at the lowest break-even price (Proposition 9.9).

Remark 9.14 (Existence). A sustainable configuration need not exist. Tirole (1988, sec. 8.1.2) reports that Baumol et al. (1982) show that natural monopolies may fail to be sustainable for some demand and cost functions. There may be no price and outputs at which firms break even, the market clears, and no entry plan at a lower or equal price earns a profit. A constrained

efficient market structure can then be upset by entry. The next proposition works out the case of Tirole's Exercise 8.1.

Proposition 9.15 (No sustainable configuration)**.** *Let AC be U-shaped. It falls strictly below an* efficient scale q^* *and rises strictly above it, with minimum $a^* = AC(q^*)$. Suppose that demand at the minimum average cost exceeds the efficient scale but is not an integer multiple of it:*

$$Q(a^*) > q^* \qquad \text{and} \qquad \frac{Q(a^*)}{q^*} \notin \{2, 3, \dots\}.$$

Then no configuration is sustainable. This covers the case in which demand cuts average cost slightly to the right of the efficient scale, so that $q^* < Q(a^*) < 2q^*$.

Proof. Suppose a sustainable configuration $(m; q_1, \dots, q_m; p)$ exists, and let P be inverse demand. The argument covers every $m \geq 1$ and uses no derivative.

First, the price equals the minimum average cost. Feasibility gives $p \geq AC(q_i) \geq a^*$ for every active firm. Because demand is decreasing and $Q(a^*) > q^*$, we also have $P(q^*) > a^*$. Suppose that $p > a^*$, and consider the entry plan

$$p^e = \min\{p,\, P(q^*)\}, \qquad q^e = q^*.$$

It satisfies $p^e \leq p$. Because $p^e \leq P(q^*)$, demand at p^e is at least q^*, so $q^e \leq Q(p^e)$. Its profit is

$$p^e q^* - C(q^*) = q^* (p^e - a^*) > 0,$$

since both p and $P(q^*)$ exceed a^*. This contradicts sustainability. Hence $p = a^*$.

Second, every active firm produces at the efficient scale. With $p = a^*$, feasibility gives $AC(q_i) \leq a^*$. Since a^* is the minimum of AC, $AC(q_i) = a^*$. The U shape makes q^* the unique minimizer, so $q_i = q^*$ for every i. Market clearing then gives $Q(a^*) = m\, q^*$.

Third, this equation contradicts the assumptions on demand. If $m = 1$, it reads $Q(a^*) = q^*$, which contradicts $Q(a^*) > q^*$. If $m \geq 2$, it gives $\frac{Q(a^*)}{q^*} = m \in \{2, 3, \dots\}$, which contradicts the integer condition. Hence no configuration is sustainable. □

The entrant in the proof matches or undercuts the incumbents' price but produces only at its efficient scale. It leaves part of the demand unserved, which the definition of sustainability allows. A numerical case shows the logic. Let $C(q) = 1 + q^2$ for $q > 0$, so $AC(q) = \frac{1}{q} + q$, with $q^* = 1$ and $a^* = 2$. Let $Q(p) = 3.5 - p$, so $Q(a^*) = 1.5$. Two firms at the efficient scale would supply 2 units at the price 2, more than the 1.5 units demanded. A single firm breaks even where $3.5 - q = \frac{1}{q} + q$, that is,

$$4q^2 - 7q + 2 = 0, \qquad q = \frac{7 \pm \sqrt{17}}{8}.$$

At the right crossing, $q \approx 1.39$ and the price is $\frac{21 - \sqrt{17}}{8} \approx 2.11$. An entrant that charges the same price and produces one unit earns $\frac{5 - \sqrt{17}}{8} \approx 0.11 > 0$. Brock and Scheinkman (1983) study a weaker test, *quantity sustainability*, in which the entrant expects the incumbent's output to stay fixed after entry (Tirole, 1988, sec. 8.1.2, n. 12). The price then adjusts to clear the market for the combined output. Brock and Scheinkman show that, under some assumptions, the crossing allocation of a single-product industry passes this test. In the example, an entrant that produces q^e faces the price $2.11 - q^e$ and earns $q^e\,(2.11 - q^e) - 1 - (q^e)^2$. This profit is largest at $q^e \approx 0.53$ and equals about -0.44 there. Every such plan therefore loses money.

Remark 9.16 (Contestability as Bertrand competition). A two-stage game yields the contestable outcome (Tirole, 1988, sec. 8.1.2). All firms first set prices simultaneously. They then choose outputs, and a positive output means entry. This timing reverses that of the capacity-then-price game of Kreps and Scheinkman (1983) (Remark 9.25). Take the setting of Proposition 9.9. Let every firm set p^c, let one firm supply $Q(p^c)$, and let the others produce nothing. Every firm earns zero. A firm that sets $p < p^c$ and produces $q \in (0, Q(p)]$ earns

$$q\left(p - AC(q)\right) \leq q\left(p - AC(Q(p))\right) < 0.$$

The first inequality holds because AC is decreasing and $q \leq Q(p)$. The second holds because $Q(p) > q_H$, where demand lies below average cost. A firm that sets a price above p^c sells nothing, since another firm supplies the whole demand at p^c. No deviation pays, so the profile is an equilibrium. Tirole sketches why it is the only one (n. 9). As Baumol et al. note, perfect contestability thus extends Bertrand competition to markets with increasing returns to scale. With constant marginal cost and no fixed cost, the same game gives the Bertrand price c. The game also makes the theory's timing explicit. Prices are fixed while firms choose quantities and entry. Section 9.3.2 questions this assumption.

9.3.2 Why airlines, and why the theory may fail

Airlines looked like the textbook case of a contestable industry. Aircraft, the largest capital asset, can be moved from one city pair to another at low cost. Entry into a new route between two airports a carrier already serves needs little capital that is specific to the route. The ideal of hit-and-run entry thus seemed close to reality. If it held, deregulated routes would be priced near average cost even when only one carrier served them, and concentration on a route would not be a concern for policy. Bailey and Panzar (1981) made this argument for city-pair markets, as Tirole (1988, sec. 8.1.2, n. 11) reports. Airline service has returns to scale, but its fixed costs are not sunk. Aircraft can be redeployed at little cost, and municipalities bear the sunk costs of runways, towers and ground facilities. Bailey and Panzar offered evidence that single-carrier routes, almost 70% of all routes, were priced roughly competitively on long hauls just after deregulation. Bailey et al. (1985) and others found instead that fares rise with concentration. Tirole describes that relation as statistically strong but not economically large.

The theory is fragile, however, in a way that matters for airlines. Its conclusions require exactly zero sunk costs together with a lag before incumbents respond. Two observations of Tirole (1988, secs. 8.1.1–8.1.2) frame the problem. First, fixed and sunk costs differ only in degree. A fixed cost does not vary with output and is committed for a short time, which defines the length of a period. A sunk cost yields benefits over a long horizon and can never be recovered. A machine rented by the month is a fixed cost, and a machine that cannot be resold is sunk. What matters is how long a commitment lasts compared with the time it takes to change prices. Second, the hit-and-run story assumes that prices adjust more slowly than entry decisions. Critics argue the reverse. In railroads, entry requires buying parcels of land, often with powers of eminent domain, and then engineering and building the line. Fares can change much sooner. Tirole adds that price adjustment "may be even faster in the airline industry, where opening a new route is a relatively fast process." Suppose the incumbent cuts its price soon after entry, measured against the time the entrant needs to invest. Hit-and-run entry then does not pay, because a natural monopoly leaves no room for two firms that compete in prices.

A simple model makes the point precise. Suppose that entry requires a sunk investment $K > 0$ and that incumbents can change fares within T periods of entry. In this subsection only, T denotes this response lag, and $\delta \in (0, 1)$ is a per-period discount factor. An entrant that

undercuts a monopolist earns a profit π^e per period until the incumbent responds. After the response the entrant earns $\pi^d \geq 0$ per period, for example $\pi^d = 0$ if the two firms then compete in prices with identical costs. Entry pays if and only if

$$\sum_{\tau=0}^{T-1} \delta^\tau \pi^e + \sum_{\tau=T}^{\infty} \delta^\tau \pi^d \geq K. \tag{9.6}$$

Summing the two geometric series gives the equivalent condition

$$\pi^e \frac{1-\delta^T}{1-\delta} + \delta^T \frac{\pi^d}{1-\delta} \geq K. \tag{9.7}$$

The first term is the value of the hit-and-run window. It is at most $T\pi^e$, and π^e cannot exceed the monopoly profit per period. Because profit accrues per unit of time, the window's value shrinks to zero as the response becomes faster.

Proposition 9.17 (The fragility of contestability)**.** *Suppose that after incumbents respond the entrant earns $\pi^d = 0$, and let π^m be the monopoly profit per period. (a) If $K = 0$, hit-and-run entry against an incumbent that earns a positive profit pays for every response lag $T \geq 1$. (b) If $K > 0$, entry against the monopoly price is unprofitable whenever $\pi^m \frac{1-\delta^T}{1-\delta} < K$. In particular, it is unprofitable whenever $T\pi^m < K$, so a fast enough response protects the monopoly price for any $K > 0$.*

Proof. With $\pi^d = 0$, condition (9.7) reads $\pi^e \frac{1-\delta^T}{1-\delta} \geq K$. (a) An incumbent profit $\pi_i > 0$ leaves room for an undercutting plan with $\pi^e > 0$, as in the proof of Proposition 9.6. With $K = 0$ and $T \geq 1$, the left side is at least $\pi^e > 0 = K$. (b) Any entrant earns $\pi^e \leq \pi^m$ per period, so the left side is at most $\pi^m \frac{1-\delta^T}{1-\delta}$. Since $\delta^\tau \leq 1$ for every τ, this bound is itself at most $T\pi^m$. □

The proposition shows a discontinuity. At $K = 0$ the price equals average cost for every positive response lag. With any positive sunk cost and a fast response, the incumbent can charge the monopoly price. Entry then depends on the second term of (9.7), the profit an entrant expects to earn after incumbents respond. The incumbent's current price no longer matters for the entry decision. Figure 9.3 illustrates the threshold.

Airline markets have several sources of sunk costs. An entrant must set up gates, counters and other airport facilities at a new station, and it must advertise to make itself known to local travelers. In his conclusion, Borenstein (1989, p. 362) names advertising and the setup of airport facilities as sunk costs of entry that may matter alongside FFPs and TACOs. Building a base of FFP members and of travel agents who book the carrier also takes time and money that cannot be recovered on exit. The response lag is short. An incumbent can change its fares much faster than the time that normally elapses between a rival's announcement of entry and its first flight (Borenstein, 1989, p. 352). A USAir executive testified that his carrier feared entry but set its prices according to the competition it faced (p. 352, n. 31). In terms of (9.7), incumbents can respond before the entrant's first flight, so the hit-and-run window is empty.

Remark 9.18 (Two other models of natural monopoly). Two models let prices adjust faster than capacity, the timing that the critique favors (Tirole, 1988, secs. 8.1.2–8.1.3 and 8.6.1). In the first, firms commit to capacity only for short periods and set prices instantly given current capacities. There is an equilibrium in which only the incumbent produces. It keeps renewing a capacity close to $Q(p^c)$ and earns almost no profit. With a lower capacity, an entrant could come in, bear duopoly losses briefly, and take over once the incumbent's commitment lapses. Tirole develops this model in his Supplementary Section 8.6.1.1.

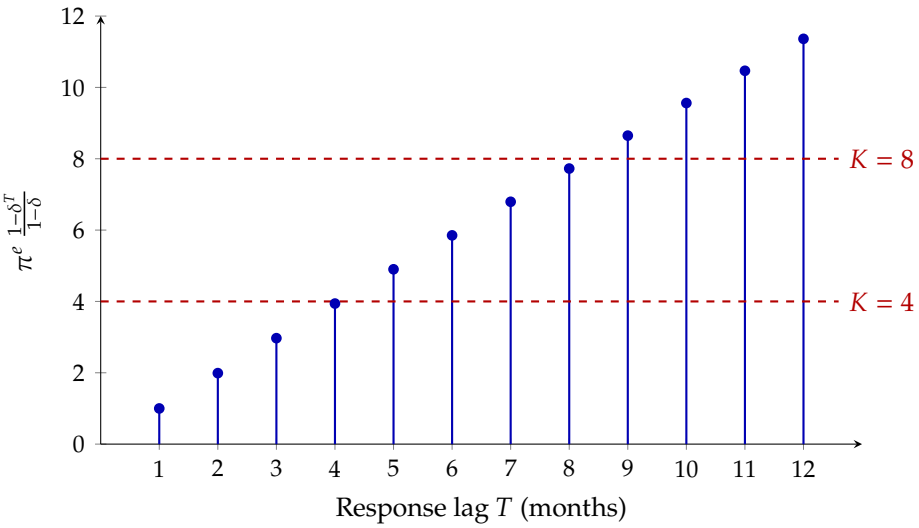

Figure 9.3: The value of hit-and-run entry when the entrant earns nothing after incumbents respond. Bars show the discounted profit earned during a response lag of T months, with $\pi^e = 1$ per month and a monthly discount factor $\delta = 0.99$. Entry pays only if the bar reaches the sunk cost. With $K = 4$ it requires a lag of at least 5 months, and with $K = 8$ at least 9 months. With $K = 0$ any lag makes entry profitable.

The second is a *war of attrition*. Two firms with cost $F + cq$ per unit of time are both active at date zero, and exit is costless. While both stay, Bertrand competition sets the price at c, and each loses F per unit of time. A firm left alone charges p^m and earns $\tilde{\pi}^m - F > 0$ per unit of time forever, where $\tilde{\pi}^m$ is the monopoly flow profit gross of the fixed cost. In this remark only, r denotes the interest rate. In a symmetric equilibrium each firm quits at a constant hazard rate x, so that it is indifferent between quitting and staying. Staying for a short time $\mathrm{d}\tau$ costs $F\,\mathrm{d}\tau$. With probability $x\,\mathrm{d}\tau$ the rival quits in that time, and the firm gains a monopoly worth $\frac{\tilde{\pi}^m - F}{r}$. Otherwise it is again indifferent and can quit at zero value. Indifference requires

$$0 = -F\,\mathrm{d}\tau + x\,\mathrm{d}\tau\,\frac{\tilde{\pi}^m - F}{r}, \qquad \text{so} \qquad x = \frac{rF}{\tilde{\pi}^m - F}.$$

In Example 9.10, $\tilde{\pi}^m = 25$ and $F = 8$, so $x = \frac{8r}{17}$. Both firms produce for a random time, which duplicates the fixed cost, and then one exits. The price is first competitive and then equal to the monopoly price. Firms earn no rents in expectation, and welfare is lower than under contestability.

Perfect contestability makes four predictions that the empirical literature can test. Each corresponds to one of the studies in this chapter.

(C1) *Structure does not affect fares.* Conditional on cost and demand, a route's fare does not depend on its concentration or on a carrier's share of the route or of its endpoint airports (Remark 9.11). Earlier studies had found instead that fares on a route rise with its concentration (Borenstein, 1989, p. 344). Borenstein cites four of these studies (Graham et al., 1983; Bailey et al., 1985; Call and Keeler, 1985; Morrison and Winston, 1987). He regards it as well established that airline pricing "does not closely reflect the perfect contestability ideal." Bailey et al. (1985) also found that a carrier's own route share raises its fares when route concentration is held fixed (p. 348, n. 18). Section 9.5 adds the carrier's share of its endpoint airports.

(C2) *Entry announcements do not hurt incumbents.* Under perfect contestability incumbents earn zero profit and have sunk nothing, so they have nothing to lose when an entrant appears. An announcement of entry should leave the incumbents' stock market values unchanged (Proposition 9.19 below). Whinston and Collins (1992) test this prediction (Section 9.6).

(C3) *Potential competition disciplines as much as actual competition.* The number of active rivals on a route should not matter once potential entrants are present (Remark 9.12). Borenstein (1989) includes a measure of potential competitors' presence at both endpoints of a route. His instrument for route share also requires that current fares respond to actual rather than potential rivals (p. 352). Goolsbee and Syverson (2008) later study how incumbents respond to the threat of entry (Section 9.8).

(C4) *Markups only cover costs.* With two or more carriers on a route, price equals marginal cost (Proposition 9.7). With one carrier, price equals average cost (Proposition 9.9). Markups over marginal cost are positive only to the extent needed to cover costs that do not vary with traffic. Berry et al. (2006) estimate markups over marginal cost and find them higher on business travelers out of large hubs (Section 9.7). Positive markups do not by themselves refute contestability, since average cost exceeds marginal cost when costs fall with segment density (Remark 9.42). Markups that differ systematically across carriers serving the same market are harder to reconcile with the theory.

9.3.3 Entry with sunk costs: what an incumbent's value loss reveals

Prediction (C2) can be tested without estimating demand or cost, by observing how incumbents' values change when entry is announced. Consider an incumbent carrier on route t. Let Π^0 be the expected present value of its future operating profits on the route just before an unanticipated entry announcement. Operating profit is revenue minus all avoidable costs, including the opportunity cost of aircraft and other assets that could be redeployed elsewhere. Let Π^1 be the same present value just after the announcement. Let $K \geq 0$ be the incumbent's investment specific to the route that is already sunk, such as local advertising or airport facilities. The incumbent's *route value*, its economic profit on the route, counts this investment as a cost:

$$V^0 = \Pi^0 - K, \qquad V^1 = \Pi^1 - K. \tag{9.8}$$

The incumbent can always exit and avoid every remaining cost, so optimal behavior after the announcement gives $\Pi^1 \geq 0$. Equivalently, $V^1 \geq -K$. The change in the firm's market value at the announcement is the loss

$$L = \Pi^0 - \Pi^1 = V^0 - V^1, \tag{9.9}$$

since the sunk investment is the same before and after.

Proposition 9.19 (What a value loss reveals)**.** *The loss satisfies $L \leq V^0 + K$. Hence $L > 0$ implies $V^0 + K > 0$: before entry the incumbent earned positive economic profits on the route, or it had sunk costs there, or both. Under perfect contestability $V^0 = 0$ and $K = 0$, so $L \leq 0$.*

Proof. From (9.9) and $V^1 \geq -K$,

$$L = V^0 - V^1 \leq V^0 - (-K) = V^0 + K.$$

If $L > 0$, then $V^0 + K \geq L > 0$. Under perfect contestability no cost is sunk, so $K = 0$, and Proposition 9.6 gives $V^0 = 0$. Hence $L \leq 0$. □

The sum $V^0 + K = \Pi^0$ is the incumbent's pre-entry *quasi-rent*, the value of operating the route over and above all avoidable costs. A measured loss is a lower bound on it. Whinston and Collins (1992, p. 447) state the argument in words. Suppose incumbents lose value when entry is announced. Then either "the incumbents could have been earning positive profits prior to entry," or "they must have had sunk costs that kept them in the market despite taking these losses." They estimate that the average incumbent on a route entered by People Express lost between \$3.7 million and \$6.5 million at the announcement (p. 452), as Section 9.6 explains.

Remark 9.20 (A low-cost entrant). The bound holds whatever the entrant's costs. An entrant with lower costs than the incumbents violates condition (i) of Definition 9.5 by itself. A positive loss says more. By revealing profits or sunk costs that existed before entry, it shows that the market would not have been contestable even without the entrant's innovation (Whinston and Collins, 1992, p. 447). For the same reason the argument does not require the entrant's low prices to be justified by its costs (p. 454, n. 23).

Remark 9.21 (Localization). Suppose the loss falls only on carriers that serve the entered route, while other carriers lose nothing. Then the rents or sunk costs are tied to operations on that route. This reveals more than the sensitivity of a route's fares to its structure. It also shows that sunk costs or other barriers to mobility prevent profits from being equalized across routes (Whinston and Collins, 1992, pp. 447–448). If airports in the same city compete closely, carriers that serve the same city pair from other airports should lose as well.

Remark 9.22 (Measured losses understate the true loss). Suppose investors assigned probability $\varphi_0 \in [0, 1)$ to entry before the announcement. The pre-announcement value of the route was then $\varphi_0 \Pi^1 + (1 - \varphi_0)\Pi^0$, and after the announcement it is Π^1. The measured change is

$$\varphi_0 \Pi^1 + (1 - \varphi_0)\Pi^0 - \Pi^1 = (1 - \varphi_0)(\Pi^0 - \Pi^1) = (1 - \varphi_0) L,$$

which is smaller than L. Misdating an event and sharing rents with workers or debtholders also bias the measured loss toward zero (Whinston and Collins, 1992, p. 453). Other forces can bias it upward, such as news about the entrant's future expansion that affects every carrier. Section 9.6 shows how Whinston and Collins separate such general effects from the effect of incumbency.

A positive loss reveals rents but not how they arise or how incumbents respond. Static oligopoly theory predicts the responses. Consider N symmetric Cournot incumbents with inverse demand $P(Q) = a - bQ$, where $a > c$ and $b > 0$, and constant marginal cost c. Firm i chooses q_i to maximize

$$\pi_i = \left(a - bQ - c\right) q_i, \qquad Q = \sum_{k=1}^{N} q_k.$$

The first-order condition is

$$a - bQ - c - b\, q_i = 0.$$

Summing over the N firms gives

$$N(a - c) - bNQ - bQ = 0, \qquad \text{so} \qquad Q = \frac{N(a - c)}{b(N + 1)}.$$

By symmetry each firm produces $\frac{Q}{N}$. Substituting into the price and the profit gives the equilibrium

$$q^* = \frac{a - c}{b(N + 1)}, \qquad P^* = a - \frac{N(a - c)}{N + 1} = \frac{a + Nc}{N + 1}, \qquad \pi^* = (P^* - c)\, q^* = \frac{(a - c)^2}{b(N + 1)^2}. \tag{9.10}$$

The middle expression uses $P^* - c = \frac{a-c}{N+1}$. When one firm enters, N becomes $N+1$ and

$$\frac{q^*(N+1)}{q^*(N)} = \frac{N+1}{N+2}, \qquad P^*(N) - P^*(N+1) = \frac{a-c}{(N+1)(N+2)}, \qquad \frac{\pi^*(N+1)}{\pi^*(N)} = \left(\frac{N+1}{N+2}\right)^2.$$

Each incumbent's output falls, the price falls, and each incumbent's profit falls. Total output rises from $\frac{N(a-c)}{b(N+1)}$ to $\frac{(N+1)(a-c)}{b(N+2)}$. Section 2.4 proves these comparative statics for general demand.

An entrant like People Express brings lower costs. The next result shows that a cost advantage makes the incumbents' losses larger.

Proposition 9.23 (Entry by a low-cost firm)**.** *In the linear Cournot model, let one entrant with marginal cost $c_e \le c$ join the N incumbents, and suppose all firms produce positive output after entry. Then each incumbent produces $\frac{a-2c+c_e}{b(N+2)}$ and earns $\frac{(a-2c+c_e)^2}{b(N+2)^2}$. Its output, the price and its profit are lower than before entry, and they fall further as c_e falls.*

Proof. The incumbents' first-order conditions are $a - bQ - c - b\,q = 0$, and the entrant's is $a - bQ - c_e - b\,q_e = 0$. Summing the $N+1$ conditions gives

$$N(a-c) + (a-c_e) - b(N+1)Q - bQ = 0, \qquad \text{so} \qquad Q = \frac{N(a-c) + (a-c_e)}{b(N+2)}.$$

The price is

$$P = a - bQ = \frac{(N+2)a - N(a-c) - (a-c_e)}{N+2} = \frac{a + Nc + c_e}{N+2}.$$

An incumbent's first-order condition gives $b\,q = P - c$, so

$$q = \frac{a + Nc + c_e - (N+2)c}{b(N+2)} = \frac{a - 2c + c_e}{b(N+2)}, \qquad \pi = (P-c)\,q = b\,q^2 = \frac{(a-2c+c_e)^2}{b(N+2)^2}.$$

Before entry, $q^* = \frac{a-c}{b(N+1)}$. Because $c_e \le c$, $a - 2c + c_e \le a - c$, and $\frac{1}{N+2} < \frac{1}{N+1}$. Hence $q < q^*$, and $\pi = bq^2 < b(q^*)^2 = \pi^*$. The price $\frac{a+Nc+c_e}{N+2}$ is below $\frac{a+Nc}{N+1}$ because $c_e \le c < a$. All three expressions increase in c_e. □

The source of entry matters for what an incumbent's loss reveals. Whinston and Collins (1992, p. 447, n. 4) illustrate the point with a simple model of entry with sunk costs, such as that of Mankiw and Whinston (1986). In such a model, entry triggered by an innovation of the entrant lowers incumbents' values. Entry triggered by a shock to demand or to costs common to all firms can raise or lower them. The linear model makes the point precise.

Proposition 9.24 (Innovation versus demand shocks)**.** *In the linear Cournot model, let N firms be active under free entry with sunk entry cost K. Free entry means $\pi^*(N) \ge K > \pi^*(N+1)$, where $\pi^*(N) = \frac{(a-c)^2}{b(N+1)^2}$. (a) If entry occurs because one potential entrant's marginal cost falls to $c_e < c$, each incumbent's profit flow falls. (b) If entry occurs because demand rises from a to $a' > a$, with $\frac{(a'-c)^2}{b(N+2)^2} \ge K$, each incumbent's profit flow changes from $\frac{(a-c)^2}{b(N+1)^2}$ to $\frac{(a'-c)^2}{b(N+2)^2}$. It rises if and only if $\frac{a'-c}{a-c} > \frac{N+2}{N+1}$. If a' is the smallest demand level at which the $(N+1)$th firm enters, it does not rise.*

Proof. Part (a) is Proposition 9.23. For part (b), the incumbent's new profit flow follows from (9.10) with $N+1$ firms and intercept a'. Comparing the square roots of the two profit flows gives the stated condition. If a' is the smallest intercept at which the $(N+1)$th firm enters, then $\frac{(a'-c)^2}{b(N+2)^2} = K \le \pi^*(N)$. □

The proposition explains why entry by a single innovative carrier is a clean experiment. When entry follows an entrant-specific innovation, the market's reaction measures the loss from entry itself. When it follows news about demand on the route, the same reaction mixes the loss with the good news. People Express was widely seen as a carrier with new products and lower costs, so its announcements fit case (a). The fit is imperfect. Whinston and Collins (1992, p. 459) acknowledge that changes in demand or costs on a route could themselves have prompted entry.

Remark 9.25 (Capacities and the Kreps-Scheinkman result). Airlines commit to schedules, and hence to seat capacity, before they set fares. Kreps and Scheinkman (1983) show that capacity choice followed by price competition yields the Cournot outcome, under concave demand and efficient rationing (Proposition 2.52). The comparative statics of (9.10) and Proposition 9.23 then apply to capacities. Entry should lead incumbents to cut capacity and sales along with price. Whinston and Collins (1992, p. 460) make this point and find the opposite. Incumbents on routes entered by People Express appear to have raised their seats offered and their sales after entry (Section 9.6).

When can entry raise an incumbent's output in a static model? Consider Cournot competition with general inverse demand $P(Q)$ and cost $C(q_i)$. Write Q_{-i} for the rivals' total output. Firm i's first-order condition is

$$P(q_i + Q_{-i}) + q_i\,P'(q_i + Q_{-i}) - C'(q_i) = 0.$$

Differentiating with respect to Q_{-i} and writing $q_i' = \frac{\mathrm{d}q_i}{\mathrm{d}Q_{-i}}$ gives

$$P'\,(q_i' + 1) + P'\,q_i' + q_i\,P''\,(q_i' + 1) - C''\,q_i' = 0.$$

Collecting the terms in q_i',

$$q_i' = -\,\frac{P' + q_i P''}{2P' + q_i P'' - C''}. \tag{9.11}$$

The second-order condition makes the denominator negative. The best response therefore slopes up exactly when $P' + q_i P'' > 0$. In the language of Bulow et al. (1985), quantities are then *strategic complements*. This requires demand convex enough that $P'' > -\frac{P'}{q_i} > 0$. With linear demand, $P'' = 0$ and quantities are strategic substitutes. An incumbent that answers entry with more output and capacity thus contradicts the standard static models unless demand is unusually convex. Whinston and Collins (1992, p. 460) suggest a dynamic interpretation instead. Incumbents may have responded aggressively in the hope of inducing the entrant to exit, or at least of discouraging its further expansion.

Contestability theory tells us when market power cannot exist. It is silent on how market power shows up in fares when the theory fails. Answering that question requires a model of pricing on a route, with several carriers, differentiated products, heterogeneous travelers and network costs. The next section builds this model. It supplies the structural reading of the fare regressions of Section 9.5 and the model that Section 9.7 estimates.

9.4 Market power in airline markets: pricing theory

The three empirical studies in this chapter rest on one body of pricing theory, which this section develops in four steps. First, we derive a route-level pricing equation from a homogeneous-goods model with a conduct parameter. This equation gives a structural reading of the fare

regressions of Section 9.5. Second, we show that airport dominance can raise a carrier's markup through product differentiation alone, with no softening of rivals' behavior. Third, we build the finite-mixture nested logit with R consumer types that Berry et al. (2006) estimate. We derive its shares, substitution patterns, markups and inversion. Fourth, we model costs on a network, where the marginal cost of a passenger depends on traffic density on each flight leg, and we derive the pricing condition of a network carrier.

Markets, carriers and products are those of Section 9.2.3. A market t is a directional origin-destination pair, carriers are firms $f = 1, \dots, F$, and $\mathcal{J}_t$ is the set of inside products in market t. We add one piece of notation: $\mathcal{J}_f(t) \subseteq \mathcal{J}_t$ collects the products that carrier f sells in market t.

9.4.1 From conduct to a route-level pricing equation

We start from the simplest model that links fares to market structure. It treats travel on a route as a homogeneous good and summarizes each carrier's behavior by a conduct parameter, as in Chapter 2 and Chapter 3.

Assumption 9.26 (Homogeneous route market)**.** On route t, carriers $f = 1, \dots, F$ sell a homogeneous product with outputs q_{ft} and total output $Q_t = \sum_f q_{ft}$. Inverse demand $P(Q_t)$ is differentiable and strictly decreasing, and the market elasticity is $\varepsilon_t = -\frac{P(Q_t)}{Q_t P'(Q_t)} > 0$. Carrier f has constant marginal cost mc_{ft} and share $s_{ft} = \frac{q_{ft}}{Q_t}$.

Definition 9.27 (Firm-level conduct)**.** The *conduct parameter* θ_{ft} of carrier f on route t is the number that satisfies

$$P(Q_t)\left(1 - \frac{\theta_{ft}}{\varepsilon_t}\right) = mc_{ft}, \qquad \text{equivalently} \qquad L_{ft} \equiv \frac{P(Q_t) - mc_{ft}}{P(Q_t)} = \frac{\theta_{ft}}{\varepsilon_t}. \tag{9.12}$$

The benchmarks follow from a conjectural-variations first-order condition. Suppose carrier f chooses q_{ft} and conjectures that rivals' total output $Q_{-f,t} = Q_t - q_{ft}$ responds as $\frac{\mathrm{d}Q_{-f,t}}{\mathrm{d}q_{ft}} = v_{ft}$. Its first-order condition is

$$P(Q_t) + q_{ft} P'(Q_t)\,(1 + v_{ft}) - mc_{ft} = 0.$$

Dividing by $P(Q_t)$ and using the definitions of s_{ft} and ε_t,

$$\frac{P - mc_{ft}}{P} = -\frac{q_{ft} P'(Q_t)}{P}\,(1 + v_{ft}) = \frac{q_{ft}}{Q_t}\left(-\frac{Q_t P'(Q_t)}{P}\right)(1 + v_{ft}) = \frac{s_{ft}(1 + v_{ft})}{\varepsilon_t}.$$

Hence $\theta_{ft} = s_{ft}(1 + v_{ft})$. Cournot conjectures ($v_{ft} = 0$) give $\theta_{ft} = s_{ft}$, which equals $\frac{1}{N}$ with N symmetric firms. Price taking gives $\theta_{ft} = 0$. When all carriers have the same cost, joint profit maximization sets $\frac{P - mc}{P} = \frac{1}{\varepsilon_t}$, so $\theta_{ft} = 1$.

We parametrize conduct between Cournot and joint profit maximization as

$$\theta_{ft} = s_{ft} + \eta_t\,(1 - s_{ft}), \qquad \eta_t \in [0, 1]. \tag{9.13}$$

Matching $\theta_{ft} = s_{ft}(1 + v_{ft})$ gives $v_{ft} = \eta_t \frac{1 - s_{ft}}{s_{ft}} = \eta_t \frac{Q_{-f,t}}{q_{ft}}$, which rearranges to $\frac{\mathrm{d}Q_{-f,t}}{Q_{-f,t}} = \eta_t \frac{\mathrm{d}q_{ft}}{q_{ft}}$. Carrier f therefore expects rivals to change their output by η_t percent when it changes its own

by one percent. We call η_t the *collusiveness* of route t. With $\eta_t = 0$ carriers play Cournot, and with $\eta_t = 1$ every carrier prices as a joint monopolist would.

The pricing equation. Write $p_t = P(Q_t)$ for the route price and take logs of (9.12):

$$\ln p_t = \ln mc_{ft} - \ln\left(1 - \frac{\theta_{ft}}{\varepsilon_t}\right).$$

The expansion $-\ln(1-x) = x + \frac{x^2}{2} + \frac{x^3}{3} + \cdots$ gives $-\ln(1-x) \approx x$ when $x = \frac{\theta_{ft}}{\varepsilon_t}$ is small, so

$$\ln p_t \approx \ln mc_{ft} + \frac{\theta_{ft}}{\varepsilon_t}.$$

Substituting (9.13),

$$\begin{aligned}\ln p_t &\approx \ln mc_{ft} + \frac{s_{ft} + \eta_t(1 - s_{ft})}{\varepsilon_t} \\ &= \ln mc_{ft} + \frac{\eta_t}{\varepsilon_t} + \frac{1-\eta_t}{\varepsilon_t}\, s_{ft}. \end{aligned} \tag{9.14}$$

The approximation is accurate for moderate Lerner indices. At $\frac{\theta_{ft}}{\varepsilon_t} = 0.2$ the exact term is $-\ln 0.8 = 0.223$, against 0.2 for the linear term, so the linear form slightly understates large markups.

Equation (9.14) splits the log price into three parts. The first is marginal cost. The second, $\frac{\eta_t}{\varepsilon_t}$, is a route-level markup shared by every carrier. The third is an own-share term with slope $\frac{1-\eta_t}{\varepsilon_t}$. Under Cournot conduct the slope is $\frac{1}{\varepsilon_t}$ and the route-level term vanishes. Under joint profit maximization the slope is zero, and every carrier's markup reflects only $\frac{1}{\varepsilon_t}$. The share coefficient therefore falls as conduct becomes more collusive.

The umbrella hypothesis. The *umbrella hypothesis* holds that a dominant carrier's high fares shelter its smaller rivals, which can then price above their competitive level. A natural way to formalize it is to let concentration raise collusiveness,

$$\eta_t = \eta_0 + \eta_1 HHI_t, \qquad \eta_1 > 0, \tag{9.15}$$

where $HHI_t = \sum_f s_{ft}^2$ is the route Herfindahl index. Substituting (9.15) into (9.14) and collecting terms,

$$\begin{aligned}\ln p_t &\approx \ln mc_{ft} + \frac{\eta_0 + \eta_1 HHI_t}{\varepsilon_t} + \frac{1 - \eta_0 - \eta_1 HHI_t}{\varepsilon_t}\, s_{ft} \\ &= \ln mc_{ft} + \frac{\eta_0}{\varepsilon_t} + \frac{1-\eta_0}{\varepsilon_t}\, s_{ft} + \frac{\eta_1}{\varepsilon_t}\, HHI_t - \frac{\eta_1}{\varepsilon_t}\, HHI_t\, s_{ft}. \end{aligned} \tag{9.16}$$

The effect of concentration on a carrier's price is $\frac{\partial \ln p_t}{\partial HHI_t} = \frac{\eta_1(1-s_{ft})}{\varepsilon_t}$. It is largest for the carriers with the smallest shares, which is exactly what an umbrella means.

Equation (9.16) maps into the market-power block of Borenstein's pricing equation (9.28), which omits the interaction $HHI_t\, s_{ft}$. Let $\bar{H}$ and $\bar{s}$ be the sample means of HHI_t and s_{ft}. Linearizing the interaction around them gives $HHI_t s_{ft} \approx \bar{H} s_{ft} + \bar{s} HHI_t - \bar{s}\bar{H}$. Holding the elasticity fixed, the route-share coefficient (RUTSHARE) is then $\phi_3 \approx \frac{1-\eta_0-\eta_1\bar{H}}{\varepsilon}$. The route-Herfindahl coefficient (RUTHERF) is $\phi_4 \approx \frac{\eta_1(1-\bar{s})}{\varepsilon}$. The umbrella hypothesis still predicts $\phi_4 > 0$,

and $\eta_1 = 0$ still gives $\phi_4 = 0$. In Borenstein's sample $\bar{H} = 0.50$ and $\bar{s} = 0.54$ (Borenstein, 1989, Table 4), so ϕ_4 is less than half of $\frac{\eta_1}{\varepsilon}$. Variation in ε_t across routes makes all three coefficients averages as well, which is one reason to control for the tourist share of a route's travelers.

Share-weighted margins. Multiplying the Lerner index $L_{ft} = \frac{\theta_{ft}}{\varepsilon_t}$ by s_{ft} and summing over carriers gives the route's share-weighted margin:

$$\sum_f s_{ft} L_{ft} = \frac{1}{\varepsilon_t} \sum_f s_{ft} \left[s_{ft} + \eta_t (1 - s_{ft}) \right] = \frac{1}{\varepsilon_t} \left[\sum_f s_{ft}^2 + \eta_t \left(\sum_f s_{ft} - \sum_f s_{ft}^2 \right) \right]$$
$$= \frac{(1 - \eta_t) HHI_t + \eta_t}{\varepsilon_t}. \tag{9.17}$$

With $\eta_t = 0$ this is the result $\frac{HHI_t}{\varepsilon_t}$ of Cowling and Waterson (1976) (Proposition 2.26). Under Cournot conduct, share-weighted margins rise with concentration even when conduct is identical on every route. A cross-route regression of margins on HHI_t in the structure-conduct-performance tradition (Chapter 1) therefore finds a positive slope without any umbrella effect. Under joint profit maximization ($\eta_t = 1$) the share-weighted margin is $\frac{1}{\varepsilon_t}$ whatever the concentration.

Functional form. Equation (9.14) explains the functional form that the airline pricing literature adopted. Profit maximization makes price proportional to marginal cost times an inverse-elasticity term, so the cost part enters in logs (Borenstein, 1989, p. 354). Borenstein parametrizes $\ln mc_{ft}$ by a carrier effect, the log of nonstop distance and logs of cost and quality variables such as load factor, aircraft size, frequency and circuity. Shares and Herfindahl indices enter linearly. Borenstein motivates the linear share with an example (Borenstein, 1989, p. 354). A rise in share from 1% to 2% should not have the same effect as a rise from 30% to 60%. Our derivation adds a theoretical reason: to first order, the log price is linear in the share. Bailey et al. (1985) had already included the observed carrier's route share and found a positive effect after controlling for route concentration (Borenstein, 1989, p. 348, n. 18). Borenstein describes his equation as a supply relation in the framework of Bresnahan (1989). The cost function is never estimated separately. It is inferred from cross-sectional variation in prices and product attributes (Borenstein, 1989, p. 348, n. 18), as in Chapter 3.

Remark 9.28 (What the share coefficient can and cannot reveal). Borenstein's *two-stage least squares* (2SLS) estimates of ϕ_3 range from 0.029 for the median fare to 0.224 for the 80th percentile fare (Borenstein, 1989, Table 2). Equation (9.16) reads these numbers as $\frac{1-\bar{\eta}}{\varepsilon}$, where $\bar{\eta} = \eta_0 + \eta_1 \bar{H}$ is the collusiveness at the mean Herfindahl index. A Cournot reading with $\bar{\eta} = 0$ requires market elasticities $\varepsilon = \frac{1}{\phi_3}$ between about 4.5 and 35. A market elasticity of 1.5 instead requires $\bar{\eta} = 1 - 1.5\,\phi_3$, between 0.66 and 0.96, which is close to joint profit maximization. Small share coefficients are thus consistent either with elastic route demand or with nearly collusive conduct. Without an independent estimate of ε the regression cannot tell the two apart. This is the identification problem of Chapter 3 in a new setting.

Two features of airline markets strain the homogeneous-goods model and motivate the rest of this section. First, the model predicts a single price on each route. Carriers on the same route charge different fares, and each sells many fares. Borenstein's relative-price equation (9.32) compares two carriers' fares on the same route, and in the homogeneous model its left side is identically zero. With a common price, (9.14) also forces carriers with larger shares to have lower marginal costs. Second, a large share may reflect a better product or a lower cost rather than market power. Demsetz (1973) made this argument for concentration across industries

(Chapter 1). In the homogeneous model the share is a sufficient statistic for cost efficiency. When costs are measured with error, the share coefficient absorbs the unmeasured part of cost. In a differentiated market, a carrier with a more attractive product has both a larger share and a higher price, so the share coefficient also absorbs quality. Instruments for the share, such as Borenstein's GENPSH (Section 9.5), address the simultaneity of share and price. They cannot separate market power from quality when the two are the same thing, as the next model shows.

9.4.2 Dominance as product differentiation: markups without an umbrella

Many of the sources of airport dominance described in Section 9.2.4 work through demand. A frequent-flyer program is worth more when the carrier flies to more places from the traveler's home airport. Frequency, convenient gates and a local reputation make a carrier's flights more attractive. Berry (1990) treats airport presence as a source of product differentiation in this sense. We now model dominance as higher non-price quality and ask what it implies for prices.

Assumption 9.29 (Logit route market)**.** Route t (subscript dropped) has single-product carriers $j = 1, \dots, J$ and an outside good $j = 0$. Consumer i has utility $u_{ij} = \delta_j - \alpha p_j + \epsilon_{ij}$ for $j \geq 1$ and $u_{i0} = \epsilon_{i0}$, with ϵ_{ij} i.i.d. type-I extreme value and $\alpha > 0$. Carrier j has constant marginal cost c_j and chooses p_j to maximize $(p_j - c_j)Ms_j(p)$, taking rivals' prices as given.

In this subsection only, δ_j denotes the non-price part of mean utility ($x_j\beta + \xi_j$ in the notation of Chapter 7), so that mean utility including price is $\delta_j - \alpha p_j$. Shares and own-price derivatives are (Chapter 7)

$$s_j = \frac{e^{\delta_j - \alpha p_j}}{1 + \sum_{k=1}^{J} e^{\delta_k - \alpha p_k}}, \qquad \frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j).$$

The first-order condition $s_j + (p_j - c_j)\frac{\partial s_j}{\partial p_j} = 0$ becomes $s_j - \alpha(p_j - c_j)s_j(1 - s_j) = 0$. Dividing by $\alpha s_j(1 - s_j)$,

$$p_j - c_j = \frac{1}{\alpha(1 - s_j)}. \tag{9.18}$$

Proposition 9.30 (Dominance without an umbrella)**.** *Under Assumption 9.29 the Bertrand-Nash equilibrium exists and is unique. In equilibrium:*

(i) Each carrier's markup $p_j - c_j = \frac{1}{\alpha(1-s_j)}$ is strictly increasing in its own share, so carriers with larger shares charge larger markups.

(ii) An increase in δ_1 raises p_1 and s_1, lowers the outside share s_0, and lowers p_k and s_k for every rival $k \neq 1$.

Proof. Part (i) is immediate from (9.18). For part (ii) and for existence and uniqueness we reduce the equilibrium to a single equation in s_0.

Step 1 (one equation per carrier). Let $m_j = p_j - c_j$ and $a_j = e^{\delta_j - \alpha c_j}$. The first-order condition (9.18) is $s_j = 1 - \frac{1}{\alpha m_j}$, which requires $m_j > \frac{1}{\alpha}$. The logit formula gives $\frac{s_j}{s_0} = e^{\delta_j - \alpha p_j} = a_j e^{-\alpha m_j}$. Substituting the first-order condition into the logit ratio,

$$1 - \frac{1}{\alpha m_j} = s_0\, a_j e^{-\alpha m_j}, \qquad \text{so} \qquad h(m_j) \equiv \left(1 - \frac{1}{\alpha m_j}\right) e^{\alpha m_j} = s_0\, a_j.$$

Step 2 (h is invertible). On $\left(\frac{1}{\alpha}, \infty\right)$, h is continuous, h tends to 0 as $m \downarrow \frac{1}{\alpha}$, and $h(m) \to \infty$ as $m \to \infty$. Its derivative is

$$h'(m) = e^{\alpha m}\left[\frac{1}{\alpha m^2} + \alpha - \frac{1}{m}\right] = e^{\alpha m}\,\frac{(\alpha m)^2 - \alpha m + 1}{\alpha m^2} > 0,$$

because $x^2 - x + 1 = \left(x - \frac{1}{2}\right)^2 + \frac{3}{4} > 0$. Hence $m_j = h^{-1}(s_0 a_j)$ is strictly increasing in $s_0 a_j$. The share is $s_j = S(s_0 a_j)$ with $S(y) \equiv 1 - \frac{1}{\alpha h^{-1}(y)}$, which is continuous and strictly increasing, with $S(y) \to 0$ as $y \to 0$ and $S(y) \to 1$ as $y \to \infty$.

Step 3 (existence and uniqueness). Shares add up to one:

$$G(s_0; a) \equiv s_0 + \sum_{j=1}^{J} S(s_0 a_j) = 1.$$

G is continuous and strictly increasing in s_0, with $G(0; a) = 0$ and $G(1; a) > 1$. A unique $s_0^* \in (0, 1)$ solves the equation, and Step 2 then gives unique markups and shares. Any equilibrium satisfies the first-order conditions, so there is at most one equilibrium. The first-order conditions are also sufficient. Given rivals' prices, the left side of $p_j - c_j = \frac{1}{\alpha(1 - s_j(p))}$ rises in p_j while the right side falls, because s_j falls in p_j. Profit therefore rises below the unique crossing and falls above it, so the crossing is the best response.

Step 4 (comparative statics). A higher δ_1 raises a_1. Since S is increasing, $G(s_0; a)$ rises at every s_0, so the solution s_0^* falls. For each $k \neq 1$, the product $s_0^* a_k$ falls, so m_k and s_k fall, and $p_k = c_k + m_k$ falls. Finally $s_1 = 1 - s_0^* - \sum_{k \neq 1} s_k$ rises because s_0^* and every s_k fall. Then $m_1 = \frac{1}{\alpha(1 - s_1)}$ rises and so does $p_1 = c_1 + m_1$. □

The existence and uniqueness result agrees with the general results for logit-type demand in Chapter 4 (Caplin and Nalebuff, 1991). The single-equation reduction is useful in its own right, since it computes the equilibrium by solving one monotone equation. Figure 9.4 uses it.

Figure 9.4 traces the equilibrium of a two-carrier route as carrier 1's quality rises from $\delta_1 = 1$ to $\delta_1 = 3$. Carrier 1's share rises from 0.185 to 0.464 and its price from 2.227 to 2.867. The rival's share falls from 0.185 to 0.129 and its price from 2.227 to 2.148. The Herfindahl index of inside shares rises from 0.500 to 0.660. Concentration rises and the rival's price falls, the opposite of an umbrella. Logit prices are strategic complements, so carrier 1's higher price alone would push p_2 up. The loss of customers to the better product outweighs this effect, and the rival's markup $\frac{1}{\alpha(1 - s_2)}$ falls with its share.

Corollary 9.31 (Relative prices)**.** *Under Assumption 9.29, an increase in δ_1 raises $\ln p_1 - \ln p_k$ for every $k \neq 1$. Along any path of shares, $\frac{\mathrm{d} \ln p_j}{\mathrm{d} s_j} = \frac{L_j}{1 - s_j}$, where $L_j = \frac{p_j - c_j}{p_j}$ is the Lerner index. With equal costs, $\ln p_1 - \ln p_k \approx \frac{L}{1 - s}(s_1 - s_k)$ for shares near a common value s with Lerner index L.*

Proof. The first claim follows from Proposition 9.30(ii), since p_1 rises and p_k falls. For the slope, differentiate (9.18): $\frac{\mathrm{d} m_j}{\mathrm{d} s_j} = \frac{1}{\alpha(1 - s_j)^2} = \frac{m_j}{1 - s_j}$. Then $\frac{\mathrm{d} \ln p_j}{\mathrm{d} s_j} = \frac{1}{p_j}\frac{\mathrm{d} m_j}{\mathrm{d} s_j} = \frac{m_j}{p_j}\frac{1}{1 - s_j} = \frac{L_j}{1 - s_j}$. A first-order expansion around the common share gives the approximation. □

The corollary is the structural counterpart of Borenstein's relative-price equation (9.32). There, the coefficient on the difference in route shares between two carriers on the same route plays the role of $\frac{L(1 - s_0)}{1 - s}$. Route shares are shares of fliers, $\frac{s_j}{1 - s_0}$, so the gap in route shares between carriers 1 and k is $\frac{s_1 - s_k}{1 - s_0}$. A positive coefficient is what product differentiation predicts,

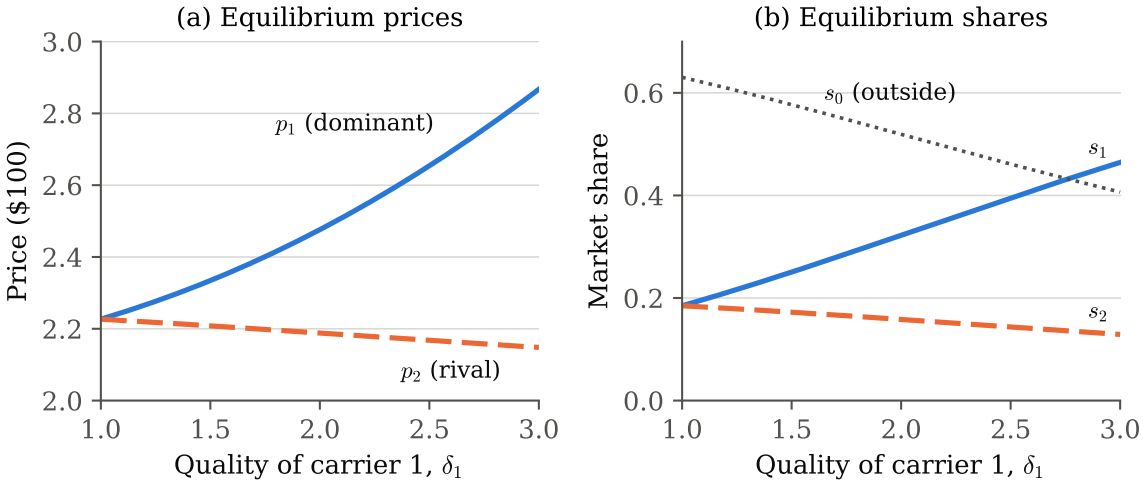

Figure 9.4: Logit Bertrand equilibrium on a route with two carriers and an outside good, as carrier 1's non-price quality δ_1 rises. Parameters are $\alpha = 1$ (prices in \$100), $c_1 = c_2 = 1$ and $\delta_2 = 1$. At $\delta_1 = 1$ both carriers charge 2.227. At $\delta_1 = 3$, $p_1 = 2.867$, $p_2 = 2.148$, $s_1 = 0.464$ and $s_2 = 0.129$. The dominant carrier's price rises while its rival's falls.

with no change in conduct. In the example of Figure 9.4, $\ln p_1 - \ln p_2$ rises from 0 to 0.289 as δ_1 goes from 1 to 3.

Remark 9.32 (Quality or cost?). The equilibrium depends on (δ_j, c_j) only through $a_j = e^{\delta_j - \alpha c_j}$. A cost advantage therefore has the same effect on shares and markups as a quality advantage of α times the cost gap. In the example of Figure 9.4, $(\delta_1, c_1) = (1.5, 1)$ and $(\delta_1, c_1) = (1, 0.5)$ give identical shares ($s_1 = 0.251$, $s_2 = 0.172$) and the same markup $m_1 = 1.334$. Only carrier 1's price differs, 2.334 against 1.834. A relation between shares and markups cannot reveal whether dominance comes from quality or from cost. Separating them requires a model of costs, which is what Section 9.4.4 and Section 9.7 provide.

Multi-product carriers. A carrier usually sells several products on a route: direct and connecting itineraries, and several fare classes. With logit demand, the first-order condition for $j \in \mathcal{J}_f$ is $s_j - \alpha s_j m_j + \alpha s_j \sum_{k \in \mathcal{J}_f} s_k m_k = 0$. Dividing by αs_j gives $m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k$. The right side does not depend on j, so all of the carrier's products carry a common markup m_f. Substituting back, $m_f = \frac{1}{\alpha} + S_f m_f$, so

$$m_f = \frac{1}{\alpha(1 - S_f)}, \qquad S_f = \sum_{k \in \mathcal{J}_f} s_k$$

(Chapter 7). Summing the logit ratios over the carrier's products gives $\frac{S_f}{s_0} = A_f e^{-\alpha m_f}$ with $A_f = \sum_{k \in \mathcal{J}_f} a_k$. The proof of Proposition 9.30 then applies with carriers in place of products and A_f in place of a_j. A carrier with a large total share on the route earns a large markup on every product it sells there.

The logit model also has a limitation that matters for airlines. Every product of a carrier carries the same dollar markup, whether it is a restricted discount ticket or an unrestricted fare. Characteristics affect the markup only through shares. The model cannot express the idea that a hub lets its carrier raise fares mainly to business travelers. That requires heterogeneity in price sensitivity, to which we now turn.

9.4.3 Consumer heterogeneity: a finite-mixture nested logit

Air travelers differ in ways that matter for pricing. Business travelers are less sensitive to price (Berry et al., 2006, p. 10, n. 9). Their trips are urgent, travel is a deductible business expense, and the traveler may not bear the full cost of the ticket. They may also value frequency, nonstop service and frequent-flyer benefits more, so tastes are correlated across characteristics. A model in which the price coefficient and the tastes vary across consumers lets markups differ across the products of one carrier. It also lets a hub's demand advantage fall on particular travelers. Earlier discrete choice models of air travel, such as that of Morrison and Winston (1986), used a logit with common coefficients (Berry et al., 2006, p. 8). Berry et al. (2006) adopt the simplest distribution with heterogeneous tastes, a two-point distribution of types. We develop the model with R types and specialize to $R = 2$ in Section 9.7.

Assumption 9.33 (Finite-mixture nested logit)**.** Market t has M_t potential travelers. Each belongs to one of R types, and type r has population share $\psi_r > 0$ with $\sum_r \psi_r = 1$. A traveler i of type r has utility

$$u_{ijt} = x_{jt}\beta_r - \alpha_r p_{jt} + \xi_{jt} + \zeta_{igt} + (1-\sigma)\epsilon_{ijt} \quad (j \in \mathcal{J}_t), \qquad u_{i0t} = \epsilon_{i0t}.$$

The shocks ϵ_{ijt} are i.i.d. type-I extreme value. All inside goods form one nest g and the outside good forms its own nest. The term ζ_{igt} is common to all inside goods for traveler i and has the distribution of Cardell (1997), which makes $\zeta_{igt} + (1-\sigma)\epsilon_{ijt}$ type-I extreme value, with $\sigma \in [0, 1)$. The unobserved quality ξ_{jt} is common to all types.

The nesting parameter σ measures the correlation of a traveler's utilities across flights. With $\sigma = 0$ the model is a mixture of logits, and as $\sigma \to 1$ flights become perfect substitutes for one another relative to the outside good (Chapter 7, Chapter 6). Berry, Carnall and Spiller write the idiosyncratic term as $\lambda\epsilon_{ij}$, so their λ equals $1 - \sigma$. In applications M_t is unobserved. They set $M_t = \kappa\, MPOP_t$, with $MPOP_t$ the geometric mean of the endpoint populations and κ a parameter to be estimated (Berry et al., 2006, p. 9).

Remark 9.34 (Discrete random coefficients). The type structure is a random coefficients logit (Chapter 8) whose mixing distribution has R support points (α_r, β_r) with probabilities ψ_r. Normal random coefficients are the usual alternative. Suppose K coefficients, price included, vary across consumers. Two types then require $2K + 1$ parameters, two values per coefficient plus ψ_1, against $2K$ for independent normals with a mean and a standard deviation each (Berry et al., 2006, p. 11). In exchange the shares have a closed form and no simulation is needed. A two-point distribution is bimodal and makes tastes correlated across characteristics by construction. The price is that it has no taste variation within a type. Mixtures of normals or more types would relax this but require numerical integration or many more parameters.

Shares. Fix a market and write δ^r_{jt} for the mean utility of type r, which includes price as in

Chapter 7. Conditional on type, the model is a nested logit, so

$$\delta^r_{jt} = x_{jt}\beta_r - \alpha_r p_{jt} + \xi_{jt}, \tag{9.19a}$$

$$D_{rt} = \sum_{k \in \mathcal{J}_t} \exp\left(\frac{\delta^r_{kt}}{1-\sigma}\right), \tag{9.19b}$$

$$s^r_{j|g,t} = \frac{1}{D_{rt}} \exp\left(\frac{\delta^r_{jt}}{1-\sigma}\right), \tag{9.19c}$$

$$\bar{s}_{rt} = \frac{D^{1-\sigma}_{rt}}{1 + D^{1-\sigma}_{rt}}, \tag{9.19d}$$

$$s^r_{jt} = s^r_{j|g,t}\, \bar{s}_{rt}, \tag{9.19e}$$

$$s_{jt} = \sum_{r=1}^{R} \psi_r\, s^r_{jt}. \tag{9.19f}$$

Here $s^r_{j|g,t}$ is the probability that a type-r traveler chooses j given that she flies, and $\bar{s}_{rt}$ is the probability that she flies at all. The last line averages over types by the law of total probability. The outside share is $s_{0t} = \sum_r \frac{\psi_r}{1+D^{1-\sigma}_{rt}}$. The *inclusive sum* D_{rt} is the denominator of type r's within-nest shares. It carries a type subscript and should not be confused with the diversion ratio D_{jk} below, which carries two product subscripts. In the rest of this subsection we drop the market subscript.

Derivatives. We differentiate the type-specific shares with respect to type-specific mean utilities and then convert to prices. From (9.19),

$$\ln s^r_j = \frac{\delta^r_j}{1-\sigma} - \ln D_r + (1-\sigma)\ln D_r - \ln\left(1 + D^{1-\sigma}_r\right) = \frac{\delta^r_j}{1-\sigma} - \sigma \ln D_r - \ln\left(1 + D^{1-\sigma}_r\right).$$

The two building blocks are

$$\frac{\partial \ln D_r}{\partial \delta^r_k} = \frac{1}{1-\sigma}\,\frac{1}{D_r}\exp\left(\frac{\delta^r_k}{1-\sigma}\right) = \frac{s^r_{k|g}}{1-\sigma}, \qquad \frac{\partial \ln\left(1 + D^{1-\sigma}_r\right)}{\partial \delta^r_k} = \bar{s}_r\,(1-\sigma)\,\frac{\partial \ln D_r}{\partial \delta^r_k} = \bar{s}_r\, s^r_{k|g} = s^r_k.$$

Therefore

$$\frac{\partial \ln s^r_j}{\partial \delta^r_k} = \frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma}\, s^r_{k|g} - s^r_k.$$

Multiplying by s^r_j and using $s^r_j\, s^r_{k|g} = s^r_k\, s^r_{j|g}$ gives the own and cross derivatives. Since $\frac{\partial \delta^r_k}{\partial p_k} = -\alpha_r$, the price derivatives of aggregate shares follow:

$$\frac{\partial s^r_j}{\partial \delta^r_j} = s^r_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}\, s^r_{j|g} - s^r_j\right], \tag{9.20a}$$

$$\frac{\partial s^r_j}{\partial \delta^r_k} = -s^r_k\left[\frac{\sigma}{1-\sigma}\, s^r_{j|g} + s^r_j\right], \qquad k \neq j, \tag{9.20b}$$

$$\frac{\partial s_j}{\partial p_k} = -\sum_{r=1}^{R} \psi_r\, \alpha_r\, \frac{\partial s^r_j}{\partial \delta^r_k}. \tag{9.20c}$$

The matrix of type-specific derivatives is symmetric, so $\frac{\partial s_j}{\partial p_k} = \frac{\partial s_k}{\partial p_j}$ in this model. Own-price derivatives are negative and cross-price derivatives are positive.

Buyer composition. Bayes' rule gives the composition of each product's buyers:

$$\mathbb{P}(r \mid j) = \frac{\psi_r \, s^r_{jt}}{s_{jt}}. \tag{9.21}$$

The numerator is the probability of being type r and buying j, and the denominator is the probability of buying j. Berry, Carnall and Spiller use these weights to compute average fares, costs and markups by type (Section 9.7). With them, the own-price elasticity and the diversion ratio take a transparent form. Dividing (9.20) by s_j,

$$\varepsilon_{jj} = -\frac{\partial s_j}{\partial p_j}\frac{p_j}{s_j} = p_j \sum_r \mathbb{P}(r \mid j)\,\alpha_r \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}\, s^r_{j|g} - s^r_j\right],$$

$$D_{jk} = -\frac{\frac{\partial s_k}{\partial p_j}}{\frac{\partial s_j}{\partial p_j}} = \frac{\sum_r \mathbb{P}(r \mid j)\,\alpha_r \left[\frac{\sigma}{1-\sigma}\, s^r_{k|g} + s^r_k\right]}{\sum_r \mathbb{P}(r \mid j)\,\alpha_r \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}\, s^r_{j|g} - s^r_j\right]}.$$

A product bought mostly by price-insensitive types has a low elasticity even at a high price. This breaks the logit's implication that elasticities rise in proportion to price (Chapter 7). Diversion from j to k is high when the types who buy j are the types for whom k has a large share. Two cheap tickets bought by the same price-sensitive travelers are therefore close substitutes, whatever their aggregate shares.

Proposition 9.35 (Who pays the premium)**.** *Under Assumption 9.33 with $\sigma = 0$, suppose carrier f sells the single product j in market t and sets its price as in Nash-Bertrand equilibrium.*

(a) The markup is

$$p_j - mc_j = \frac{s_j}{\sum_r \psi_r \alpha_r s^r_j (1 - s^r_j)} = \frac{1}{\sum_r \mathbb{P}(r \mid j)\,\alpha_r (1 - s^r_j)}.$$

(b) Let $R = 2$. Holding all prices fixed, a marginal increase in a characteristic x^h_j of product j raises the share of type-2 buyers $\mathbb{P}(2 \mid j)$ if and only if $\beta^h_2(1 - s^2_j) > \beta^h_1(1 - s^1_j)$.

Proof. (a) The first-order condition is $s_j + (p_j - mc_j)\frac{\partial s_j}{\partial p_j} = 0$. With $\sigma = 0$, (9.20) gives $\frac{\partial s_j}{\partial p_j} = -\sum_r \psi_r \alpha_r s^r_j (1 - s^r_j)$. Solving for the markup gives the first expression. Dividing numerator and denominator by s_j and using (9.21) gives the second.

(b) Write $\mathbb{P}(2 \mid j) = \left[1 + \frac{\psi_1 s^1_j}{\psi_2 s^2_j}\right]^{-1}$, which is increasing in $\ln s^2_j - \ln s^1_j$. With $\sigma = 0$, $\frac{\partial \ln s^r_j}{\partial \delta^r_j} = 1 - s^r_j$ and $\frac{\partial \delta^r_j}{\partial x^h_j} = \beta^h_r$. Hence $\frac{\partial(\ln s^2_j - \ln s^1_j)}{\partial x^h_j} = \beta^h_2(1 - s^2_j) - \beta^h_1(1 - s^1_j)$. □

Part (a) says that the markup is the inverse of a buyer-weighted average price sensitivity. When type-specific shares are small, the markup is close to $\frac{1}{\bar\alpha_j}$, where $\bar\alpha_j = \sum_r \mathbb{P}(r \mid j)\alpha_r$ is the mean price coefficient among j's buyers. Part (b) says which characteristics move the buyer mix. Combine the two with $\alpha_2 < \alpha_1$. A characteristic that type 2 values more, such as hub

presence valued by business travelers, tilts j's buyers toward type 2. This lowers $\bar{\alpha}_j$ and raises the markup on j. Products bought mainly by tourists keep low markups even when the hub carrier sells them. The hub premium thus falls on the travelers who value the hub, which is the mechanism behind the results of Section 9.7. In the logit model, by contrast, the markup $\frac{1}{\alpha(1-s_j)}$ depends on characteristics only through the share.

Remark 9.36 (Nesting and multi-product carriers). With $\sigma > 0$ the same steps give $p_j - mc_j = \left(\sum_r \mathbb{P}(r \mid j)\, \alpha_r \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s^r_{j|g} - s^r_j \right] \right)^{-1}$. If within-nest shares are small, the bracket is close to $\frac{1}{1-\sigma}$ and the markup is close to $\frac{1-\sigma}{\bar{\alpha}_j}$. Closer substitution among flights (larger σ) lowers markups. A product with a large within-nest share among its own buyers earns a higher markup. With multi-product carriers the markups solve the system (9.23) below. They differ across a carrier's products according to buyer composition, unlike the common logit markup $\frac{1}{\alpha(1-S_f)}$.

Inversion. Estimation requires the vector ξ_t that rationalizes observed shares. For given demand parameters $\theta_d = (\sigma, \{\alpha_r, \beta_r, \psi_r\}_{r=1}^R)$ and market size, (9.19) defines shares $s_t(\xi_t; \theta_d)$, and we must solve $s_t(\xi_t; \theta_d) = s_t^{obs}$ for ξ_t. Berry (1994) shows that this inverse exists and is unique (Chapter 7, Chapter 8). Berry, Carnall and Spiller compute it with "a slight variation" of the contraction of Berry et al. (1995) (Berry et al., 2006, p. 17). One natural variation dampens the step by $1 - \sigma$:

$$\xi^{n+1} = \Phi(\xi^n), \qquad \Phi(\xi) \equiv \xi + (1-\sigma)\big[\ln s^{obs} - \ln s(\xi; \theta_d)\big]. \tag{9.22}$$

A fixed point of Φ satisfies $\ln s(\xi; \theta_d) = \ln s^{obs}$. The next lemma shows why the dampening works.

Lemma 9.37 (Contraction for the finite-mixture nested logit)**.** *At every ξ, all elements of the Jacobian of Φ are positive, and each row sums to $\sum_r \mathbb{P}(r \mid j)\big[\sigma + (1-\sigma)\bar{s}_r\big] \le \sigma + (1-\sigma)\max_r \bar{s}_r < 1$. Hence Φ is a contraction in the sup norm, with modulus at most $\sigma + (1-\sigma)\bar{S}$, on any convex set of ξ on which every inside share satisfies $\bar{s}_r \le \bar{S} < 1$.*

Proof. Each δ^r_k moves one for one with ξ_k, so by (9.19) and (9.21)

$$\frac{\partial \ln s_j}{\partial \xi_k} = \frac{1}{s_j} \sum_r \psi_r s^r_j \frac{\partial \ln s^r_j}{\partial \delta^r_k} = \sum_r \mathbb{P}(r \mid j) \Big[\frac{\mathbf{1}\{j=k\}}{1-\sigma} - \frac{\sigma}{1-\sigma}\, s^r_{k|g} - s^r_k \Big].$$

Multiplying by $1 - \sigma$ and using $\sum_r \mathbb{P}(r \mid j) = 1$,

$$(1-\sigma)\frac{\partial \ln s_j}{\partial \xi_k} = \mathbf{1}\{j=k\} - \sum_r \mathbb{P}(r \mid j)\big[\sigma s^r_{k|g} + (1-\sigma) s^r_k\big].$$

The Jacobian of Φ is therefore $\frac{\partial \Phi_j}{\partial \xi_k} = \sum_r \mathbb{P}(r \mid j)\big[\sigma s^r_{k|g} + (1-\sigma) s^r_k\big] > 0$. Summing over k and using $\sum_k s^r_{k|g} = 1$ and $\sum_k s^r_k = \bar{s}_r$ gives the row sum. With positive elements, the sup norm of the Jacobian equals its largest row sum. The mean value theorem then bounds $\|\Phi(\xi) - \Phi(\xi')\|_\infty$ by the modulus times $\|\xi - \xi'\|_\infty$ on a convex set. □

The set on which inside shares are bounded by $\bar{S}$ is convex, because D_r is a convex function of ξ. Applying the contraction mapping theorem (Appendix B) also requires a set that Φ maps into itself. The bounding argument of Berry et al. (1995) supplies one (Chapter 8). In airline

city pairs, actual trips are a small fraction of potential trips. Inside shares are then small and the modulus is close to σ, so the iteration converges quickly.

Markups. Within a single market, carrier f chooses the prices of its products $\mathcal{J}_f(t)$ to maximize $\sum_{j\in\mathcal{J}_f(t)}(p_j - mc_j)M_t s_j(p)$. The first-order condition for $j \in \mathcal{J}_f(t)$ is

$$s_j + \sum_{k\in\mathcal{J}_f(t)} (p_k - mc_k)\frac{\partial s_k}{\partial p_j} = 0.$$

Let Ω be the ownership matrix and Δ the matrix with (j,k) element $\frac{\partial s_j}{\partial p_k}$ (Chapter 4). The (j,k) element of $(\Omega \odot \Delta)^\top$ is $\Omega_{kj}\frac{\partial s_k}{\partial p_j}$, so stacking the conditions gives

$$s + (\Omega \odot \Delta)^\top (p - mc) = 0 \quad \Longrightarrow \quad p - mc = -\left[(\Omega \odot \Delta)^\top\right]^{-1} s, \qquad \Delta = -\sum_{r=1}^{R} \psi_r \, \alpha_r \, \frac{\partial s^r}{\partial \delta^r}, \tag{9.23}$$

where $\frac{\partial s^r}{\partial \delta^r}$ is the matrix with (j,k) element $\frac{\partial s_j^r}{\partial \delta_k^r}$ from (9.20).[2] In this model Ω and Δ are both symmetric, so the transpose is immaterial. It matters for general demand systems. The markups depend only on the demand parameters and on observed prices and shares. Given demand estimates, marginal cost follows as $mc = p + \left[(\Omega \odot \Delta)^\top\right]^{-1} s$, without any cost data.

How aggregate data identify types. Berry, Carnall and Spiller explain how market-level data can distinguish two consumer types from one (Berry et al., 2006, pp. 18–19). The key is variation across markets in the number of similar products. The following example makes their argument quantitative.

Example 9.38 (Two types from aggregate shares)**.** Consider two city pairs, A and B, identical in every respect except their sets of products. Products are identical except for price. Market A has a product H at \$200 and a product L at \$100. Market B has H at \$200 and two products L_1 and L_2 at \$100. In market A we observe $s_H = s_L$.

One type. In a nested logit with a single type, within-nest shares are proportional to $\exp\left(\frac{\delta_j}{1-\sigma}\right)$. Equal shares in market A therefore imply $\delta_H = \delta_L$. In market B the three products then have equal mean utilities and equal shares, for any α and σ. The same conclusion holds in any model whose error is additive and i.i.d. across products (Berry et al., 2006, p. 18).

Two types. Let $\alpha_1 = 3$ and $\alpha_2 = 0.1$ per \$100, $\psi_1 = 0.9$, $\sigma = 0.4$ and $\delta_j^r = \xi_j - \alpha_r p_j$ with $\xi_L = 0$. Setting $\xi_H = 0.903$ equates the two shares in market A at 0.0567. In market A, 97% of type 1's flights are on L, while 79% of type 2's flights are on H. Adding L_2 in market B splits type 1's demand for cheap flights and barely touches type 2's demand for H. Market B shares become 0.0483 for H and 0.0438 for each cheap product, so H's share is 10% above each of the others (Table 9.1, Figure 9.5). Under one type every product loses 17.5% of its share when L_2 enters. Under two types H loses 14.7% and L loses 22.7%.

The substitution patterns explain the difference. In market B, 28% of each cheap product's buyers are type 2, against 98% of H's buyers. A rise in the price of L_1 diverts 0.277 of its lost

[2] Berry, Carnall and Spiller define Δ with (j,k) element $\frac{\partial s_k}{\partial p_j}$ for products of the same carrier and write $p = \Delta^{-1}s + mc$ (Berry et al., 2006, pp. 15–16). The equation holds when Δ contains the negatives of the price derivatives. Their formula $\Delta = \gamma\alpha_1\Delta_1 + (1-\gamma)\alpha_2\Delta_2$, with Δ_r the derivatives with respect to mean utility and γ the type-1 probability, delivers exactly these negatives, since $\frac{\partial s^r}{\partial p} = -\alpha_r \frac{\partial s^r}{\partial \delta^r}$.

sales to L_2 and only 0.017 to H. A one-type model would divert equal fractions to L_2 and H. The farther apart α_1 and α_2, the larger the gap between the shares of H and L in market B. Data with many such comparisons across markets therefore pin down the dispersion of price coefficients.

Which type values hubs? Now add a hub characteristic x_j^h with type-specific coefficients β_r^h. Differentiating (9.19) as in Lemma 9.37,

$$\frac{\partial \ln s_j}{\partial x_j^h} = \sum_r \mathbb{P}(r \mid j)\, \beta_r^h \, \frac{\partial \ln s_j^r}{\partial \delta_j^r},$$

a buyer-weighted average of type-specific responses. In market A, with $(\beta_1^h, \beta_2^h) = (0.2, 1.0)$ the semi-elasticities are 0.579 for H and 0.499 for L. With $(\beta_1^h, \beta_2^h) = (1.0, 0.2)$ they are 0.151 for H and 0.794 for L. How the shares of cheap and expensive products respond to hub presence thus reveals which type has the large hub coefficient (Berry et al., 2006, p. 19).

Table 9.1: Two-type identification example: market shares and buyer composition

		Market A	Market B		$\mathbb{P}(r=2 \mid j)$	
Product	Price ($)	both models	one type	two types	A	B
H	200	0.0567	0.0467	0.0483	0.977	0.980
L in A, L_1 in B	100	0.0567	0.0467	0.0438	0.256	0.284
L_2	100		0.0467	0.0438		0.284
Outside good		0.8867	0.8598	0.8641		

Notes: Both models are calibrated to reproduce market A exactly. The two-type model has $\alpha_1 = 3$, $\alpha_2 = 0.1$ (per $100), $\psi_1 = 0.9$, $\sigma = 0.4$, $\xi_L = 0$ and $\xi_H = 0.903$. The one-type model is a nested logit with the same σ. Our computations.

Remark 9.39 (The role of nesting in the example). The direction of the departure from the one-type prediction depends on the whole specification. With $\sigma = 0$ and the same α_r and ψ_r, recalibrating ξ_H to fit market A gives market B shares of 0.0530 for H and 0.0576 for each cheap product. Without nesting, flights compete mainly with the outside good. Type 2 values every flight highly because α_2 is small, so it gives the new cheap product a larger share than type 1 does, and H loses more. The nesting parameter makes flights compete with one another within each type. What identifies the types is the existence of departures from the one-type prediction, and the data determine their direction.

Random coefficients also change how markups respond to entry. Berry, Carnall and Spiller stress that with random coefficients, introducing similar products drives markups down (Berry et al., 2006, p. 18). In Example 9.38, the inverse semi-elasticity of L's demand, $-s_L\left(\frac{\partial s_L}{\partial p_L}\right)^{-1}$, is the markup a single-product seller of L would choose. It falls from 0.453 ($45) in market A to 0.352 ($35) in market B, because L_2 competes for exactly the travelers who buy L. A one-type nested logit with the same σ predicts a fall of only 9%, which comes from the decline in L's shares alone.

9.4.4 Network costs and economies of density

The cost side of hubbing rests on an engineering argument. Larger aircraft are cheaper to fly per seat mile, at least on longer routes (Berry et al., 2006, pp. 3–4). For a given flight frequency,

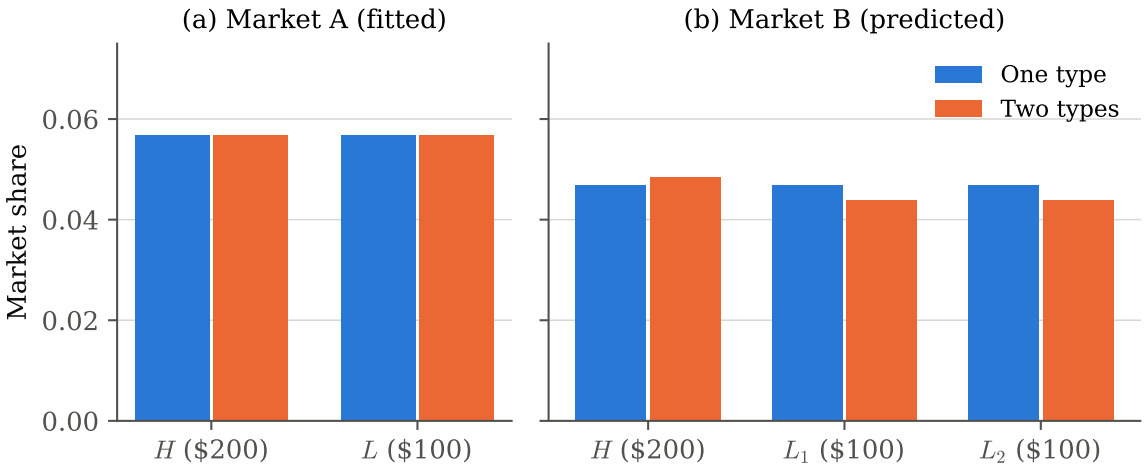

Figure 9.5: Identifying two types from aggregate shares. Both models fit market A, where the $200 and $100 products have equal shares. In market B, which adds a second $100 product, the one-type model predicts three equal shares. The two-type model predicts that the expensive product keeps more of its share, because the two cheap products compete for the same price-sensitive travelers. Parameters as in Table 9.1.

a densely traveled spoke can use larger aircraft. A hub combines passengers bound for many destinations on one large aircraft to the hub, where they change planes. We first define the relevant cost concepts, then work through a stylized network, and finally derive the pricing condition of a network carrier.

Definition 9.40 (Returns to density and to scale)**.** Let $C(Q, P, w)$ be a carrier's total cost, with traffic Q (for example passenger miles), number of points served P and input prices w. Write $\varepsilon_{CQ} = \frac{\partial \ln C}{\partial \ln Q}$ and $\varepsilon_{CP} = \frac{\partial \ln C}{\partial \ln P}$. *Returns to density* and *returns to scale* are

$$RTD = \frac{1}{\varepsilon_{CQ}}, \qquad RTS = \frac{1}{\varepsilon_{CQ} + \varepsilon_{CP}}. \tag{9.24}$$

Returns to density measure the cost of adding traffic to a fixed network, and returns to scale the cost of expanding traffic and the network together. Since $\varepsilon_{CQ} = \frac{Q}{C}\frac{\partial C}{\partial Q}$, the density elasticity also equals the ratio of marginal to average cost of traffic. Caves et al. (1984) estimate an airline cost function (Berry et al., 2006, p. 4). Holding the route structure fixed, total cost rises only 80% as fast as traffic. This means $\varepsilon_{CQ} \approx 0.8$ and $RTD \approx \frac{1}{0.8} = 1.25$. Berry, Carnall and Spiller point out two limits of this approach. An aggregate cost function ignores details of route structure that determine densities. Holding the number of endpoints fixed, for instance, densities fall as a carrier operates more hubs (Berry et al., 2006, p. 4, n. 7). And route-level cost data do not exist, since route-level total or average cost is not even well defined. Brueckner and Spiller (1994) instead model the marginal cost of a passenger on each leg as a function of that leg's density and sum over the legs of an itinerary. They find that funneling passengers through hub airports raised traffic densities and let carriers reduce costs (Berry et al., 2006, pp. 4–5). Brueckner et al. (1992) make the related point that itineraries through a hub may have lower costs because they raise spoke density (Berry et al., 2006, p. 2). Berry, Carnall and Spiller adopt the leg-level approach.

Example 9.41 (Hub-and-spoke versus point-to-point costs)**.** A carrier serves n outer cities and one hub city. Every pair of the $n+1$ cities has A round-trip passengers. Each leg has cost $C(Q) = aQ^{\gamma}$ with $0 < \gamma \leq 1$, so legs have *economies of density*, marginal and average cost falling with traffic, when $\gamma < 1$. All legs have equal length and we ignore circuity.

Point to point. Every city pair gets a nonstop leg. There are $\frac{n(n+1)}{2}$ legs, each carrying density A, so

$$C^{PP} = \frac{n(n+1)}{2}\, aA^{\gamma}.$$

Hub and spoke. There are n spokes. The spoke from outer city e carries the A passengers between e and the hub and the A passengers between e and each of the other $n-1$ outer cities. Its density is $A + (n-1)A = nA$, so

$$C^{HS} = n\, a(nA)^{\gamma} = aA^{\gamma}\, n^{1+\gamma}.$$

Comparison. Dividing,

$$\frac{C^{HS}}{C^{PP}} = \frac{aA^{\gamma} n^{1+\gamma}}{\frac{n(n+1)}{2} aA^{\gamma}} = \frac{2n^{\gamma}}{n+1}.$$

Hubbing is cheaper if and only if $2n^{\gamma} < n+1$. With $\gamma = 1$ this requires $n < 1$, so hubbing is never cheaper: connecting passengers fly two legs instead of one. With $n = 10$ and $\gamma = 0.7$ the ratio is $\frac{2\times 10^{0.7}}{11} = \frac{10.02}{11} = 0.91$. For $\gamma = 0.7$ hubbing lowers total cost once $n \geq 7$, and for $\gamma = 0.8$ once $n \geq 27$.

Marginal costs. Leg marginal cost is $c(Q) = a\gamma Q^{\gamma-1}$. A nonstop passenger in the point-to-point network costs $a\gamma A^{\gamma-1}$. A connecting passenger in the hub network flies two spokes of density nA and costs $2a\gamma(nA)^{\gamma-1}$, a ratio of $2n^{\gamma-1}$. A passenger to or from the hub flies one spoke, a ratio of $n^{\gamma-1} < 1$. With $n = 10$ and $\gamma = 0.7$ the connecting ratio is 1.00 and the hub-endpoint ratio is 0.50.

Figure 9.6 plots both ratios. Three lessons emerge. Economies of density are necessary for a hub to save cost in this setting, because connecting passengers use two legs. The savings grow with the size of the network, since each spoke pools more city pairs. And passengers who start or end at the hub have the lowest marginal cost, because they use one dense spoke. This last point anticipates the finding of Section 9.7 that carriers with large hubs have lower marginal costs on flights out of their hubs. The firm-level elasticity of 0.8 is not the same object as the leg-level γ. If the two were equal, hubbing would lower total cost in this stylized network only with at least 27 outer cities. The example ignores the extra distance of connecting trips, the value of frequency, congestion at the hub and the fact that many thin city pairs would get no nonstop service at all.

Itinerary marginal cost. Let $\mathcal{L}_f$ be the set of legs (spokes) that carrier f flies. As in Section 9.2.3, $\mathcal{L}(j)$ is the set of legs in the itinerary of product j. The density Q_ℓ of leg ℓ counts the passengers on all itineraries that use it, in every market (9.3). Legs are carrier specific, so only carrier f's products contribute to the density of a leg in $\mathcal{L}_f$. Leg ℓ has total cost $C_\ell(Q_\ell, w_\ell)$ and marginal cost $c_\ell(Q_\ell, w_\ell) = \frac{\partial C_\ell}{\partial Q_\ell}$, where w_ℓ collects exogenous leg characteristics such as distance and airport congestion. Following Brueckner and Spiller (1994), the marginal cost of product j is the sum of its legs' marginal costs plus a product-specific shock ω_j:

$$mc_j = \sum_{\ell \in \mathcal{L}(j)} c_\ell(Q_\ell, w_\ell) + \omega_j. \tag{9.25}$$

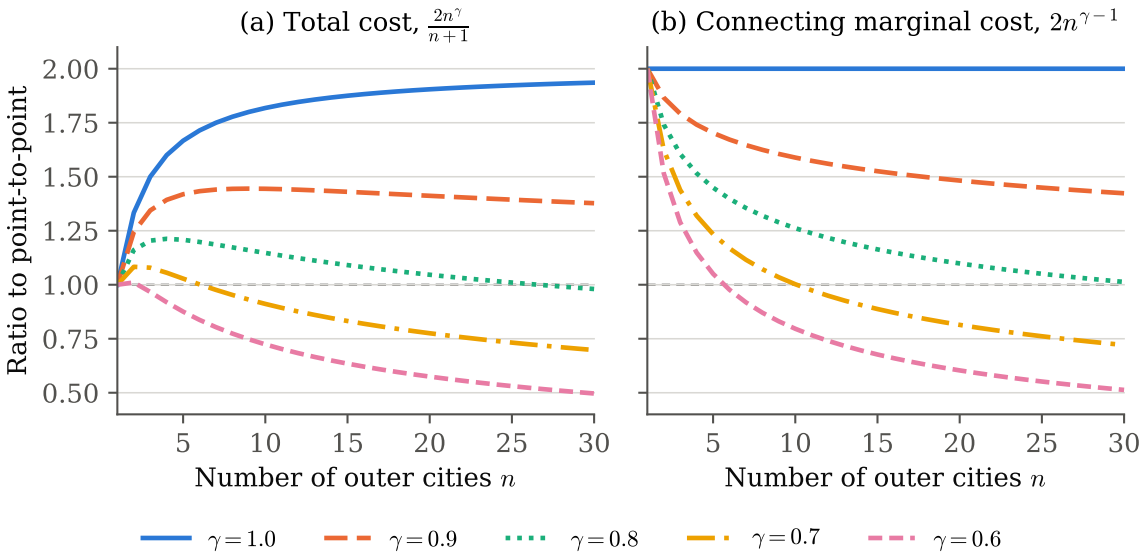

Figure 9.6: Hub-and-spoke relative to point-to-point costs in Example 9.41, as functions of the number of outer cities n for several leg cost elasticities γ. Panel (a) shows total network cost, panel (b) the marginal cost of a connecting passenger. Values below the dashed line favor the hub.

The carrier's total cost is

$$C_f = \sum_{\ell \in \mathcal{L}_f} C_\ell(Q_\ell, w_\ell) + \sum_t \sum_{j \in \mathcal{J}_f(t)} \omega_j q_j + FC_f, \tag{9.26}$$

where FC_f is fixed cost. The term $\omega_j q_j$ exists only to give marginal cost an additive error (Berry et al., 2006, p. 13). Legs are shared by many products, so a product's total cost is undefined while its marginal cost is well defined. Shared legs create economies of scope across itineraries. The itinerary New York-Chicago-San Diego shares a spoke with New York-Chicago-Seattle. More demand for New York-San Diego raises traffic on the New York-Chicago leg (Berry et al., 2006, p. 2, n. 5). With economies of density, the extra traffic lowers the marginal cost of serving New York-Seattle.

The pricing condition of a network carrier. Assume that demand in market t depends only on the prices of products in market t. Using (9.26), carrier f's profit is

$$\pi_f = \sum_t \sum_{j \in \mathcal{J}_f(t)} (p_j - \omega_j)\, q_j(p) - \sum_{\ell \in \mathcal{L}_f} C_\ell(Q_\ell, w_\ell) - FC_f.$$

Differentiate with respect to the price of a product $j \in \mathcal{J}_f(t)$. Products in other markets do not respond to p_j, so the revenue terms give $q_j + \sum_{k \in \mathcal{J}_f(t)} (p_k - \omega_k) \frac{\partial q_k}{\partial p_j}$. The cost terms give $-\sum_{\ell \in \mathcal{L}_f} c_\ell(Q_\ell, w_\ell) \frac{\partial Q_\ell}{\partial p_j}$, with

$$\frac{\partial Q_\ell}{\partial p_j} = \sum_{k \in \mathcal{J}_f(t):\, \ell \in \mathcal{L}(k)} \frac{\partial q_k}{\partial p_j}.$$

Exchanging the order of summation over legs and products,

$$\sum_{\ell \in \mathcal{L}_f} c_\ell \sum_{k \in \mathcal{J}_f(t):\, \ell \in \mathcal{L}(k)} \frac{\partial q_k}{\partial p_j} = \sum_{k \in \mathcal{J}_f(t)} \frac{\partial q_k}{\partial p_j} \sum_{\ell \in \mathcal{L}(k)} c_\ell.$$

Collecting terms and using (9.25),

$$\frac{\partial \pi_f}{\partial p_j} = q_j + \sum_{k \in \mathcal{J}_f(t)} \Big[p_k - \omega_k - \sum_{\ell \in \mathcal{L}(k)} c_\ell(Q_\ell, w_\ell) \Big] \frac{\partial q_k}{\partial p_j} = q_j + \sum_{k \in \mathcal{J}_f(t)} (p_k - mc_k) \frac{\partial q_k}{\partial p_j} = 0. \tag{9.27}$$

This is the condition of Berry et al. (2006, p. 15).

Equation (9.27) has the same form as the single-market condition behind (9.23). The network enters only through the level of each mc_k, evaluated at network-wide equilibrium densities. A lower price in market t raises density on the legs its products share with other markets. With economies of density this lowers the marginal cost of the carrier's products elsewhere, and those products are repriced in turn. Equilibrium prices are therefore linked across all markets that share legs, even though each first-order condition involves one market only. For estimation, (9.23) and (9.25) combine into $p_j - \text{markup}_j(\theta_d) = \sum_{\ell \in \mathcal{L}(j)} c_\ell(Q_\ell, w_\ell) + \omega_j$, a regression of price net of markup on leg cost terms.

Densities are endogenous in that regression. A product with high unobserved demand ξ raises the density of its legs, which lowers marginal cost when there are economies of density. Demand shocks thus move density and price together, and shocks to ω may be correlated across products that share legs. Estimation must instrument for density with variables that shift traffic on a leg but not product costs. Berry, Carnall and Spiller use population and network characteristics of the endpoint cities (Section 9.7).

Remark 9.42 (Markups are not profits). Let a leg have cost $C_\ell(Q) = F_\ell + aQ^\gamma$ with $F_\ell \geq 0$ and $\gamma < 1$. Average cost is $\frac{F_\ell}{Q} + aQ^{\gamma-1}$ and marginal cost is $\gamma a Q^{\gamma-1}$, so

$$AC - MC = \frac{F_\ell}{Q} + (1-\gamma) a Q^{\gamma-1} > 0.$$

Pricing at marginal cost loses $Q(AC - MC) = F_\ell + (1-\gamma)aQ^\gamma$. At the break-even price $p = AC$, the Lerner index is $1 - \frac{MC}{AC}$. With $F_\ell = 0$ this equals $1 - \gamma$. More generally, at $p = AC$ the Lerner index is $1 - \varepsilon_{CQ} = 1 - \frac{1}{RTD}$, so a density elasticity of 0.8 implies a break-even markup of 20% of price. Positive markups over marginal cost are thus consistent with zero economic profit. Berry, Carnall and Spiller warn that airlines may be unprofitable even with large markups (Berry et al., 2006, p. 16). Fixed costs may be large, and marginal cost may decline over a wide range of output. The contestability prediction (C4) of Section 9.3 must be read with this in mind. Markups signal market power only when they exceed what is needed to cover the gap between average and marginal cost.

The theory of this section organizes the evidence that follows. The conduct model of Section 9.4.1 and its umbrella term frame Borenstein's regressions in Section 9.5. Proposition 9.30 predicts the asymmetry he finds between dominant carriers and their rivals. The finite-mixture model, its markup formula (9.23) and the network cost structure (9.25) are the model that Berry, Carnall and Spiller take to data in Section 9.7.

9.5 Hubs and high fares: Borenstein (1989)

Borenstein (1989) asks whether the dominance of a route or of an airport lets a carrier raise its fares, and whether its rivals benefit when it does. The paper is a reduced-form study. It regresses fares on measures of market structure, cost and service quality across a large cross-section of routes. It reads the coefficients through pricing theory of the kind developed

in Section 9.4. We follow the paper from its question to its contribution, derive its estimating equations and instruments, and reproduce its four tables. Table 9.8 at the end of the section maps the study. As in the rest of the chapter, f indexes carriers and t indexes routes, which here are directional airport pairs.[3]

9.5.1 The question

By the late 1980s it was well established that airline fares do not behave as the contestability benchmark predicts. Fares on a route rise with the route's concentration (Graham et al., 1983; Bailey et al., 1985; Call and Keeler, 1985; Morrison and Winston, 1987). This finding contradicts prediction (C1) of Section 9.3.2, but it leaves open the source of the market power. The traditional reading is that concentration makes tacit or explicit collusion easier. Borenstein proposes a second source, the size of a carrier's operations at the endpoints of a route (Borenstein, 1989, pp. 344–345).

The question has two parts. The first concerns a carrier's own fares. Holding costs and service quality fixed, does a carrier charge more when it carries a larger share of a route's passengers? Does it charge more when it carries a larger share of the passengers who begin their trips at the route's endpoint airports? The second part concerns its rivals. Do the high fares of a dominant carrier create an *umbrella effect*, a shelter under which the smaller carriers on the same route can also price high? Collusion theories predict an umbrella, since every firm in a concentrated market shares in the collusive price. Theories in which dominance is an advantage specific to one carrier predict none.

The answer matters for policy. If concentration facilitates collusion, the relevant market structure is the route, and policy should keep routes unconcentrated. If dominance of an airport is the source, the relevant structure is the hub. A merger that raises a carrier's share of an airport can then raise fares on every route from that airport. The mergers of 1986 and 1987 raised exactly this issue (Section 9.2.2), and Borenstein draws much of his anecdotal evidence from their regulatory dockets.

The answer, stated in the abstract (p. 344), has two parts. A carrier's share of the passengers on a route and its share of the passengers at the endpoint airports both raise its markup over cost significantly. The high markups of a dominant carrier, however, create little umbrella for carriers with smaller operations in the same markets. The paper offers several explanations for this asymmetry, all of which work through advantages specific to the dominant carrier.

9.5.2 Setting

Section 9.2.4 described the mechanisms through which airport dominance may confer market power. They are reputation, frequent-flyer programs, travel agent commission overrides, biased reservation systems, and control of gates and slots. All of them favor the carrier with the most flights at an airport, and all of them act on every route that touches the airport. They therefore predict an effect of a carrier's airport share on its fares that is distinct from the effect of its route share. They also predict that the airport effect is strongest for the fares paid by business travelers, who belong to frequent-flyer programs and are least sensitive to price.

Testimony in the merger cases illustrates the mechanisms. In the USAir-Piedmont case, Piedmont's vice-president for planning stated that Piedmont would never consider entering the

[3] Borenstein indexes airlines by i and routes by j. He writes the coefficients of his equation (1) as $\alpha_i, \beta_1, \gamma_1, \ldots, \gamma_6$, $\delta_1, \ldots, \delta_6$ and $\rho_1, \ldots, \rho_{24}$. We write $a_f, b_D, \gamma_1, \ldots, \gamma_6, \phi_1, \ldots, \phi_6$ and $\varrho_1, \ldots, \varrho_{24}$, because α, β, δ and ρ have other meanings in this book. Page numbers in this section refer to the journal pages of the article.

route from Pittsburgh to Washington National (p. 345, n. 2). The reason was USAir's dominant position at Pittsburgh. He added that Piedmont might compete with USAir from its own hub at Baltimore to Pittsburgh, because "that is strength against strength." The testimony suggests that presence at the endpoints of a route governs who serves it. Borenstein exploits this link to construct his instrument for route share (Section 9.5.5).

Two further features of the setting shape the design. First, airport capacity was scarce at several large airports. Part of a high fare at such an airport may be a competitive scarcity rent common to all carriers there. The design must separate it from carrier-specific market power (Equation (9.5)). Second, several cities have more than one airport. Borenstein treats flights from different airports as separate markets and leaves their substitutability for future work (p. 348).

Section 9.4 provides two models that frame the empirical work. In the conduct model behind Equation (9.14), a carrier's log price rises linearly in its route share, and a degree of collusiveness that rises with concentration produces an umbrella. In the logit model of Proposition 9.30, an increase in one carrier's attractiveness raises its own price and share and lowers the prices of its rivals. Borenstein's two estimating equations are built to discriminate between these predictions.

9.5.3 Data

Sources and sample. The data cover the third quarter of 1987. Fares and passenger counts come from the DB1A ticket sample, flight operations from the Service Segment Data, and enplanements from the Nonstop Market Data (Section 9.2.3). Costs per available seat-mile come from the DOT's *Air Carrier Traffic Statistics* and *Air Carrier Financial Statistics*. Populations come from the *Statistical Abstract of the United States* and the tourism index from the *Census of Service Industries* (pp. 363–364). The ticket conventions are those of Section 9.2.3. Round trips count as two directional trips at half fare each, and first-class, interline, international and sub-$10 tickets are dropped. Tickets that use a segment missing from the Service Segment Data, fewer than 1% of passengers, are also dropped (p. 362).

The sample covers the nine largest domestic carriers, namely American, USAir, Continental, Delta, Eastern, Northwest, Piedmont, TWA and United (p. 349, n. 20). Continental and Eastern belonged to one holding company, Texas Air. They operated as separate companies with different costs, reputations and regions, and Borenstein treats them as separate firms. Only local passengers count toward a route. A local passenger's ticket begins at one endpoint and ends at the other, with at most one change of plane in each direction (p. 349, n. 21). Through and connecting passengers, for whom an endpoint is neither origin nor destination, do not count.

The nine carriers served 5,428 routes. On 3,591 of them, at least one of the nine carriers held at least 10% of the route's passengers and carried at least 10 passengers per day. These routes form the sample for the pricing equation. On 1,508 routes at least two carriers met both criteria, and these routes form the sample for the relative-price equation (p. 355). The unit of observation is a carrier-route pair. When several carriers qualify on a route, Borenstein keeps one of them, drawn at random, because the errors of different carriers on the same route are unlikely to be independent (p. 354). The pricing sample therefore has one observation per route.

Dependent variables. For each carrier-route pair, sort the fares paid by the carrier's passengers from lowest to highest, counting each fare once per passenger. FR20, FR50 and FR80 are the

20th, 50th and 80th percentiles of this passenger-weighted distribution (p. 348, n. 19). The three percentiles serve two purposes. The median is less sensitive than the mean to reporting errors. The three points also let every coefficient differ between deeply discounted fares and the high fares that business travelers tend to pay. Each regression uses the log of one percentile as its dependent variable.

Table 9.2 reports summary statistics for the pricing sample. The mean 80th-percentile fare, $187, is 1.86 times the mean 20th-percentile fare, which shows how much fares vary within a carrier-route pair. The observed carrier's mean route share is 0.54. It is high because a carrier enters the sample only if it holds at least 10% of the route. The mean airport origination share is 0.24 and the mean route Herfindahl index is 0.50. A typical observation involves 0.67 changes of plane per passenger and routings 7.5% longer than the nonstop distance. Delta supplies the most observations (18%) and TWA the fewest (5%).

Table 9.2: Summary statistics of the pricing-equation sample

Variable	Unit	Mean	Std. dev.	Minimum	Maximum
FR20	dollars	100.39	35.03	22.00	329.00
FR50	dollars	129.44	42.80	27.00	359.00

GENPSH	fraction	0.3752	0.2344	0.0238	1.0000
TOTMILE	miles	1,145.45	750.94	105.00	5,176.00

Notes: 3,591 carrier-route observations, third quarter of 1987. Values are rounded from the paper, which prints more digits. The paper labels the instrument GENPSH as GEOENPSH in this table. TOTMILE is the average total routing mileage, so $CIRC = \frac{TOTMILE}{DISTANCE}$. Shares of observations by carrier: American 0.140, USAir 0.101, Continental 0.141, Delta 0.180, Eastern 0.072, Northwest 0.094, Piedmont 0.110, TWA 0.051, United 0.111. The table also reports the means of the 24 airport scarcity variables, which are omitted here. Source: Borenstein (1989), Table 4.

Descriptive evidence. Before any regression, Borenstein (1989, Table 1) compares yields, that is, fares per mile, at six airports dominated by one carrier. Table 9.3 reproduces the table and Figure 9.7 plots it. For each airport the table gives three yields. The first is the dominant carrier's yield on routes to or from the airport. The second is the same carrier's yield on the rest of its system, and the third is the yield of other carriers on routes to or from the airport. Yields are reported by band of nonstop distance and over all distances.

Over all distances, the dominant carrier's yield at its hub exceeds its yield elsewhere at all six airports. The gap ranges from 17% for USAir at Pittsburgh ($\frac{20.32}{17.42} = 1.17$) to 70% for TWA at St. Louis ($\frac{18.50}{10.86} = 1.70$). At five of the six airports, the dominant carrier's yield also exceeds that of other carriers at the same airport. The exception is O'Hare, the least dominated airport in

Table 9.3: Yields at six dominated airports, third quarter of 1987 (cents per mile)

	Nonstop route distance (miles)						
	< 200	200–500	500–1000	1000–1500	1500–2000	> 2000	All
All domestic flights	37.96	25.82	17.46	11.42	9.12	7.16	12.91
TWA at St. Louis (STL): 82% of enplanements, 60% of originations							
TWA not to or from STL	34.37	28.63	18.50	12.63	9.32	8.37	10.86
TWA to or from STL	62.08	33.71	19.27	14.70	11.68	7.79	18.50
Others to or from STL	n.a.	25.37	17.98	11.00	8.61	7.61	14.41
Northwest at Minneapolis (MSP): 77% of enplanements, 65% of originations							
Northwest not to or from MSP	58.57	32.76	20.47	12.59	9.36	7.85	14.41

Others to or from MSP	45.59	33.15	18.70	11.10	8.38	7.88	14.89
USAir at Pittsburgh (PIT): 84% of enplanements, 63% of originations							
USAir not to or from PIT	45.54	28.39	17.31	11.59	9.48	7.98	17.42
USAir to or from PIT	53.49	31.69	15.22	13.26	9.60	8.72	20.32
Others to or from PIT	55.84	29.04	18.19	12.70	7.84	6.87	12.61
American at Dallas/Fort Worth (DFW): 60% of enplanements, 47% of originations							
American not to or from DFW	48.62	25.26	20.56	12.00	9.89	8.51	12.15
American to or from DFW	30.28	20.08	20.77	15.49	15.55	9.11	17.24
Others to or from DFW	29.50	21.73	18.43	11.86	11.32	6.41	14.51
United at Chicago O'Hare (ORD): 50% of enplanements, 43% of originations							
United not to or from ORD	45.88	24.36	16.87	12.15	9.88	7.50	10.08
United to or from ORD	64.94	33.10	20.06	9.32	8.78	6.05	14.19
Others to or from ORD	68.88	33.30	21.37	10.35	8.15	7.14	14.99
Delta at Atlanta (ATL): 55% of enplanements, 61% of originations							
Delta not to or from ATL	36.73	28.84	18.62	11.97	10.10	6.17	12.68
Delta to or from ATL	60.06	36.75	21.92	13.88	10.46	8.23	19.79
Others to or from ATL	50.34	31.20	19.17	12.92	8.99	8.38	17.44

Notes: Yield is the fare divided by the nonstop origin-to-destination mileage, in cents per mile, from the DB1A ticket sample for domestic flights. The shares in each heading are the dominant carrier's shares of enplanements and of originations at the airport. The paper prints a dash for other carriers on St. Louis routes under 200 miles (n.a.). Source: Borenstein (1989), Table 1.

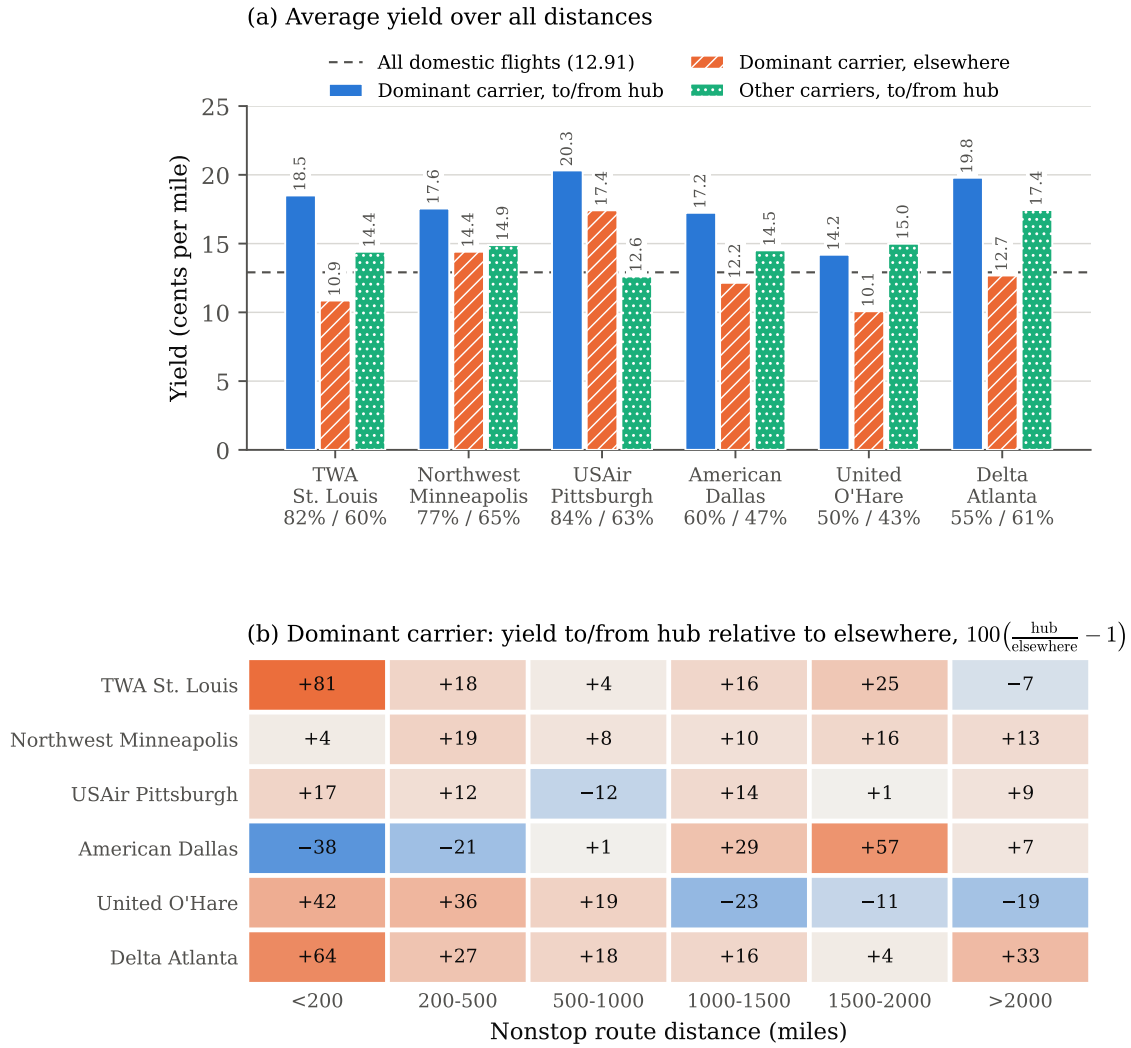

Figure 9.7: Yields at six airports dominated by one carrier, third quarter of 1987. Panel (a) shows three yields over all distances. They are the dominant carrier's yield on routes to or from its hub, its yield elsewhere in its system, and the yield of other carriers on routes to or from the hub. The two percentages under each airport are the dominant carrier's shares of enplanements and of originations there. Panel (b) shows, for each distance band, the percentage by which the dominant carrier's yield to or from its hub exceeds its yield elsewhere. Yields fall with distance, so panel (a) mixes fare levels with the distance composition of each group, while panel (b) holds distance roughly fixed. Redrawn from Borenstein (1989), Table 1.

the table. There United's yield of 14.19 cents falls short of the other carriers' 14.99 cents.

The comparison over all distances has a weakness. Yields fall steeply with distance, from 37.96 cents per mile on routes under 200 miles to 7.16 cents on routes over 2,000 miles. A group that flies shorter routes therefore shows a higher average yield even if it charges the same fare as others at each distance. Panel (b) of Figure 9.7 compares the dominant carrier with itself within distance bands. Its hub yield exceeds its yield elsewhere in 29 of the 36 cells. The exceptions are Dallas on short routes (−38% and −21%) and O'Hare on routes over 1,000 miles (−23%, −11% and −19%). The others are Pittsburgh at 500 to 1,000 miles (−12%) and St. Louis over 2,000 miles (−7%). Against other carriers at the same airport, the dominant carrier has the higher yield in 26 of the 35 cells with data. United at O'Hare is lower in five of six bands. USAir's 61% advantage over other carriers at Pittsburgh over all distances shrinks to between −16% and +27% within bands, so most of it reflects the distance mix.[4]

Borenstein argues that costs do not explain the hub premium (p. 356). Carriers have somewhat higher load factors on flights to and from their hubs, which lowers cost per passenger. Passengers to or from a hub also fly routes about as long as, or longer than, the carrier's other passengers. The higher cost per mile of short flights therefore does not explain the gap either. The table cannot separate airport dominance from route dominance, because a carrier that dominates an airport usually dominates the routes from it. The regressions attempt this separation.

9.5.4 The estimating equations

The pricing equation. Borenstein's first equation explains the log of a fare percentile by cost, quality and market-structure variables. Let P_{ft} denote one of FR20, FR50 or FR80 for carrier f on route t. Each percentile has its own regression with its own coefficients. In our notation, his equation (1), with an error term u_{ft} added, is

$$\begin{aligned}\ln P_{ft} = {} & a_f + b_D \ln DISTANCE_t + \gamma_1 \ln LOADFAC_{ft} + \gamma_2 \ln EQUIP_{ft} \\ & + \gamma_3 \ln FREQ_{ft} + \gamma_4 \ln CIRC_{ft} + \gamma_5 STOP_{ft} + \gamma_6 PLANECHG_{ft} \\ & + \phi_1 ORGSHARE_{ft} + \phi_2 ORGHERF_t + \phi_3 RUTSHARE_{ft} + \phi_4 RUTHERF_t \\ & + \phi_5 \ln COMPCOST_{ft} + \phi_6 \ln TOURIST_t + \sum_{k=1}^{24} \varrho_k APT_{kt} + u_{ft}.\end{aligned} \tag{9.28}$$

The coefficient letters group the variables by their hypothesized role (p. 349). The carrier effects a_f capture carrier-wide differences in cost and reputation. Distance, with coefficient b_D, primarily affects production cost. The six γ variables affect both cost and service quality, so their signs are ambiguous in advance. The six ϕ variables primarily indicate market power. The 24 coefficients ϱ_k measure scarcity rents at airports that may be congested. Table 9.4 defines each variable and gives the sign that Borenstein expects.

Constructed variables. Several variables are averages over the two endpoints $e \in \{1, 2\}$ of the route. Let ω_{te} be the share of the route's travelers whose tickets originate at endpoint e. Let o_{fe} be carrier f's share of all passenger originations at airport e, and let $TRIX_e$ be the tourism

[4] The within-band counts and percentages are our calculations from Table 1 of the paper.

Table 9.4: Variables of the pricing equation

Variable	Definition and construction	Group	Sign
FR20, FR50, FR80	Percentiles of the passenger-weighted distribution of the fares paid to the carrier on the route. A round trip counts as two trips at half fare.	dependent	
DISTANCE	Nonstop mileage between the endpoints (d_t in Section 9.2.3).	cost	+
LOADFAC	Load factor of the segments used by the carrier's passengers on the route, averaged over the segments of an itinerary by distance and over itineraries by passengers.	cost, quality	?
EQUIP	Seats per plane, averaged in the same way.	cost, quality	?
FREQ	Minimum number of flights in the quarter on any segment of an itinerary, averaged over itineraries by passengers.	cost, quality	?
CIRC	Average total routing mileage of the carrier's passengers (TOTMILE) divided by DISTANCE.	cost, quality	?
STOP	Average number of on-plane stops per passenger.	cost, quality	?
PLANECHG	Average number of changes of plane per passenger.	cost, quality	?
ORGSHARE	Carrier's share of passenger originations at the two endpoints, averaged with weights equal to the shares of the route's travelers whose tickets originate at each endpoint.	market power	+
ORGHERF	Herfindahl index of originations at the two endpoints, averaged with the same weights.	market power	?
RUTSHARE	Carrier's share of the route's local passengers.	market power	+
RUTHERF	Herfindahl index of the route's local passengers.	market power	?
COMPCOST	Average standardized cost per available seat-mile of the other carriers on the route, weighted by their route shares.	market power	+
TOURIST	Tourism index (hotel income from group and tourist customers over personal income) of each endpoint, weighted by the share of travelers who originate at the other endpoint.	market power	−
APT_k	Indicator that airport k is an endpoint, divided by DISTANCE in thousands of miles.	scarcity	+

Notes: "Group" is the role that Borenstein assigns to each variable and "Sign" the sign he expects, with ? for an ambiguous sign. Load factor, equipment, frequency and stops come from the Service Segment Data, fares, shares and circuity from the DB1A sample, and enplanements from the Nonstop Market Data. Source: Borenstein (1989), pp. 349–351 and Appendix.

index of the metropolitan area of e. Then

$$ORGSHARE_{ft} = \sum_{e=1}^{2} \varpi_{te}\, o_{fe}, \qquad ORGHERF_t = \sum_{e=1}^{2} \varpi_{te} \sum_k o_{ke}^2, \tag{9.29}$$
$$TOURIST_t = \varpi_{t1}\, TRIX_2 + \varpi_{t2}\, TRIX_1.$$

The tourism measure weights each endpoint by the share of travelers who start at the other end, so it measures the tourist appeal of the route's destinations. Origination shares exclude connecting passengers. Borenstein reports that measures based on enplanements, which include them, give very similar results (p. 349).

The cost of rivals enters through

$$COMPCOST_{ft} = \sum_{k \neq f} \frac{s_{kt}}{1 - s_{ft}}\, COST_k, \tag{9.30}$$

where s_{kt} is carrier k's route share, so that $s_{ft} = RUTSHARE_{ft}$. $COST_k$ is a standardized cost per available seat-mile. To construct it, Borenstein regresses cost per available seat-mile on a constant and average length of haul across the 17 carriers with data. He then adds each carrier's residual to 0.08, roughly the average cost of a carrier with the mean length of haul (p. 363). Small carriers without data receive 0.08. COMPCOST proxies for the competitiveness of rivals, whose prices are endogenous and whose service data are incomplete (p. 351).

Finally, the scarcity variables are

$$APT_{kt} = \frac{1000 \cdot \mathbf{1}\{k \text{ is an endpoint of } t\}}{DISTANCE_t}, \tag{9.31}$$

for 24 airports (p. 351). They are the 22 airports that the Federal Aviation Administration monitored for congestion and the airports of Orange County and Long Beach, which faced strict local limits on takeoffs and landings. Four of the monitored airports allocated slots: O'Hare, Kennedy, La Guardia and Washington National.

Expected signs. The γ variables move cost and quality in directions that push price opposite ways (pp. 349–350). A higher load factor lowers cost per passenger, which lowers fares. Full flights also tend to operate at peak times, when the opportunity cost of aircraft is high, which raises fares. Crowded planes, finally, lower service quality and reservation prices. Larger aircraft have a lower cost per seat-mile on flights over 500 miles. They are also more comfortable and thought to be safer, which raises demand. Frequent service lowers cost per flight, because aircraft on dense routes fly more hours per day. It also lowers the frequency delay of Section 9.2.1, the gap between a traveler's preferred departure time and the nearest flight (Douglas and Miller, 1974). Frequency delay matters most to travelers with high time values, who pay the high fares. Circuity, stops and changes of plane raise cost, by lengthening routings or shortening average hauls, and they lower quality.

Among the ϕ variables, Borenstein expects ORGSHARE, RUTSHARE and COMPCOST to raise fares and TOURIST to lower them (pp. 350–351). The concentration measures have ambiguous signs, and their interpretation drives the paper. Holding the carrier's own route share fixed, a higher RUTHERF means that the traffic the carrier does not carry is more concentrated. If a dominant carrier's high price creates an umbrella, this raises the observed carrier's price, so $\phi_4 > 0$. If a dominant carrier instead has a competitive advantage through marketing devices, it may lower the profit-maximizing price of its rivals, so $\phi_4 < 0$. Endpoint

concentration is ambiguous for a related reason. A carrier may prefer many small rivals at its airports to one large rival, while coordination, such as an agreement not to enter one another's routes, is easier among few firms.

Functional form. A firm with market power sets price equal to marginal cost times a markup that depends on the elasticity of the demand it faces. Logs turn this product into a sum, and earlier studies used the same multiplicative form (Graham et al., 1983; Bailey et al., 1985). Most variables therefore enter in logs, with constant elasticities. Section 9.4.1 derives this specification from a model of conduct. Let collusiveness rise with concentration as $\eta_t = \eta_0 + \eta_1 HHI_t$, and let the elasticity be a common ε. Because the equation omits the interaction $HHI_t s_{ft}$ of Equation (9.16), the route-share coefficient is then $\phi_3 \approx \frac{1-\eta_0-\eta_1\bar{H}}{\varepsilon}$ and the route-Herfindahl coefficient is $\phi_4 \approx \frac{\eta_1(1-\bar{s})}{\varepsilon}$. Here $\bar{H}$ and $\bar{s}$ are the sample means of RUTHERF and RUTSHARE. The cost and quality variables parametrize $\ln mc_{ft}$, and the constant terms are absorbed by the carrier effects.

The theory thus implies that shares enter linearly, and Borenstein gives a direct argument for the same choice (p. 354). A log specification would give a rise in share from 1% to 2% the same effect as a rise from 30% to 60%, which is implausible. ORGSHARE enters linearly for the same reason, and the two Herfindahl indices enter linearly for ease of comparison. The signs and approximate significance of the estimates are robust to logs for each of these variables. STOP and PLANECHG also enter linearly, so each stop or change of plane has the same proportional effect on price.

Remark 9.28 shows that a Cournot reading of the 2SLS share coefficients ($\bar{\eta} = 0$, so $\varepsilon = \frac{1}{\phi_3}$) would require route elasticities of $\frac{1}{0.1120} = 8.9$, $\frac{1}{0.0288} = 34.7$ and $\frac{1}{0.2238} = 4.5$ for the three percentiles. The variation across percentiles adds a further difficulty. A homogeneous-goods model has one price per route, and hence one elasticity for all fares, while the share coefficients differ nearly eightfold across percentiles. Each percentile behaves as if it faced its own demand. A model with differentiated products and heterogeneous travelers delivers this pattern (Section 9.4.3).

The scarcity terms need a different treatment (p. 354). A scarcity rent should add the same dollar amount to every fare from an airport, whatever the route. Suppose the fare is $P_{ft} = P^0_{ft} + R_k$, where P^0_{ft} is the fare without the rent and R_k is the rent at endpoint k. Taking logs and using $\ln(1+x) \approx x$ for small x,

$$\begin{aligned} \ln P_{ft} &= \ln P^0_{ft} + \ln\left(1 + \frac{R_k}{P^0_{ft}}\right) \\ &\approx \ln P^0_{ft} + \frac{R_k}{P^0_{ft}}. \end{aligned}$$

If the rent-free fare is proportional to distance, $P^0_{ft} = c\, DISTANCE_t$, the last term becomes

$$\frac{R_k}{c\, DISTANCE_t} = \frac{R_k}{1000\, c} \cdot \frac{1000}{DISTANCE_t} = \varrho_k\, APT_{kt}, \qquad \text{with } \varrho_k = \frac{R_k}{1000\, c}.$$

The coefficient ϱ_k is thus the rent as a fraction of the fare on a 1,000-mile route. A plain indicator would instead make the rent proportional to the fare and assign larger rents to longer routes. Estimating the additive form directly would require iterative nonlinear methods, which would have been difficult with his number of observations and variables. Borenstein therefore calls

the distance scaling a partial solution. Fares rise less than proportionally with distance (b_D lies between 0.33 and 0.41 in Table 9.5), so dividing by distance overcorrects somewhat.

The relative-price equation. The second equation compares two carriers on the same route. Add to Equation (9.28) a route effect Υ_t that collects every determinant of fares common to all carriers on route t, observed or not. Collect the variables that vary across carriers on a route in the row vector

$$z_{ft} = \left(\ln LOADFAC_{ft}, \ln EQUIP_{ft}, \ln FREQ_{ft}, \ln CIRC_{ft}, STOP_{ft}, PLANECHG_{ft}\right),$$

with coefficients $\gamma = (\gamma_1, \ldots, \gamma_6)^\top$. The pricing equation becomes

$$\ln P_{ft} = a_f + \Upsilon_t + z_{ft}\gamma + \phi_1 ORGSHARE_{ft} + \phi_3 RUTSHARE_{ft} + \phi_5 \ln COMPCOST_{ft} + u_{ft}.$$

Here Υ_t absorbs distance, the two Herfindahl indices, the tourism index, the scarcity terms and any unobserved demand or cost shifter at the route level. Write this equation for carriers a and b on route t and subtract. The route effect cancels because $\Upsilon_t - \Upsilon_t = 0$. Borenstein also omits the difference in COMPCOST (p. 355, n. 35). Its role in the pricing equation was to proxy for the other carriers on the route. In the relative-price equation one rival enters directly and the remaining rivals are common to both carriers. The result is his equation (4):

$$\begin{aligned}\ln P_{at} - \ln P_{bt} = {} & a_a - a_b + \gamma_1(\ln LOADFAC_{at} - \ln LOADFAC_{bt}) \\ & + \gamma_2(\ln EQUIP_{at} - \ln EQUIP_{bt}) + \gamma_3(\ln FREQ_{at} - \ln FREQ_{bt}) \\ & + \gamma_4(\ln CIRC_{at} - \ln CIRC_{bt}) + \gamma_5(STOP_{at} - STOP_{bt}) \\ & + \gamma_6(PLANECHG_{at} - PLANECHG_{bt}) + \phi_1(ORGSHARE_{at} - ORGSHARE_{bt}) \\ & + \phi_3(RUTSHARE_{at} - RUTSHARE_{bt}) + u_{at} - u_{bt}.\end{aligned} \tag{9.32}$$

The coefficients are those of Equation (9.28). The two carriers are drawn at random among those that meet the sample criteria (p. 355). The carrier effects enter as the difference $a_a - a_b$, which a regression implements with indicators equal to +1 for carrier a and −1 for carrier b.

Differencing has a benefit and a cost. The benefit is that every unobserved route-level shifter of demand or cost drops out. The estimates of ϕ_1 and ϕ_3 then no longer rely on the route controls of Equation (9.28). The cost is that the coefficients on route-level market structure, ϕ_2 and ϕ_4, are no longer identified. The equation answers a narrower question, which is the one the asymmetry hypothesis poses. Does the carrier with the larger share of a route, or of its endpoints, charge more than its rival on the same route? Under a complete umbrella with a homogeneous product, $\eta_t = 1$ and every carrier on the route has conduct $\theta_{ft} = 1$. The share term in Equation (9.14) then vanishes, and all carriers charge the same markup, so $\phi_3 = 0$ in Equation (9.32). Under the differentiated-products model of Proposition 9.30, the relative price instead rises with the share gap. Let s be a common share of all potential travelers, L the Lerner index there and s_0 the outside share. Corollary 9.31 gives a slope of $\frac{L}{1-s}$ in these shares, or $\frac{L(1-s_0)}{1-s}$ in route shares. The latter is the structural counterpart of ϕ_3 in Equation (9.32).

9.5.5 Estimation and identification

Why least squares fails. A carrier's route share depends on its own price. To see the consequence, add a share equation to the pricing equation and solve the two jointly. Suppress the other

regressors, which we take as exogenous, and write

$$\begin{aligned} \ln P_{ft} &= \phi_3 s_{ft} + u_{ft}, \\ s_{ft} &= \Psi_{ft} - b_s \ln P_{ft} + v_{ft}. \end{aligned}$$

Here $s_{ft} = RUTSHARE_{ft}$, Ψ_{ft} collects exogenous shifters of the share, $b_s > 0$ measures how fast the share falls with the carrier's own price, and v_{ft} is an unobserved demand shifter. Substitute the first equation into the second:

$$s_{ft} = \Psi_{ft} - b_s \phi_3 s_{ft} - b_s u_{ft} + v_{ft}.$$

Collect the terms in s_{ft} and solve, assuming $1 + b_s\phi_3 > 0$:

$$s_{ft} = \frac{\Psi_{ft} - b_s u_{ft} + v_{ft}}{1 + b_s \phi_3}.$$

Let $\mathrm{Var}(u_{ft}) = \sigma_u^2$ and $\mathrm{Cov}(u_{ft}, v_{ft}) = \sigma_{uv}$, and let Ψ_{ft} be uncorrelated with both errors. The ordinary least squares (OLS) estimator then has probability limit

$$\operatorname{plim} \hat{\phi}_3^{\mathrm{OLS}} = \phi_3 + \frac{\mathrm{Cov}(s_{ft}, u_{ft})}{\mathrm{Var}(s_{ft})} = \phi_3 + \frac{\sigma_{uv} - b_s \sigma_u^2}{(1 + b_s\phi_3)\,\mathrm{Var}(s_{ft})}. \tag{9.33}$$

With other regressors present, $\mathrm{Var}(s_{ft})$ is the variance of the share after projection on them. Two forces compete. The simultaneity term $-b_s\sigma_u^2$ biases the estimate down. A carrier hit by a positive cost or pricing shock charges more and loses passengers, so high prices go with low shares. The term σ_{uv} biases the estimate up if unobserved quality raises both the share and the price, which is the efficiency argument of Demsetz (1973) in airline form. A Hausman test (described below) rejects the exogeneity of RUTSHARE and RUTHERF (p. 352), so the preferred estimates use instruments.

The instrument for route share. An instrument must shift a carrier's route share without entering its pricing equation. Measures of rivals' presence at the endpoint airports come to mind. The airport dominance effects of Section 9.2.4, however, make such measures candidates for the pricing equation itself (p. 352). Borenstein resolves the problem with an asymmetry. The marketing advantages of airport dominance do not require large operations at both ends of a route. Entry onto a route, in contrast, benefits from presence at both ends. The excluded instrument is the carrier's share of the geometric means of endpoint enplanements,

$$GENPSH_{ft} = \frac{\sqrt{ENP_{f1}\,ENP_{f2}}}{\sum_k \sqrt{ENP_{k1}\,ENP_{k2}}}, \tag{9.34}$$

which is his equation (2). Here ENP_{k1} and ENP_{k2} are carrier k's average daily enplanements at the two endpoints of route t during the quarter, and the sum runs over all carriers (p. 352).

The geometric mean gives the instrument its content. It is zero when a carrier has no enplanements at one of the endpoints. For a given total $ENP_{f1} + ENP_{f2}$, it is largest when the two are equal. GENPSH therefore rewards balanced presence at both ends. ORGSHARE, which appears in the pricing equation, averages the carrier's endpoint shares linearly. A carrier with a large share at one end and a small share at the other can have a high ORGSHARE but a low GENPSH. Conditional on ORGSHARE, GENPSH thus varies with the balance of the carrier's presence across the endpoints. It also varies with connecting operations, since enplanements

count connecting passengers and originations do not. Borenstein chooses enplanements because they better measure a carrier's investment in physical capital and long-term labor contracts at an airport (p. 352, n. 30).

Two pieces of evidence support relevance. The first comes from Berry (1992), which Borenstein cites as a 1989 working paper (p. 352, n. 29). Berry starts from the 1,225 possible city pairs among the 50 largest U.S. cities (Berry, 1992, p. 903). He drops 6 pairs that have no listings in the Origin and Destination Survey, which leaves 1,219 markets (Berry, 1992, p. 903, n. 9, and p. 904). He measures entry between the first and the third quarter of 1980 (Berry, 1992, p. 904). Of the 3,590 potential entrants that already served both cities of a pair, 6.46% entered it. Of those that served one city, 0.36% entered, a rate about 18 times lower. Only 4 of the 47,600 potential entrants that served neither city entered, a rate of 0.01% (Berry, 1992, Table III). The second piece of evidence is Borenstein's own. In the first stage of the estimation, both ORGSHARE and GENPSH are highly significant (p. 352). The paper does not report the first-stage coefficients or F statistics.

The exclusion restriction requires that GENPSH affect fares only through route share. Borenstein states the condition plainly. It is valid if a carrier's current prices respond to actual competition but not to threats of entry (p. 352). He defends it on timing grounds. An incumbent can change its fares much faster than a rival can move from announcing entry to flying. It therefore need not price against potential entrants in advance. The USAir testimony quoted in Section 9.3.2 supports this view.

If the restriction fails, the bias has a predictable sign. Potential entrants with large operations at both endpoints raise the denominator of Equation (9.34), so a carrier's GENPSH is low exactly when such entrants are present. Suppose a carrier that faces well-placed potential entrants holds its fares down to deter entry, a practice called *limit pricing*. Its fares then rise with GENPSH at a given route share, and the true equation contains a term $\phi_G \, GENPSH_{ft}$ with $\phi_G > 0$. Ignore RUTHERF for the moment, write $g_{ft} = GENPSH_{ft}$, and let a tilde denote the residual after projection on the included exogenous regressors. The IV estimator has probability limit

$$\begin{aligned} \operatorname{plim} \hat{\phi}_3^{\mathrm{IV}} &= \frac{\operatorname{Cov}(\tilde{g}_{ft}, \ln P_{ft})}{\operatorname{Cov}(\tilde{g}_{ft}, \tilde{s}_{ft})} \\ &= \frac{\phi_3 \operatorname{Cov}(\tilde{g}_{ft}, \tilde{s}_{ft}) + \phi_G \operatorname{Var}(\tilde{g}_{ft})}{\operatorname{Cov}(\tilde{g}_{ft}, \tilde{s}_{ft})} \\ &= \phi_3 + \frac{\phi_G}{\pi_1}. \end{aligned} \tag{9.35}$$

The second line substitutes the true equation and uses $\operatorname{Cov}(\tilde{g}_{ft}, u_{ft}) = 0$. In the third line, $\pi_1 = \frac{\operatorname{Cov}(\tilde{g}_{ft}, \tilde{s}_{ft})}{\operatorname{Var}(\tilde{g}_{ft})}$ is the first-stage coefficient on GENPSH. Since $\pi_1 > 0$ and $\phi_G > 0$, limit pricing against potential entrants biases the estimated share effect upward. A violation of this kind would make Borenstein's estimates of ϕ_3 too large. The POTCOMP specification below offers a check. Controlling for potential competitors should absorb part of this bias and lower the route-share coefficients. Instead they rise slightly (Panel B of Table 9.5), which suggests that the bias is small.

Potential competition. Borenstein addresses the exclusion restriction in a second way, by measuring potential competition directly (pp. 352–353). The variable

$$POTCOMP_{ft} = \frac{\sum_{k \in \mathcal{P}_t} \sqrt{ENP_{k1} \, ENP_{k2}}}{\sum_{k} \sqrt{ENP_{k1} \, ENP_{k2}}} \tag{9.36}$$

has the construction of GENPSH, but its numerator sums over the set $\mathcal{P}_t$ of carriers with less than 1% of the route's traffic (p. 364). These carriers are present at the endpoints but not yet significant on the route. In an alternative specification POTCOMP enters Equation (9.28) directly, while GENPSH still instruments route share. POTCOMP may itself be endogenous. High fares on a route attract entry, which turns potential competitors into actual ones and lowers POTCOMP. A positive shock u_{ft} therefore goes with a low POTCOMP, which biases its coefficient toward a negative value (p. 359, n. 44).

The instrument for route concentration. The route Herfindahl index contains the square of the carrier's own share, so it is endogenous whenever RUTSHARE is. Borenstein constructs an instrument by decomposing the index (p. 353). Write s_{ft} for the carrier's share and $HHI_t = RUTHERF_t$. Split the sum of squared shares into the carrier's own term and its rivals' terms:

$$\begin{aligned} HHI_t &= s_{ft}^2 + \sum_{k \neq f} s_{kt}^2 \\ &= s_{ft}^2 + (1 - s_{ft})^2 \sum_{k \neq f} \left(\frac{s_{kt}}{1 - s_{ft}} \right)^2 \\ &= s_{ft}^2 + (1 - s_{ft})^2 H_{-f,t}. \end{aligned}$$

Here $H_{-f,t}$ is the Herfindahl index of the traffic that carrier f does not carry, computed from each rival's share of that traffic. Solving the last line for $H_{-f,t}$ expresses it in observed variables:

$$H_{-f,t} = \frac{RUTHERF_t - RUTSHARE_{ft}^2}{(1 - RUTSHARE_{ft})^2}.$$

The instrument rests on two assumptions. (a) GENPSH is a valid instrument for RUTSHARE. (b) The division among rivals of the traffic that carrier f does not carry is exogenous to f's price. In Borenstein's example, TWA's price on the Boston to Los Angeles route does not affect how the passengers it does not get divide between American and United. Under (b), $H_{-f,t}$ is exogenous. Replace the own share by its fitted value $\widehat{RUTSHARE}_{ft}$ from the first-stage regression on all exogenous variables:

$$IRUTHERF_{ft} = \widehat{RUTSHARE}_{ft}^2 + \frac{RUTHERF_t - RUTSHARE_{ft}^2}{(1 - RUTSHARE_{ft})^2} \left(1 - \widehat{RUTSHARE}_{ft}\right)^2. \quad (9.37)$$

This is Borenstein's equation (3). In the constructed index, each rival's share becomes $s_{kt} \frac{1 - \widehat{RUTSHARE}_{ft}}{1 - s_{ft}}$. The rescaling leaves the Herfindahl index of the traffic not carried by f equal to $H_{-f,t}$, as Borenstein notes. IRUTHERF then serves as the excluded instrument for RUTHERF. The same assumption (b) is needed for COMPCOST, whose weights in Equation (9.30) are the rivals' shares of the traffic that f does not carry (p. 353).

Remark 9.43 (When is assumption (b) plausible?). Assumption (b) holds exactly in a logit model of route demand, holding rivals' prices fixed. Route shares are shares of the route's passengers, so the outside good drops out and $s_{kt} = \frac{e^{\delta_{kt}}}{\sum_j e^{\delta_{jt}}}$, with the sum over the carriers on the route. Then

$$\frac{s_{kt}}{1 - s_{ft}} = \frac{e^{\delta_{kt}}}{\sum_{j \neq f} e^{\delta_{jt}}},$$

which involves neither δ_{ft} nor p_{ft}. This is the independence of irrelevant alternatives of Chapter 7. The assumption fails when some rivals are closer substitutes for f than others, for example when one rival shares f's hub airport. It can also fail in equilibrium, since rivals adjust their prices when f changes its own.

Remark 9.44 (A constructed instrument). IRUTHERF is a nonlinear function of first-stage fitted values. Substituting such a function for RUTHERF in the second stage would not in general give consistent estimates, because the first-stage residual does not drop out of a nonlinear function. Borenstein instead uses IRUTHERF as an excluded instrument in the first-stage regression for RUTHERF. Any function of exogenous variables is a valid instrument, so this use is consistent under (a) and (b). The nonlinearity affects only how strongly IRUTHERF predicts RUTHERF.

Load factor and the Hausman test. Load factor may also be endogenous, since a low fare fills planes. Borenstein instruments it with LOADPOP, the passenger-weighted average over itineraries of the summed populations of all cities where the traveler is on the ground, including stops and connections (pp. 353, 363). The idea is that populous cities along an itinerary add traffic to its segments and so raise load factors. A Hausman test does not reject exogeneity of LOADFAC at any reasonable significance level, so the reported estimates treat it as exogenous (pp. 356–357).

The Hausman test compares two estimators (Hausman, 1978). Under the null hypothesis that the suspect regressors are exogenous, OLS is consistent and efficient, while 2SLS is consistent but less precise. Under the alternative only 2SLS is consistent. Let $\hat{\vartheta}_S$ collect the estimated coefficients on the suspect regressors and $\hat{V}$ their estimated variance matrix. The statistic

$$\mathcal{H} = \left(\hat{\vartheta}_S^{\text{2SLS}} - \hat{\vartheta}_S^{\text{OLS}}\right)^{\top} \left[\hat{V}^{\text{2SLS}} - \hat{V}^{\text{OLS}}\right]^{-1} \left(\hat{\vartheta}_S^{\text{2SLS}} - \hat{\vartheta}_S^{\text{OLS}}\right) \tag{9.38}$$

is asymptotically χ^2 under the null, with degrees of freedom equal to the number of suspect regressors (Section A.3.6). A large value rejects exogeneity. For RUTSHARE and RUTHERF the test rejects, and for LOADFAC it does not.

Treating LOADFAC as endogenous anyway raises the estimated ORGSHARE effects somewhat and raises all standard errors (p. 357, n. 38). The LOADFAC coefficient itself becomes much more negative and much less precise (p. 358, n. 40). Simultaneity predicts the opposite movement. Low fares raise load factors, which pushes the least-squares coefficient down, so a correction should make it less negative.

Variables without instruments. A carrier's choices of nonstop versus connecting service, aircraft size, frequency, stops, changes of plane and circuity are part of its network design. They may respond to the same shocks as its fares (p. 353). Even LOADPOP is open to doubt, since the populations are exogenous but their summation by itinerary depends on routing choices. For lack of instruments, Borenstein treats these variables as exogenous and interprets their coefficients with possible biases in mind.

Pooling and the error structure. A test rejects a common constant across carriers, so the equation includes carrier fixed effects a_f (pp. 353–354). A further test of common slopes across carriers does not reject pooling at conventional levels, so all other coefficients are common to the nine carriers. The scarcity coefficients ϱ_k are common by construction, since a scarcity rent is the same for every carrier at an airport. The same tests applied to Equation (9.32) again do not reject pooling (p. 355). Keeping one carrier per route gives up information to secure independent errors. A modern study would keep every qualifying carrier and cluster the standard errors by route (Section A.8.2).

The estimator. The preferred estimates are 2SLS with asymptotic standard errors. The procedure has three steps. First, regress RUTSHARE on GENPSH and all included exogenous regressors, and keep the fitted values. Second, construct IRUTHERF from Equation (9.37). Third, estimate Equation (9.28) by 2SLS, treating RUTSHARE and RUTHERF as endogenous, with GENPSH and IRUTHERF as excluded instruments. With two endogenous regressors and two excluded instruments, the equation is exactly identified. Let X_{ft} be the row of regressors, let Z_{ft} be the same row with GENPSH and IRUTHERF in place of RUTSHARE and RUTHERF, and let ϑ be the coefficient vector. The estimator solves the sample analogue of $\mathbb{E}[Z_{ft}^{\top} u_{ft}] = 0$,

$$\hat{\vartheta} = \Big(\sum_{t} Z_{ft}^{\top} X_{ft} \Big)^{-1} \sum_{t} Z_{ft}^{\top} \ln P_{ft},$$

where each route t contributes the one carrier f selected for it. The paper treats the endogeneity in Equation (9.32) in the same way, without detailing the instrument for the share difference. OLS estimates are reported for comparison.

9.5.6 Results

The pricing equation. Table 9.5 reproduces Table 2 of the paper. Panel A gives the 2SLS estimates of Equation (9.28) for the three fare percentiles. Panel B gives the market-power coefficients from two alternative specifications, one with POTCOMP added and one estimated by OLS. The paper summarizes the carrier effects and the scarcity coefficients in the text without reporting them. Figure 9.8 plots the main market-power coefficients with 95% confidence intervals.

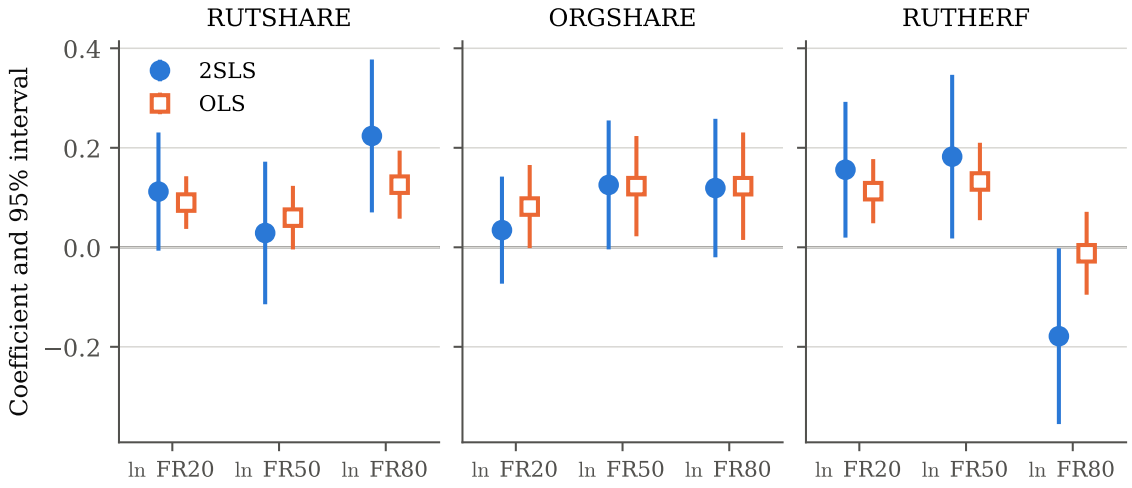

Figure 9.8: Market-power coefficients of the pricing equation by fare percentile, with 95% confidence intervals (estimate plus or minus 1.96 standard errors). Filled circles are 2SLS estimates and hollow squares OLS estimates. The route-share and airport-share effects are positive at every percentile. The route-Herfindahl effect, which holds the carrier's own share fixed, changes sign at the 80th percentile. Redrawn from Borenstein (1989), Table 2.

Route share raises fares. Holding route concentration fixed, a one percentage point increase in a carrier's route share raises its fares by between 0.03% (FR50) and 0.22% (FR80) (p. 357). Consider a dominant carrier with 70% of a route and rivals with 10% each. All of them face the

same route Herfindahl index, so the comparison holds RUTHERF fixed automatically. The fare gap in log points is

$$0.60 \times 0.1120 = 0.067, \qquad 0.60 \times 0.0288 = 0.017, \qquad 0.60 \times 0.2238 = 0.134$$

for FR20, FR50 and FR80. Borenstein summarizes this as a premium "from 2% to 12%."[5] The effect is larger on the 20th and 80th percentiles than on the median, which Borenstein finds surprising. Yet a *Chow test*, here a test of whether a coefficient is equal across the three percentile regressions, does not reject equality (p. 358). Only the FR80 coefficient is significant at 1%. The FR20 coefficient is significant at 10%, and the FR50 coefficient is not significant.

Airport share also raises fares, and more so at the high end of the fare distribution. The FR80 coefficient on ORGSHARE, 0.1191, is about three times the FR20 coefficient, 0.0345, and Borenstein reports that the difference is significant at 10% (p. 358). Travelers who pay full coach fares are much more likely to be active members of frequent-flyer programs than travelers on deep discounts. A stronger effect on high fares therefore fits the FFP mechanism. A one standard deviation increase in ORGSHARE, 0.1305, raises the three log fares directly by

$$0.1305 \times 0.0345 = 0.0045, \qquad 0.1305 \times 0.1254 = 0.0164, \qquad 0.1305 \times 0.1191 = 0.0155,$$

which the paper rounds to 0.5%, 1.6% and 1.6%. Consider a carrier with half the originations at both endpoints. It charges median and high-end fares about $0.5 \times 0.12 = 0.06$, or 6%, above those of a carrier with a very small presence at the two airports (p. 358).

These figures ignore an indirect channel. Airport dominance also raises a carrier's share of every route from the airport. Borenstein estimates the size of this channel in a companion discussion paper, "The Competitive Advantage of a Dominant Airline" (p. 358).[6] A one point increase in a carrier's share of originations at an airport raises its share of a route by up to 0.33 points, depending on its initial share. At the FR80 coefficient on route share, the indirect channel adds at most $0.33 \times 0.2238 = 0.074$ to the direct ORGSHARE coefficient of 0.1191. When RUTSHARE and RUTHERF are dropped from the equation, a one point increase in ORGSHARE raises the three percentiles by 0.24%, 0.26% and 0.24%, each significant at 1% (p. 360, n. 46). These reduced-form effects exceed the sums of the direct and maximal indirect effects implied by Table 9.5, which are 0.07, 0.13 and 0.19 per unit of ORGSHARE.[7] By the omitted-variable formula, the reduced-form coefficient picks up the full sample association of airport share with route share and route concentration, which can exceed the causal channel.

Route concentration, holding the carrier's own share fixed, has mixed effects. It raises low-end and median fares and lowers high-end fares, and all three coefficients are significant at 5%. Borenstein illustrates with a merger. Let firm 1 carry half of a route's passengers and two rivals a quarter each. A merger of the two rivals changes the route Herfindahl index from

$$0.5^2 + 2 \times 0.25^2 = 0.375 \qquad \text{to} \qquad 0.5^2 + 0.5^2 = 0.5,$$

an increase of 0.125, slightly more than half a standard deviation ($\frac{0.125}{0.2237} = 0.56$). Holding firm 1's share fixed, its log fares change by

$$0.125 \times 0.1559 = 0.019, \qquad 0.125 \times 0.1822 = 0.023, \qquad 0.125 \times (-0.1787) = -0.022$$

[5] The arithmetic gives 1.7% to 13.4% in log points, or 1.7% to 14.4% as exact percentage changes $e^{0.60\,\hat{\phi}_3} - 1$. The author's rounded range understates the upper end.

[7] The sums are $0.0345 + 0.33 \times 0.1120$, $0.1254 + 0.33 \times 0.0288$ and $0.1191 + 0.33 \times 0.2238$. This comparison is our calculation.

at the three percentiles. The paper reports the first and last, a 1.9% rise in the low-end fare and a 2.2% fall in the high-end fare (p. 358). Endpoint concentration may lower low-end fares and raise high-end fares, but none of the ORGHERF coefficients differs significantly from zero.

The cost and quality coefficients mostly have the expected signs when they are significant (pp. 358–359). The elasticities of fares with respect to distance (0.33 to 0.41) and rivals' costs (0.50 to 0.84) are positive and below one. Load factor has a negative coefficient, significant only for FR20, where a 10% higher load factor lowers the fare by about 0.75%. Frequency has positive elasticities of 0.014, 0.024 and 0.043, larger for high fares, and a Chow test rejects their equality across percentiles (p. 358, n. 41). Business travelers value frequent service most.

Borenstein adds a caution about the frequency premium (p. 358, n. 42). In a competitive market, higher quality would raise price only if it raised cost. After controlling for load factor, frequent flights may even be cheaper, because they allow more intensive use of ground labor. The frequency premium may therefore reflect market power more than a payment for quality.

Each on-plane stop lowers fares by 3% to 13% and each change of plane by 3% to 8%, so lower-quality products sell for less. Circuity, holding stops and changes fixed, raises fares significantly but modestly. At the mean circuity of 1.0754, the effect is $0.1458 \ln 1.0754 = 0.011$ at FR20 and $0.2062 \ln 1.0754 = 0.015$ at FR80, which brackets the author's "about 1.4%" (p. 359). A trip with one change of plane has a lower 80th-percentile fare than a nonstop trip if

$$-0.0616 + 0.2062 \ln CIRC < 0 \qquad \Longleftrightarrow \qquad \ln CIRC < \frac{0.0616}{0.2062} = 0.299.$$

With the approximation $\ln CIRC \approx CIRC - 1$, the extra mileage may not exceed about 30% of the nonstop distance, the figure in the paper. The exact bound is $e^{0.299} - 1 = 0.35$, or 35%.

Tourism lowers fares, with elasticities of −0.019, −0.056 and −0.099, so the effect grows toward the high end of the distribution. Borenstein's reading is that on leisure routes carriers do not cut their deepest discounts much. Instead they make more seats available at moderate discounts and at unrestricted discount fares (p. 359).

Carrier effects and scarcity rents. All carrier constants differ significantly from zero (p. 359). The gap between the highest and the lowest carrier is 30% for FR20 and 20% for FR80. Holding all regressors fixed, Continental, Eastern and Piedmont charge the lowest fares and United and Delta the highest. The scarcity estimates are positive and significant at the two largest airports, O'Hare (3% to 5%) and Atlanta (1% to 3%), and at Denver (2% to 4%) and Cleveland (0% to 3%). Ten airports show consistently negative and significant effects, mostly between 1% and 7% (p. 359, n. 43). They are Dallas/Fort Worth, Los Angeles, Newark, La Guardia, Kennedy, Miami, Houston Intercontinental, Las Vegas, Kansas City and Fort Lauderdale. The paper does not state the route distance at which these percentages apply. Under the scaling of Equation (9.31), a coefficient ϱ_k is the effect on a 1,000-mile route.

The negative estimates are puzzling for a measure of scarcity rents, which cannot be negative. They are especially puzzling at La Guardia and Kennedy, which were slot-controlled. Three features of the design may explain them. The airport terms absorb any airport-specific cost or demand factor, such as local fuel prices or wages (p. 351, n. 26), in addition to rents. Several of the negative airports serve leisure destinations, such as Las Vegas, Miami and Fort Lauderdale, whose travel mix the tourism index may capture imperfectly. Newark, La Guardia and Kennedy also compete for New York travelers, while the model treats each airport as a separate market. Dropping the distance scaling changes the results for some airports noticeably (p. 354, n. 34), so the airport estimates are sensitive to functional form as well.

Potential competition. Adding POTCOMP leaves the other estimates nearly unchanged (Panel B of Table 9.5). The RUTSHARE coefficients rise slightly, to 0.1196, 0.0564 and 0.2470, and

the FR80 coefficient on RUTHERF becomes more negative. POTCOMP itself has negative coefficients, significant at 5% for FR20 only. The effect is small. A one standard deviation increase in POTCOMP, 0.159, lowers the log fare by $0.159 \times 0.0589 = 0.009$ at FR20 and by less at the other percentiles (p. 359). Any endogeneity bias in POTCOMP points in the negative direction, so the true effect may be smaller still.

Least squares. The OLS estimates in Panel B tell the same qualitative story with smaller standard errors. The OLS route-share coefficients, 0.0899, 0.0596 and 0.1259, lie below the 2SLS estimates at FR20 and FR80 and above them at FR50. By Equation (9.33), OLS understates the share effect when the simultaneity term $b_s\sigma_u^2$ outweighs the quality term σ_{uv}, which fits the two tails. The OLS route-Herfindahl coefficients are positive and significant for FR20 and FR50 and near zero for FR80.

The relative-price equation. Table 9.6 reproduces Table 3 of the paper. The first three columns estimate Equation (9.32), and the last three drop the difference in route shares. In the full equation, the route-share and airport-share coefficients have the signs found in Table 9.5, but none is individually significant. Their standard errors are two to three times those in Table 9.5.

Table 9.6: The relative-price equation: estimates of Equation (9.32)

Notes: Each variable enters as the difference between the two carriers on a route. Standard errors in parentheses, asymptotic for equation (4). Significance marks as printed in the paper: # 10%, † 5%, * 1%. Carrier effects are included but not reported. Source: Borenstein (1989), Table 3.

Borenstein traces the imprecision to two sources (p. 359). First, the instrument for the difference in route shares is less effective than GENPSH is in the pricing equation, though still significant. The fitted share difference is therefore closer to a linear combination of the other regressors. Second, the differences in RUTSHARE and ORGSHARE between two carriers on the same route are much more highly correlated than the levels in the pricing equation. A test of the joint significance of the two share differences rejects zero at 1% for all three fare percentiles.[8]

[8]Several coefficients that the paper marks as significant at 1% have t statistics between 2.33 and 2.58. Examples

Dropping the route-share difference confirms the diagnosis of collinearity. The ORGSHARE coefficients rise to 0.0742, 0.2117 and 0.2986, and their standard errors fall to under a third of their previous size. Dropping the ORGSHARE difference instead raises the RUTSHARE coefficients and lowers their standard errors (p. 360, n. 45). Without the route-share term, the ORGSHARE coefficients measure the direct effect of airport share plus its indirect effect through route share. A carrier with 50% of the traffic at each endpoint charges high-end fares $0.40 \times 0.2986 = 0.119$ log points, about 12%, above a rival with 10% at each endpoint (p. 360). The corresponding gaps at FR20 and FR50 are 0.030 and 0.085 log points.

The other coefficients agree with those of the pricing equation when significant, with one exception. Load factor now has positive coefficients, significant for FR50 and FR80. Across routes, denser routes with higher load factors may have lower fares. Within a route, the carrier with the higher load factor may carry more connecting traffic, which raises the opportunity cost of its seats and hence its fares (p. 360).

Robustness. The paper reports several further checks, mostly in footnotes.

- Airport shares based on enplanements instead of originations change the results very little (p. 349).
- Treating Continental and Eastern as one firm in the share calculations changes the results slightly. The changes reinforce the finding that large airport and route shares yield market power (p. 349, n. 20).
- The signs and approximate significance are robust to logs instead of levels of the shares and Herfindahl indices in Equation (9.28) (p. 354), and of the shares in Equation (9.32) (p. 355).
- The aircraft-size coefficient does not differ between routes with average flight lengths above and below 500 miles, and the two estimates are very similar (p. 350, n. 22).
- Scarcity variables without the distance scaling yield similar route-share and airport-share effects, though some airport estimates change noticeably (p. 354, n. 34).
- In Equation (9.32), a proportional fare difference that varied with distance would make the errors heteroskedastic. Regressions of the squared residuals on DISTANCE give t statistics below one for all three percentiles (p. 355, n. 36).
- Treating LOADFAC as endogenous leaves the market-power conclusions intact (p. 357, n. 38).

9.5.7 From descriptive results to economic inferences

Regression coefficients describe conditional correlations. They become economic conclusions only through a chain of reasoning that rules out alternatives. We reconstruct Borenstein's chain one conclusion at a time, with the evidence and the test behind each step. Table 9.7 lists the competing hypotheses, their predictions for the two equations, and the verdict of the evidence.

The first conclusion is that dominance raises a carrier's own fares. The evidence is the positive RUTSHARE and ORGSHARE coefficients in Table 9.5. The Hausman test shows that route share is endogenous, and the estimates that support the conclusion instrument it with

are ln FREQ in the 2SLS FR50 column of Table 2 ($t = 2.51$) and STOP in the FR20 column of Table 3 ($t = 2.37$). These marks match one-sided rather than two-sided cutoffs. We reproduce the marks as printed.

Table 9.7: Hypotheses, predictions and evidence in Borenstein (1989)

Hypothesis	Prediction	Evidence
Perfect contestability	$\phi_1 = \phi_2 = \phi_3 = \phi_4 = 0$ in Equation (9.28).	Rejected. RUTSHARE and ORGSHARE raise fares (Table 9.5). The share differences are jointly significant at 1% (Table 9.6).
Collusive umbrella	$\phi_4 > 0$ at every percentile. Under a complete umbrella, $\phi_3 = 0$ in Equation (9.32).	Not supported. $\phi_4 > 0$ for FR20 and FR50 but $\phi_4 < 0$ for FR80. The carrier with the larger shares charges more than its rival on the same route.
Carrier-specific dominance (Proposition 9.30)	$\phi_1, \phi_3 > 0$ in both equations. ϕ_4 may be negative.	Supported by the own-share effects in both equations and by the absence of a consistent umbrella.
Frequent-flyer mechanism	ORGSHARE effect larger for high fares than for low fares.	Supported. The FR80 coefficient is about three times the FR20 coefficient, and the difference is significant at 10%.
Scarcity rents	$\varrho_k > 0$ and equal for all carriers at airport k.	Mixed. Positive at O'Hare, Atlanta, Denver and Cleveland, negative at ten airports.
Quality premia	Positive frequency effect, larger for high fares.	Found, but the premium may reflect market power (p. 358, n. 42).

Notes: The hypotheses are stated in terms of the coefficients of Equation (9.28) and Equation (9.32). The first row corresponds to prediction (C1) of Section 9.3.2.

GENPSH. The relative-price equation then removes every route-level unobservable. The joint test of the share differences in Table 9.6 still rejects zero at 1%.

The second conclusion is that the dominant carrier's market power does not spill over to its rivals. Two results support it. Holding the carrier's own share fixed, route concentration raises low-end fares but lowers high-end fares. An umbrella would raise all of them. Within a route, the carrier with the larger shares charges more, while a complete umbrella would equalize fares. In the paper's words, "the market power of a dominant airline does not spill over substantially to other airlines serving the same airport or routes" (p. 362).

The third conclusion concerns mechanisms. The airport-share effect is concentrated in high fares, which are paid mostly by business travelers who belong to frequent-flyer programs. This pattern fits FFPs and TACOs. The evidence cannot separate the individual devices, however, or rule out other sunk costs of entry, such as advertising and the setup of airport facilities (p. 362). The fourth conclusion is that scarcity rents are a separate phenomenon. Because the airport terms are common to all carriers at an airport, they cannot absorb the carrier-specific effect of airport share.

Borenstein considers several alternative explanations. Scarcity rents are handled by the airport terms. Quality differences are handled by the service variables, with the caution that their coefficients need not be quality premia. The cash value of frequent-flyer bonuses could explain the airport-share effect only in part. Realistic calculations put that value at one or two percentage points of fares at most (Borenstein, 1988), and deeply discounted travelers rarely redeem mileage (p. 358, n. 39). The loyalty-inducing effect of the bonuses can still be large if their kickback aspect matters. Potential competition is handled by POTCOMP and the endogeneity of load factor by the Hausman test.

The asymmetry between a dominant carrier's fares and its rivals' fares maps directly into the theory of Section 9.4. In the conduct model with collusiveness rising in concentration, every carrier's markup rises with the route Herfindahl index, so concentration lifts the fares of

small carriers too. In the differentiated-products model of Proposition 9.30, an increase in one carrier's attractiveness, from FFP value or reputation, raises its price and share and lowers its rivals' prices. By Corollary 9.31, the dominant carrier's price relative to its rivals' then rises with the share gap, which is the pattern of Table 9.6. Borenstein's evidence fits the second model.

The policy conclusion is measured. "It would be futile and probably unwise for the government to try to deter airlines from forming hubs" (p. 360). Borenstein cites substantial evidence that hub-and-spoke systems use aircraft and other inputs more efficiently than the point-to-point systems of the regulated era. Hub operations may bring cost savings that raise total surplus even if carriers keep them as profit. They may also bring more frequent flights, easier connections and more nonstop service. These benefits must be weighed against the higher fares that airport dominance brings (p. 362). Carlton et al. (1980) propose one way to analyze such benefits (p. 362, n. 47).

The quality coefficients should not be read as hedonic prices for this welfare calculation (p. 362, n. 48). Quality also affects cost, which confounds the coefficients. Even without that problem, Spence (1975) showed that a firm with market power chooses quality to suit the marginal consumer. If inframarginal travelers value quality more than marginal ones, as is likely in air travel, the coefficients reflect the marginal traveler's valuation. They then underestimate the average traveler's valuation of hub service.

9.5.8 Limitations and critiques

The first critique is the one Demsetz (1973) raised against structure-conduct-performance regressions (Chapter 1). A large route or airport share may reflect a better product or a lower cost instead of market power. Berry et al. (2006, pp. 5–6) press this point. Reduced-form price regressions do not show how prices relate to costs or what determines markups over cost. Ticket restrictions, which explain much of the variation of fares within a route, are absent from the data, and earlier studies could not control for them. Their response is to model demand, with an explicit unobserved product characteristic, together with costs and equilibrium pricing (Section 9.7).

A related limitation is that the paper has no explicit cost function. Following Bresnahan (1989), Borenstein infers costs from cross-sectional variation in prices and product attributes (p. 348, n. 18). The coefficients of the cost and quality variables therefore mix cost and demand effects. Markups and marginal costs are not separately identified, which is the gap that a structural model fills.

Whinston and Collins (1992, p. 446) raise two critiques that apply to all pricing regressions of the period. These studies treat their samples as sets of unrelated routes, although the routes form an interrelated network. The effective cost of serving a route depends on where the plane can fly next (p. 446, n. 2). The studies also need controls for demand and cost conditions, and market-structure variables are likely to be correlated with what the controls miss. Their event study is designed to avoid both problems (Section 9.6).

The exclusion restriction for GENPSH is open to doubt, as Borenstein acknowledges. Later evidence sharpens the doubt. Goolsbee and Syverson (2008) identify routes on which Southwest becomes a credible entrant because it begins operating at the second endpoint. Incumbents cut fares significantly in response, before Southwest starts flying the route. In the working-paper version of their study, operating at both endpoints goes with a probability of entering the route about 70 times higher than on other routes. This finding supports the relevance of a both-endpoints instrument and contradicts its exclusion. By Equation (9.35), fare cuts against

potential entrants bias the 2SLS share effect upward, so the route-share coefficients in Table 9.5 may overstate the effect of route dominance.

Several regressors that the paper treats as exogenous are equilibrium outcomes. Borenstein acknowledges this for the service variables. The same concern applies to ORGSHARE, since a carrier's fares affect how many travelers begin their trips with it at an airport. The paper instruments route share but not airport share. If high unobserved quality raises both airport share and fares, the ORGSHARE coefficients overstate the effect of dominance.

The pricing equation imposes a common share coefficient on routes with different elasticities and conduct. By Equation (9.14), ϕ_3 then estimates an average of $\frac{1-\eta_t}{\varepsilon_t}$ across routes, weighted by the identifying variation, and the same holds for ϕ_4. The conduct-parameter literature raises the same concern about reading an estimated conduct parameter as a structural constant (Corts, 1999, Chapter 3). Even a precise ϕ_3 cannot separate elastic demand from nearly collusive conduct without outside information on ε (Remark 9.28).

The design uses a single cross-section and one carrier per route. Without time variation, only the relative-price equation controls for unobserved route characteristics, and that equation is imprecise because of collinearity and a weaker instrument. Fare percentiles mix fare classes whose restrictions are unobserved, so a high FR80 may reflect a carrier's mix of restricted and unrestricted tickets as well as its markup. Finally, airports in the same city are treated as separate markets. Section 9.6 studies entry by a low-fare carrier on routes from Newark. The entry reduced the value of incumbents on the entered airport pairs much more than the value of carriers serving the same city pairs from other New York airports. That evidence supports treating airports in a city as differentiated products, a weaker assumption than treating them as separate markets.

9.5.9 Contribution

The paper made four contributions. First, it provided the first systematic evidence that a carrier's dominance of its endpoint airports predicts its fares, beyond the concentration of the route. This moved the policy debate from route concentration to airport concentration. Second, it documented an asymmetry. Dominant carriers charge more, and their rivals do not share in the premium. The finding shifted the interpretation of the concentration-price correlation from collusion toward carrier-specific advantages, such as those created by FFPs, TACOs and reservation systems.

Third, the paper introduced two identification devices that later work adopted. Scarcity rents are separated from market power by restricting airport effects to be common across carriers, and presence at both endpoints of a route serves as a shifter of route share. Fourth, by estimating separate equations for three fare percentiles, the paper showed that market power and quality premia differ across fare types. This heterogeneity anticipated the two-type demand model of Berry et al. (2006).

The paper also set the agenda for the other two studies of this chapter. Whinston and Collins (1992) measure route-specific rents without the cost and demand controls that a pricing regression needs. Berry et al. (2006) separate markups from costs and explain the absence of an umbrella through the sorting of business travelers. Borenstein (1991) pursued the question with directional city-pair effects (Berry et al., 2006, p. 5). Comparing routes into and out of a hub city, he found higher fares on flights out of the hub.

Table 9.8: Identification and counterfactual map of Borenstein (1989)

Observed data	The DOT ticket sample for the third quarter of 1987, with service segment and nonstop market data. Fare percentiles, route and endpoint shares and Herfindahls, and cost and quality variables for one carrier on each of 3,591 airport-pair routes.
Latent objects	Carrier-route markups and marginal costs, unobserved service quality, and route-level demand and cost shocks.
Estimated parameters	The coefficients of (9.28) on market structure (ϕ_1 to ϕ_6) and on cost and quality (γ_1 to γ_6), carrier effects and 24 airport effects, for three fare percentiles.
Identifying variation	Cross-route differences in dominance, with route share instrumented by GENPSH (9.34), the carrier's share of geometric-mean endpoint enplanements. A relative-price equation differences out route-level unobservables.
Maintained assumptions	GENPSH is excluded from the pricing equation. Shares do not proxy for unobserved quality or cost, airport share is exogenous, and the share coefficients are common across routes.
Counterfactual and what it holds fixed	No equilibrium is simulated. The coefficients compare fares at different levels of dominance, holding the measured cost and quality variables fixed.
Conclusion	A carrier with 70 percent of a route charges 2 to 12 percent more than rivals with 10 percent, and endpoint dominance raises high fares most. Rivals share little of the premium. The reading rests on the exclusion of the instruments.
One limitation	Without a model of cost or demand, a high fare that reflects market power cannot be told apart from a high fare for a better product.
Source and our additions	The four tables are Borenstein's. The bias formulas (9.33) and (9.35), Proposition 9.30 and Table 9.7 are our reconstructions.
Tools in the appendices	Sections A.2 and A.3.

9.6 Entry and incumbent value: Whinston and Collins (1992)

The pricing regressions of Section 9.5 infer market power from the cross-section of fares. They need controls for demand and cost on every route, and they treat routes as unrelated although each route is part of a network. Whinston and Collins (1992) approach the same questions from the stock market.[9] They ask how investors revalued incumbent airlines on the days People Express announced entry into their markets. A fall in an incumbent's value reveals rents on the route before entry, or sunk costs that keep the incumbent there after entry. Perfect contestability rules out both (Section 9.3).

This section first develops the event-study method in general form (Section 9.6.1). It then follows the paper in the order used for every case study in this book. We take up the question and its logic, the setting and data, and the estimating equations. Then come the results on value, the price and capacity responses to entry, and finally interpretation, limitations and contribution. Table 9.15 at the end of the section maps the study.

9.6.1 Event-study methodology

An *event study* measures the effect of a discrete piece of news on the market value of a firm. The method goes back to Fama et al. (1969), and Brown and Warner (1985) and MacKinlay (1997) are standard references. In industrial organization it was used early to measure the effects of regulation (Schwert, 1981; Rose, 1985). We present the method with general notation and then specialize it to the abnormal-dollar form that Whinston and Collins use.

The premise is *market efficiency*. The equity value of a firm equals the expected present value of the cash flows to its shareholders, given all public information. News that changes expected future profits therefore changes the share price as soon as it becomes public. The change in value in a short window around the news, net of the return the stock would have earned anyway, measures the change in expected discounted profits.

Normal returns and the market model. Index trading days by τ and firms by f. Let $R_{f\tau}$ be the return on firm f's stock on day τ, including dividends. Let R^0_τ be the risk-free rate and R^m_τ the return on the market portfolio. We work with *excess returns* $r_{f\tau} \equiv R_{f\tau} - R^0_\tau$ and $r^m_\tau \equiv R^m_\tau - R^0_\tau$. The *normal return* is the return expected in the absence of the event, and a model of it is the first ingredient of every event study.

Assumption 9.45 (Market model)**.** For each firm f and day τ,

$$r_{f\tau} = a_f + b_f\, r^m_\tau + u_{f\tau}, \tag{9.39}$$

with $\mathbb{E}[u_{f\tau} \mid r^m] = 0$, $\mathrm{Var}(u_{f\tau} \mid r^m) = \sigma^2_f$, and $\mathrm{Cov}(u_{f\tau}, u_{f\tau'} \mid r^m) = 0$ for $\tau \neq \tau'$, where r^m is the vector of market excess returns on all days.

The coefficient b_f is the firm's *beta*, its exposure to market-wide news. The capital asset pricing model (CAPM) implies $a_f = 0$ and $b_f = \frac{\mathrm{Cov}(r_{f\tau}, r^m_\tau)}{\mathrm{Var}(r^m_\tau)}$. The market model leaves a_f free, which guards against small errors in the pricing model. In this section a_f denotes this intercept. It does not denote the carrier effects of Borenstein's pricing equation. The errors may be correlated across firms on the same day. This possibility matters when several firms are affected by the same news, and we return to it below.

[9] Page and footnote numbers in this section refer to the journal pages of the article, and table numbers to its tables.

Estimation and event windows. An event k affects firm f and becomes public on trading day τ_k, the *announcement day*. The *event window* is a short set of days around τ_k, $\mathcal{W}_k = \{\tau_k - w^-, \dots, \tau_k + w^+\}$, with $w = w^- + w^+ + 1$ days. Days before τ_k allow for leakage of the news, and days after it allow for slow absorption. The *estimation window* $\mathcal{T}_0$ is a set of L_0 days that contains no event, usually a long period before $\mathcal{W}_k$. On $\mathcal{T}_0$ we estimate (9.39) by ordinary least squares (OLS):

$$\hat{b}_f = \frac{\sum_{\tau \in \mathcal{T}_0} (r^m_\tau - \bar{r}^m)(r_{f\tau} - \bar{r}_f)}{\sum_{\tau \in \mathcal{T}_0} (r^m_\tau - \bar{r}^m)^2},$$
$$\hat{a}_f = \bar{r}_f - \hat{b}_f \, \bar{r}^m,$$

where $\bar{r}_f$ and $\bar{r}^m$ are means over $\mathcal{T}_0$. The residual variance estimate is $\hat{\sigma}^2_f = \frac{1}{L_0 - 2} \sum_{\tau \in \mathcal{T}_0} (r_{f\tau} - \hat{a}_f - \hat{b}_f r^m_\tau)^2$.

Definition 9.46 (Abnormal and cumulative abnormal returns)**.** The *abnormal return* of firm f on a day $\tau \in \mathcal{W}_k$ is the prediction error

$$\widehat{AR}_{f\tau} = r_{f\tau} - \hat{a}_f - \hat{b}_f \, r^m_\tau.$$

The *cumulative abnormal return* over the window is $\widehat{CAR}_{fk} = \sum_{\tau \in \mathcal{W}_k} \widehat{AR}_{f\tau}$.

Under the null hypothesis that the event has no effect, (9.39) also holds on the window days. Substituting it into the definition gives the decomposition

$$\widehat{AR}_{f\tau} = u_{f\tau} - (\hat{a}_f - a_f) - (\hat{b}_f - b_f) \, r^m_\tau.$$

The first term is the true error on day τ. The other two terms are estimation error from $\mathcal{T}_0$. We compute the variance conditional on market returns in four steps. First, write the fitted normal return as $\hat{a}_f + \hat{b}_f r^m_\tau = \bar{r}_f + \hat{b}_f (r^m_\tau - \bar{r}^m)$. Second, use the OLS results $\mathrm{Var}(\bar{r}_f) = \frac{\sigma^2_f}{L_0}$, $\mathrm{Var}(\hat{b}_f) = \frac{\sigma^2_f}{S_m}$ with $S_m = \sum_{s \in \mathcal{T}_0} (r^m_s - \bar{r}^m)^2$, and $\mathrm{Cov}(\bar{r}_f, \hat{b}_f) = 0$. Third, note that $u_{f\tau}$ for $\tau \in \mathcal{W}_k$ is uncorrelated with the estimation-window errors. Fourth, add the pieces:

$$\mathrm{Var}\left(\widehat{AR}_{f\tau} \mid r^m\right) = \sigma^2_f \left[1 + \frac{1}{L_0} + \frac{(r^m_\tau - \bar{r}^m)^2}{S_m}\right]. \tag{9.40}$$

The bracket exceeds one only through estimation error, which vanishes as L_0 grows. For long estimation windows we use $\mathrm{Var}(\widehat{AR}_{f\tau}) \approx \sigma^2_f$ and $\mathrm{Var}(\widehat{CAR}_{fk}) \approx w \, \sigma^2_f$. The test statistic for one event is then

$$z_{fk} = \frac{\widehat{CAR}_{fk}}{\hat{\sigma}_f \sqrt{w}},$$

which is approximately standard normal under the null when the daily errors are normal and L_0 is large. With normal errors and a moderate L_0, it is approximately a t variable with $L_0 - 2$ degrees of freedom.

Many events and clustered calendar dates. With K events the natural statistic is the average $\overline{CAR} = \frac{1}{K} \sum_{k=1}^{K} \widehat{CAR}_k$. Its variance is

$$\mathrm{Var}\left(\overline{CAR}\right) = \frac{1}{K^2} \left[\sum_k \mathrm{Var}\left(\widehat{CAR}_k\right) + \sum_{k \neq k'} \mathrm{Cov}\left(\widehat{CAR}_k, \widehat{CAR}_{k'}\right)\right].$$

Suppose the events fall on different calendar dates and the errors of different firms on different days are uncorrelated. The covariances then vanish up to estimation-error terms of order $\frac{\sigma_f^2}{L_0}$. The usual test then divides $\overline{CAR}$ by $\frac{1}{K}\sqrt{\sum_k \operatorname{Var}\left(\widehat{CAR}_k\right)}$, which is the standard deviation of the average when the covariances are zero. When events cluster on the same dates, the covariances are not zero. Firms in one industry share industry news that the market return does not absorb. Suppose K firms are hit on the same days, each with $\operatorname{Var}(\widehat{CAR}_k) = w\sigma^2$, and every pair of errors has correlation ρ. In this paragraph only, ρ denotes this correlation rather than a pass-through rate. Then

$$\begin{aligned}\operatorname{Var}\left(\overline{CAR}\right) &= \frac{1}{K^2}\left[Kw\sigma^2 + K(K-1)\rho\, w\sigma^2\right] \\ &= \frac{w\sigma^2}{K}\left[1 + (K-1)\rho\right].\end{aligned}$$

With $K = 10$ and $\rho = 0.3$ the variance is 3.7 times the value that assumes independence. Ignoring the correlation would overstate the precision of the estimate. Whinston and Collins face exactly this problem, because each entry announcement hits several airlines on the same day.

The dummy-variable form. The two-step procedure has an equivalent one-step form. We estimate a single regression on $\mathcal{T}_0 \cup \mathcal{W}_k$ and add an indicator for each window day:

$$r_{f\tau} = a_f + b_f\, r_\tau^m + \sum_{s \in \mathcal{W}_k} \gamma_{fs}\, \mathbf{1}\{\tau = s\} + u_{f\tau}. \tag{9.41}$$

Proposition 9.47 (Equivalence of the two forms)**.** *OLS on* (9.41) *gives the estimation-window estimates* $(\hat{a}_f, \hat{b}_f)$*, and* $\hat{\gamma}_{fs} = \widehat{AR}_{fs}$ *for every* $s \in \mathcal{W}_k$*. Under the null of no event effect, the variance of* $\hat{\gamma}_{fs}$ *equals* (9.40)*.*

Proof. The OLS objective splits into window days and estimation days:

$$\sum_{s \in \mathcal{W}_k} \left(r_{fs} - a - b\, r_s^m - \gamma_s\right)^2 + \sum_{\tau \in \mathcal{T}_0} \left(r_{f\tau} - a - b\, r_\tau^m\right)^2.$$

Each γ_s appears in one squared term only. For any (a, b), the choice $\gamma_s = r_{fs} - a - b\, r_s^m$ sets that term to zero, which is its minimum. The remaining objective is the sum over $\mathcal{T}_0$, which is minimized by the estimation-window OLS estimates. Hence $\hat{\gamma}_{fs} = r_{fs} - \hat{a}_f - \hat{b}_f r_s^m = \widehat{AR}_{fs}$. Under the null, $\hat{\gamma}_{fs}$ equals the decomposition of $\widehat{AR}_{fs}$ given above, so its variance is (9.40). □

Summing the coefficients gives the cumulative abnormal return, $\sum_s \hat{\gamma}_{fs} = \widehat{CAR}_{fk}$, and the regression delivers its standard error directly. A restricted version uses a single indicator equal to one on all w window days. Its coefficient is then close to the average daily abnormal return, and w times the coefficient estimates the cumulative effect. The match is not exact, because the window days now also enter the estimate of b_f. The difference vanishes when L_0 is large relative to w. The regression form has two further advantages. It allows the event effect to depend on firm characteristics, and it allows many firms and events to be estimated jointly. Whinston and Collins use both features.

Systems of firms and seemingly unrelated regressions. Stack the equations of N_c firms for day τ as $y_\tau = X_\tau \theta + u_\tau$. Here y_τ is the $N_c \times 1$ vector of excess returns and θ stacks all parameters. The

matrix X_τ collects each firm's regressors, with zeros in the positions of other firms' parameters. A system of *seemingly unrelated regressions* (SUR) assumes

$$\mathbb{E}[u_\tau u_\tau^\top] = \Sigma, \qquad \mathbb{E}[u_\tau u_{\tau'}^\top] = 0 \quad \text{for } \tau \neq \tau',$$

so errors are correlated across firms on the same day but not across days (Zellner, 1962). The generalized least squares (GLS) estimator and its variance are

$$\hat{\theta}_{GLS} = \Big(\sum_\tau X_\tau^\top \Sigma^{-1} X_\tau \Big)^{-1} \sum_\tau X_\tau^\top \Sigma^{-1} y_\tau,$$
$$\operatorname{Var}\left(\hat{\theta}_{GLS}\right) = \Big(\sum_\tau X_\tau^\top \Sigma^{-1} X_\tau \Big)^{-1}.$$

Feasible GLS replaces Σ by $\hat{\Sigma} = \frac{1}{N_d} \sum_\tau \hat{u}_\tau \hat{u}_\tau^\top$, built from equation-by-equation OLS residuals over the N_d trading days. Section A.2.5 reviews the estimator.

Remark 9.48 (When SUR matters). If every equation has the same regressors and no parameter is shared across equations, GLS reduces to OLS equation by equation (Zellner, 1962). Neither condition holds in the application below. The regressors differ across firms, because they are scaled by each firm's own equity value and exposure. The key parameters are common to all firms, which is a cross-equation restriction. SUR then gains efficiency, it weights volatile stocks less, and its standard errors account for the correlation of same-day errors across firms hit by the same event.

Choice of window. A longer window captures more of the event's effect, including news that leaks before the announcement. It also adds the noise of unrelated news on each extra day. With a window that ends on the announcement day, $w^+ = 0$ and $\mathcal{W}_k = \{\tau_k - w + 1, \ldots, \tau_k\}$. Whinston and Collins use one-, two- and three-day windows of this form (p. 450). In early work they also tried a three-day window centered on the announcement day and found no information arriving after it (n. 19). Figure 9.9 shows the windows.

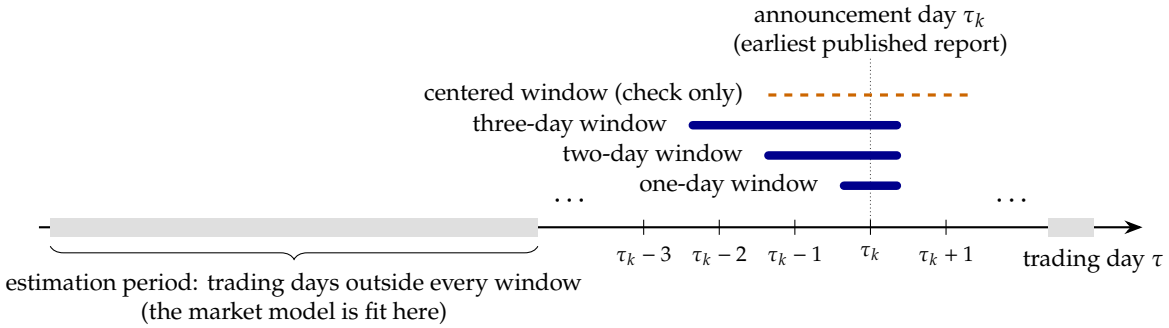

Figure 9.9: Event windows for an announcement on trading day τ_k. Solid bars are the one-, two- and three-day windows that end on the announcement day. The dashed bar is the centered three-day window used only to check for information arriving after the announcement. The market-model parameters are estimated from the days outside all windows.

Abnormal dollar values. The standard event study measures the effect of an event as a return. Whinston and Collins argue that the effect of their events is better measured in dollars (p. 449). The dollar loss from being an incumbent in one entered market should depend on that market's

profits, and not on the overall size of the carrier. A loss of \$5 million is a return of -2 percent for a firm worth \$250 million and -0.2 percent for a firm worth \$2.5 billion. A model with a common abnormal return would force the larger carrier's dollar loss to be ten times larger. We now derive the return equation implied by a dollar effect. Whinston and Collins (1990) give a formal derivation from the CAPM, and we give the simple version.

Let $V_{f\tau}$ be the market value of firm f's equity at the end of day τ and $D_{f\tau}$ the dividends it pays on day τ. With a constant number of shares, the return is

$$R_{f\tau} = \frac{V_{f\tau} + D_{f\tau} - V_{f,\tau-1}}{V_{f,\tau-1}},$$

so the dollar gain to shareholders on day τ is $G_{f\tau} \equiv V_{f\tau} + D_{f\tau} - V_{f,\tau-1} = V_{f,\tau-1} R_{f\tau}$. We build $G_{f\tau}$ in three steps.

Step 1 (normal gain). On a day without events, the CAPM gives $R_{f\tau} = R^0_\tau + b_f(R^m_\tau - R^0_\tau) + u_{f\tau}$. Multiplying by $V_{f,\tau-1}$,

$$G_{f\tau} = V_{f,\tau-1}\left[R^0_\tau + b_f(R^m_\tau - R^0_\tau)\right] + V_{f,\tau-1} u_{f\tau}.$$

The normal dollar gain and its noise both scale with the value of the firm.

Step 2 (event gain). Let $\mathbf{1}_\tau$ equal one if some event occurs on day τ. Let $\Delta_f(Z_\tau)$ be the expected dollar change in firm f's value from the events of day τ, whose characteristics are collected in Z_τ. Allow also a constant daily abnormal dollar gain a_f, which absorbs small errors in the pricing model. Then

$$G_{f\tau} = V_{f,\tau-1}\left[R^0_\tau + b_f(R^m_\tau - R^0_\tau)\right] + a_f + \mathbf{1}_\tau \, \Delta_f(Z_\tau) + V_{f,\tau-1} u_{f\tau}.$$

The event adds a fixed dollar amount that does not scale with $V_{f,\tau-1}$.

Step 3 (divide by value). Dividing by $V_{f,\tau-1}$ and subtracting R^0_τ from both sides gives

$$R_{f\tau} - R^0_\tau = a_f \frac{1}{V_{f,\tau-1}} + b_f\left(R^m_\tau - R^0_\tau\right) + \mathbf{1}_\tau \frac{\Delta_f(Z_\tau)}{V_{f,\tau-1}} + u_{f\tau}. \tag{9.42}$$

This is equation (1) of Whinston and Collins (1992), where the error $u_{f\tau}$ is serially uncorrelated. In return units the event effect is $\frac{\Delta_f(Z_\tau)}{V_{f,\tau-1}}$, so a fixed dollar loss is a larger return for a smaller firm. The intercept also enters in dollars. As a check, the authors re-estimated every specification with an added firm-specific constant in return units, and the estimated value changes were nearly identical (n. 8). They also allowed the dollar effect to differ across firms, and equality was not rejected (nn. 6 and 32). Both checks support the dollar formulation.

Identifying assumptions. The event-study estimate measures the change in expected discounted profits only under the following conditions.

(E1) *Efficiency.* Prices incorporate public news within the window.

(E2) *Correct dating and surprise.* The news first reaches the market inside the window, and it was not anticipated before the window.

(E3) *No confounding news.* No other news inside the window moves the same firms in a way correlated with their exposure to the event.

(E4) *Normal-return model.* Equation (9.39) (or its dollar form) describes returns outside the events, with stable b_f and serially uncorrelated errors. Contemporaneous correlation across firms is allowed.

(E5) *Equity captures the change.* The change in firm value accrues to shareholders, rather than being shared with debtholders or workers.

Failures of (E2) and (E5) bias the estimates toward zero. Remark 9.22 makes this precise for anticipation. If investors had assigned probability φ_0 to entry before the announcement, the measured change in value is only $(1 - \varphi_0)L$, a fraction of the true loss L. Section A.13 treats the general method and its pitfalls.

9.6.2 Question, logic, and setting

Whinston and Collins pose two questions. The first is whether airline routes carry route-specific profits or sunk costs, which is a test of the contestable-market model of Baumol et al. (1982). The second is how localized airline competition is. Competition might operate at the level of the airport pair, the city pair, or the whole network. Both questions matter for the merger policy debates of 1986–1987 described in Section 9.2.2.

Earlier evidence came from pricing studies (Graham et al., 1983; Call and Keeler, 1985; Bailey et al., 1985; Morrison and Winston, 1987; Borenstein, 1989). These studies regress route fares on demand and cost proxies and on measures of market structure. Whinston and Collins name two weaknesses. The studies treat routes as unrelated although each belongs to a network, and they need convincing controls for demand and cost. Without good instruments, market structure is likely correlated with unobserved demand and cost conditions (p. 446). Stock-market reactions to entry avoid both problems, at the price of the assumptions (E1) to (E5).

The logic. The test rests on Proposition 9.19. An incumbent that loses value L at an unanticipated entry announcement must have had $V^0 + K \geq L$. It earned positive economic profits on the route before entry, or it had sunk costs that keep it there despite the loss, or both. A perfectly contestable market has $V^0 = 0$ and $K = 0$, so it implies $L \leq 0$. A significant value loss for incumbents therefore rejects contestability. In the authors' words, the losses "provide a lower bound on the level of profits or sunk costs existing in these markets prior to entry" (p. 447). The remarks that follow Proposition 9.19 add three refinements. The bound holds even though People Express had lower costs than the incumbents (Remark 9.20). Losses confined to incumbents of the entered route show that rents are tied to that route (Remark 9.21). Anticipation makes the measured loss a lower bound (Remark 9.22).

Why People Express. The authors chose entry by a single carrier for two reasons (pp. 446–447). First, industry observers saw People Express as the embodiment of postderegulation innovations in product and cost (Section 9.2.2). If all events share this common driving force, they should have similar effects on airline values. Second, the predictions are clear. By Proposition 9.24, entry triggered by an entrant's own innovation lowers incumbents' values, while entry triggered by a common demand or cost shock can raise or lower them (n. 4). An announcement driven by People Express's own innovation carries mostly bad news for incumbents, which makes the sign of the effect interpretable.

The setting. People Express was a low-frill carrier based at Newark airport. Its 24 entry events of 1984 and 1985 all involved airports without slot controls, and 22 of them involved Newark (Section 9.2.2). Its stock traded over the counter, so its own value can be tracked through the events (n. 15). The authors exclude airport pairs at the four slot-constrained airports listed in Section 9.2.4 and international routes, where regulation limits access (n. 9).

The choice of 1984 and 1985 has three advantages (p. 450). Six years had passed since the Airline Deregulation Act of 1978. Nearly all flight restrictions imposed after the 1981 strike

of air traffic controllers (PATCO) had been lifted. Only Denver and Los Angeles were still constrained in 1984, and no event involves them while constrained (n. 10). Finally, the period precedes the merger wave.

9.6.3 Data

The study needs four kinds of information: the dates of the events, the incumbents in each entered market, daily stock returns for a panel of airlines, and the airlines' operations.

Events. The authors searched *Aviation Daily*, *The Wall Street Journal* and *The New York Times* for every report of People Express entry. They read every 1984 and 1985 issue of *Aviation Daily*, which reached New York on the morning of its publication date (n. 11). The event date is the publication date of the earliest report making clear that People Express would enter the route. Usually this is the first report of People Express's own announcement. In three cases it is an *Aviation Daily* "Intelligence Column" report. Table 9.9 lists the 24 events. By our count they fall on 17 distinct dates, with up to three events on one date, so the model must allow several events per day.

Table 9.9: The 24 People Express entry events, 1984–1985

Date	Airport pair	Source	Date	Airport pair	Source
1984-05-10	EWR-Minneapolis	AD	1985-04-11	EWR-Birmingham	AD[b]
1984-08-17	EWR-Miami	AD, NYT, WSJ	1985-04-17	EWR-Raleigh/Durham	AD[c]

1985-04-10	EWR-Ft. Lauderdale	AD	1985-08-28	EWR-St. Louis	AD, NYT, WSJ

Notes: EWR is Newark. AD is *Aviation Daily*, NYT *The New York Times*, WSJ *The Wall Street Journal*. Dates are year-month-day. (a) The report adds "Probably also Cleveland and New Orleans." (b) *Aviation Daily* "Intelligence Column" report that People Express would begin service. (c) Article saying People Express was finalizing plans to serve these three markets. (d) "Intelligence Column" report that People Express had secured a gate. Source: Whinston and Collins (1992), Appendix.

Market information. For each event the authors read the *Official Airline Guide* issue published just before the event date. It lists every flight between two airports, by carrier and aircraft type. They recorded each carrier's nonstop flights per week on the entered airport pair, and on all other airport pairs in the same city pair. Only jet flights were counted. The only consequence is that Delta would have been an incumbent in the Newark-Albany and Newark-Providence events had nonjet flights counted (n. 13). Aircraft capacities convert flights into seats (n. 14). A *seat-mile* is one seat flown one mile, and a carrier's seat-miles on a route are its seats times the route distance.

Table 9.10 collects the descriptive statistics that the paper reports. Five of the 24 events had no incumbent. The 19 events with incumbents averaged 1.68 incumbents, and the average over all 24 events is $1.68 \times \frac{19}{24} = 1.33$, the figure the paper reports for the entered pair. The average incumbent offered 7,100 seats per week on a route of average length 892 miles.

Table 9.10: Descriptive statistics for the People Express events

Statistic	Value	Location
Entry events (involving Newark)	24 (22)	p. 450
Events with no incumbent on the entered pair	5	p. 451
Incumbents per event, events with incumbents (s.d.)	1.68 (0.78)	p. 451
Seats per week, average incumbent (s.d.)	7,100 (3,283)	p. 451
Distance of entered routes, miles (s.d.)	892 (549)	p. 451
Seat-miles per week, entered airport pair	8,718,000	p. 455
Seat-miles per week, other airports in the city pair	21,860,000	p. 455
Incumbents per event, entered pair	1.33	p. 455
Incumbents per event, other airports	2.71	p. 455
$\mathbb{P}(OSM > 0 \mid SM > 0)$, all events	0.719	p. 455
$\mathbb{P}(OSM > 0 \mid SM > 0)$, New York-area events	0.793	p. 455
Share of departures at newly entered airport, carriers with $SM > 0$	44.3%	p. 456
Same, carriers with $SM > 0$ or $OSM > 0$	59.1%	p. 456
Annual departures at newly entered airport, average carrier	3,444	fn. 26
Annual departures at newly entered airport, entered-pair incumbent	29,616	fn. 26
Annual revenue per seat-mile, incumbents (weighted, $)	0.081	p. 452
Firms in the stock panel, all exchanges	20	p. 451
of which traded on NYSE or AMEX every day	16	p. 451
of which traded over the counter	4	p. 451

Notes: SM and OSM are a carrier's seat-miles on the entered airport pair and on other airport pairs of the same city pair. The departure shares exclude the Minneapolis-Tampa event and condition on events with some incumbent. Revenue per seat-mile weights each airline by its share of the seat-miles People Express entered against. Locations are journal pages. Source: Whinston and Collins (1992).

Stock data. Daily returns come from the CRSP tape for all airline stocks on the New York and American Stock Exchanges. Sixteen carriers traded every day of the sample. The authors added four carriers traded over the counter (OTC). The NYSE firms are American, Alaska Air, Delta, Eastern, Northwest Orient, Pacific Southwest, Pan Am, Piedmont, Republic, Trans World, United, USAir and Western. The AMEX firms are Continental, Ozark and Texas Air. The OTC firms are Air California, America West, Midway and People Express (n. 15). Texas Air held the stock of Continental and New York Air. Its event variables are combinations of those two airlines' variables, weighted by its ownership shares. Nearly all of each firm's operations were in air transport. The exception is United, whose airline operations still accounted for over five-eighths of its assets (n. 16).

Unit of observation. An observation is a firm on a trading day of 1984–1985. The dependent variable is the excess return $R_{f\tau} - R^0_\tau$. There are $N_c = 19$ carriers besides People Express, plus People Express itself.

9.6.4 Estimating equations and specifications

Each event k has a set of measurable characteristics Z^k_f for each carrier f, such as the carrier's seats on the entered route. The dollar change in carrier f's value from event k is modeled as a known function $g(Z^k_f; \Lambda)$ of these characteristics and a parameter vector Λ. Whinston and Collins write this function as $f(Z^k_i, \Lambda)$, and we use g because f indexes firms. Let E_τ be the set of events whose window contains day τ. The total dollar change on day τ is

$$\Delta_f(Z_\tau) = \sum_{k \in E_\tau} g(Z^k_f; \Lambda). \tag{9.43}$$

Substituting (9.43) into (9.42), and using $\mathbf{1}_\tau = 1$ exactly when E_τ is nonempty, gives the basic estimating equation for carrier f:

$$R_{f\tau} - R^0_\tau = a_f \frac{1}{V_{f,\tau-1}} + b_f \left(R^m_\tau - R^0_\tau\right) + \sum_{k \in E_\tau} \frac{g(Z^k_f; \Lambda)}{V_{f,\tau-1}} + u_{f\tau}. \tag{9.44}$$

The empty sum is zero on days without events, so the indicator is no longer needed. People Express has its own equation, in which g is replaced by a function $h(X^k; \lambda_{PE})$ of event characteristics X^k. In every specification below, $h = \lambda_{PE}$, a constant dollar change per event. The $N_c = 19$ carrier equations and the People Express equation form a system with contemporaneously correlated errors, estimated jointly as in Remark 9.48.

With a w-day window, event k belongs to E_τ on each of the days $\tau_k - w + 1, \ldots, \tau_k$. The coefficients then measure the average daily dollar change, and the paper reports w times this average as the total value change over the window (p. 452). All estimates below are totals in this sense.

Specification 1: incumbency on the entered pair. The simplest specification makes each carrier's loss proportional to its seat-miles on the entered route:

$$g(Z^k_f; \Lambda) = \lambda_{SM}\, SM^k_f. \tag{9.45}$$

Here SM^k_f is carrier f's annualized seat-miles on the airport pair entered in event k, equal to its weekly seat-miles just before the announcement times 52. The parameter λ_{SM} is the dollar change in value per annualized seat-mile. The paper calls it γ.

Two considerations motivate seat-miles (pp. 451–452). Within an event, it is natural that each incumbent's loss is proportional to its share of the seats on the route. Across events, the total loss of incumbents should grow with market size, measured by seats. Customer values and costs both rise with distance, so a seat on a 2,000-mile route should carry a larger dollar effect than a seat on a 200-mile route. Seat-miles combine the two. This choice matches industry practice of reporting operating profit per available seat-mile (n. 17). The data allow no seasonal adjustment (n. 18).

The authors note reasons why other forms might fit better. Longer routes may face more competition from connecting service, so losses could fall with distance. If People Express entered at a scale independent of market size, the total loss would not depend on seats. Effects could also be firm specific. Footnote 32, reported with the results below, tests these alternatives.

Specification 2: general effects. An announcement could lower the values of carriers that are not incumbents on the entered route (p. 454). Three channels are possible. Entry could set off competitive adjustments throughout the network, including in regulated segments where rents are likely, such as slot-constrained airports and international routes. Carriers own aircraft, and entry announcements may coincide with changes in aircraft values. The announcement may also reveal information about the likely scale of People Express's future expansion. To absorb such effects the authors add a firm fixed effect per event:

$$g(Z_f^k; \Lambda) = \lambda_f + \lambda_{SM}\, SM_f^k. \tag{9.46}$$

The paper writes the fixed effect as α_i, the same symbol as the intercept in (9.42). We write λ_f to keep the two apart. If the general effect works through slot values, λ_f is related to the number of slots carrier f holds. If it works through information about future expansion, λ_f is related to the probability that carrier f is an incumbent in a later People Express event.

Specification 3: other airports in the city pair. Twenty-two events involve Newark, which competes to some extent with La Guardia and Kennedy for New York traffic. Both of these airports are slot constrained, so carriers there may hold regulatory rents that entry at Newark could erode. If Newark incumbents also tend to serve the same city from La Guardia or Kennedy, the seat-mile variable could pick up losses that belong to those airports. The authors add OSM_f^k, carrier f's annualized seat-miles between the two cities of event k at airport combinations other than the entered pair:

$$g(Z_f^k; \Lambda) = \lambda_f + \lambda_{SM}\, SM_f^k + \lambda_{OSM}\, OSM_f^k. \tag{9.47}$$

In all but 2 of the 24 events, the other seat-miles are slot-constrained departures from La Guardia or Kennedy to the airport that People Express entered from Newark (p. 455). The paper's symbol for λ_{OSM} is ϕ.

The other airports offered about two and a half times as many seat-miles as the entered pair (Table 9.10), mostly because they had more incumbents. Carriers often served both: the probability that $OSM_f^k > 0$ given $SM_f^k > 0$ is 0.719 overall and 0.793 for New York-area events. The contrast between λ_{SM} and λ_{OSM} is therefore identified mainly by comparing carriers that serve both the entered pair and other airports with carriers that serve only other airports. Without demand or cost differences between airports in the same city, the two effects per seat-mile should be similar. Their difference measures differentiation between airports.

Specification 4: separate New York fixed effects. Suppose slots at a constrained airport could be shifted freely across the markets served from it. Then entry would lower the profit of every

departure at that airport equally. Each carrier would bear the same loss per slot, regardless of which city it serves, and *OSM* would pick up little of it (p. 455). The firm effects already absorb most of such a loss, since 22 events involve Newark. To be safe, the authors allow separate firm effects for the two non-New York events:

$$g(Z_f^k;\Lambda) = \lambda_f + \lambda_f^{NNY} I_k^{NNY} + \lambda_{SM}\, SM_f^k + \lambda_{OSM}\, OSM_f^k, \tag{9.48}$$

where $I_k^{NNY} = 1$ if event k is not in the New York area. The general effect is λ_f in New York events and $\lambda_f + \lambda_f^{NNY}$ elsewhere. Separate effects also absorb informational losses that depend on whether People Express was expected to keep expanding from Newark.

Specification 5: the newly entered airport. In every event except Minneapolis-Tampa, People Express entered an airport for the first time. It thereby also entered connecting city pairs between the new city and the rest of its network. Carriers on those connecting routes could lose value too. Entered-pair incumbents held large shares at the newly entered airport: 44.3 percent of its departures on average, and 59.1 percent including carriers with $OSM > 0$ (Table 9.10). To separate route incumbency from airport presence, the authors add $EPORT_f^k$, carrier f's departures at the airport entered in event k, in the year of the event. It is zero for all carriers in the Minneapolis-Tampa event (n. 27). The most elaborate specification is

$$g(Z_f^k;\Lambda) = \lambda_f + \lambda_f^{NNY} I_k^{NNY} + \lambda_{SM}\, SM_f^k + \lambda_{OSM}\, OSM_f^k + \lambda_{EP}\, EPORT_f^k. \tag{9.49}$$

The paper's symbol for λ_{EP} is η.

The estimating equation in full. Substituting (9.49) into (9.44) shows that every specification is linear in its parameters. Let $n_\tau = |E_\tau|$ be the number of events whose window contains day τ, and n_τ^{NNY} the number of those outside New York. Then

$$\begin{aligned} R_{f\tau} - R_\tau^0 = a_f \frac{1}{V_{f,\tau-1}} + b_f\left(R_\tau^m - R_\tau^0\right) + \lambda_f \frac{n_\tau}{V_{f,\tau-1}} + \lambda_f^{NNY} \frac{n_\tau^{NNY}}{V_{f,\tau-1}} \\ + \lambda_{SM} \frac{\sum_{k\in E_\tau} SM_f^k}{V_{f,\tau-1}} + \lambda_{OSM} \frac{\sum_{k\in E_\tau} OSM_f^k}{V_{f,\tau-1}} + \lambda_{EP} \frac{\sum_{k\in E_\tau} EPORT_f^k}{V_{f,\tau-1}} + u_{f\tau}. \end{aligned}$$

Each regressor is a predetermined exposure divided by the previous day's equity value. Linear SUR applies directly.

Identification. The parameters are identified from two sources of variation. Event timing separates event days from ordinary days, and the market model absorbs market-wide news on all days. Within event days, carriers differ in their exposure to each event. A carrier that is not an incumbent anywhere in an event reveals the general effect λ_f through its returns on event days. Comparing incumbents with non-incumbents on the same days, relative to each carrier's own general effect, identifies λ_{SM}. The *OSM* and *EPORT* effects are identified because these exposures are imperfectly correlated with *SM*. The price of this flexibility is precision. Each λ_f is estimated from about 17 event dates, and each λ_f^{NNY} from two events.

9.6.5 Results on value

The simplest specification. Table 9.11 reproduces Table 1 of the paper, specification (9.45) for the three windows. Incumbents on the entered route lost between \$0.0109 and \$0.0191 of value per

annualized seat-mile. The effect is precise in every window. Dividing the rounded estimates by their standard errors gives t statistics of −3.11, −3.00 and −3.13. The paper reports a range of −2.98 to −3.15, computed from unrounded estimates (p. 452).

Table 9.11: Total value response to People Express entry, simplest specification

	Event window		
Variable	One-day	Two-day	Three-day
Incumbent effect per annualized seat-mile, λ_{SM} (\$)	−0.0109	−0.0147	−0.0191
	(0.0035)	(0.0049)	(0.0061)
People Express effect, λ_{PE} (\$1,000s)	−354	440	−1,293
	(1,103)	(1,548)	(1,914)
t statistic for λ_{SM} (computed from rounded entries)	−3.11	−3.00	−3.13

Notes: Specification (9.45), estimated by SUR on the daily returns of 19 carriers and People Express, 1984–1985. Windows end on the announcement day. Entries are total value changes over the window. Standard errors in parentheses. The last row is computed by us. Source: Whinston and Collins (1992), Table 1.

Magnitudes. The estimates translate into dollars as follows. The paper reports a loss per incumbent of \$3.7 million to \$6.5 million (p. 452). Dividing by the coefficients recovers the annualized seat-miles of the average incumbent:

$$\frac{\$3.7 \text{ million}}{0.0109} \approx 339 \text{ million}, \qquad \frac{\$6.5 \text{ million}}{0.0191} \approx 340 \text{ million seat-miles per year}.$$

The product of the mean seats and the mean distance gives a slightly smaller figure, $7{,}100 \times 892 \times 52 \approx 329$ million, because the paper averages the product of seats and distance over incumbents. Events with incumbents had 1.68 incumbents on average, so the loss per event for all incumbents combined is

$$1.68 \times \$3.7 \text{ million} \approx \$6.2 \text{ million} \quad \text{to} \quad 1.68 \times \$6.5 \text{ million} \approx \$10.9 \text{ million}.$$

These are after-tax losses to shareholders. At the 46 percent corporate tax rate of the period, the pretax loss per incumbent is

$$\frac{\$3.7 \text{ million}}{1 - 0.46} \approx \$6.8 \text{ million} \quad \text{to} \quad \frac{\$6.5 \text{ million}}{1 - 0.46} \approx \$12.0 \text{ million}.$$

A second comparison scales the loss by revenue. The incumbents' weighted average annual revenue per seat-mile was \$0.081 (n. 20). The pretax loss per seat-mile as a fraction of a year's revenue is

$$\frac{0.0109}{0.54 \times 0.081} = \frac{0.0109}{0.0437} \approx 0.25 \quad \text{to} \quad \frac{0.0191}{0.54 \times 0.081} = \frac{0.0191}{0.0437} \approx 0.44.$$

Here $0.54 = 1 - 0.46$ converts the after-tax loss per seat-mile into a pretax loss. The paper reports 25 to 43 percent. An incumbent that flew its planes on the entered route completely empty would lose its revenue while bearing the same costs. A loss of 0.25 to 0.44 years of revenue is therefore comparable to flying the route empty for $0.25 \times 12 = 3$ to $0.44 \times 12 \approx 5$ months. The authors conclude that route profits or sunk costs before entry were substantial.[10]

[10] The paper's introduction rounds these figures to a loss of "\$3 million to \$6 million" per incumbent and a pretax loss of "\$6 million and \$12 million" (p. 447). We use the figures of Section 4 of the paper.

Biases. The estimates could understate the true loss for three reasons (p. 453). Events may be misdated, the market may have anticipated part of the news, and some of the loss may fall on debtholders or on workers who share rents. A fourth reason concerns connecting traffic. A seat on the entered route also serves connecting passengers, so the loss per seat averages the losses on the two kinds of traffic. People Express entered mainly the city-pair market. To the extent that entry hurt city-pair traffic more than connecting traffic, the loss per seat understates the loss in the city-pair market. Entry can still hurt connecting traffic, through lost economies of density, reduced frequency, or arbitrage between fares (n. 21). Reasons the estimates might overstate the loss motivate the richer specifications below.

People Express's own value. The estimated changes in People Express's value are small, at most $1.3 million in absolute value. They are also imprecise, each within one standard error of zero, and of inconsistent sign.[11] The authors offer two readings (pp. 453–454). The scale of expansion may have been fully anticipated, with only its location unknown. Then People Express's value would not move while its targets lost value. This reading predicts zero expected loss for the set of all possible incumbents, which the general effects below contradict. The panel lacks only one notable possible incumbent, Frontier Airlines, so it comes close to that set (n. 22). Alternatively, the scale was unanticipated, and each extra entry yielded People Express little return while lowering incumbents' profits. Some observers thought that the move into major markets was a mistake. The test does not require optimal entry choices. A low-price entrant reveals incumbents' sunk costs whether or not its prices cover its own costs (n. 23).

The richer specifications. Table 9.12 reproduces Table 2 of the paper, which adds the controls of specifications (9.46) to (9.49) for the one-day window. The results for two- and three-day windows are similar and appear in Whinston and Collins (1990).

Table 9.12: Total value response to entry, one-day window, five specifications

Variable	(1)	(2)	(3)	(4)	(5)
Airport-pair incumbent effect, λ_{SM}	−0.0109	−0.0127	−0.0158	−0.0144	−0.0126
	(0.0035)	(0.0040)	(0.0053)	(0.0054)	(0.0058)
Other airports incumbent effect, λ_{OSM}			0.0025	0.0020	0.0026
			(0.0028)	(0.0028)	(0.0029)

Sum of estimated fixed effects ($1,000s)		−30,841			−36,238
		(17,621)			(19,136)

Notes: Column (1) is specification (9.45) and repeats the one-day column of Table 9.11. Columns (2) to (5) are specifications (9.46), (9.47), (9.48) and (9.49). λ_{SM} and λ_{OSM} are dollars per annualized seat-mile. λ_{EP} is dollars per annual departure at the newly entered airport. Standard errors in parentheses. The fixed-effect sums are reported only for columns (2) and (5). Source: Whinston and Collins (1992), Table 2.

The incumbency effect survives every control. Its estimate rises slightly in absolute value, from −0.0109 in column (1) to −0.0126 in column (5). Its precision falls, and the column (5)

[11] The paper describes them as below $1 million in absolute value (p. 453). This holds for the one- and two-day windows. The three-day estimate in its Table 1 is −$1.293 million.

t statistic is −2.18 (our ratio of the rounded entries gives −2.17). The two- and three-day estimates of specification (9.49) are −0.0154 (0.0082) and −0.0142 (0.0101). Their average across the three windows,

$$\frac{-0.0126 - 0.0154 - 0.0142}{3} = -0.0141,$$

is close to the average of the three columns of Table 9.11 (n. 28),

$$\frac{-0.0109 - 0.0147 - 0.0191}{3} = -0.0149.$$

The losses are tied to incumbency on the entered route.

General effects. The sum of the 19 estimated fixed effects in column (5) is −$36.2 million per event. Divided equally among the 19 carriers, it is a general loss of $\frac{36{,}238}{19} \approx \$1.9$ million per carrier and event. The column (5) incumbency effect for the average incumbent is 0.0126×339 million ≈ $4.3 million. An incumbent therefore loses about 4.3 + 1.9 = $6.2 million, more than three times the $1.9 million loss of a non-incumbent (journal p. 456). The general part is $\frac{1.9}{6.2} \approx 30$ percent of an incumbent's loss.

The picture reverses for the industry. Per event, the incumbency loss of all incumbents together is about $0.0126 \times 52 \times 8{,}718{,}000 \approx \$5.7$ million. The general losses total $36.2 million. General effects are therefore $\frac{36.2}{36.2+5.7} \approx 86$ percent of the industry loss, "over 80%" in the paper's words. Weighting the fixed effects by each carrier's extent of incumbency gives a general loss of $3.75 million for the average incumbent. On that basis an incumbent loses $\frac{4.3+3.75}{3.75} \approx 2.1$ times as much as a non-incumbent (n. 29). The general effects fall more heavily on carriers that were more likely to be incumbents. Their source remains unclear. Competitive spillovers through the network, aircraft values and information about People Express's future scale are all consistent with them.

The non-New York fixed effects are not reported. They rest on two events only and are noisy. A *quasi-likelihood ratio test*, a likelihood-ratio-type test computed from the SUR objective, does not reject equality of the New York and non-New York fixed effects at conventional levels (p. 457).

Other airports in the city. The *OSM* effect is small, positive and insignificant in all three columns. It is an order of magnitude smaller than the *SM* effect.[12] The two- and three-day estimates are 0.0028 (0.0039) and −0.0017 (0.0048), so even the sign is unstable (n. 30). The authors reject equality of the *SM* and *OSM* effects at the 2.5 percent level. For intuition, if the two column (5) estimates were uncorrelated, the difference −0.0152 would have standard error $\sqrt{0.0058^2 + 0.0029^2} \approx 0.0065$ and a z statistic of −2.34. Airports in the same city are differentiated, on the demand side, the cost side, or both. This finding agrees with the high value carriers placed on La Guardia and Kennedy slots despite the existence of Newark.

The authors warn against reading the result as the absence of substitution between airports (p. 457). Entry need not harm sellers of substitutes. People Express served mainly travelers with a low willingness to pay. Its entry might lead the Newark incumbent to cut frequency or crowd its coach cabin, or might make Newark less attractive in general. La Guardia carriers would then gain business travelers, and the gain could exceed their loss of discount passengers (n. 31).

The newly entered airport. The *EPORT* coefficient is negative, small and insignificant, −33.8 (38.2) dollars per annual departure. For the average carrier, with 3,444 annual departures at

[12] The paper's text reads "an order of magnitude smaller than the OSM effect" (p. 457). The intended comparison is with the SM effect.

the newly entered airport, it implies a loss of $33.8 \times 3{,}444 \approx \$0.12$ million. For entered-pair incumbents, with 29,616 departures, it implies $33.8 \times 29{,}616 \approx \$1.0$ million. This is small next to their \$4.3 million loss from incumbency on the entered pair (p. 458).

Robustness. Footnote 32 reports two further checks for the one-day window. The first replaces SM_f^k by

$$\left[\lambda_0 + \lambda_1 SEATS_k + \lambda_2 DIST_k + \lambda_{SM}\, DIST_k\, SEATS_k\right] SH_f^k,$$

where $SEATS_k$ and $DIST_k$ are the route's total seats and distance and SH_f^k is carrier f's seat share on the entered pair. The same construction replaces OSM_f^k. Specification (9.49) is the case $\lambda_0 = \lambda_1 = \lambda_2 = 0$. A test of the six added parameters comes nowhere close to rejecting it. The most important added term is distance. With it alone, the losses per seat-mile at the sample means are -0.0118 (0.0059) on the entered pair and -0.0009 (0.0047) at other airports. The second check gives each firm its own seat-mile coefficient in specification (9.45). Equality is not rejected, and the average coefficient is -0.0105. A firm-specific constant in return units also leaves the estimates nearly unchanged (n. 8).

9.6.6 Price, quantity, and capacity responses

The stock market reveals expected losses. Section 5 of the paper asks what incumbents did after entry, using prices, ticket sales and schedules. The evidence corroborates the value results and adds a surprise about quantities.

Data. Prices and quantities come from the Department of Transportation's Origin and Destination Survey, a 10 percent sample of tickets, for the first quarters of 1984, 1985 and 1986 (n. 33). The outcomes are year-to-year percentage changes in the mean coach price, in the standard deviation of coach prices, and in coach tickets sold. Only New York-area events are used. Two events of the first quarter of 1985 are dropped, since their year of entry is ambiguous. By the dates in Table 9.9, these are Rochester and Cincinnati. Nashville is dropped because it had no Newark incumbent in the first quarter of 1984. San Francisco is dropped because People Express switched to another airport pair in that city pair within a year. The data cover all direct flights between Newark and the new city, including multistop flights without a change of plane. The final samples have 7 markets entered in 1984 and 8 entered in 1985.

Design. The design is a *difference in differences* (Section A.12). Each cohort serves as the control for the other in one period. Let $\ln P_{ty}$ be the log mean incumbent price in market t in the first quarter of year y. Let $D_{ty} = 1$ if People Express announced entry into t before that quarter. Consider the model

$$\ln P_{ty} = \mu_t + \nu_y + \varphi_E\, D_{ty} + e_{ty}, \tag{9.50}$$

with market effects μ_t, year effects ν_y and a constant entry effect φ_E. For the 1984 cohort, D is $(0, 1, 1)$ in 1984, 1985 and 1986. For the 1985 cohort it is $(0, 0, 1)$. First differences remove the market effects:

$$\ln P_{t,y+1} - \ln P_{ty} = (\nu_{y+1} - \nu_y) + \varphi_E\,(D_{t,y+1} - D_{ty}) + (e_{t,y+1} - e_{ty}).$$

Comparing cohorts within a period removes the year effects. Write $\bar{\Delta}_p^c$ for the mean change of cohort c in period p. If the error changes have the same mean in both cohorts,

$$\mathbb{E}\left[\bar{\Delta}_{84\text{–}85}^{84} - \bar{\Delta}_{84\text{–}85}^{85}\right] = \varphi_E\,(1 - 0) = \varphi_E,$$
$$\mathbb{E}\left[\bar{\Delta}_{85\text{–}86}^{85} - \bar{\Delta}_{85\text{–}86}^{84}\right] = \varphi_E\,(1 - 0) = \varphi_E.$$

Each period yields one estimate of φ_E. The paper reports percentage changes, which approximate log changes when changes are small.

The identifying assumptions are three. The timing of entry is unrelated to market-specific changes in demand and cost, which is the parallel-trends condition. The effect is a one-time level shift, so the 1984 cohort shows no further effect in its second year. Entry into one market does not change outcomes in the control markets.

The data offer no separate check of the first two assumptions. Only one year, 1984, precedes the entry of both cohorts, so no period shows how the two cohorts' prices change when neither is entered. The 1985 cohort's change in 1984–1985 is the control change. Under parallel trends it measures the year effect $\nu_{85} - \nu_{84}$. The change the 1984 cohort would have had without entry in that period is never observed, so the control change cannot test parallel trends. The 1984 cohort's change in 1985–1986 adds the year effect $\nu_{86} - \nu_{85}$ to any change in that cohort's entry effect. The 1985 cohort is entered in that period, so it cannot separate the two terms. Under the three assumptions, the four mean changes depend on three parameters, the two year effects and φ_E. The assumptions therefore imply one testable restriction, that the two contrasts are equal. A separate test for differential trends would require an earlier year, such as 1983, so that one change precedes the entry of both cohorts. A check of how the effect evolves would require markets that People Express had not entered by the first quarter of 1986, such as markets it never entered.

The paper tests each contrast with a two-sample t statistic. With cohort means $\bar{y}_1, \bar{y}_2$, standard deviations s_1, s_2 and sizes $n_1 = 7$, $n_2 = 8$,

$$t = \frac{\bar{y}_1 - \bar{y}_2}{s_p \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}, \qquad s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2},$$

which has $n_1 + n_2 - 2 = 13$ degrees of freedom under normality. The two-sided 5 percent cutoff is 2.16.[13]

Table 9.13 reproduces Tables 3 and 4 of the paper. The last row of each panel adds the difference-in-differences contrast of the treated cohort minus the control cohort in each period. Figure 9.10 plots the price columns.

Prices. The pattern is similar in the two periods (p. 459). In markets entered during a year, the mean incumbent price fell by about 35 percent. In markets not entered that year it barely moved. The two contrasts are −35 points each, with t statistics of 2.5 and 3.5. Their equality is consistent with the three assumptions. So are the 2 percent rise in the 1985 cohort's prices before its entry and the flat prices of the 1984 cohort in the year after its entry. None of these patterns confirms the assumptions, because offsetting departures from them reproduce all four changes. Suppose the true effect is −25 points and fades by 10 points in its second year. Suppose also that, without entry, prices in the 1984 cohort would have fallen 10 points more than in the 1985 cohort in 1984–1985. Let prices in the 1985 cohort rise 2 points in 1984–1985, as observed. Let all prices fall 10 points in 1985–1986 for reasons unrelated to entry. These values give exactly the changes −33, +2, 0 and −35 of Panel A. Even after the cuts, People Express's average fare in the first quarter after entry was 19 percent below the incumbents' mean fare.

[13] Recomputing the statistics from the rounded entries of Table 9.13 reproduces the printed values for price and price dispersion to within about 0.2. The match is closest when the reported standard deviations are read as computed with divisor n. For the two quantity columns of Table 3 the same formulas give about 1.7 to 1.9, where the paper prints 0.6. Either value lies below the 5 percent cutoff, so the conclusion that the quantity contrasts are imprecise is unaffected.

Table 9.13: Year-to-year percentage changes for incumbents, by entry cohort

	Mean price		Sales quantity		S.d. of price	
Markets entered in	1984–85	1985–86	1984–85	1985–86	1984–85	1985–86

t statistic, 1984 versus 1985 (13 d.f.)	2.1	2.3	1.2	0.1	2.5	2.6
Treated minus control (computed)	−23	−16	+17	+1	−50	−18

Notes: Each cell is the mean across markets of the percentage change in the outcome between first quarters, with the cross-market standard deviation in parentheses. Panel A covers incumbents on the entered Newark airport pair. Panel B covers incumbents on other airport pairs of the same city pair, typically Kennedy or La Guardia to the newly entered airport. The treated cohort is the one entered during the period (1984 cohort in 1984–85, 1985 cohort in 1985–86). The last row of each panel is computed by us. Source: Whinston and Collins (1992), Tables 3 and 4.

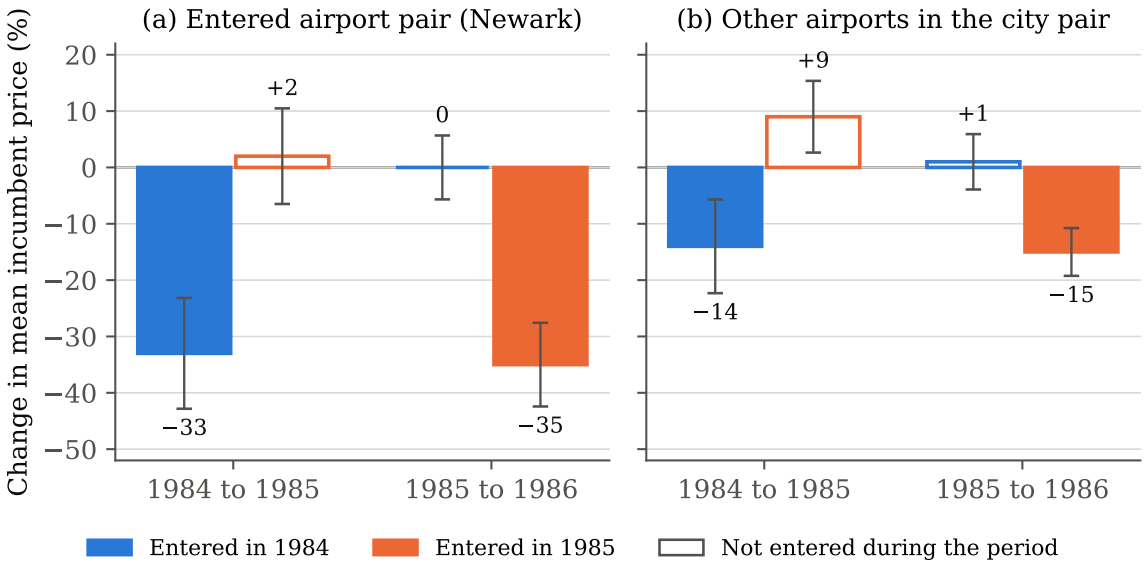

Figure 9.10: Percentage change in the mean incumbent price by entry cohort and period. Filled bars are the cohort entered during the period, and open bars the cohort not entered during it. Whiskers show plus or minus one standard error of the cohort mean, computed as the reported cross-market standard deviation divided by $\sqrt{n}$ (n = 7 and 8). Redrawn from Whinston and Collins (1992), Tables 3 and 4.

Price dispersion fell, or rose less, in entered markets. The contrast is larger in 1984–1985 (−55 points, $t = 2.6$) than in 1985–1986 (−20 points, $t = 1.0$). The authors speculate that airlines grew more skilled at *yield management*, the dynamic allocation of seats across fare classes, over the period. By 1985–1986 an incumbent could target its price cuts where they mattered most, without lowering all fares.

Quantities and revenue. Incumbents sold more tickets after entry, if anything. The contrasts are +72 and +74 points, but the variation across markets is large and neither is significant. Revenue fell much less than the price cuts alone would imply (n. 34). In 1984–1985, revenue in entered markets rose 21 percent (s.d. 22) against 33 percent (s.d. 28) in markets not entered. In 1985–1986 the figures are 3 percent (s.d. 29) and 10 percent (s.d. 16). Revenue understates the incumbents' loss, because carrying more passengers raises costs and, as we see next, incumbents also added capacity.

Capacity. The authors compared incumbents' nonstop seats on the entered route one year after the announcement with seats at the announcement, using the *Official Airline Guide*. Seats rose 25 percent on average (s.d. 42). Domestic seats at Newark offered by carriers other than People Express rose 11 percent a year over 1984–1986. That benchmark includes the entered markets, so the comparison understates the gap (n. 35). Nearly all of the increase came from flight frequency. Seats per flight rose only 6 percent (s.d. 20), against 3 percent at Newark. The capacity increases were larger for the 1984 cohort, 48 percent (s.d. 52), than for the 1985 cohort, 5 percent (s.d. 14) (n. 36).

Other airports in the city pair. Panel B shows the same pattern on a smaller scale (pp. 460–461). Prices fell 14 and 15 percent in the treated cohorts, the "15%" the paper quotes, while the control cohorts' prices rose 9 and 1 percent. The contrasts are −23 points ($t = 2.1$) and −16 points ($t = 2.3$). Quantity changes are small and insignificant. Incumbent capacity on these routes rose 1 percent (s.d. 30) in the year after entry, against a 1 percent decline at Kennedy and La Guardia. Seats per flight fell 4 percent (s.d. 9), against a 2 percent decline at those airports, so frequency again rose. Price dispersion again fell relative to controls, more in 1984 than in 1985. The smaller price response matches the small *OSM* value effect. Airports in a city are substitutes, but imperfect ones.

Interpretation. The quantity and capacity responses discriminate among models of competition (p. 460). Under price taking, each incumbent sells where price equals its marginal cost. Entry lowers the market price and moves each incumbent down its supply curve, so its output falls. Price cuts together with rising sales and capacity are hard to square with any simple price-taking model. The rents revealed by the value losses are therefore not the efficiency rents of a competitive market.

Static oligopoly models predict the same direction as price taking. In symmetric Cournot competition each firm's output falls when the number of firms rises (9.10), and by Remark 9.25 the same holds for capacities. By (9.11), the observed responses fit static models only if quantities are strategic complements, which requires unusually convex demand. They are consistent with a dynamic strategy. Industry observers claimed that incumbents responded aggressively to induce exit, or at least to discourage further expansion. The larger capacity increases in 1984 fit this interpretation. The responses also show that the value losses did not reflect a temporary adjustment toward a smaller scale of operations.

The authors add a caution (pp. 458–459). Demand or cost conditions may have changed in the entered markets, and such changes might even have caused entry. The size of the effects and the view that the events reflected People Express's own strategy make it plausible that

most of the change is a response to entry.

9.6.7 Conclusions, limitations, and contribution

What the paper concludes, and where. Table 9.14 lists each conclusion of the paper with the evidence and the test behind it. The value results come from the *SM* rows of Tables 9.11 and 9.12. The contrast between airports comes from the *OSM* rows and the test of equal effects. The general effects come from the fixed-effect sums. The incumbent responses come from Table 9.13 and the schedule comparisons.

Table 9.14: Conclusions of Whinston and Collins (1992) and the supporting evidence

Conclusion	Evidence	Test
Route-specific profits or sunk costs exist, so airline routes are not contestable	$\lambda_{SM} < 0$ in all windows (Table 1) and all specifications (Table 2, SM row). Loss of \$3.7 to \$6.5 million per incumbent	t tests of $\lambda_{SM} = 0$: -2.98 to -3.15 (Table 1), -2.18 (Table 2, column 5)
Local market structure matters, and profits are not equalized across routes	Incumbency loss survives firm fixed effects. An incumbent loses \$6.2 million versus \$1.9 million for a non-incumbent (Table 2, column 5)	t test of λ_{SM} with fixed effects, fixed-effect sum
Airports in the same city are differentiated	λ_{OSM} small, positive, insignificant (Table 2, columns 3 to 5)	Test of $\lambda_{SM} = \lambda_{OSM}$, rejected at 2.5 percent
Large industry-wide effects of unclear origin	Sum of fixed effects $-$\$36.2 million, over 80 percent of industry loss (Table 2, column 5)	Standard error of the sum, quasi-likelihood ratio test of New York versus other fixed effects
Incumbents cut prices sharply but raised capacity and sales	Price contrasts of -35 points on the entered pair and -23 and -16 at other airports. Seats +25 percent (Tables 3 and 4, schedule data)	Two-sample t tests with 13 degrees of freedom

Notes: Table numbers refer to Whinston and Collins (1992), reproduced here as Tables 9.11 to 9.13.

From descriptive results to economic inferences. The chain of reasoning has three links. The first is statistical. Incumbents' abnormal dollar changes on announcement days are negative and proportional to their seat-miles on the entered route. The second is the efficient-markets link. Under (E1) to (E5) the abnormal change equals the change in expected discounted profits caused by the news. The third is theoretical. By Proposition 9.19, a loss of expected profits from entry implies pre-entry rents or sunk costs, which contestability excludes. Each richer specification in Table 9.12 rules out an alternative reading of the first link. Slot rents at nearby airports, general industry effects and connecting markets cannot account for the incumbency loss.

Advantages over pricing regressions. The event study needs no model of the network, and no controls for each route's demand and cost. The variation comes from the timing of announcements and from incumbents' exposure, which People Express's strategy determined. The method also measures the level of rents in dollars, as a lower bound, where a pricing regression delivers a correlation between fares and structure.

Limitations. The design has several limitations, some noted by the authors and some raised by the logic of the method.

- The sample is small. There are 24 events on 17 dates, and 22 involve Newark. The general effects use 19 parameters, and the non-New York effects rest on two events.

- Dating and anticipation bias the estimates toward zero. People Express's expansion was public and ongoing, so markets probably expected some entry. Later work on Southwest finds that incumbents cut fares once entry becomes likely, before the entrant starts flying (Goolsbee and Syverson, 2008). News about entry can therefore arrive well before any announcement.
- The general effects remain unexplained. Information about People Express's future scale, competitive spillovers and aircraft values cannot be separated. If informational effects are correlated with incumbency, part of the *SM* effect could be informational. The separate New York effects address this only partly.
- Entry into a carrier's markets might signal that People Express intended to "go after" that carrier. This informational effect would also load on incumbency. The authors see no way to control for it without strong assumptions about its form, and they find little evidence of such a pattern (n. 25).
- Seat-miles measure capacity. They do not count passengers. Connecting traffic is not controlled for, and the loss per seat is assumed common across routes up to the robustness checks of footnote 32.
- The bound $L \leq V^0 + K$ cannot separate pre-entry profits from sunk costs. The value change also embeds the expected post-entry game, including the incumbents' own aggressive responses.
- External validity is limited. People Express was a special entrant, with a new low-frill product and low labor costs, in a transitional period after deregulation.
- The price and capacity evidence uses 7 and 8 markets, with no formal control for changes in demand. Only one year precedes the entry of both cohorts. The design therefore cannot separate differential trends from effects that change after entry, and offsetting departures pass its one testable restriction. If incumbents moved aircraft from control markets into entered markets, the control group is affected by entry and the quantity contrasts are overstated.

Contribution. Whinston and Collins (1992) gave a market-based test of contestability that does not depend on controls for route demand and cost. Their incumbency loss confirms the conclusion of the pricing studies that local structure matters, and it adds a dollar measure of rents. They gave market-based evidence that airports serving the same city are differentiated, and they documented large industry-wide effects of entry announcements. Their price and capacity evidence showed incumbents responding to a low-fare entrant with deep price cuts and more capacity. The abnormal-dollar formulation, with exposure measures that vary across firms, carries over to event studies of mergers (Chapter 11). Section 9.8 compares what this design identifies with the pricing regressions of Section 9.5 and the structural model of Section 9.7.

9.7 Hubs, costs, and markups: Berry, Carnall and Spiller (2006)

Berry et al. (2006) bring the question of Section 9.5 into the framework of Section 9.4. On ticket data of the same kind, they estimate a differentiated-products demand system with two consumer types, a network model of marginal cost and a static Nash pricing equilibrium. The model separates the two channels through which a hub can change the hub carrier's fares:

Table 9.15: Identification and counterfactual map of Whinston and Collins (1992)

Observed data	Daily stock returns of 19 incumbent carriers, People Express and the market around 24 entry announcements in 1984 and 1985. Airline schedules for seat-miles, and DOT coach prices and tickets for the first quarters of 1984 to 1986.
Latent objects	Incumbents' pre-entry route profits V^0, route-specific sunk costs K, normal returns, and investors' expectations.
Estimated parameters	Carrier intercepts and market betas, the dollar change per annualized seat-mile on the entered pair (λ_{SM}) and at other airports (λ_{OSM}), firm fixed effects, and entry effects on prices, tickets and seats.
Identifying variation	The timing of the announcements and differences in carriers' exposure to the entered routes, estimated jointly by seemingly unrelated regressions. For prices, the 1984 and 1985 entry cohorts serve as each other's controls.
Maintained assumptions	Efficient markets, correct dating, unanticipated events and no confounding news, (E1) to (E5). Losses proportional to seat-miles, and year effects common to both cohorts.
Counterfactual and what it holds fixed	The value change compares expected profits with and without the entry news, holding other information fixed. By Proposition 9.19 it bounds pre-entry profits plus sunk costs.
Conclusion	Incumbents lose \$3.7 to \$6.5 million per incumbent and event, and their fares fall about 35 percent relative to markets not yet entered. Routes are not contestable. The inference rests on efficient markets and unanticipated announcements.
One limitation	There are 24 events, 22 of them at Newark, and anticipation biases the measured losses toward zero.
Source and our additions	Tables 1 to 4 are the paper's. Propositions 9.19 and 9.47 and the remarks after them formalize the paper's logic in this book.
Tools in the appendices	Sections A.12 and A.13.

higher markups and lower costs. This section follows their analysis from the question to the conclusions, and Table 9.24 at its end maps the study. As throughout the chapter, page, table, figure and footnote numbers refer to the 1996 working paper (Berry et al., 1996).

9.7.1 The question

Section 9.2.2 described the two views of hubs that coexisted by the mid-1980s. Critics held that hubs raise entry barriers and fares for passengers who start their trips at a hub. Carriers and some economists held that hubs reduce costs. The two effects are not mutually exclusive (Berry, 1990). A hub can raise the markup over marginal cost for some travelers and lower marginal cost at the same time. On the demand side, Berry, Carnall and Spiller think of a hub as shifting out the demand for the hubbing carrier's flights out of its hub city. Those flights may appeal especially to price-inelastic consumers, so the shift can also make demand less elastic (p. 1). On the cost side, densely traveled spokes may have lower marginal costs. Economies of spoke density then create economies of scope across itineraries that share a spoke (p. 2).

A fare regression cannot separate the two effects. Write the fare of product j as $p_j = mc_j + m_j$, with m_j the markup. If hub presence raises m_j and lowers mc_j, the change in the fare is

$$\Delta p_j = \Delta m_j + \Delta mc_j, \qquad \Delta m_j > 0, \quad \Delta mc_j < 0.$$

A regression of fares on hub presence estimates the sum. Without a model of markups or of costs it cannot recover the two terms. As the authors note, Borenstein (1989) has no model of costs or demand. In their words, he "attempts to control for market-level unobservables by, for example, introducing city-pair level fixed effects" (p. 5). His relative-price equation (9.32) has the same effect, since it differences out everything common to the carriers on an airport-pair route. Brueckner and Spiller (1994) take the opposite route. They estimate density economies from itineraries that pass through hubs without originating there, to avoid hub markups (p. 4). That choice discards the markets where hub effects should be largest. In the authors' words, reduced form regressions "do not allow us to make statements about how prices relate to costs, or what are the determinants of markups over cost" (p. 6).

The strategy of the paper is to treat hub presence as one characteristic in a differentiated-products model of demand. Combined with a cost model and an equilibrium assumption, the demand model yields a markup for every product. Marginal cost is then "observed" as price minus the model's markup (p. 5), and its relation to spoke density reveals economies of density. The model is the finite-mixture nested logit of Section 9.4.3 with $R = 2$ types, combined with the network costs of Section 9.4.4. The authors summarize their findings in five claims (abstract and pp. 2–3), which we examine against their tables below.

(i) Travelers come in two distinct types. One has the attributes of a tourist: high price sensitivity and low willingness to pay for frequent-flyer features, frequency and nonstop service. The other has those of a business traveler.

(ii) Hubs give the hub carrier two advantages: lower costs and higher markups on hub-originating passengers.

(iii) The hub carrier's ability to raise prices is focused on business travelers. They shift toward the hub carrier even though they pay a premium of about 20% over non-hub carriers.

(iv) The hub carrier does not provide a "monopoly umbrella" to its rivals. Non-hub carriers lose business travelers and market share at the same time, which the authors call a "competitive scissor."

(v) There are economies of density on longer routes and none on routes shorter than about 500 miles, which the authors call the "Southwest effect."

9.7.2 Data

The data come from the DOT ticket sample (DB1A) and the Service Segment Databank (DB27R) described in Section 9.2.3, for the fourth quarter of 1985 (p. 19). The quarter follows Brueckner et al. (1992) and Brueckner and Spiller (1994). Those studies used only four-segment round trips that did not originate at hub cities, to avoid demand-side hub effects. Berry, Carnall and Spiller model hub markups explicitly, so they keep hub origins and itineraries with any number of segments up to two per direction. The ticket conventions are those of Section 9.2.3: round trips only, without itineraries chosen by a single sampled passenger and without extreme fares. Southwest is absent, because it reported all its sales as one-way tickets and so did not fit the product definition (p. 14, n. 11). The quarter precedes the merger wave of 1986–1987 and Borenstein's sample from 1987.

The unit of observation is a *product* j, a unique combination of carrier, itinerary and fare in a directional city-pair market t (Section 9.2.3). The sample has 122,871 products in 14,122 markets. The products use 4,963 distinct carrier legs, flown by 32 carriers out of 262 origins, and represent 1,107,894 sampled passengers (p. 19). About 30% of the markets have a single product and another 30% have no more than five. About 1% have more than one hundred products, with a maximum of 874 in the New York to Miami market. The quantity q_{jt} is the number of sampled passengers (NPASS) and the price p_{jt} is the round-trip fare (FARE). Market size is built from $MPOP_t$, the geometric mean of the two endpoint populations, $\sqrt{\text{origin population} \times \text{destination population}}$ (Appendix). A *leg* ℓ is a nonstop segment flown by one carrier. Its density Q_ℓ comes from DB27R and adds the two directions, because the trips are round trips (Appendix, n. 4).

A structural model has more than one dependent variable. Each product contributes two endogenous outcomes, its market share and its fare, and leg densities are endogenous as well. The inversion of demand turns the share into the demand error ξ_{jt}. The pricing condition turns the fare into the cost error ω_{jt}. The regressors are the product and market characteristics in Table 9.16 and the leg cost terms. The instruments are discussed in Section 9.7.5.

Table 9.17 reproduces the descriptive statistics. The mean round-trip fare is \$276 with a standard deviation of \$149. The number of sampled passengers per product has mean 9.0, standard deviation 31.3 and maximum 2,798, so most products are bought by very few sampled passengers. This fact matters for the sampling error discussed in Section 9.7.5. Slightly fewer than half of the products (46.6%) have a single segment. HUBSIZE is zero for most products, with mean 0.017 and standard deviation 0.045. Second-leg distances and densities are set to zero for one-segment products (p. 21), which explains their low means. In the appendix statistics the means of DIRECT and NSEGS are 0.4666602 and 1.5333398, which sum to exactly two, and their standard deviations are identical. In this sample DIRECT therefore equals $2 - NSEGS$, so "direct" means a single segment.

The raw correlations among the endogenous variables point the wrong way for a naive test of density economies (Table 2). Price is positively correlated with the densities of the first and second outbound legs (0.084 and 0.122). Price and the number of passengers are negatively correlated (−0.063). The number of passengers is correlated with the first-leg density at 0.068 and with the second-leg density at −0.120, and the two densities are correlated at 0.164. The authors read the positive price-density correlations as evidence that one must control for markups and distance before economies of density can appear (p. 21). One reason is that dense

Table 9.16: Variables in the model of Berry, Carnall and Spiller

Variable	Definition (units)	Role
Demand side (product j of carrier f in market t)		
FARE	Round-trip fare ($100)	Type-specific (α_r)
DIRECT	1 if the itinerary has one segment, 0 if it has two	Type-specific
HUBSIZE	If the origin is a hub of carrier f: the sum of the population potentials of all city pairs that f connects through that hub. Zero otherwise	Type-specific
TEMPDIFF	Difference between the mean January temperatures of origin and destination (10°F)	Type-specific, market level
TRIPS-D	Minimum over the itinerary's legs of f's departures on the leg (1,000 per quarter)	Type-specific
CONSTANT	1	Common
CONGEST-D	Number of endpoints (0, 1 or 2) that are slot controlled	Common, market level
MDIST, MDIST^2	Great-circle distance between the endpoints (1,000 miles), and its square	Common, market level
Cost side (summed over the legs $\ell \in \mathcal{L}(j)$ of the itinerary)		
NSEGS	Number of legs (1 or 2)	Leg constant
CONGEST-S	Takeoffs and landings at the four slot-controlled airports (0 to 4)	Leg cost shifter
CONGEST-C	Takeoffs and landings at the 24 airports under FAA flow control (0 to 4)	Leg cost shifter
DIST, DENS	Leg distance d_ℓ (1,000 miles) and leg density Q_ℓ (100,000 passengers per quarter, both directions), with powers and interactions	Cubic polynomial
TRIPS-C	Leg departures F_ℓ (1,000 per quarter)	Column IV only

Notes: The population potential of a city pair is the geometric mean of the two populations. The slot-controlled airports are Chicago O'Hare, New York Kennedy and La Guardia, and Washington National (p. 20, n. 13). The flow-control list includes Orange County and Long Beach (p. 21, n. 14). The text calls the slot-control count CONGEST-C and the flow-control count DOT-CONGEST, while Tables 3 and 5 label the cost-side congestion variables CONGEST-S and CONGEST-C. We match the labels by their sample means in Table 3 (0.315 and 1.766), which equal the appendix means of the slot-control count (0.3149) and of the flow-control count (1.7656). Source: Berry et al. (1996), pp. 20–21 and Appendix.

Table 9.17: Descriptive statistics, 122,871 origin-destination-fare-carrier products

Variable	Mean	Std. dev.	Min	Max
FARE ($100)	2.764	1.488	0.110	18.33
NPASS (passengers)	9.017	31.299	1.000	2798.0
DIRECT (fraction)	0.466	0.498	0.000	1.000
HUBSIZE	0.017	0.045	0.000	0.210
TEMPDIFF (10°F)	0.286	2.077	−6.520	6.520
TRIPS-D (minimum, 1,000 per quarter)	0.293	0.179	0.001	1.595
CONGEST-D (number of airports)	0.202	0.413	0.000	2.000
MDIST (1,000 miles)	1.009	0.608	0.030	2.776
DIST, first outbound leg (1,000 miles)	0.710	0.503	0.021	2.704
DIST, second outbound leg (1,000 miles)	0.351	0.479	0.000	2.611
DENS, first outbound leg (100,000 per quarter)	0.593	0.475	0.00003	4.553
DENS, second outbound leg (100,000 per quarter)	0.361	0.493	0.000	4.553
TRIPS-C, first leg (1,000 departures per quarter)	0.349	0.214	0.001	1.595
TRIPS-C, second leg (1,000 departures per quarter)	0.212	0.249	0.000	1.594

Notes: Statistics across products. Second-leg values are zero for one-segment products. Source: Berry et al. (1996), Table 1.

legs connect large cities and hubs, where demand and markups may be high. In a subsample of small four-segment markets, the sampling frame of Brueckner and Spiller, the raw correlation between price and density is negative (p. 21, n. 15).

9.7.3 Demand

Market size. The model needs an outside good, and hence a number of potential trips in each market. Berry, Carnall and Spiller assume that this number is proportional to the geometric mean of the endpoint populations, $M_t = \kappa\, MPOP_t$, with κ a parameter to be estimated (p. 9). Each potential trip is treated as a separate consumer, with no correlation of tastes across trips by the same person. The observed shares are therefore functions of κ:

$$s_{jt}^{obs}(\kappa) = \frac{q_{jt}}{\kappa\, MPOP_t}, \qquad s_{0t}^{obs}(\kappa) = 1 - \sum_{j \in \mathcal{J}_t} s_{jt}^{obs}(\kappa). \tag{9.51}$$

Because q_{jt} counts passengers in a 10% sample, κ also absorbs the sampling rate.

Unobserved product characteristics. The term ξ_{jt} captures ticket restrictions, such as advance-purchase and Saturday-stay requirements, together with unmeasured quality such as food and service (p. 9). Firms and consumers observe it. Tickets with different restrictions have systematically different prices, so ξ_{jt} is correlated with price by construction and price is endogenous. The authors assume instead that ξ_{jt} is mean independent of the other observed characteristics, such as distance and DIRECT. They defend this assumption with an extreme case. Suppose every carrier offers the same menu of restrictions on every itinerary, for example an unrestricted fare, an advance-purchase fare with a Saturday stay, and an advance-purchase fare without one. Then the restrictiveness of a ticket is unrelated to x_{jt}. The authors concede that "it is not hard to think of stories which would violate" the assumption (p. 9). A hub carrier that sells relatively more unrestricted fares out of its hub would be one such story, since ξ_{jt} would then rise with HUBSIZE.

Utility. A potential traveler i in market t is of type $r \in \{1, 2\}$, with $\mathbb{P}(r = 1) = \psi$ and $\mathbb{P}(r = 2) = 1 - \psi$. In the notation of Assumption 9.33, a type-r traveler has utility

$$u_{ijt} = \delta_{jt}^{r} + \zeta_{igt} + (1 - \sigma)\epsilon_{ijt} \quad (j \in \mathcal{J}_t), \qquad u_{i0t} = \epsilon_{i0t}, \tag{9.52}$$

with type-specific mean utility

$$\begin{aligned} \delta_{jt}^{r} = {} & \beta_0 + \beta^{M} MDIST_t + \beta^{MM} MDIST_t^2 + \beta^{C} CONGEST\text{-}D_t \\ & + \beta_r^{D} DIRECT_j + \beta_r^{h} HUBSIZE_{jt} + \beta_r^{T} TEMPDIFF_t + \beta_r^{F} TRIPS\text{-}D_j - \alpha_r p_{jt} + \xi_{jt}. \end{aligned} \tag{9.53}$$

All inside goods form one nest and the outside good forms the other. Berry, Carnall and Spiller write the idiosyncratic term as $\nu_i(\lambda) + \lambda\epsilon_{ij}$ (p. 11). In our notation $\lambda = 1 - \sigma$, their $\nu_i(\lambda)$ is ζ_{igt}, their type-1 probability γ is ψ, and their market-size factor μ is κ. As $\sigma \to 0$ the choices within a market become uncorrelated and the model reduces to a mixture of two logits. As $\sigma \to 1$ the correlation of choices within the market goes to one (p. 12).

Shares. Specializing (9.19) to two types, the shares of a type-1 traveler are (p. 12)

$$s_{j|g,t}^{1} = \frac{e^{\frac{\delta_{jt}^{1}}{1-\sigma}}}{D_{1t}}, \qquad D_{1t} = \sum_{k \in \mathcal{J}_t} e^{\frac{\delta_{kt}^{1}}{1-\sigma}}, \qquad \bar{s}_{1t} = \frac{D_{1t}^{1-\sigma}}{1 + D_{1t}^{1-\sigma}}, \qquad s_{jt}^{1} = s_{j|g,t}^{1}\, \bar{s}_{1t}, \tag{9.54}$$

and the type-2 shares have the same form with δ_{jt}^2. The predicted share of product j is the type-weighted average

$$s_{jt} = \psi\, s_{jt}^1(p_t, x_t, \xi_t) + (1-\psi)\, s_{jt}^2(p_t, x_t, \xi_t). \tag{9.55}$$

Why two types. Section 9.4.3 gave the reasons why business travelers are less sensitive to price than leisure travelers and why tastes are correlated across characteristics (p. 10, n. 9). A two-point distribution is the simplest bimodal distribution with correlated tastes (p. 10). The fat upper tail of fares per mile discussed in Section 9.2.3 supports it. A mixture of two normal distributions fits that distribution far better than a single normal. The authors compare the two components of that mixture with the estimated model (p. 11, n. 10). The components are $N(0.2375, 0.0781)$ and $N(0.5946, 0.2752)$, so the second is also far more dispersed. The model's mean fare per mile for type 1, 0.237, equals the mean of the first component (0.2375). For type 2 the model gives 0.414, against 0.589 from the mixture.[14] Type 1 accounts for 73% of tickets in the model, against a weight of 0.598 in the mixture. Five coefficients vary by type: those on FARE, DIRECT, HUBSIZE, TEMPDIFF and TRIPS-D. By Remark 9.34, two types need 11 parameters for these five coefficients, against 10 for independent normal random coefficients, and they deliver closed-form shares. The authors mention extensions they do not pursue (p. 11). Tastes could be drawn from two normal distributions instead of two points, there could be more than two types, and nests could group airports within a city or carriers within a market.

The role of each characteristic. The constant, MDIST, MDIST^2, CONGEST-D and TEMPDIFF are the same for every product in a market. They shift the demand for air travel relative to the outside good (p. 20). They also cancel from each type's within-nest shares $s_{j|g,t}^r$ in (9.54). At given prices they therefore leave the choice among flights of a traveler of either type unchanged. The paper concludes that TEMPDIFF "has no power to explain the choice between products" (p. 20). This holds within a type. Aggregate shares can still move, because these variables change the mix of types among the travelers who fly. By (9.55), the share of product j among the inside goods is

$$\frac{s_{jt}}{\sum_{k\in\mathcal{J}_t} s_{kt}} = \sum_{r=1}^{2} w_{rt}\, s_{j|g,t}^r, \qquad w_{1t} = \frac{\psi\, \bar{s}_{1t}}{\psi\, \bar{s}_{1t} + (1-\psi)\, \bar{s}_{2t}}, \qquad w_{2t} = 1 - w_{1t},$$

where w_{rt} is the share of type r among the travelers who fly. A change in a market-level variable leaves each $s_{j|g,t}^r$ fixed and moves the weights. If it raises every type-r mean utility by c_r, then $\frac{\partial \ln \bar{s}_{rt}}{\partial c_r} = 1 - \bar{s}_{rt}$. The weights therefore change when the coefficient differs across types, as for TEMPDIFF. They also change under a common coefficient whenever the two types' inside shares differ. The aggregate choice among flights then shifts toward the flights that the type gaining weight prefers. DIRECT, HUBSIZE and TRIPS-D vary across carriers and itineraries within a market, so they also govern substitution among flights within each type. HUBSIZE weights each city pair the carrier connects through its hub by the pair's population potential. The authors prefer it to a hub dummy or to the number of points served, neither of which accounts for the relative importance of the city pairs (p. 20). TEMPDIFF measures appeal to tourists. Because its coefficient varies by type, it shifts the type mix and can help separate the types (p. 20).

[14] The fitted formula in footnote 10 gives the second component a mean of 0.5946, while the comparison in the same footnote quotes 0.589. Likewise, the weight on the first component is 0.5987 in the formula and 0.598 in the comparison. We report all four numbers as printed.

The model lets hub presence affect markups through the composition of buyers. By (9.21), product j's buyers are of type 2 with probability $\mathbb{P}(2 \mid j) = \frac{(1-\psi)s_{jt}^2}{s_{jt}}$. By Proposition 9.35 and Remark 9.36, a single-product markup is close to $\frac{1-\sigma}{\bar{\alpha}_j}$ when within-nest shares are small, where $\bar{\alpha}_j = \mathbb{P}(1 \mid j)\alpha_1 + \mathbb{P}(2 \mid j)\alpha_2$. If $\beta_2^h > \beta_1^h$ and $\alpha_2 < \alpha_1$, a larger HUBSIZE tilts the buyers of the hub carrier's products toward type 2, lowers $\bar{\alpha}_j$ and raises the markup. Because $\mathbb{P}(2 \mid j)$ is a logistic function of $\ln s_{jt}^2 - \ln s_{jt}^1$, its shift is proportional to $\mathbb{P}(2 \mid j)\big(1 - \mathbb{P}(2 \mid j)\big)$ and is largest near an even mix. The markup $\frac{1-\sigma}{\bar{\alpha}_j}$ is convex in $\mathbb{P}(2 \mid j)$, however. With the column III price coefficients, the markup response is largest for products whose buyers are already about 90% type 2.

9.7.4 Costs and pricing

Leg costs and product marginal cost. The cost side follows Brueckner and Spiller (1994), as in Section 9.4.4. Leg ℓ of carrier f has total cost $C_\ell(Q_\ell, w_\ell)$ and marginal cost $c_\ell(Q_\ell, w_\ell)$, where w_ℓ includes the leg's distance and the characteristics of its endpoint airports (p. 13). The carrier's cost is (9.26), and the marginal cost of product j is (9.25), the sum of its legs' marginal costs plus a product-specific term ω_{jt}. The authors give the product-specific cost the form $\omega_{jt} q_{jt}$ only so that marginal cost has an additive error (p. 13). Fixed costs may also fall with hubbing, but the model uses only marginal costs and cannot capture that effect.

Prior beliefs about distance, density and frequency. The authors expect a complicated relation among distance, density and flight frequency (pp. 13–14). On short routes air travel competes with cars and, in a few places, trains. Carriers may then spend density savings on more frequent flights, which let travelers choose departure times precisely. The East and West Coast shuttles and Southwest are examples. On short routes large aircraft may also not pay, because takeoffs and landings are a large share of cost. That cost does not vary with distance and is not offset by savings in the air. The data have no model of frequency but do report quarterly trips on each leg. Frequency enters some specifications as an exogenous cost shifter. These considerations call for a flexible functional form.

The leg marginal cost function. Segment marginal cost is a cubic polynomial in leg distance d_ℓ (1,000 miles) and leg density Q_ℓ (100,000 passengers per quarter), with congestion shifters. Write χ_{mn} for the coefficient on $d_\ell^m Q_\ell^n$, and n_ℓ^S and n_ℓ^C for the leg's takeoffs and landings at slot-controlled and at flow-control airports. In columns I to III of Table 5, leg marginal cost in \$100 is

$$\begin{aligned} c_\ell = {} & \chi_{00} + \chi_{10} d_\ell + \chi_{20} d_\ell^2 + \chi_{30} d_\ell^3 + \chi_{01} Q_\ell + \chi_{02} Q_\ell^2 + \chi_{03} Q_\ell^3 \\ & + \chi_{11} d_\ell Q_\ell + \chi_{21} d_\ell^2 Q_\ell + \chi_{12} d_\ell Q_\ell^2 + \chi_S n_\ell^S + \chi_C n_\ell^C . \end{aligned} \tag{9.56}$$

Column IV adds nine terms in leg departures F_ℓ (1,000 per quarter):

$$\sum_{k=1}^{9} \chi_k^F \, h_k(F_\ell, d_\ell, Q_\ell), \qquad (h_1, \ldots, h_9) = (F,\ F^2,\ F^3,\ Fd,\ Fd^2,\ F^2 d,\ FQ,\ F^2 Q,\ FQ^2), \tag{9.57}$$

with the leg subscripts dropped inside the list. Summing (9.56) over the legs of product j,

$$mc_{jt} = \chi_{00}\, NSEGS_j + \chi_{10} \sum_{\ell \in \mathcal{L}(j)} d_\ell + \cdots + \chi_{12} \sum_{\ell \in \mathcal{L}(j)} d_\ell Q_\ell^2 + \chi_S\, CONGEST\text{-}S_j + \chi_C\, CONGEST\text{-}C_j + \omega_{jt}. \tag{9.58}$$

The leg constant summed over legs becomes the coefficient on the number of segments. The mean of ω_{jt}, written $\bar{\omega}$, enters as a separate constant in product marginal cost (p. 21). Table 5 does not report it. Because NSEGS takes the values 1 and 2, $\bar{\omega}$ and χ_{00} are separately identified.

Economies of density on leg ℓ mean that the leg's marginal cost falls as its density rises. From (9.56),

$$\frac{\partial c_\ell}{\partial Q_\ell} = \chi_{01} + 2\chi_{02}Q_\ell + 3\chi_{03}Q_\ell^2 + \chi_{11}d_\ell + \chi_{21}d_\ell^2 + 2\chi_{12}d_\ell Q_\ell, \tag{9.59}$$

and the leg has economies of density at (d_ℓ, Q_ℓ) when this derivative is negative. In Example 9.41 the leg cost aQ^γ has economies of density everywhere when $\gamma < 1$. The polynomial lets the sign vary with distance and density.

What the cost model leaves out. Prices, shares and densities are endogenous. Flight frequency is treated as exogenous. The data aggregate traffic to the carrier, route and fare over a quarter, so they cannot show which flights are full or how uncertainty about demand resolves before departure. The model therefore has no capacity constraints and no demand uncertainty. The authors warn that "some of what we label as a markup in fact represents a shadow price of capacity" (p. 14). Marginal cost may also vary with factors such as time-of-day capacity, which the data do not record (p. 5).

Pricing. Following Berry (1990), prices form a static Nash equilibrium in which each carrier sets the prices of all its products in all markets (pp. 6 and 14). The authors recognize that this is a simplification. Yield management allocates seats across fare classes dynamically, and tacit collusion would add another layer, but both are left for future work (p. 15). In the notation of Section 9.4.4, carrier f's profit is (p. 15)

$$\pi_f = \sum_t \sum_{j \in \mathcal{J}_f(t)} p_{jt}\, q_{jt}(p) - \sum_{\ell \in \mathcal{L}_f} C_\ell(Q_\ell, w_\ell) - \sum_t \sum_{j \in \mathcal{J}_f(t)} \omega_{jt}\, q_{jt}(p) - FC_f. \tag{9.60}$$

Differentiating with respect to p_{jt} and exchanging the sums over legs and products, as in the derivation of (9.27), gives

$$q_{jt} + \sum_{k \in \mathcal{J}_f(t)} \frac{\partial q_{kt}}{\partial p_{jt}} \Big[p_{kt} - \omega_{kt} - \sum_{\ell \in \mathcal{L}(k)} c_\ell(Q_\ell, w_\ell) \Big] = q_{jt} + \sum_{k \in \mathcal{J}_f(t)} \frac{\partial q_{kt}}{\partial p_{jt}} (p_{kt} - mc_{kt}) = 0. \tag{9.61}$$

Dividing by $M_t = \kappa\, MPOP_t$ turns quantities into shares. Stacking the conditions of market t gives (9.23):

$$p_t - mc_t = -\left[(\Omega_t \odot \Delta_t)^\top \right]^{-1} s_t, \qquad \Delta_t = -\psi\, \alpha_1 \frac{\partial s_t^1}{\partial \delta_t^1} - (1-\psi)\, \alpha_2 \frac{\partial s_t^2}{\partial \delta_t^2}, \tag{9.62}$$

where the (j,k) element of $\frac{\partial s_t^r}{\partial \delta_t^r}$ is given by (9.20).[15] Here Δ_t has (j,k) element $\frac{\partial s_{jt}}{\partial p_{kt}}$, as in Chapter 4.

Three features of (9.62) drive the empirical work. First, the markup depends only on the demand parameters and on prices and shares (p. 16). It involves no cost parameter. Second,

[15] The paper writes $p = \Delta^{-1}s + mc$ with Δ the matrix of derivatives $\frac{\partial s_k}{\partial p_j}$ for products of the same firm (p. 15). That equation holds when Δ contains the negatives of these derivatives. The paper's second expression, $\Delta = \gamma\alpha_1\Delta_1 + (1-\gamma)\alpha_2\Delta_2$ with Δ_r the derivatives with respect to mean utility (p. 16), has the right sign. It equals $-(\Omega_t \odot \Delta_t)^\top$ in our notation. See the footnote to (9.23).

markups are not profits. Airlines may be unprofitable even with large markups, because fixed costs may be large and marginal cost may fall over a wide range of output (p. 16, Remark 9.42). Third, the network enters the pricing condition only through the level of each mc_{kt}, evaluated at equilibrium densities.

9.7.5 Estimation and identification

The estimator. The parameters split into demand and cost parameters:

$$\theta_d = (\sigma, \kappa, \psi, \alpha_1, \alpha_2, \beta_1, \beta_2), \qquad \theta_c = (\bar{\omega}, \chi), \qquad \theta = (\theta_d, \theta_c).$$

Here β_r collects type r's taste coefficients, including the common ones. The estimator follows Berry (1994) and Berry et al. (1995) (pp. 16–17). For a trial value of θ it computes the two structural errors in five steps.

1. Compute observed shares $s_t^{obs}(\kappa)$ from (9.51).
2. Solve $s_t(\xi_t; \theta_d) = s_t^{obs}(\kappa)$ for $\xi_t(\theta_d)$ in each market, with the contraction (9.22). Berry (1994) guarantees a unique solution. The shares (9.54) and (9.55) are analytic, so no simulation is needed. With 122,871 products the authors call this "fortunate" (p. 17).
3. Evaluate Δ_t at $(p_t, \xi_t(\theta_d))$ and compute the markups $b_t(\theta_d) = -\left[(\Omega_t \odot \Delta_t)^\top\right]^{-1} s_t$ from (9.62).
4. Compute the cost error from (9.58), with the observed densities as data:

$$\tilde{\omega}_{jt}(\theta) = p_{jt} - b_{jt}(\theta_d) - \bar{\omega} - \sum_{\ell \in \mathcal{L}(j)} c_\ell(d_\ell, Q_\ell, n_\ell^S, n_\ell^C; \chi). \tag{9.63}$$

5. Form the moments below and evaluate the objective.

The identifying assumption is that both errors are mean independent of a vector of instruments z_{jt}:

$$\mathbb{E}\left[\xi_{jt}(\theta_{d0}) \,\middle|\, z_{jt}\right] = 0, \qquad \mathbb{E}\left[\tilde{\omega}_{jt}(\theta_0) \,\middle|\, z_{jt}\right] = 0. \tag{9.64}$$

With $N = 122{,}871$ products and instrument matrices Z_{jt}^d and Z_{jt}^c built from z_{jt}, the sample moments and the GMM estimator are

$$g_N(\theta) = \frac{1}{N} \sum_t \sum_{j \in \mathcal{J}_t} \begin{pmatrix} Z_{jt}^{d\top} \xi_{jt}(\theta_d) \\ Z_{jt}^{c\top} \tilde{\omega}_{jt}(\theta) \end{pmatrix}, \qquad \hat{\theta} = \arg\min_\theta \; g_N(\theta)^\top W g_N(\theta), \tag{9.65}$$

as in Chapter 8. Given θ_d, the cost error is linear in $(\bar{\omega}, \chi)$. These parameters can therefore be concentrated out by linear instrumental variables, like the linear parameters in Chapter 8. The paper does not say how the search was organized.

Instruments. Price, shares and densities are endogenous. All other product and market characteristics are treated as exogenous shifters of cost or demand, including the network structure of each carrier (pp. 17–18). The instruments for leg densities include population and network characteristics at the endpoint cities. The instruments for prices and markups add characteristics of the other products in the market (p. 18). The authors chose the instrument vector by experimenting with simple versions of the model on a 10% sample of the data and then held it fixed for the full estimation (p. 18). The full list is not reported.

Each group of instruments rests on an economic argument. A product's own characteristics shift its demand and, through the share, its markup. Rival products' characteristics shift the markup through the intensity of competition, as in Berry et al. (1995). Population and network characteristics at the endpoints shift a leg's density through traffic to and from other markets. Conditional on the included characteristics, they are excluded from the product's own demand and cost errors. That exclusion requires the network to be exogenous. If carriers built hubs where unobserved demand is high, network instruments would be correlated with ξ. The paper does not model entry or network choice and refers to Berry (1990) and Reiss and Spiller (1989) for that problem (p. 16, n. 12).

Standard errors. The errors are assumed independent across markets (p. 17). Within a market, demand and cost errors have a factor structure, with market-specific components that are correlated across the demand and cost equations. One parametrization consistent with this description is

$$\xi_{jt} = a_t + e_{jt}, \qquad \tilde{\omega}_{jt} = b_t + u_{jt}, \qquad \operatorname{Cov}(a_t, b_t) \neq 0, \tag{9.66}$$

with e_{jt} and u_{jt} idiosyncratic. The structure enters the variance of the moments, $V = \operatorname{Var}\left(\sum_{j \in \mathcal{J}_t} g_{jt}\right)$ summed over independent markets, where g_{jt} is the summand of (9.65). The asymptotic variance of $\hat{\theta}$ is then the usual sandwich $(G^\top W G)^{-1} G^\top W V W G (G^\top W G)^{-1}$, with G the derivative of the moments (Section A.5). Treating each market as a cluster would be the nonparametric alternative.

Sampling error in shares. The inversion assumes that the econometrician observes expected shares (Berry, 1994). In Berry et al. (1995) shares were fractions of roughly 100 million households, so sampling error was negligible. Here more than one million sampled passengers are spread over more than 120,000 products, so the average product has fewer than 10 sampled passengers (p. 17). A rough calculation shows the magnitude. If a product's sampled count $\hat{n}_j$ has mean n_j and approximately Poisson variation, the delta method gives $\operatorname{Var}(\ln \hat{n}_j) \approx \frac{1}{n_j}$. The standard deviation of the log share is then about 0.33 at $n_j = 9$ and 0.71 at $n_j = 2$. By the derivative in the proof of Lemma 9.37, $\frac{\partial \ln s_j}{\partial \xi_j}$ lies between $1 - \max_r \bar{s}_r$ and $\frac{1}{1-\sigma}$. It is close to one for the only product in a market, the case of about 30% of markets (p. 19). It is close to $\frac{1}{1-\sigma}$ when within-nest shares are small. An error in $\ln s_j^{obs}$ therefore moves ξ_j by between $1 - \sigma$ and about one times the error. To first order, random sampling noise has mean zero and is independent of the instruments. Three problems remain. Standard errors that ignore the noise are too small. Because the logarithm is concave, $\ln \hat{n}_j$ has a second-order bias of about $-\frac{1}{2n_j}$, which varies with expected sales and hence with the instruments. The authors also drop itineraries chosen by a single sampled passenger (p. 19). This screen applies to itineraries. It does not remove carrier-itinerary-fare products bought by one sampled passenger, and Table 1 reports a minimum NPASS of 1.000 and a mean of 9.017. Their log shares carry the largest sampling error, with a standard deviation near one by the Poisson approximation above. The itinerary screen still selects the sample on sales, and sales vary with the instruments. The authors leave the correction for future research (p. 17). Chapter 8 discusses the general problem.

Identification of the types. Some readers of early versions asked how market-level data can identify two unobserved types (p. 18). The authors give two arguments, and the structure of the model supplies more.

The first argument concerns the price coefficients. Example 9.38 works it out with numbers. In a model with one type and i.i.d. additive errors, two products with equal shares in one market must also have equal shares when a third, similar product is added. With two types

and flights that are close substitutes within each type ($\sigma > 0$), the cheap products compete for the same price-sensitive travelers. Adding a cheap product then lowers the share of the cheap incumbent more than that of the expensive one. The farther apart the two price coefficients, the stronger this effect. Fares and characteristics vary widely within and across markets (Table 1), so departures from the one-type model are easy to detect (p. 18). The same mechanism makes the markup response depend on how similar the entrant is. In a one-type model an entrant lowers markups only through the incumbent's own shares. Its effect then depends on its mean utility. It does not depend on how close its price is to the incumbent's. In Example 9.38, L's markup falls by 22% under two types and by 9% under one type.[16]

The second argument assigns the hub taste to the right type (pp. 18–19). HUBSIZE shifts the mean utility of all products of carrier f out of the origin. Summing the derivatives in (9.20) over $k \in \mathcal{J}_f(t)$, for $j \in \mathcal{J}_f(t)$,

$$\frac{\partial \ln s_{jt}}{\partial HUBSIZE_{ft}} = \sum_{r=1}^{2} \mathbb{P}(r \mid j)\, \beta_r^h \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} S^r_{f|g,t} - S^r_{ft} \right], \tag{9.67}$$

where $S^r_{f|g,t} = \sum_{k \in \mathcal{J}_f(t)} s^r_{k|g,t}$ and $S^r_{ft} = \sum_{k \in \mathcal{J}_f(t)} s^r_{kt}$ are carrier f's within-nest and total shares among type-r travelers. For a given type the bracket is the same for all of the carrier's products. Differences between the hub responses of a carrier's cheap and expensive products therefore come only through the buyer weights $\mathbb{P}(r \mid j)$. The price coefficients pin down these weights. If the price-sensitive type likes hubs more, the shares of cheap products respond more to hub size, and conversely. Comparing the relative shares of cheap and expensive products of the same carrier at hub and non-hub origins thus identifies β_1^h and β_2^h separately.

Three further sources of identification come from the structure. TEMPDIFF moves the inside share of each type at a rate that depends on β_r^T and so changes the type mix of a market's travelers. The demand coefficient on DIRECT and the cost coefficient on NSEGS are separately identified even though $DIRECT = 2 - NSEGS$. The first is pinned down by shares through ξ and the second by prices net of markups through ω. Finally, the market-size factor κ is identified mainly by functional form, through how inside shares vary across markets of different size. Its large standard errors in Table 5 reflect this.

9.7.6 Results

A descriptive price regression

Before estimating the model, Berry, Carnall and Spiller regress the fare on cost variables, and then on cost and demand variables, by ordinary least squares (Table 9.18). The distance coefficient is 1.004, about \$100 per 1,000 miles. Density has the expected sign but a small magnitude. An increase of 100,000 passengers per quarter in spoke density lowers the fare by about \$9 (p. 21). Adding demand variables makes the density coefficient slightly more negative, from −0.088 to −0.094.[17] The R^2 is 0.173 without and 0.177 with the demand variables, so observed costs and characteristics explain little of the variation in fares. The HUBSIZE coefficient is 2.097 (0.094), which the authors describe as consistent with the "Borenstein" effect

[16] The authors write that without random coefficients "markups and prices will not respond to the number of similar products in the market" (p. 18). In a one-type model markups do fall with entry, through the incumbent's shares. The size of the fall does not depend on the entrant's similarity.

[17] The text says instead that the magnitude of the density coefficient "decreases further" when demand variables are added (p. 22). We follow Table 3.

of hubs on markups (p. 22). By our arithmetic, a one standard deviation increase in HUBSIZE (0.045) raises the fare by $2.097 \times 0.045 = 0.094$, or \$9.[18]

The authors stress that these regressions are "for descriptive purposes only, as the estimated coefficients bear little necessary relationship to the parameters of the model" (p. 21). The reasons follow from Section 9.7.4. The fare equals marginal cost plus a markup that depends on demand. Density is endogenous. HUBSIZE can lower costs and raise markups at once. The OLS coefficient on HUBSIZE is the net of the two, exactly the sum $\Delta m_j + \Delta mc_j$ of Section 9.7.1.

Table 9.18: Ordinary least squares regressions of fare on cost and demand variables

	Cost only	Cost and demand	Mean
CONSTANT	1.704 (0.013)	1.545 (0.022)	1.000
NSEGS	−0.113 (0.013)	−0.011 (0.017)	1.533
CONGEST-S	0.084 (0.007)	0.082 (0.008)	0.315
CONGEST-C	0.012 (0.005)	0.012 (0.005)	1.766
DIST	1.004 (0.008)	1.004 (0.008)	1.062

TRIPS-D		0.019 (0.040)	0.294
R^2	0.173	0.177	

Notes: Dependent variable FARE in \$100. Standard errors in parentheses. Cost variables are sums over the legs of the itinerary. The number of observations is not printed in the table. The sample is the 122,871 products of Table 9.17. Source: Berry et al. (1996), Table 3.

Demand estimates

Table 9.19 reproduces the demand panel of Table 5 with the implied composition of travelers from Table 4. Column I has a single type. Column II lets only the price coefficient differ across types. Column III lets the coefficients on FARE, DIRECT, HUBSIZE, TEMPDIFF and TRIPS-D differ. Column IV keeps the demand specification of column III and adds leg departures to marginal cost. The coefficient reported for FARE multiplies minus the fare in \$100, so a positive value means that travelers dislike higher fares.

One type. In column I the nesting parameter is $\sigma = 0.395$ with a standard error of 0.020, so the pure logit ($\sigma = 0$) is rejected with a t statistic near 20 (p. 22). Choices among flights in a market are correlated relative to the outside good. The other coefficients have the expected signs. Travelers prefer direct flights, flights from uncongested airports and flights on the hubbing airline. The distance terms have an inverse U shape. As distance rises, air travel becomes more attractive relative to driving, but the total demand for travel may fall (p. 22). The inside utility

[18] The text also says that the coefficient on DIRECT is "fairly large, about \$75" (p. 22), but Table 3 has no DIRECT row. Since DIRECT equals 2 − *NSEGS* in this sample, a regression that included NSEGS, DIRECT and a constant would be perfectly collinear. We do not report the \$75 figure as an estimate.

Table 9.19: Demand estimates and implied composition of travelers

Notes: GMM estimates, standard errors in parentheses. FARE coefficients multiply minus the fare in $100. In column II the type-2 coefficients other than FARE equal the type-1 coefficients. The row $\sigma = 1 - \lambda$ converts the paper's nesting parameter to the book's convention and has the same standard error. Table 4 prints 0.616 for the type-1 HUBSIZE coefficient in column IV. The averages in the bottom panel weight products by predicted passengers of each type. Source: Berry et al. (1996), Table 5 (demand panel) and Table 4 (bottom panel).

peaks at $MDIST = \frac{\beta^M}{2|\beta^{MM}|}$, which is $\frac{0.528}{2\times0.126} = 2.10$ (2,095 miles) in column I and $\frac{0.772}{2\times0.206} = 1.87$ (1,874 miles) in column III.

Two price coefficients. In column II the type-1 price coefficient is $\frac{0.696}{0.068} = 10.2$ times the type-2 coefficient, which the authors describe as "nearly ten times" (p. 23). Price-sensitive travelers make up 92.4% of potential travelers but only 71% of passengers. They are much less likely to buy a ticket at all.

Five type-specific coefficients. In column III the type-2 share of potential travelers falls from almost 8% to 2.5% (p. 23). Type 2 is a small minority of the population but more than a quarter of passengers (26.8%). Relative to type 1, type 2 cares more about direct flights (1.014 against 0.414), about hub size at the origin (0.761 against 0.285) and about frequency (0.954 against 0.329). Its valuation of TEMPDIFF is a little lower (0.049 against 0.052) and less precisely estimated. The authors conclude that "the data and the model together can identify two types of consumers that can sensibly be labeled 'tourist' and 'business' " (p. 23). Two type-2 coefficients are imprecise. HUBSIZE 2 has a t statistic of $\frac{0.761}{0.423} = 1.8$ and TRIPS-D 2 one of $\frac{0.954}{0.395} = 2.4$.

The column IV puzzle and willingness to pay. In column IV the type-1 HUBSIZE coefficient (0.615) exceeds the type-2 coefficient (0.368). The authors call this the only puzzling result and resolve it with marginal willingness to pay (p. 23). Utility is linear in characteristics and price, so an indifference curve in the space of characteristic k and fare satisfies $\beta_r^k \, \mathrm{d}x^k - \alpha_r \, \mathrm{d}p = 0$. Its slope is the marginal willingness to pay of type r, in dollars when the fare is measured in \$100:

$$WTP_r^k = \left.\frac{\mathrm{d}p}{\mathrm{d}x^k}\right|_{u_r \text{ constant}} = \frac{\beta_r^k}{\alpha_r} \times \$100. \tag{9.68}$$

The nesting parameter scales both coefficients equally and does not enter. For HUBSIZE in column III,

$$WTP_1^h = \frac{0.285}{0.829} \times \$100 = \$34, \qquad WTP_2^h = \frac{0.761}{0.077} \times \$100 = \$988$$

per unit of HUBSIZE. In column IV the values are $\frac{0.615}{0.986} \times \$100 = \$62$ and $\frac{0.368}{0.111} \times \$100 = \$332$. Type 2's willingness to pay for hub size is higher in both columns, which removes the puzzle. HUBSIZE has no natural unit, so Table 9.20 also scales it by its standard deviation, 0.045. A one standard deviation increase in HUBSIZE is worth \$1.55 to a tourist and \$44.47 to a business traveler in column III.

The dollar values for type 2 are large because its price coefficient is small. A business traveler is almost indifferent to fares over the relevant range, so any characteristic it values has a large price equivalent. The ratio of two estimates is also imprecise when the denominator is small. The type-2 price coefficient in column III has a standard error of 0.017 on a value of 0.077. The ranking is the robust finding: type 2 values hub size, directness and frequency far more than type 1 in every specification.

Price sensitivity. The last row of Table 9.20 translates the price coefficients into semi-elasticities. From (9.20), a type-r traveler's demand for product j falls by $\alpha_r \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g}^r - s_j^r\right]$ log points per \$100, which is at most $\frac{\alpha_r}{1-\sigma}$. In column III a \$10 fare increase therefore lowers a tourist's demand for a product by at most 0.138 log points, about 13%. It lowers a business traveler's demand by at most 0.013 log points, about 1.3%. The elasticity of aggregate demand for a product is the buyer-weighted average of the type elasticities (Section 9.4.3).

Table 9.20: Marginal willingness to pay and price sensitivity implied by the demand estimates

	Column III		Column IV	
	Type 1	Type 2	Type 1	Type 2
DIRECT ($ for a one-segment itinerary)	50	1,317	30	789
HUBSIZE ($ per unit)	34	988	62	332
HUBSIZE ($ per standard deviation, 0.045)	1.55	44.47	2.81	14.92
TRIPS-D ($ per 1,000 departures per quarter)	40	1,239	39	444
TRIPS-D ($ per standard deviation, 0.179)	7.1	221.8	7.0	79.5
TEMPDIFF ($ per 10°F)	6.3	63.6	5.0	45.0
$\frac{\alpha_r}{1-\sigma}$ (fall in a product's share per $100, in logs)	1.384	0.129	1.598	0.180

Notes: Our computations from the Table 5 estimates. Willingness to pay is $\frac{\beta_r^k}{\alpha_r} \times \$100$, from (9.68). Standard deviations of HUBSIZE and TRIPS-D are from Table 1. The last row is the upper bound on the semi-elasticity of a type-r traveler's demand for a product, attained when the product's shares are small.

Who travels. Type 2 is 2.52% of potential travelers and 26.81% of passengers in column III. A type-2 potential traveler is therefore $\frac{26.81}{2.52} \times \frac{97.48}{73.19} = 14.2$ times as likely to fly as a type-1 potential traveler. The authors note that these proportions match a 1993 survey in which 8% of air travelers accounted for 44% of all trips (p. 24, n. 16). The mean fare paid by type 1 is $204, and type 2 pays almost $150 more ($351). Business travelers get something for the extra dollars. Across all products ξ has mean zero, but passengers favor high-quality tickets, so its mean across tickets sold is about 0.98. It is about 30% higher for type 2 and 12% lower for type 1 (p. 24). The Table 4 averages give $\frac{1.30}{0.98} = 1.33$ and $\frac{0.86}{0.98} = 0.88$. Business travelers buy tickets with fewer restrictions and higher unmeasured quality.

Stability across specifications. The type structure is stable. Across columns II to IV, type 2 is 2.5% to 7.7% of potential travelers and 27% to 40% of passengers. The ratio of price coefficients is 10.2, 10.8 and 8.9. The type-2 willingness to pay for hub size falls from $988 in column III to $332 in column IV, so its magnitude depends on the cost specification. Tables 6 and 7 use column III only, and the paper reports no standard errors for them.

Cost estimates

Table 9.21 reproduces the cost panel of Table 5. The polynomial makes individual coefficients hard to interpret (p. 23), so the authors summarize them through the derivative (9.59) below. Several patterns are still visible. In columns I to III congestion raises leg marginal cost. In column III each takeoff or landing at a slot-controlled airport adds $6.0 and each at a flow-control airport $7.1. In column IV the slot-control coefficient turns negative (−0.033). The negative NSEGS coefficient implies a negative intercept in leg marginal cost, which the authors read as a sign of problems with the specification near zero distance and density (p. 23). The linear distance term is positive. The linear density term is also positive, which by itself does not support economies of density. The interaction terms nevertheless imply economies of density over a wide range (p. 24). Adding trips in column IV changes the distance and density terms substantially. For example, the linear distance coefficient falls from 3.181 to 0.155, and the NSEGS coefficient becomes positive.

Table 9.21: Leg marginal cost estimates

Notes: GMM estimates, standard errors in parentheses. Leg marginal cost in $100, distance in 1,000 miles, density in 100,000 passengers per quarter, trips in 1,000 departures per quarter. The coefficient names refer to (9.56) and (9.57). The standard error of DIST^3 in column II is printed as 0.247. Source: Berry et al. (1996), Table 5 (cost panel).

Hubs, markups, and the sorting of travelers

Table 6 turns the column III estimates into a comparison of hub and non-hub carriers. Its construction uses the buyer composition (9.21). For each product the model predicts the number of passengers of each type, $\hat{n}_{jrt} = \hat{\kappa}\, MPOP_t\, \hat{\psi}_r\, \hat{s}^r_{jt}$, where $\hat{\psi}_1 = \hat{\psi}$ and $\hat{\psi}_2 = 1 - \hat{\psi}$. Because the model fits observed shares exactly, $\hat{n}_{jrt} = q_{jt}\mathbb{P}(r \mid j)$.

Markets are classified by the largest HUBSIZE among the carriers that serve them. HUBSIZE is zero for 93.5% of origin-carrier combinations. A *non-hub market* has HUBSIZE equal to zero for every carrier. A *small-hub market* has a largest HUBSIZE strictly between 0 and 0.01. A *large-hub market* has at least one carrier with HUBSIZE of 0.01 or more, about the largest third of hubs. Within hub markets, a *hub carrier* has positive HUBSIZE at the origin and the others are non-hub carriers. The 778 markets served only by hub carriers, with 5.2% of passengers, are excluded.

For market category m, carrier group h and type r, a characteristic x such as the fare or marginal cost is averaged in two steps. First, within each market t it is averaged over the group's products with weights equal to predicted type-r passengers. Second, the market averages are averaged across the markets in category m with weights equal to total passengers q_t:

$$\bar{x}_{t,h,r} = \frac{\sum_{j \in \mathcal{J}_t^h} \hat{n}_{jrt}\, x_{jt}}{\sum_{j \in \mathcal{J}_t^h} \hat{n}_{jrt}}, \qquad \bar{x}_{m,h,r} = \frac{\sum_{t \in m} q_t\, \bar{x}_{t,h,r}}{\sum_{t \in m} q_t}. \tag{9.69}$$

Averaging within markets first controls for differences across markets in distance, population and other market characteristics. Levels remain hard to compare across market categories, so the authors focus on hub and non-hub differences within a category (p. 25). In this subsection only, F and M denote the average fare and marginal cost. They do not denote the number of carriers or market size here. Subscripts H and N mark hub and non-hub carriers. The average markup is $\frac{F-M}{F}$, and the three hub premia are

$$\text{fare} = \frac{F_H - F_N}{F_N}, \qquad \text{marginal cost} = \frac{M_N - M_H}{M_N}, \qquad \text{markup} = \frac{(F_H - M_H) - (F_N - M_N)}{F_N - M_N}. \tag{9.70}$$

The marginal-cost premium is positive when the hub carrier's cost is lower.[19]

Table 9.22 reproduces Table 6 with markets and carriers in rows. Panel B adds our recomputation of the premia from the rounded averages. The printed premia use unrounded averages, so the two differ slightly.

Market composition. Non-hub markets are 82% of markets but carry only 31% of passengers (p. 25). The remaining passengers are split almost evenly between small-hub and large-hub markets. Non-hub markets have the highest share of tourists (75.8%) and large-hub markets the highest share of business travelers (29.6%).

Small hubs. In small-hub markets the two carrier groups look alike. Hub carriers carry 40.0% of type-1 and 39.3% of type-2 passengers, so non-hub carriers carry 60% of the market. The two groups have nearly identical passenger mixes (26.4% and 27.0% type 2). Type 1 pays \$206 on both. Type 2 pays 3.7% more on hub carriers, whose marginal cost for type 2 is 4.5% higher.[20] Non-hub carriers' products have 14% to 18% higher ξ and more trips (p. 26).

[19] The table notes print the markup premium without the inner brackets.

[20] The text says that hub carriers in small-hub markets have "4% lower marginal costs" for type-2 travelers (p. 26). Table 6 shows a marginal cost of \$111 for hub carriers against \$106 for non-hub carriers. Its marginal-cost premium of −4.5% means, by the table's definition, a higher cost for hub carriers. We follow the table.

Table 9.22: Fares, marginal costs and markups of hub and non-hub carriers (column III estimates)

Panel A. Averages by market type, customer type and carrier type

Type	Carrier	Pct of market	Pct of car. tot.	Pct of type	Fare ($)	MC ($)	Markup (%)	Fare per mile ($)	Avg ξ	Avg direct	Avg trips
Non-hub markets: 31% of passengers, 82% of markets, 800 miles											
1	Non-hub	75.8	100	100	224	93	58.6	0.387	0.601	0.522	336
2	Non-hub	24.2	100	100	296	111	62.4	0.488	1.005	0.542	340
Small-hub markets: 32% of passengers, 9% of markets, 954 miles, population 3.8 million											
1	Hub	73.2	73.6	40.0	206	96	53.4	0.301	0.650	0.792	399
1	Non-hub		73.0	60.0	206	95	53.8	0.302	0.771	0.778	404
2	Hub	26.8	26.4	39.3	306	111	63.7	0.398	0.942	0.809	410
2	Non-hub		27.0	60.7	295	106	63.9	0.398	1.074	0.819	430
Large-hub markets: 37% of passengers, 9% of markets, 842 miles, population 3.0 million											
1	Hub	70.4	67.0	62.3	215	91	57.8	0.336	0.875	0.922	469
1	Non-hub		76.8	37.7	205	109	46.7	0.313	0.566	0.622	362
2	Hub	29.6	33.0	72.9	319	98	69.2	0.474	1.321	0.927	484
2	Non-hub		23.2	27.1	268	133	50.4	0.403	0.836	0.665	371

Panel B. Hub premia (%), as printed and recomputed from the rounded averages of Panel A

		Printed			Recomputed		
Market	Type	Fare	MC	Markup	Fare	MC	Markup
Small hub	1	0.1	−1.1	−0.8	0.0	−1.1	−0.9
Small hub	2	3.7	−4.5	3.3	3.7	−4.7	3.2
Large hub	1	5.0	16.8	29.9	4.9	16.5	29.2
Large hub	2	19.0	26.1	63.4	19.0	26.3	63.7

Notes: Group headings give each market category's share of passengers and of markets, its average market distance and, for hub markets, its average population. "Pct of market" is the share of the type among the market category's passengers. "Pct of car. tot." is the share of the type among the carrier group's passengers. "Pct of type" is the share of the type's passengers who fly the carrier group. Averages are computed as in (9.69), markups as $\frac{F-M}{F}$ and premia as in (9.70). Average trips are departures per quarter. The 778 markets served only by hub carriers (5.2% of passengers) are excluded. In non-hub markets the paper prints 100 in the "Pct of car. tot." column for both types. By the definition above, the type shares among non-hub carriers there are 75.8% and 24.2%, as in the "Pct of market" column. The entries of 100 in the "Pct of type" column are correct, since every carrier in these markets is a non-hub carrier. Source: Berry et al. (1996), Table 6. Panel B recomputation: our computations.

Large hubs. In large-hub markets the hub premium appears. By our arithmetic on Table 6, hub carriers carry about 65% of all passengers: $0.704 \times 0.623 + 0.296 \times 0.729 = 0.654$. The product is exact if each "Pct of type" entry is an aggregate share of the category's type-r passengers. If the entries instead average market-level shares as in (9.69), the product omits cross-market covariances and is only an approximation. Hub carriers carry 72.9% of business travelers and 62.3% of tourists, so their passengers are 33.0% type 2 against 23.2% for non-hub carriers (p. 25). Business travelers pay \$319 on the hub carrier against \$268 on non-hub carriers, a premium of 19.0%. The hub carrier's marginal cost for these tickets is \$98 against \$133, an advantage of 26.1%. Its markup per ticket is therefore \$221 against \$135, which is 63.4% higher (63.7% from the rounded averages). Tourists pay 5.0% more on the hub carrier, which has a 16.8% cost advantage and a 29.9% higher markup. The business-ticket Lerner index is 69.2% for hub carriers and 50.4% for non-hub carriers.

The fare premium can be decomposed into a markup gain and a cost advantage, both measured relative to the non-hub fare. Subtracting and adding the two marginal costs,

$$\frac{F_H - F_N}{F_N} = \frac{(F_H - M_H) - (F_N - M_N)}{F_N} - \frac{M_N - M_H}{F_N}. \tag{9.71}$$

For business travelers in large hubs this gives

$$\frac{319 - 268}{268} = \frac{221 - 135}{268} - \frac{133 - 98}{268}, \qquad \text{that is,} \qquad 19.0\% = 32.1\% - 13.1\%.$$

The hub carrier's markup gain exceeds its fare premium, because lower cost finances part of the markup. The authors make the same point with different numbers, a 29% markup premium net of a 10% cost advantage.[21]

Hub carriers in large hubs also sell different products. Their products are more often direct (0.922 and 0.927 against 0.622 and 0.665), have more departures (469 and 484 against 362 and 371) and have higher ξ. Non-hub carriers' products have values of ξ about 35% smaller than those of hub carriers (p. 26). Part of the hub premium is therefore a payment for directness, frequency and unmeasured quality, which business travelers value most.

Figure 9.11 plots the premia.[22] The pattern supports claims (ii) and (iii). In small hubs the premia are close to zero for both types. In large hubs the hub carrier earns a substantial premium from business travelers and a small one from tourists, while enjoying lower marginal cost for both. Business travelers "are not just willing to pay the 20% premia that hub airlines charge," they also fly the hub carrier more often than its rivals (p. 26).

No umbrella: the competitive scissor. The hub carrier's high fares do not protect its rivals. Non-hub carriers in large-hub markets charge less than non-hub carriers in non-hub markets (\$205 against \$224 for tourists, \$268 against \$296 for business travelers). They also lose the business travelers, so their passenger mix is more price sensitive (p. 27). Both blades of the scissor lower their average yield and the profitability of serving the hub airport. This is claim (iv), and it matches Borenstein's finding of little umbrella effect (Section 9.5). The fare comparison runs across market categories, which the authors warn against elsewhere (p. 25).

[21] The text quotes the large-hub type-2 comparison as fares of "\$305 vs. \$255" and average costs of "\$94 vs. \$118," a cost advantage of 20%. It gives markups of "\$211 vs. \$137," or 53% higher (p. 26). Table 6 gives fares of \$319 and \$268, marginal costs of \$98 and \$133 and premia of 19.0%, 26.1% and 63.4%. Recomputing from the rounded Table 6 averages gives 19.0%, 26.3% and 63.7%. The 29% and 10% decomposition in the text follows from the text's numbers. We use the table throughout.

[22] The text describes a Figure 4 that presents these results (p. 26, n. 17), but the posted working paper does not contain it. Our figure plots the numbers of Table 6 and does not reproduce Figure 4.

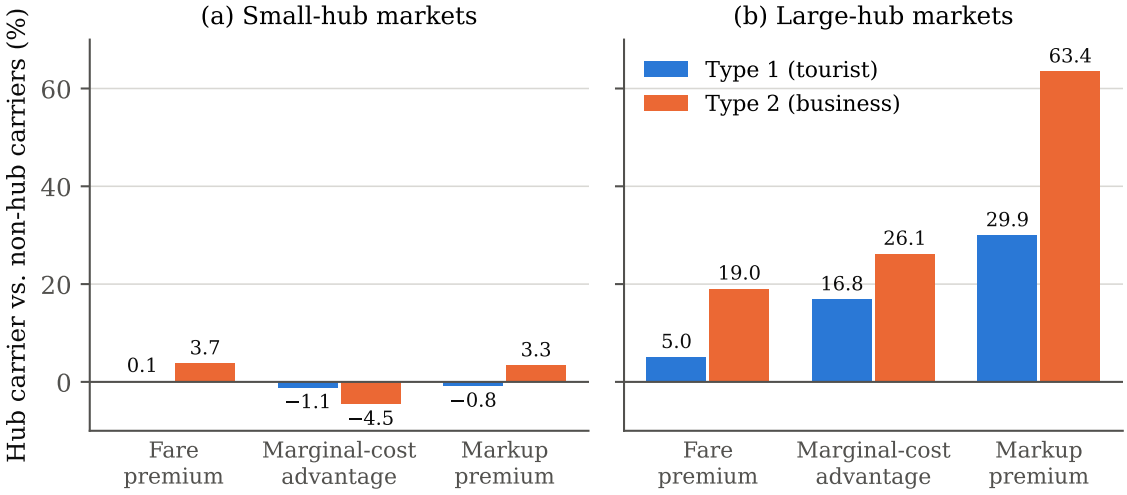

Figure 9.11: Hub premia by market and traveler type. The fare premium is the percentage by which the hub carrier's average fare exceeds that of non-hub carriers. The marginal-cost advantage and the markup premium are defined in (9.70). Redrawn from the bottom panel of Table 6 of Berry et al. (1996), based on the column III estimates.

The within-market evidence is cleaner: non-hub carriers' business fares are 16% below the hub carrier's ($\frac{268}{319} = 0.84$).

A dynamic interpretation. The authors suggest an explanation, untested in the paper, of two trends after deregulation (p. 27). Once a carrier builds a major hub at an airport, its rivals see business customers move away and their yields fall. Marginal carriers then find it profitable to cut service to that city, and airport concentration rises without any entry barrier. Brueckner and Spiller (1994) document this rise. Hubs also give their carriers price and cost advantages that ease entry out of the hub into new city pairs. That could explain the fall in concentration at the level of city-pair markets. For empirical models of airline entry they refer to Reiss and Spiller (1989) and Berry (1992).[23]

Economies of density

Table 9.23 reproduces Table 7, the derivative of leg marginal cost with respect to density (9.59) at column III estimates, for five distances and six densities. With the column III coefficients the derivative is

$$\frac{\partial c_\ell}{\partial Q_\ell} = 1.584 + 2(0.164)Q_\ell + 3(-0.238)Q_\ell^2 - 3.891 d_\ell + 1.270 d_\ell^2 + 2(0.524) d_\ell Q_\ell . \tag{9.72}$$

Panel B of the table evaluates this formula. It reproduces 29 of the 30 printed cells to within 0.006, which is rounding. The exception is the cell for 250 miles and density 1.50.[24]

[23] The text cites "Berry (1991)" here, while the reference list contains Berry (1992), the published entry model.

[24] Table 7 prints −0.27 for 250 miles and 150,000 passengers per quarter. Formula (9.72) gives −0.031, which also fits the neighboring cells (0.568 at density 1.00 and −0.980 at 2.00). We treat the printed value as a typographical error.

Table 9.23: Derivative of leg marginal cost with respect to density (column III)

	Leg density (100,000 passengers per quarter)					
Leg distance	0.25	0.50	0.75	1.00	1.50	2.00
Panel A. As printed in Table 7						
250 miles	0.794	0.808	0.733	0.568	−0.27	−0.980
500 miles	0.125	0.204	0.194	0.096	−0.369	−1.190
1,000 miles	−0.737	−0.527	−0.406	−0.373	−0.576	−1.135
1,500 miles	−0.964	−0.623	−0.371	−0.207	−0.148	−0.446
2,000 miles	−0.556	−0.084	0.299	0.593	0.914	0.879
Panel B. Computed from the Table 5 column III coefficients						
250 miles	0.793	0.807	0.732	0.567	−0.031	−0.985
500 miles	0.124	0.203	0.193	0.094	−0.373	−1.196
1,000 miles	−0.738	−0.527	−0.407	−0.375	−0.579	−1.141
1,500 miles	−0.965	−0.623	−0.372	−0.209	−0.151	−0.451
2,000 miles	−0.557	−0.084	0.298	0.592	0.912	0.874

Notes: \$100 per 100,000 passengers per quarter. A negative entry means economies of density. Panel B evaluates (9.72) (our computations). Source: Berry et al. (1996), Table 7.

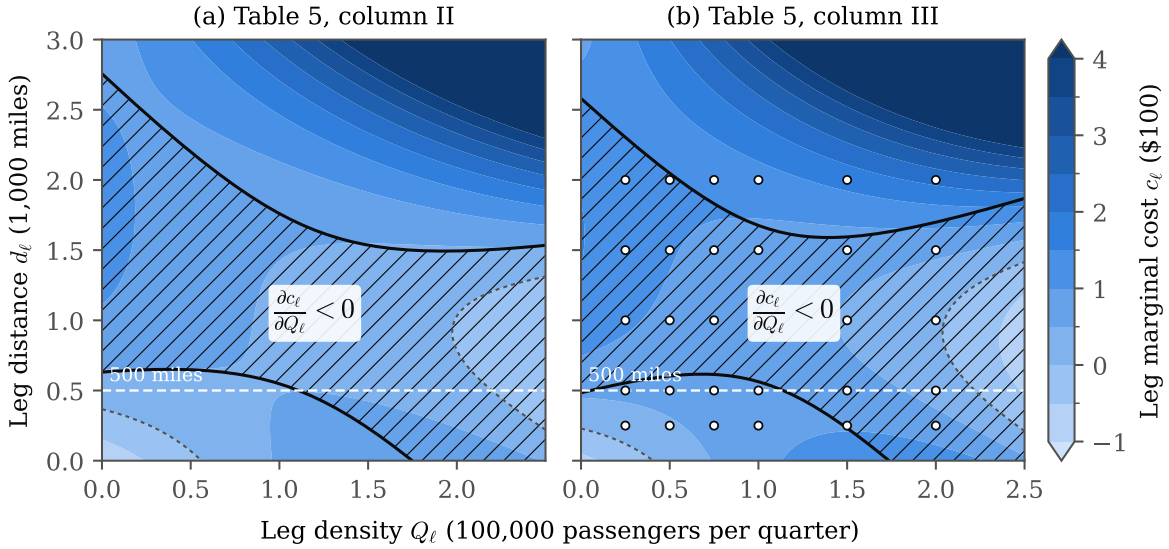

Figure 9.12: Leg marginal cost over leg density and distance. Shading gives the level of c_ℓ in \$100 from (9.56), with congestion terms and the product-level constant set to zero. The hatched region, bounded by the solid curve, has $\frac{\partial c_\ell}{\partial Q_\ell} < 0$ (economies of density). Dotted curves mark $c_\ell = 0$, where the polynomial turns negative. The dashed line marks 500 miles, and the dots in panel (b) are the grid points of Table 9.23. Leg densities above 250,000 passengers per quarter, up to the observed maximum of 455,300, are not shown. Constructed from Berry et al. (1996), Table 5, columns II and III.

Figure 9.12 redraws the cost surface for columns II and III. The working paper shows the same surfaces as three-dimensional plots in Figures 1 to 3.[25] The two columns give the same basic shape (p. 27), with three distance ranges.

- Below about 500 miles, marginal cost rises with density up to about 150,000 passengers per quarter and then falls (p. 27). In column III the derivative turns negative above a density of 1.48 at 250 miles and above 1.14 at 500 miles. The introduction's summary of no economies of density below about 500 miles (p. 3) therefore holds only up to these densities. The authors explain that over short distances the cruising efficiency of larger aircraft may not make up for their higher takeoff and landing costs. Higher density must then be met with more flights.
- Between 500 and 1,500 miles there are economies of density at all densities (p. 28). In column III the derivative is negative for legs between 617 and 1,589 miles at every observed density, up to 455,300 passengers per quarter.
- Above 1,500 miles, the authors find that marginal cost rises with density except at very low densities (p. 28). At 2,000 miles the column III derivative is negative below 55,000 passengers per quarter and positive from there to about 284,000. Above that density the negative cubic term in density turns it negative again. At 2,000 miles this second sign change lies outside Table 9.23 and Figure 9.12. It lies inside the observed range, whose maximum in Table 9.17 is 455,300. Such densities are far in the upper tail, since first outbound legs have a mean density of 59,300 and a standard deviation of 47,500. The derivative also turns negative at high densities inside the observed range at every distance from 1,590 miles to the longest observed leg of 2,704 miles. Below about 1,870 miles this happens inside the plotted range, where the upper edge of the hatched region in panel (b) of Figure 9.12 rises with density. At 1,700 miles, for example, the derivative is negative below 95,100 passengers per quarter and again above 200,400. The authors offer two explanations for the rising cost (p. 28). Polynomials tend to curl up or down at the corners of the data, and the same caution applies to these high-density sign changes. Alternatively, the largest aircraft are already in use on long legs, so more density can only be met with more flights.

Most leg-carrier combinations in the data lie either under 500 miles or inside the region with economies of density, as the authors' Figure 3 shows (p. 28). Few legs fall in the long-distance, high-density corner where marginal cost rises steeply.

The derivatives are large. At 1,000 miles and 100,000 passengers per quarter, the leg's marginal cost falls at a rate of about $37 per additional 100,000 passengers, or about $3.70 per additional 10,000. Because the derivative steepens with density, doubling density to 200,000 lowers it by about $64. Average product marginal costs in Table 6 range from $91 to $133. The authors suspect that the polynomial makes the cost surface "too curvy," so they stop short of the detailed cost analysis they perform for demand (p. 28). They still read the results as consistent with economies of density over a wide range. The average market distance in large-hub markets, 842 miles, lies inside the band where column III implies economies of density at all densities. The cost advantage of large hub carriers in Table 6 is consistent with this.

The absence of density economies on short legs below about 150,000 passengers per quarter is the "Southwest effect" (p. 28). A non-hubbing carrier that offers frequent service on such

[25] Figures 1 to 3 are titled "Col II Table 4" and "Col III Table 4," while the text says that they correspond to columns II and III. The cost parameters are in Table 5, so the titles should read Table 5.

legs loses little by not hubbing, because a hub would not lower its costs there. The authors infer that Southwest's success may reflect a cost niche as well as lower labor costs. They add that Southwest's move toward national service takes it into the distance range where density economies, and hence hubs, may be more efficient (p. 3, n. 6). In terms of Example 9.41, short legs below that density behave like $\gamma \geq 1$, where hubbing never saves cost, and legs of 600 to 1,600 miles behave like $\gamma < 1$.

9.7.7 Conclusions, limitations, and contribution

The authors' conclusions. The conclusions (pp. 28–29) restate the claims of Section 9.7.1 with their evidence. The data and model identify two types of travelers with sensible business and tourist tastes (Tables 4 and 5). Economies of density imply that hubs save costs (Tables 5 and 7). Hubs let carriers charge a premium, but the ability to raise prices is much greater for business travelers. Out of large hubs these travelers pay about 20% more, while the premium for tourists is about 5% or less (Table 6). The authors argue that the welfare consequences of the premium "need not be negative" (p. 29). Business travelers receive a higher-quality product in observed and unobserved characteristics. They are a larger share of hub carriers' passengers, and their demand is inelastic. Aside from the issues the model leaves out, "the negative welfare consequences of hubs appear to be rather small" (p. 29).

From tables to economic inferences. The chain of inference has five links. Table 3 shows that reduced-form coefficients mix markups and costs, which motivates the structural model. Table 5 rejects the logit and finds two price coefficients an order of magnitude apart. The other type-specific coefficients and the Table 4 composition give the second type business tastes. The pricing condition converts demand estimates into markups and hence into marginal costs. Table 6 then compares hub and non-hub carriers within markets, and Table 7 shows where costs fall with density. Every inference after the first depends on the demand model and on static Nash pricing. No formal test accompanies the Table 6 premia or the Table 7 derivatives.

Alternative interpretations the authors consider. The authors flag several alternatives themselves. Part of a measured markup may be a shadow price of capacity (p. 14). Hubs may lower fixed costs, which the model cannot detect (pp. 5 and 14). Pricing may be dynamic, through yield management, or collusive (pp. 15 and 28). The curvature of the cost surface may be an artifact of the polynomial (p. 28). Network structure may affect entry and exit, and frequent-flyer programs and travel-agent commissions may exploit agency problems between the traveler and the payer, which the model does not represent (p. 28).

Limitations. Several further limitations follow from the design.

- The welfare claim is informal. A formal calculation would compute each type's expected surplus from the nested logit inclusive value (Chapter 7). It would then solve for counterfactual prices and densities without hubs and compare the two (Chapter 10). Because densities and costs are linked across the network, the counterfactual would require re-solving the equilibrium in all markets at once.
- The marginal costs are residuals of the pricing condition. If hub carriers do not price as static Nash competitors, the conduct error is absorbed into marginal cost. The measured cost advantage of hub carriers then mixes cost with conduct, the problem studied in Chapter 3.

- Ticket restrictions enter only through ξ, which is assumed mean independent of the observed characteristics and of the network. If hub carriers systematically offer less restricted tickets out of their hubs, part of the measured hub taste is a taste for restrictions.
- The type distribution has two points and no heterogeneity within a type. The nest groups all flights together, so flights of the same carrier or from the same airport are no closer substitutes than others.
- Shares are measured with large sampling error, which is not corrected.
- Southwest, the carrier behind the "Southwest effect," is absent from the data. The short-haul cost estimates come from the other carriers.
- The definition of a hub is not documented in the available file beyond a list referred to in the Table 6 notes, and HUBSIZE has no natural unit.
- The analysis uses one quarter of data, so it cannot study how hubs form, a limitation the authors acknowledge when they leave the dynamic interpretation untested.

Contribution. The paper is the first to separate the cost advantages of hubs from hub markups within one structural model. It shows that market-level data can identify discrete consumer types, here with closed-form shares and without simulation. It also estimates network marginal costs from spoke densities without accounting cost data, through the pricing condition. Its substantive findings explain why the hub premium falls on business travelers and why it creates no umbrella for rivals.

9.8 Synthesis: what three methods teach about hub premia

The three papers of this chapter study the same industry, use the same public data source and ask related questions. Their methods differ: pricing regressions, an event study of stock returns, and a structural model of demand, cost and pricing. This section compares what each method identifies, asks what each paper adds given the other two, assembles the evidence on the sources of hub premia, and applies it to merger policy.

9.8.1 Three designs side by side

Table 9.25 summarizes the three designs. For each paper the rows give the observation, the dependent variable, the key regressors, the source of identification and the headline result.

All three papers reject perfect contestability, through different predictions of Section 9.3.2. Borenstein finds that fares depend on route and airport dominance holding costs fixed, against prediction (C1). Whinston and Collins find that entry announcements reduce incumbents' values, against (C2). By Proposition 9.19, this reveals route-specific profits or sunk costs. Borenstein's route-share and route-concentration effects survive when POTCOMP controls for potential competitors (Panel B of Table 9.5), against (C3). The small POTCOMP coefficient alone does not test (C3), because under perfect contestability fares equal average cost whatever the number of potential entrants. Berry, Carnall and Spiller find large markups where the hub carrier also has lower costs, against (C4), with the caveat of Remark 9.42 that markups are not profits. The rejections come from three different kinds of evidence, which makes the verdict robust.

Table 9.24: Identification and counterfactual map of Berry, Carnall and Spiller (2006)

Observed data	DOT round-trip tickets for the fourth quarter of 1985, with segment traffic from DB27R. Fares, shares and characteristics of 122,871 carrier-itinerary-fare products in 14,122 directional city-pair markets.
Latent objects	Two traveler types and their population shares, product quality ξ_{jt}, cost shocks, leg marginal costs and markups.
Estimated parameters	The type-1 probability ψ and type-specific price and taste coefficients, including the hub tastes β^h_r. The nesting parameter σ, the market-size factor κ, and the coefficients χ of leg costs in distance and density.
Identifying variation	The moments (9.64), with own and rival product characteristics and endpoint population and network variables as instruments. Within-carrier differences between cheap and expensive products at hub and non-hub origins separate the types' hub tastes (9.67).
Maintained assumptions	A two-type nested logit, exogenous characteristics and networks, static multiproduct Nash pricing, and a polynomial leg cost in distance and density.
Counterfactual and what it holds fixed	No new equilibrium is computed. Markups and marginal costs are evaluated at observed fares, and hub premia compare hub and non-hub carriers within markets.
Conclusion	Out of large hubs business travelers pay about 20 percent more and tourists about 5 percent or less. Hub carriers also have lower marginal costs, with density economies on longer routes. The decomposition rests on static Nash pricing.
One limitation	Marginal costs are residuals of the pricing condition, so any departure from Nash pricing is absorbed into measured cost.
Source and our additions	The tables come from the 1996 working paper. Example 9.38, Proposition 9.35 and Lemma 9.37, the factor structure (9.66) and the sampling-error calculation are ours.
Tools in the appendices	Sections A.5 and B.7.

Table 9.25: Three designs for one question

	Borenstein (1989)	Whinston and Collins (1992)	Berry et al. (2006)
Method	Reduced-form pricing regressions	Event study of stock returns	Structural demand, cost and pricing model
Data and period	DOT ticket sample (DB1A), 1987Q3, with Service Segment and Nonstop Market data	24 People Express entry announcements in 1984–1985, daily returns of 20 carriers, airline schedules, DB1A first quarters of 1984–1986	DB1A round trips, 1985Q4, with segment traffic from DB27R
Observation	One randomly chosen qualifying carrier per airport-pair route (3,591 routes, and 1,508 for the relative-price equation)	Carrier and trading day	Carrier-itinerary-fare product in a directional city-pair market (122,871 products in 14,122 markets)
Dependent variable	Logs of the 20th, 50th and 80th percentile fares, and log fare ratios of two carriers	Daily excess return	Shares and fares, through the inversion (ξ) and the pricing condition (ω)
Key regressors	Route share, endpoint share, route and endpoint Herfindahls, cost and quality controls, airport effects	Annualized seat-miles on the entered pair (SM) and at other airports (OSM), departures at the entered airport (EPORT), firm effects	Fare, DIRECT, HUBSIZE, TEMPDIFF, TRIPS-D (type-specific), distance, congestion, leg distance-density polynomial
Identification	2SLS with constructed instruments (GENPSH, IRUTHERF), carrier effects, differencing within routes	Timing of announcements and differences in carriers' exposure, estimated by SUR	GMM with exogenous characteristics, network and rival-product instruments, and Nash pricing
Headline	A carrier with 70% of a route charges 2% to 12% more than rivals with 10%. Endpoint dominance raises fares, more at the high end. Little umbrella effect	Incumbents lose \$3.7 to \$6.5 million per incumbent and event. Incumbent fares fall about 35% after entry, relative to markets not entered. Contestability rejected	Large-hub premium of 19% for business travelers and 5% for tourists, with lower marginal cost. Density economies at medium distances. No umbrella
Main maintained assumptions	Exclusion of the instruments. Shares not proxies for unobserved quality	Efficient markets, correct dating, no confounding news, unanticipated events	Two-type nested logit, exogenous characteristics and network, static Nash pricing, polynomial costs

Notes: Sources are Borenstein (1989, Tables 2–4), Whinston and Collins (1992, Tables 1 and 3) and Berry et al. (1996, Tables 1 and 5–7). The People Express events and the 20 carriers are described in Section 9.6.

9.8.2 What each method identifies

Borenstein's regressions identify a conditional correlation between dominance and fares. Under the exclusion restrictions on his instruments, the route-share coefficient measures how a carrier's fare responds to its share. By (9.14), this response is a markup effect only if the share does not proxy for lower cost or higher quality. The regressions cannot tell a high price that reflects market power from one that reflects a better product, because they contain no model of either. Their strength is breadth and transparency: thousands of routes and a specification any reader can check.

Whinston and Collins identify a bound. By Proposition 9.19, the market value an incumbent loses at an entry announcement is at most the sum of its pre-entry route profits and its sunk costs. A positive loss proves that one of the two is positive. The design needs no model of demand or costs and no controls for route characteristics, because the stock market prices the route's prospects. It identifies the existence and a lower bound of route-specific rents, and how localized they are. It cannot say whether the rents come from pricing, costs or quality, and it cannot separate profits from sunk costs.

Berry, Carnall and Spiller identify primitives: type-specific demand, product markups and leg marginal costs. With these they can separate the fare premium into a markup and a cost component, and in principle simulate counterfactuals. The price is a set of functional forms and behavioral assumptions. The two-type nested logit, the exogeneity of characteristics and network, static Nash pricing and the cost polynomial all shape the answer.

9.8.3 The contribution of each paper given the other two

Given the other two papers, Whinston and Collins add evidence that does not depend on controls or on an equilibrium model. Their value losses show that route-level rents exist, which both other papers presume. The difference between the entered airport pair and other airports in the same city pair shows that airports within a city are differentiated. Under the assumptions of (9.50), the 35% fall in incumbent fares after entry measures how much of the fare level depends on the absence of a low-fare competitor.

Given the other two, Berry, Carnall and Spiller add the decomposition and the mechanism. They explain Borenstein's asymmetry, a dominant carrier with high fares and rivals without, through the sorting of business travelers. This is the logic of Proposition 9.30 and Proposition 9.35. The hub carrier attracts the inelastic travelers and leaves its rivals with the elastic ones, so rivals cannot raise their fares. Borenstein's finding that endpoint dominance raises high-end fares about three times as much as low-end fares anticipates the business travelers' taste for hubs. The density economies show that part of the hub carrier's markup is financed by lower cost. In large hubs the business fare premium is 19% of the non-hub fare, while the markup gain is 32%.

Given the other two, Borenstein adds the broad pattern. His regressions cover thousands of routes and nine carriers. They show that carrier-specific dominance of routes and airports predicts fares. Route concentration as such does not. His airport effects separate scarcity rents, common to all carriers at an airport, from carrier-specific dominance. His results set the agenda that the other two papers pursue.

Together the papers are more than the sum of their parts, because each covers another's weakness. The structural model answers the quality confound in Borenstein's regressions. The event study supplies market-based evidence that does not depend on the structural model's equilibrium assumption. Borenstein's breadth offsets the narrow sample of 24 events, 22 of

them at Newark. The fit is imperfect. The papers use different periods (1984–1985, 1985Q4, 1987Q3) and different market definitions (airport pairs and city pairs), and none of them studies the formation of hubs.

9.8.4 Sources of hub premia

Table 9.26 collects the evidence on five candidate sources of the hub premium. The table shows which source each method can address. It also shows that no single paper speaks to all five.

Table 9.26: Sources of hub premia: what each paper shows

Source	Borenstein (1989)	Whinston and Collins (1992)	Berry et al. (2006)	Later work
Lower cost (density economies)	Not identified. Cost controls only	Not measured	Density economies for legs of roughly 600 to 1,600 miles, and below about 500 only above about 110,000 to 150,000 passengers. Hub carriers' marginal cost 26% lower for business tickets in large hubs	Brueckner and Spiller (1994) on density economies from spoke data
Quality and demand (frequency, nonstop service, network breadth)	Frequency raises fares, more at the high end. Cannot be separated from market power	Not separable from rents	Business travelers value directness, hub size and frequency far more. Hub carriers' products have higher ξ	Berry (1990) on airport presence as differentiation
Market power from dominance	Route and endpoint shares raise own fares. Little umbrella	Route-specific rents revealed by value losses	Business markups 63% higher on hub carriers in large hubs. No umbrella	Ciliberto and Tamer (2009): competitive effects rise with airport presence
Sunk costs, entry barriers and potential competition	Potential competition has a small effect	Losses reveal profits or sunk costs. Contestability rejected	Entry and network taken as given	Goolsbee and Syverson (2008): incumbents cut fares when Southwest threatens entry
Scarcity rents (slots, gates)	Airport effects: O'Hare +3% to 5%, Atlanta +1% to 3%, Denver +2% to 4%. Common to all carriers	Firm effects may include slot values	Congestion raises cost and lowers demand. Rents not separated	Ciliberto and Williams (2010): gate control raises fares where gates are scarce

Notes: Borenstein's airport effects are from p. 359 of his article. Details of each paper are in Section 9.5, Section 9.6 and Section 9.7, and of the later work in Section 9.8.6.

The table suggests a division of the hub premium. A substantial part of the fare gap between hub and non-hub carriers reflects quality that business travelers value and lower costs on medium-haul legs. Market power from dominance is real, but it is concentrated on business travelers and does not spill over to rivals. Route-specific rents and sunk costs keep potential entry from eliminating it. Scarcity of airport facilities adds a premium that is common to all

carriers at an airport, and control of gates turns it into a source of carrier-specific advantage.

9.8.5 Merger policy: two hypothetical mergers

Consider an antitrust agency reviewing two hypothetical mergers. Merger A combines two network carriers with large hubs, of the kind represented by Delta and United. Merger B combines two low-cost carriers that fly mostly point to point, of the kind represented by JetBlue and Southwest. The three papers leave both cases open. They tell the agency where to look. The formal tools, upward pricing pressure, merger simulation and retrospective studies, are developed in Chapter 11.

Merger A: two hub carriers. Borenstein's results predict higher fares on routes where the merging carriers' combined route share rises, and at airports where their combined endpoint share rises. The largest effects arise on hub-to-hub routes, where each carrier competes from its own stronghold. The absence of an umbrella shows that a carrier's dominance does little to raise its rivals' fares. It does not predict how rivals would respond to a change in ownership. Both that response and the discipline that rivals impose on the merging carriers depend on diversion and on equilibrium pricing. Berry, Carnall and Spiller predict that the price effect falls mainly on business travelers. A merger enlarges the network connected through each hub and so raises each hub's HUBSIZE. By Proposition 9.35, that tilts the buyers of the merged carrier's hub products further toward business travelers and raises markups on the tickets they buy. Tourists would see smaller changes. The same paper also points to efficiencies. Combining traffic on overlapping spokes raises density, and on legs of roughly 600 to 1,600 miles that lowers marginal cost. An efficiency defense is therefore plausible for overlapping medium-haul spokes and weak for short ones. Whinston and Collins show that route-level rents survive potential competition, so the loss of an actual competitor on overlap routes matters. They also show how much entry by a low-fare carrier can cut fares. The incumbents' aggressive responses that they document, however, suggest that such entry is costly and uncertain.

The agency would want the overlapping routes and the airports where both carriers have large shares. It would want diversion ratios by fare class and the density and distance of the spokes that would be combined. It would also want a merger simulation with heterogeneous travelers. Remedies that open gates and slots at the hubs speak to the facility-based advantages that Ciliberto and Williams (2010) measure. The papers that matter most for merger A are Berry, Carnall and Spiller, for the decomposition of the premium into markups and costs, and Borenstein, for the link between dominance and fares.

Merger B: two low-cost carriers. For merger B the most relevant evidence concerns entry. Under the assumptions of (9.50), Whinston and Collins find that entry by a low-fare carrier cut incumbents' mean fares by about 35%. Their event study finds that it cost each incumbent \$3.7 to \$6.5 million in value per event. A low-cost carrier is a source of discipline, so merging two of them removes an independent low-fare competitor on overlap routes. Goolsbee and Syverson (2008) show that incumbents cut fares when Southwest becomes a likely entrant, before it starts flying. The merger would also remove each carrier as a potential entrant on the other's routes. On the cost side, Berry, Carnall and Spiller find economies of density below about 500 miles only on dense legs, above about 110,000 to 150,000 passengers per quarter. Combining short-haul point-to-point networks therefore saves cost through density only where the combined legs are that dense. Their cost estimates exclude Southwest, so this inference rests on other carriers' short legs. Borenstein's dominance results matter less here, unless the merger creates a dominant position at airports where both carriers concentrate. The agency

would want the overlapping routes and the routes where each carrier is a likely entrant. It would also want estimated entry probabilities and the fare changes on routes where one carrier entered against the other. The papers that matter most for merger B are Whinston and Collins and, among later work, Goolsbee and Syverson.

9.8.6 Later evidence*

Price dispersion. Borenstein and Rose (1994) study the dispersion of fares that one carrier charges different passengers on the same route. In the working-paper version, the expected absolute difference between the fares of two of a carrier's passengers on a route averages 36% of the carrier's mean fare. Dispersion is higher on more competitive routes, which they interpret as price discrimination in monopolistically competitive markets, against travelers who are less willing to switch flights or carriers. Gerardi and Shapiro (2009) revisit the question with a panel from the first quarter of 1993 to the third quarter of 2006. Competition reduces dispersion, as the textbook theory of price discrimination predicts. The effect is pronounced on routes with a heterogeneous mix of business and leisure travelers. They attribute the contrast with Borenstein and Rose to omitted-variable bias in cross-sectional estimates. Both papers rest on the heterogeneity of travelers that Berry, Carnall and Spiller model as two types.

The threat of entry. Goolsbee and Syverson (2008) use the expansion of Southwest's network to identify routes where the probability of entry rises abruptly. We cite their NBER Working Paper 11072 (January 2005, revised August 2008), whose table numbers may differ from those of the published article. A route is threatened when Southwest begins to serve its second endpoint without yet flying the route. A descriptive probit of Southwest's entry into a route in a given quarter shows the size of the jump (Table I). Presence at one endpoint raises the entry probability only slightly above a baseline near zero. Presence at both raises it by a further factor of about 70, to 18.5% per quarter (p. 5).

Let τ_0 be the quarter in which Southwest first serves both endpoints of route t, and let τ_e be the quarter in which it starts flying the route. In this discussion τ indexes quarters. For incumbent carrier f, the authors estimate the event-study regression

$$y_{ft\tau} = \gamma_{ft} + \gamma_{f\tau} + \sum_k \beta_k D^0_{t\tau k} + \sum_k \lambda_k D^e_{t\tau k} + e_{ft\tau} \tag{9.73}$$

(pp. 6–7). The outcome $y_{ft\tau}$ is the passenger-weighted mean log fare, and γ_{ft} and $\gamma_{f\tau}$ are carrier-route and carrier-quarter fixed effects. The threat dummy $D^0_{t\tau k}$ equals one when $\tau = \tau_0 + k$ and Southwest does not yet fly the route. It runs from $k = -8$ to $k = 2$, and one more dummy pools the quarters from $\tau_0 + 3$ on. The entry dummies $D^e_{t\tau k}$ mark the quarter τ_e, the two quarters after it, and the quarters from $\tau_e + 3$ on. The omitted period is the 9th through 12th quarters before τ_0, so each coefficient measures log fares relative to that baseline. Observations are weighted by passengers, and standard errors are clustered by route-carrier pair (p. 7).

Column (1) of their Table II gives $\hat{\beta}_0 = -0.186$ (0.073). Since $e^{-0.186} = 0.830$, fares are about 17% lower by the quarter τ_0 (p. 8). They begin to fall about three quarters before τ_0. Southwest announces its arrival at an airport months in advance, and insiders may learn of it earlier (p. 9). Once Southwest flies the route, fares are 21% below the baseline, since $e^{-0.237} = 0.789$. By the end of the window they are over 29% lower, since $e^{-0.344} = 0.709$ (p. 9). Over half of Southwest's total effect on incumbents' fares thus occurs before entry. The cuts occur only on threatened routes and not on routes from nearby airports. This answers the question that

Borenstein's potential competition variable and Whinston and Collins's announcements could only approach. Potential competition does discipline incumbents when the entrant is credible and the threat is specific to a route.

Gates and the hub premium. Ciliberto and Williams (2010) measure the role of airport facilities directly, with data from the competition plans that major airports must file with the DOT. Our numbers come from the February 2009 author manuscript (MPRA Paper 38636), then forthcoming in the *Journal of Law and Economics*. The hub premium rises with the fare. It is below 10% at the 10th percentile of the fare distribution and almost 25% at the 90th (p. 3). Their Table 7 adds the measures of barriers to entry to the fare regression. The premium on tickets out of a hub then falls from about 12% to about 6%, and the premium on tickets into a hub from 12.7% to 9.3% (pp. 21–22). In the authors' summary, the premium falls by almost half (p. 22). Control of gates leased on an exclusive basis is a key determinant. The coefficient on the carrier's share of gates at the origin airport, OwnGatesOrigin, is 0.163. A rise in that share from 10% to 30% therefore raises fares by about $0.20 \times 0.163 \approx 3\%$. Gate control explains high fares only where gates are scarce relative to departures (pp. 23–24). These results support Borenstein's facility mechanism and fit the finding of Berry, Carnall and Spiller that the premium falls on high-fare, business tickets.

Entry games. Ciliberto and Tamer (2009) estimate entry games in airline markets without assuming a unique equilibrium, in the tradition of Berry (1992). They find heterogeneous competitive effects. The effects of large carriers differ from those of low-cost carriers and Southwest, and a carrier's competitive effect increases with its airport presence. Airport presence thus shapes market structure as well as fares, as Berry, Carnall and Spiller conjecture in their dynamic interpretation.

Merger retrospectives. The airline mergers of the mid-1980s, which motivated much of this literature, have been studied after the fact, and Section 11.6 places these retrospectives among the general methods of merger evaluation.

9.9 Bibliographic notes

Borenstein (1989) built on earlier studies of airline pricing. They regressed route fares on route concentration and cost controls (Graham et al., 1983; Bailey et al., 1985; Call and Keeler, 1985; Morrison and Winston, 1987). These studies established that fares rise with concentration, against the contestability benchmark of Baumol et al. (1982) and Baumol (1982). Section 9.3 follows the textbook account of Tirole (1988, sec. 8.1). Tirole also presents the critique that prices adjust faster than entry. He treats the war of attrition as an alternative model of natural monopoly (sec. 8.1.3). Levine (1987), who had regulated, managed and studied airlines, summarizes the view that airport dominance insulates a carrier from competition (Borenstein, 1989, p. 345, n. 3). Borenstein (1991) followed his 1989 study with directional city-pair comparisons, which show higher fares on flights out of a hub than into it. Price dispersion within routes became a separate topic. Borenstein and Rose (1994) found more dispersion on more competitive routes in a cross-section, and Gerardi and Shapiro (2009) found the opposite in a panel.

The cost side of hubbing has its own lineage. Caves et al. (1984) estimated economies of density from an aggregate airline cost function. Brueckner et al. (1992) and Brueckner and Spiller (1994) moved to marginal costs at the level of flight legs, the approach that Berry et al. (2006) adopt. Brueckner and Spiller (1991) study competition and mergers in hub-and-spoke

networks. There, economies of density on a shared spoke link costs across markets (Berry et al., 1996, p. 2, n. 5). On the demand side, Morrison and Winston (1986) estimated an early logit model of air travel choices, and Berry (1990) treated airport presence as a source of product differentiation. The structural approach of Berry et al. (2006) builds on the inversion of Berry (1994) and the estimator of Berry et al. (1995) (Chapters 7 and 8).

Entry into airline markets is a large literature of its own. Reiss and Spiller (1989) and Berry (1992) directly investigate the determinants of entry into city-pair markets (Whinston and Collins, 1992, p. 446, n. 1). Berry's model treats the number of carriers on a route as an equilibrium outcome. Ciliberto and Tamer (2009) estimated airline entry games that allow multiple equilibria and heterogeneous competitive effects. Ciliberto et al. (2021) estimate a game in which carriers choose entry and prices simultaneously, with correlated shocks to demand and cost. Ignoring endogenous entry biases their estimates of demand elasticities. In a simulated merger of American and US Airways, the outcomes after the merger depend on how the merged firm's characteristics are modeled. Their framework addresses a limitation of all three papers of this chapter, none of which models how carriers choose the routes they serve (Section 9.8). Goolsbee and Syverson (2008) studied how incumbents respond to the threat of entry by Southwest, and Ciliberto and Williams (2010) measured how control of gates sustains the hub premium. The event-study method that Whinston and Collins (1992) adapt goes back to Fama et al. (1969). Early uses in regulation include Schwert (1981) and Rose (1985), and MacKinlay (1997) gives a survey. Event studies of mergers are treated in Section 11.6.6.

The airline mergers of the mid-1980s were studied after the fact by Borenstein (1990), Kim and Singal (1993) and Peters (2006). Chapter 11 places these retrospectives among the general methods of merger evaluation. On the collusion side, Miller (2010) asks whether the settlement of the airline tariff publishing case reduced coordination among carriers (Section 13.5.3). Dynamic models of entry, network formation and competition among airlines go beyond the scope of this edition.

9.10 Exercises

1. *A contestable natural monopoly.* Let $C(q) = F + cq$ for $q > 0$ and $C(0) = 0$, and let market demand be $Q(p) = A - p$, with $A > c$ and $(A - c)^2 > 4F$.

   (a) Derive the sustainable price p^c of Proposition 9.9 as a function of (A, c, F). Verify that it equals average cost at the quantity demanded and that it gives $7 - \sqrt{17}$ when $A = 12$, $c = 2$ and $F = 8$.

   (b) Show that p^c falls toward c as $F \to 0$. Compute the deadweight loss at p^c and at the monopoly price, and explain why the first is the smallest loss compatible with zero profit.

   (c) Now set $F = 0$ and let entry require a sunk investment K. The incumbent charges the monopoly price, and demand and profits are monthly flows. An entrant that slightly undercuts the incumbent earns the monopoly profit per month until the incumbent responds, and nothing afterward. With $A = 12$, $c = 2$, $K = 100$ and a monthly discount factor of 0.99, find the shortest response lag T, in months, at which entry pays. Relate your answer to Proposition 9.17.

   (d) Let instead $C(q) = 1 + q^2$ for $q > 0$, with $C(0) = 0$, and $Q(p) = A - p$. Find the efficient scale and the minimum average cost. For which values of A does Proposition 9.15 imply that no configuration is sustainable? At $A = 3.8$, find the single firm's break-even

price at the right crossing and the profit of the entry plan used in the proof of the proposition.

2. *Dominance without an umbrella.* Consider the logit route market of Assumption 9.29 with two carriers and an outside good, $\alpha = 1$ (prices in \$100), $c_1 = c_2 = 1$ and $\delta_2 = 1$.

   (a) Using the single-equation reduction in the proof of Proposition 9.30, compute the Bertrand equilibrium for $\delta_1 \in \{1, 2, 3\}$. Check your answers against $p_1 = p_2 = 2.227$ at $\delta_1 = 1$ and $p_1 = 2.867$, $p_2 = 2.148$ at $\delta_1 = 3$.

   (b) Verify each claim of Proposition 9.30 at these points, and compute the route Herfindahl index of inside shares at each.

   (c) Regress $\ln p_1 - \ln p_2$ on $s_1 - s_2$ across the three points. Compare the slope with the approximation of Corollary 9.31, and explain what it implies for the sign of the route-share coefficient in Borenstein's relative-price equation (9.32).

3. *Reading Borenstein's estimates.*

   (a) Use the 2SLS estimates with POTCOMP in Panel B of Table 9.5. For each fare percentile, compute the fare gap between a carrier with 70% of a route and rivals with 10% each. Compare your numbers with those of the main specification.

   (b) On a route, carrier 1 has 40% of the passengers and three rivals have 30%, 20% and 10%. The two smallest rivals merge. Compute the change in the route Herfindahl index and the implied changes in carrier 1's three fares, holding its share fixed. Explain why the calculation holds the share fixed and why this matters for reading ϕ_4 as an umbrella effect.

   (c) Derive (9.37) and show that the rescaled rival shares leave the Herfindahl index of the traffic not carried by f unchanged.

   (d) Following Remark 9.28, compute the value of $\bar{\eta} = \eta_0 + \eta_1 \bar{H}$ implied by each 2SLS route-share coefficient if the route elasticity is $\varepsilon = 2$. What outside information would discriminate between this reading and a Cournot reading?

4. *Event-study algebra.*

   (a) Two carriers have equity values of \$250 million and \$2.5 billion. Compute the dollar loss each would suffer under a common abnormal return of -1%. Explain why Whinston and Collins prefer the dollar formulation (9.42).

   (b) Using $\lambda_{SM} = -0.0109$, the average incumbent's 7,100 weekly seats and the average distance of 892 miles, compute the implied loss per incumbent. Compare it with the \$3.7 million reported in the paper. Show that the gap can arise because the mean of a product differs from the product of the means, and state the sign of the covariance it requires.

   (c) Three incumbents are hit by the same announcement, and their abnormal returns have pairwise correlation 0.5. By what factor does the variance of their average abnormal return exceed the variance computed under independence?

   (d) If investors had assigned probability 0.4 to entry before the announcement, what true loss per incumbent corresponds to a measured loss of \$3.7 million (Remark 9.22)?

5. *People Express as a difference in differences.* Use Panel A of Table 9.13.

(a) Compute the two difference-in-differences estimates of the effect of entry on the mean incumbent price and their average.

(b) Compute the pooled two-sample t statistic for the 1984–85 contrast, reading the reported standard deviations first with divisor $n-1$ and then with divisor n. Compare both with the printed value of 2.5.

(c) State the identifying assumptions of (9.50). Explain why the 1985 cohort's change in 1984–85 and the 1984 cohort's change in 1985–86 cannot test them. Name the additional data that could.

(d) Explain why the quantity and capacity columns are hard to reconcile with Cournot competition, using (9.11).

6. *Who pays the hub premium?* Use the column III estimates of Table 9.19.

(a) Compute an approximate standard error for type 2's willingness to pay for HUBSIZE by the delta method, ignoring the covariance between the two estimates. Is the ranking of the two types' willingness to pay robust to this imprecision?

(b) By Remark 9.36, a single-product markup is close to $\frac{1-\sigma}{\tilde{\alpha}_j}$ when within-nest shares are small. Compute this approximation for a product whose buyers have the composition of hub carriers' passengers in large-hub markets (33.0% type 2) and of non-hub carriers' passengers there (23.2% type 2).

(c) Compare your answers with the average markups $F-M$ implied by Table 9.22. Explain why the approximation at the average buyer composition understates the average markup. (Note that $\frac{1}{\tilde{\alpha}}$ is convex in $\mathbb{P}(2 \mid j)$.)

7. *Economies of density.* Use the column III cost estimates of Table 9.21.

(a) Write the leg marginal cost polynomial and derive $\frac{\partial c_\ell}{\partial Q_\ell}$.

(b) Reproduce three cells of Table 9.23 and identify the printed cell that the formula does not reproduce.

(c) At 250 miles, find the positive density at which the derivative changes sign. At 2,000 miles, find both densities at which it changes sign. Say which of them lies inside the range of Table 9.23 and what the other suggests about the polynomial where the data are thin.

(d) Discuss what the sign pattern implies for hubbing on short and on medium-haul routes, and connect it to the cost ratio $\frac{2n^\gamma}{n+1}$ of Example 9.41.

8. *An acquisition at a hub.* A network carrier that dominates a hub airport proposes to acquire a low-cost carrier. The low-cost carrier flies point to point, and a third of its departures use the acquirer's hub. Drawing on the three papers of this chapter and on Section 9.8, write a short memo to an antitrust agency. Identify the travelers and routes most likely to face higher fares. State the efficiencies the merging parties could claim and how credible they are. Explain what the agency should infer from the absence of an umbrella effect. Name the additional evidence you would request, and say which paper's method would best analyze it.

Chapter 10

Valuing New Goods

10.1 Introduction

Markets add products all the time. Bresnahan (1997, p. 237) cites a count of more than 22,000 new-product introductions in 1994. In ready-to-eat cereal alone, about 190 new brands entered between 1980 and 1992 (Hausman, 1997, pp. 213–215). Some new products are small variations on existing ones, and some transform an industry. Either way, a new good changes what consumers can buy, and so it changes their welfare. Official price indexes compare the prices of goods sold in two periods. They therefore miss the gain from a good that did not exist in the first period. The size of that gain matters for the measurement of inflation and real income, for the returns to research, and for competition policy.

This chapter asks three questions. What is the welfare value of a new good, and why does a conventional price index miss it? How can an estimated demand system measure that value, in product space and in characteristics space? And how do market power and the responses of rival firms change the answer?

The questions are hard for a simple reason. The value of a new good is the area under its compensated demand curve between the price at which it sells and the price at which demand would vanish. Prices that high are almost never observed (Berry and Pakes, 2007, Section 1).[1] Every estimate therefore extrapolates demand beyond the data. The answer depends on the functional form, on the instruments that identify the slope of demand, and on the model of competition. The chapter makes each of these dependences explicit.

Sections 10.2 to 10.4 develop the theory. Section 10.2 defines the value of a new good through its virtual price and relates it to the exact cost-of-living index. It also derives index-number bounds and the variety correction for preferences with a constant elasticity of substitution (CES). Section 10.3 asks how much of the value the data can identify. It compares canonical functional forms and derives a lower bound that needs only convexity. Section 10.4 adds imperfect competition. It splits the welfare gain into a variety effect and a price effect, separates private from social returns, and studies how the introducing firm and its rivals reprice. The first case study, in Sections 10.5 and 10.6, is Hausman's valuation of Apple-Cinnamon Cheerios and Bresnahan's critique of its instruments and of its treatment of competition.

Section 10.7 turns to characteristics space. It derives consumer surplus in random utility models and shows how the idiosyncratic taste shocks of logit-type models build a value of variety

[1] Throughout this chapter, page, section and table numbers for Berry and Pakes (2007) refer to the authors' manuscript dated July 2, 2007 (41 pages). Its Section 5.4 starts on p. 31, and Tables 5 to 7 are on pp. 33–36. We did not check the published article, whose numbering may differ.

into the functional form. The remaining case studies apply these ideas. Section 10.8 studies Trajtenberg's measurement of innovation in computed tomography scanners. Section 10.9 studies Petrin's valuation of the minivan with micro moments, and Section 10.10 studies Gentzkow's bundle model of print and online newspapers, in which a new good may complement old ones. Section 10.11 compares the four studies and draws out five determinants of a measured value.

The chapter draws on much of the book. The duality results, the almost ideal demand system, multistage budgeting and the virtual prices of withdrawn products come from Chapter 5. Multiproduct Bertrand pricing comes from Chapter 4, and free entry from Chapter 2. The discrete-choice models are those of Chapters 6 to 8. The counterfactual equilibria of this chapter use the same machinery as the merger simulations of Chapter 11. Sections B.4 and B.5 collect the duality results and the extreme value algebra, and Sections A.3, A.5 and A.7 the methods of instrumental variables, the generalized method of moments and simulation.

A few conventions hold throughout. We write y for income, as Hausman and Petrin do, where Chapter 5 writes I. The virtual price of good n is p_n^V. Market shares are s_j, and budget or revenue shares are w_j. The CES elasticity of substitution is η, because σ denotes the nesting parameter of the nested logit. In Sections 10.4 and 10.5 the elasticities ε_{kj} are signed, so own-price elasticities are negative. Elsewhere a scalar ε is an own-price elasticity written as a positive number, as in the rest of the book. When a paper uses a symbol that the book reserves for another object, we rename it at first use.

10.2 The welfare value of a new good: virtual prices and exact measures

A new good raises welfare because consumers can buy something they could not buy before. This section turns that statement into a number. Following Hicks (1940), we treat the period before the introduction as a period in which the good is rationed at zero. The value of the good is then the compensating variation of raising its price from the observed level to its *virtual price*. At that price the consumer would choose not to buy the good. We derive this result, relate it to the exact cost-of-living index of Konüs (1939), and show why price indexes that link new goods in after their introduction miss it. We then derive index-number bounds, state what separability buys, and derive the variety correction of Feenstra (1994). The duality tools come from Section 5.2, and Section 5.7.2 treats virtual prices for the almost ideal demand system.

10.2.1 Setting and notation

A consumer chooses quantities $q = (q_1, \dots, q_n)^\top \geq 0$ of n goods at prices $p = (p_1, \dots, p_n)^\top$, all positive, with income y. We write $q_j(p, y)$ for Marshallian demand, $v(p, y)$ for indirect utility, $e(p, u)$ for the expenditure function and $h_j(p, u)$ for Hicksian demand. Good n is the new good. It is unavailable in period 0 and sold at price p_n in period 1. We write p_{-n} for the prices of the other goods and (p_{-n}, p_n) for the full price vector. Following Hausman (1997) and Petrin (2002) we write income as y. Chapter 5 writes I for the same object.

Assumption 10.1 (Preferences)**.** The utility function U is continuous, strictly increasing and strictly quasi-concave on $\mathbb{R}^n_+$.

Under Assumption 10.1 demands are single valued and continuous, and the duality

identities of Lemma 5.4 hold:

$$e\big(p, v(p,y)\big) = y, \qquad h_j(p,u) = q_j\big(p, e(p,u)\big), \qquad \frac{\partial e(p,u)}{\partial p_j} = h_j(p,u). \tag{10.1}$$

The last identity is Shephard's lemma (Proposition 5.6). The expenditure function is nondecreasing and concave in p, so each Hicksian demand is nonincreasing in its own price (Proposition 5.5).

10.2.2 A new good as a rationed good

Hicks (1940) treated rationing and new goods with the same tool. As Hausman (1997, p. 211) puts it, new products are a special case of rationing in which demand for the good is zero. Before the introduction, the consumer solves the usual problems with the extra constraint $q_n = 0$. We call the resulting value functions the *rationed* indirect utility and expenditure functions:

$$v^R(p_{-n}, y) = \max\Big\{U(q) : \sum_{j \neq n} p_j q_j \leq y,\ q_n = 0\Big\}, \tag{10.2}$$

$$e^R(p_{-n}, u) = \min\Big\{\sum_{j \neq n} p_j q_j : U(q) \geq u,\ q_n = 0\Big\}. \tag{10.3}$$

Neither function depends on p_n, because a bundle with $q_n = 0$ costs the same at every price of good n. Section 5.7.2 writes e_{-i} for e^R.

Definition 10.2 (Virtual prices)**.** The *Hicksian virtual price* $p_n^V(p_{-n}, u)$ of good n is the virtual price of Definition 5.44, the lowest price at which Hicksian demand h_n is zero. The *Marshallian virtual price* (or choke price) is the same object for Marshallian demand, $p_n^M(p_{-n}, y) = \inf\{p_n > 0 : q_n(p_{-n}, p_n, y) = 0\}$. Either price is $+\infty$ if the corresponding demand is positive at every price.

In both cases demand stays at zero at every price above the virtual price. For Hicksian demand this follows because h_n is nonincreasing in p_n. For Marshallian demand, suppose the optimal bundle at p_n has $q_n = 0$. Raising p_n leaves its cost unchanged and shrinks the budget set, so the same bundle stays optimal. Hausman (1997, p. 212, n. 5) uses the Hicksian version, because the exact welfare measure keeps utility constant. The two versions coincide when demand for good n has no income effect. For a normal good the Hicksian virtual price at the period-1 utility is at least the Marshallian one (Lemma 5.46).

The next lemma is the formal content of the virtual-price idea. Rothbarth (1941) introduced it, and Neary and Roberts (1980) give a modern treatment of rationing along these lines. Deaton and Muellbauer (1980b, Section 4.3, pp. 109–113) give the textbook treatment through the restricted cost function, which Lemma 10.5 below develops.

Lemma 10.3 (Rationing as a price, Rothbarth, 1941; Neary and Roberts, 1980)**.** *Let Assumption 10.1 hold and fix p_{-n}, y and u.*

(a) For every $p_n > 0$, $v(p_{-n}, p_n, y) \geq v^R(p_{-n}, y)$ and $e(p_{-n}, p_n, u) \leq e^R(p_{-n}, u)$.

(b) If $p_n^M(p_{-n}, y)$ is finite, then $v^R(p_{-n}, y) = v\big(p_{-n}, p_n^M(p_{-n}, y), y\big)$.

(c) If $p_n^V(p_{-n}, u)$ is finite, then $e^R(p_{-n}, u) = e\big(p_{-n}, p_n^V(p_{-n}, u), u\big)$.

Proof. (a) Any bundle that is feasible in the rationed problem has $q_n = 0$. Its cost is therefore the same at every p_n, and it is feasible in the unrationed problem at every p_n. Maximizing over a larger set gives a weakly larger maximum, and minimizing over a larger set gives a weakly smaller minimum.

(b) Write p_n^M for $p_n^M(p_{-n}, y)$ and let $q^* = q(p_{-n}, p_n^M, y)$. Marshallian demand is continuous in prices, so $q_n^* = 0$ at the infimum in Definition 10.2. Hence $\sum_{j \neq n} p_j q_j^* = p^\top q^* \leq y$, and q^* is feasible in the rationed problem. This gives $v^R(p_{-n}, y) \geq U(q^*) = v(p_{-n}, p_n^M, y)$. Part (a) at $p_n = p_n^M$ gives the reverse inequality.

(c) The argument is the same with $h(p_{-n}, p_n^V, u)$ in place of q^*. Its nth component is zero, so it is feasible in the rationed cost minimization, and $e^R(p_{-n}, u) \leq e(p_{-n}, p_n^V, u)$. Part (a) gives the reverse inequality. □

Remark 10.4 (The virtual price as a shadow price). Suppose U is differentiable, the good would be bought at the actual price, and the rationed optimum q^R has $q_j^R > 0$ for every $j \neq n$. Write the ration as $q_n \leq 0$, with multiplier $\mu \geq 0$, and the budget with multiplier $\lambda > 0$. The Kuhn-Tucker conditions are

$$\frac{\partial U(q^R)}{\partial q_j} = \lambda p_j, \qquad j \neq n,$$
$$\frac{\partial U(q^R)}{\partial q_n} = \lambda p_n + \mu = \lambda\Big(p_n + \frac{\mu}{\lambda}\Big).$$

Define $\tilde{p}_n = p_n + \frac{\mu}{\lambda}$. The two lines are then the first-order conditions of the unrationed problem at prices $(p_{-n}, \tilde{p}_n)$. The budget is unchanged, because the ration contributes $(\tilde{p}_n - p_n) \cdot 0 = 0$ to spending. Since the conditions are sufficient under strict quasi-concavity, q^R is the unrationed demand at $(p_{-n}, \tilde{p}_n, y)$. The price $\tilde{p}_n$ equals the marginal rate of substitution between good n and money at q^R. It is the price at which the consumer is just unwilling to buy the first unit, the Marshallian virtual price. The multiplier $\mu = \lambda(p_n^M - p_n)$ is the utility value of relaxing the ration by one unit, and $\frac{\mu}{\lambda}$ is its money value. Rothbarth called such prices the "virtual price system" (Hausman, 1997, p. 211).

The remark finds the shadow price at the rationed optimum, holding income fixed. The welfare measures below hold utility fixed, and for them it helps to treat the ration $q_n = z$ as a variable. The cost function with a fixed quantity of one good is the consumer's analogue of a short-run cost function. The unrestricted cost function is its long-run envelope (Deaton and Muellbauer, 1980b, p. 110).

Lemma 10.5 (Restricted expenditure function, Deaton and Muellbauer, 1980b)**.** *Let Assumption 10.1 hold and let U be differentiable. For a ration $z \geq 0$ of good n, define the* restricted expenditure function

$$\tilde{e}(p, u, z) = \min\Big\{p^\top q : U(q) \geq u,\ q_n = z\Big\} = p_n z + \min_{q_{-n}}\Big\{\sum_{j \neq n} p_j q_j : U(q_{-n}, z) \geq u\Big\}. \tag{10.4}$$

(a) $e^R(p_{-n}, u) = \tilde{e}(p, u, 0)$, and $e(p, u) = \min_{z \geq 0} \tilde{e}(p, u, z)$, with the minimum at $z = h_n(p, u)$.

(b) Suppose the minimizing q_{-n} in (10.4) has $q_j > 0$ for every $j \neq n$, and let $\kappa > 0$ be the multiplier on the utility constraint. Define the shadow price *of the ration as $\tilde{p}_n(p_{-n}, u, z) = \kappa \frac{\partial U}{\partial q_n}$. Then*

$$\frac{\partial \tilde{e}(p, u, z)}{\partial z} = p_n - \tilde{p}_n(p_{-n}, u, z), \tag{10.5}$$

and $h_n\big(p_{-n}, \tilde{p}_n(p_{-n}, u, z), u\big) = z$.

Proof. (a) With $z = 0$ the term $p_n z$ vanishes, and the problem in (10.4) is the rationed problem (10.3). For the second claim, minimize $p^\top q$ subject to $U(q) \geq u$ in two steps. The first step fixes $q_n = z$ and minimizes over q_{-n}, which gives $\tilde{e}(p, u, z)$. The second step minimizes over z. The minimizing z is the nth component of the cost-minimizing bundle, $h_n(p, u)$.

(b) Write $g(z)$ for the inner minimum in (10.4). Its Lagrangian is

$$\mathcal{L} = \sum_{j \neq n} p_j q_j - \kappa\big[U(q_{-n}, z) - u\big].$$

At an interior optimum the first-order conditions are $p_j = \kappa \frac{\partial U}{\partial q_j}$ for $j \neq n$. The envelope theorem gives

$$g'(z) = \frac{\partial \mathcal{L}}{\partial z} = -\kappa \frac{\partial U}{\partial q_n} = -\tilde{p}_n(p_{-n}, u, z).$$

Adding the derivative of $p_n z$ gives (10.5). Now consider the unrestricted cost minimization at prices $(p_{-n}, \tilde{p}_n)$ and the bundle (q_{-n}, z). The conditions $p_j = \kappa \frac{\partial U}{\partial q_j}$ hold for $j \neq n$ by construction. The condition for good n, $\tilde{p}_n = \kappa \frac{\partial U}{\partial q_n}$, holds by the definition of $\tilde{p}_n$. Under Assumption 10.1 these conditions are sufficient. The bundle is therefore the Hicksian demand at $(p_{-n}, \tilde{p}_n, u)$, and its nth component is z. □

The shadow price is the money value of one more unit of the ration. It equals the fall in the cost of staying on the indifference curve when that unit is supplied free (Deaton and Muellbauer, 1980b, p. 113). By part (b), the function $z \mapsto \tilde{p}_n(p_{-n}, u, z)$ is the inverse of the compensated demand curve for good n. At $z = 0$ it is the price at which the consumer just chooses not to buy, the Hicksian counterpart of the shadow price in Remark 10.4. The derivative (10.5) vanishes at $z = h_n(p, u)$, which is the envelope property of part (a). Deaton and Muellbauer state the three results as their equations (3.1), (3.2) and (3.7) (pp. 110–112).

10.2.3 The compensating variation of a new good

Hold income y and the other prices p_{-n} fixed across the two periods for now. Period-0 utility is $u^0 = v^R(p_{-n}, y)$ and period-1 utility is $u^1 = v(p_{-n}, p_n, y)$. By Lemma 10.3(a), $u^1 \geq u^0$.

Definition 10.6 (Value of a new good)**.** The *compensating variation* of the new good is

$$CV = e^R(p_{-n}, u^1) - y, \tag{10.6}$$

the extra income a consumer without access to the good would need to reach the period-1 utility. The *equivalent variation* is $EV = y - e(p_{-n}, p_n, u^0)$, the income that could be taken from the consumer in period 1 while leaving her at the period-0 utility.

The definition takes the period-1 standard of living as the reference, as Hausman (1997, eqs. 3–4) and Petrin (2002, p. 720) do. Read from period 1 back to period 0, CV is the compensating variation of withdrawing the good. Read forward, it is the equivalent variation of the introduction. We follow both papers and call it the compensating variation of the new good. The convention matches the treatment of product withdrawals in (5.104).

Proposition 10.7 (Value of an introduction)**.** *Let Assumption 10.1 hold, and write* $p_n^V = p_n^V(p_{-n}, u^1)$. *Then*

$$CV = e\left(p_{-n}, p_n^V, u^1\right) - e\left(p_{-n}, p_n, u^1\right) \tag{10.7}$$

$$= \int_{p_n}^{p_n^V} h_n\left(p_{-n}, t, u^1\right) \mathrm{d}t = \int_{p_n}^{\infty} h_n\left(p_{-n}, t, u^1\right) \mathrm{d}t. \tag{10.8}$$

The same formulas give EV with u^0 *in place of* u^1. *If the virtual price is infinite,* $e^R(p_{-n}, u) = \lim_{t\to\infty} e(p_{-n}, t, u)$, *and the last integral in (10.8) still equals CV, whether finite or infinite. If good n is normal, then* $EV \leq CV$.

Proof. We prove the finite case first, in four steps.

First, the duality identity (10.1) gives $e(p_{-n}, p_n, u^1) = e(p, v(p, y)) = y$.

Second, Lemma 10.3(c) gives $e^R(p_{-n}, u^1) = e(p_{-n}, p_n^V, u^1)$. Substituting both results into (10.6) gives (10.7).

Third, Shephard's lemma gives $\frac{\partial e(p_{-n}, t, u^1)}{\partial t} = h_n(p_{-n}, t, u^1)$. The function $t \mapsto e(p_{-n}, t, u^1)$ is concave, hence absolutely continuous on compact intervals, so the fundamental theorem of calculus gives

$$e\left(p_{-n}, p_n^V, u^1\right) - e\left(p_{-n}, p_n, u^1\right) = \int_{p_n}^{p_n^V} h_n\left(p_{-n}, t, u^1\right) \mathrm{d}t.$$

Fourth, $h_n(p_{-n}, t, u^1) = 0$ for every $t \geq p_n^V$, so the integral can run to infinity.

For EV, the rationed duality identity gives $e^R(p_{-n}, v^R(p_{-n}, y)) = y$, that is, $y = e^R(p_{-n}, u^0)$. Hence $EV = e^R(p_{-n}, u^0) - e(p_{-n}, p_n, u^0)$, and the same four steps apply at u^0.

Now let the virtual price be infinite. The function $t \mapsto e(p_{-n}, t, u)$ is nondecreasing and bounded above by $e^R(p_{-n}, u)$ by Lemma 10.3(a), so it has a limit $L \leq e^R(p_{-n}, u)$. Suppose $L < e^R(p_{-n}, u)$. The bundle $h(p_{-n}, t, u)$ costs at most L, so $t\, h_n(p_{-n}, t, u) \leq L$ and $h_n \to 0$ as $t \to \infty$. Its other components are bounded because their prices are positive. Along a convergent subsequence the limit bundle $\bar{q}$ has $\bar{q}_n = 0$, satisfies $U(\bar{q}) \geq u$ by continuity, and costs at most L. This contradicts the definition of $e^R(p_{-n}, u)$. Hence $L = e^R(p_{-n}, u)$, and the fundamental theorem of calculus on $[p_n, t]$ with $t \to \infty$ gives the improper integral.

Finally, if good n is normal, $h_n(p_{-n}, t, u)$ is nondecreasing in u (the proof of Proposition 5.12). Since $u^1 \geq u^0$, the integrand at u^1 is at least the integrand at u^0 for every t, and $EV \leq CV$. □

The restricted expenditure function of Lemma 10.5 gives the same value as an integral over quantities.

Corollary 10.8 (The value of a new good along the quantity axis)**.** *Let* $q_n^1 = h_n(p, u^1)$, *and suppose the conditions of Lemma 10.5(b) hold at* $u = u^1$ *for every* $z \in [0, q_n^1]$. *Then*

$$CV = \int_0^{q_n^1} \left[\tilde{p}_n(p_{-n}, u^1, z) - p_n\right] \mathrm{d}z. \tag{10.9}$$

Proof. By Lemma 10.5(a) and the duality identity (10.1),

$$e^R(p_{-n}, u^1) = \tilde{e}(p, u^1, 0), \qquad y = e(p, u^1) = \tilde{e}(p, u^1, q_n^1).$$

Substituting both into (10.6) gives

$$CV = \tilde{e}(p, u^1, 0) - \tilde{e}(p, u^1, q_n^1) = -\int_0^{q_n^1} \frac{\partial \tilde{e}(p, u^1, z)}{\partial z} \mathrm{d}z.$$

Inserting (10.5) gives (10.9). □

The integrand is the height of the compensated inverse demand curve above the price. Each unit before the last is worth more to the consumer than she pays for it, and the corollary adds up these surpluses. Proposition 10.7 adds up the same area along the price axis.

The value of a new good is therefore the area to the left of its compensated demand curve, between the price at which it sells and its virtual price. Figure 10.1 shows this area together with a rectangle that reappears in Proposition 10.11. The formula needs the compensated demand curve over a range of prices at which the good has never sold. Section 10.3 studies what this means for estimation.

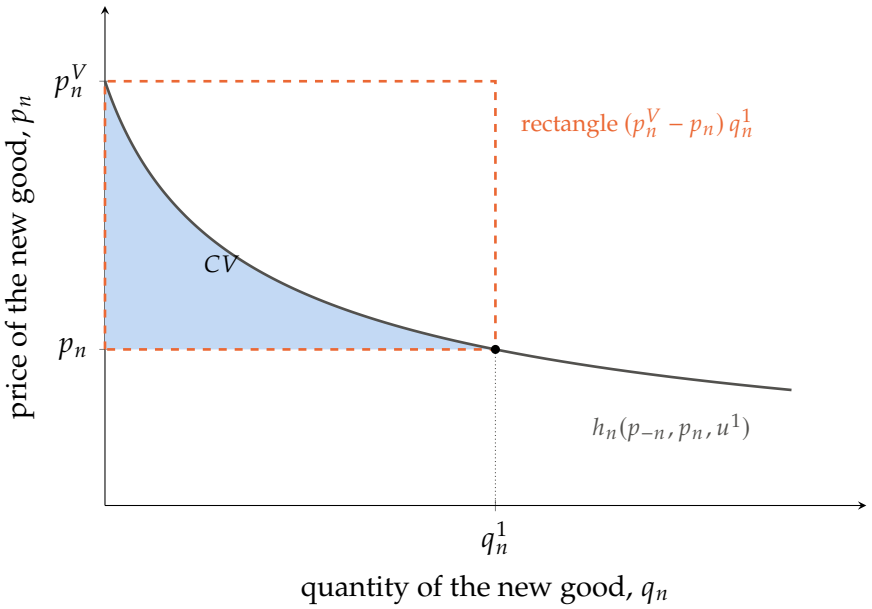

Figure 10.1: The value of a new good. The curve is a compensated demand curve at the period-1 utility u^1. The good sells at p_n, where the consumer buys q_n^1, and demand reaches zero at the virtual price p_n^V. The shaded area is the compensating variation of Proposition 10.7. The dashed rectangle is the Paasche bound of Proposition 10.11. The curve drawn is $h_n = \frac{1-\ln p_n}{p_n}$, so that $p_n = q_n^1 = 1$ and $p_n^V = e$. The shaded area is 0.50 and the rectangle is 1.72.

Remark 10.9 (Other prices, Marshallian surplus and Willig's approximation). If the prices of the other goods also change, from p_{-n}^0 to p_{-n}^1, the definition gives $CV = e^R(p_{-n}^0, u^1) - e(p^1, u^1) = e\left(p_{-n}^0, p_n^V(p_{-n}^0, u^1), u^1\right) - y$. This is equation (4) of Hausman (1997) with all prices allowed to move, and Section 10.4.1 decomposes it. The *Marshallian surplus* of the new good is $CS = \int_{p_n}^{p_n^M} q_n(p_{-n}, t, y)\, \mathrm{d}t$. The argument of Proposition 5.12 applied on $[p_n, \infty)$ gives $EV \leq CS \leq CV$ for a normal good. Willig (1976) shows that the proportional gap $\frac{CV-CS}{CS}$ is approximately $\frac{\bar{\varepsilon}_y\, CS}{2y}$ when the surplus is a small fraction of income, where $\bar{\varepsilon}_y$ is the income elasticity of demand. His bounds replace $\bar{\varepsilon}_y$ by its smallest and largest values over the price path. For a new good this path ends where the quantity reaches zero. If $\frac{\partial q_n}{\partial y}$ stays positive along the way, the income elasticity $\frac{\partial q_n}{\partial y}\frac{y}{q_n}$ grows without bound, and the upper bound loses its force. Example 10.20 shows that the exact calculation is easy in any case.

Deaton and Muellbauer (1980b, Section 7.4, pp. 184–188) give a textbook account of these welfare measures. They define both variations as differences of cost functions (their eqs. 4.1–4.2, p. 186). Our CV is their compensating variation for the move from p^1 back to p^0, the withdrawal

of the good. They also explain why a Marshallian area is not exact in general. It treats the marginal utility of income as constant, and that cannot hold for all price changes (p. 185). For one good, the Hicksian and Marshallian demands coincide when utility is quasi-linear in another good (Exercise 7.21, p. 189).

10.2.4 The cost-of-living index and the new-goods bias

A cost-of-living index asks how much more, or less, income a consumer needs in period 1 to be as well off as in period 0 (Hausman, 1997, p. 209). Pollak (1989) develops the theory.

Definition 10.10 (Konüs cost-of-living index)**.** The *cost-of-living index* between price vectors p^0 and p^1 at reference utility u is

$$P(p^0, p^1, u) = \frac{e(p^1, u)}{e(p^0, u)}. \tag{10.10}$$

The index depends on the reference utility unless preferences are homothetic. Deaton and Muellbauer (1980b, Section 7.1, pp. 170–173) develop the index from the cost function. They show that homotheticity is both necessary and sufficient for the index to be the same at every reference utility (p. 173). With a new good the period-0 cost of reaching u is $e^R(p^0_{-n}, u)$, which by Lemma 10.3(c) equals $e(p^0_{-n}, p^V_n, u)$. The period-0 price vector is therefore completed by the virtual price, $p^0 = (p^0_{-n}, p^V_n(p^0_{-n}, u))$. With the period-1 reference and unchanged other prices,

$$P(p^0, p^1, u^1) = \frac{e(p_{-n}, p_n, u^1)}{e(p_{-n}, p^V_n, u^1)} = \frac{y}{y + CV} < 1. \tag{10.11}$$

The cost of living falls when a good is introduced. In the notation of Lemma 10.5, the index is $\frac{e(p,u^1)}{\tilde{e}(p,u^1,0)}$. Its reciprocal is the ratio of restricted to unrestricted cost, which Deaton and Muellbauer (1980b, Exercise 7.16, p. 184) propose as a measure of the cost of a ration. Hausman (1997, p. 212) writes y^* for $e(p_{-n}, p^V_n, u^1)$ and reports the reciprocal $\frac{y^*}{y}$, the cost of the period-1 standard of living without the good relative to its cost with the good.

Statistical agencies compute *matched-model* indexes. They compare the prices of goods sold in both periods and add a new good to the sample only after it has been introduced. Hausman (1997, p. 210, n. 1) notes that this procedure misses the gain at introduction, the welfare difference relative to a base period in which the good was not sold. When the other prices do not change, every matched-model index equals one between periods 0 and 1, whatever its formula. Comparing with (10.11),

$$\frac{P^{MM}}{P(p^0, p^1, u^1)} - 1 = \frac{CV}{y}, \tag{10.12}$$

where $P^{MM} = 1$ is the matched-model index. The proportional overstatement of the price index equals the value of the new good as a share of income. Bresnahan (1997, pp. 237–238) puts the point in terms of timing. Official indexes link a new good in only after it has been sold for a while. They treat it as irrelevant in its early stages, and the later the link, the larger the understatement of its value.

10.2.5 Index-number bounds

Index numbers built from observed prices and quantities bound the exact index. Let q^0 and q^1 be the bundles bought in periods 0 and 1, with $q^0_n = 0$ and $q^1_n > 0$. Complete the period-0

prices with the Hicksian virtual price at the period-1 utility, $p_n^0 = p_n^V(p_{-n}, u^1)$. The *Laspeyres* and *Paasche* indexes are

$$P_L = \frac{(p^1)^\top q^0}{(p^0)^\top q^0}, \qquad P_P = \frac{(p^1)^\top q^1}{(p^0)^\top q^1}. \tag{10.13}$$

The Laspeyres index does not need p_n^0, because $q_n^0 = 0$. We write $w_n = \frac{p_n q_n^1}{y}$ for the period-1 budget share of the new good.

Proposition 10.11 (Index-number bounds for a new good)**.** *Let Assumption 10.1 hold, hold p_{-n} and y fixed, and suppose $p_n^V = p_n^V(p_{-n}, u^1)$ is finite.*

(a) The Laspeyres index records no change: $P_L = 1$.

(b) The Paasche index is $P_P = \frac{y}{y + (p_n^V - p_n)q_n^1}$.

(c) The exact index lies between them, $P_P \le P(p^0, p^1, u^1) \le P_L$. Equivalently,

$$0 \le CV \le (p_n^V - p_n)\, q_n^1. \tag{10.14}$$

(d) In share form, $\frac{CV}{y} \le w_n\left(\frac{p_n^V}{p_n} - 1\right)$.

Proof. (a) Since $q_n^0 = 0$ and the other prices are unchanged, $(p^1)^\top q^0 = \sum_{j \ne n} p_j q_j^0 = (p^0)^\top q^0$.

(b) The numerator is period-1 spending, $(p^1)^\top q^1 = y$. The denominator is

$$(p^0)^\top q^1 = \sum_{j \ne n} p_j q_j^1 + p_n^V q_n^1 = y - p_n q_n^1 + p_n^V q_n^1 = y + (p_n^V - p_n) q_n^1.$$

(c) By Proposition 10.7, $CV = \int_{p_n}^{p_n^V} h_n(p_{-n}, t, u^1)\, \mathrm{d}t$. Hicksian demand is nonnegative and nonincreasing in its own price, and $h_n(p_{-n}, p_n, u^1) = q_n^1$ by (10.1). Hence, for every $t \in [p_n, p_n^V]$,

$$0 \le h_n(p_{-n}, t, u^1) \le q_n^1.$$

Integrating over $[p_n, p_n^V]$ gives (10.14). Substituting the bounds into (10.11) gives $P_P \le P \le 1 = P_L$.

(d) Divide (10.14) by y and write $(p_n^V - p_n)q_n^1 = p_n q_n^1 \left(\frac{p_n^V}{p_n} - 1\right)$. □

The Laspeyres bound is the matched-model index of Section 10.2.4, and it says nothing. The Paasche bound is the rectangle in Figure 10.1. Hausman (1997, p. 212) describes the index-number approach of Hicks and Rothbarth as measuring the change in real income by the ratio $\frac{p_n^V q_n}{p_n q_n}$. The ratio compares the value of the new good's purchases at the virtual price with their value at the actual price. Its numerator minus its denominator is the rectangle. Hausman calls the approach approximately correct but notes that it ignores the income compensation needed to stay on the indifference curve. Proposition 10.11 adds that the rectangle is an upper bound. Part (d) is the logic behind the rule of thumb that Section 10.5 examines: the new good's share times the proportional gap between its virtual and actual prices.

Corollary 10.12 (Linear, convex and concave demand)**.** *Under the conditions of Proposition 10.11, if $h_n(p_{-n}, t, u^1)$ is linear in t on $[p_n, p_n^V]$, then $CV = \frac{1}{2}(p_n^V - p_n)q_n^1$. If it is convex on that interval, $CV \le \frac{1}{2}(p_n^V - p_n)q_n^1$. If it is concave, $CV \ge \frac{1}{2}(p_n^V - p_n)q_n^1$.*

Proof. The chord joining (p_n, q_n^1) and $(p_n^V, 0)$ is $\ell(t) = q_n^1 \frac{p_n^V - t}{p_n^V - p_n}$, and its integral over $[p_n, p_n^V]$ is the triangle $\frac{1}{2}(p_n^V - p_n)q_n^1$. A linear function equals its chord. A convex function lies below its chord between the two endpoints, and a concave function lies above it. Integrating gives the three claims. □

Remark 10.13 (The Konüs inequalities and a second-order view). Part (c) of Proposition 10.11 is a case of two inequalities due to Konüs (1939). Deaton and Muellbauer (1980b, Section 7.1, eqs. 1.3–1.4, p. 172) give the standard proof. The bundle q^1 is one way to reach u^1 at prices p^0, so it costs at least the minimum, $(p^0)^\top q^1 \geq e(p^0, u^1)$. Since $(p^1)^\top q^1 = e(p^1, u^1)$,

$$P_P = \frac{(p^1)^\top q^1}{(p^0)^\top q^1} \leq \frac{e(p^1, u^1)}{e(p^0, u^1)} = P(p^0, p^1, u^1).$$

The same argument with q^0 at prices p^1 gives $P_L \geq P(p^0, p^1, u^0)$. In general the two bounds apply at different reference utilities, so the true index need not lie between them (p. 172). With a new good the Laspeyres index equals one. Lemma 10.3(a) puts the true index below one at every reference utility. This is why part (c) can bracket the index at the single reference u^1.

Deaton and Muellbauer also show that the Laspeyres index is a first-order approximation to the true index (eqs. 1.6–1.7, p. 174). For a new good the first-order term is zero. Expand $t \mapsto e(p_{-n}, t, u^1)$ to second order around p_n^V. By Shephard's lemma its first derivative there is $h_n(p_{-n}, p_n^V, u^1) = 0$, so

$$CV = e\left(p_{-n}, p_n^V, u^1\right) - e\left(p_{-n}, p_n, u^1\right) \approx -\frac{1}{2}\frac{\partial h_n}{\partial p_n}\left(p_n^V - p_n\right)^2.$$

The value of a new good is thus a pure substitution effect, which an index with fixed base weights cannot capture. If h_n is linear on $[p_n, p_n^V]$, the expansion is exact. Substituting $-\frac{\partial h_n}{\partial p_n} = \frac{q_n^1}{p_n^V - p_n}$ then gives $CV = \frac{1}{2}(p_n^V - p_n)q_n^1$, as in Corollary 10.12. Their first-order approximation to a compensating variation, the reference quantities times the price changes (eq. 4.3, p. 187), is here the Paasche rectangle $(p_n^V - p_n)q_n^1$.

10.2.6 Separability: which demand curves are needed

Applying Proposition 10.7 seems to require the whole expenditure function. Hausman (1997, p. 213, n. 7) argues that under the usual separability assumptions only the demand curve for the new good must be estimated. The next result makes the claim precise for homothetic separability, the first case of Gorman's two-stage budgeting theorem (Proposition 5.36).

Assumption 10.14 (Homothetic separability)**.** The goods are split into a group N that contains good n and the remaining goods. Utility is $U(q) = F(q_{-N}, \phi(q_N))$, where F is strictly increasing in its last argument and the subutility ϕ is continuous, increasing, quasi-concave and homogeneous of degree one.

Let $P_N(p_N) = \min\{p_N^\top q_N : \phi(q_N) \geq 1\}$ be the unit cost of the subutility. It is the exact price index of the group. Let $w_{n|N}(p_N) = \frac{\partial \ln P_N}{\partial \ln p_n}$ be the within-group budget share of good n, which depends only on the prices of the group.

Proposition 10.15 (New goods in a separable group)**.** *Under Assumptions 10.1 and 10.14, the following hold.*

(a) *The expenditure function has the form* $e(p,u) = E(p_{-N}, P_N(p_N), u)$*, where* E *is the expenditure function for the goods outside* N *and a composite good* $Q_N = \phi(q_N)$ *with price* P_N*.*

(b) *Fix* p_{-n} *and* u*. Suppose the Hicksian demand for the composite is positive at every* p_n *below the smallest* p_n *at which* $\frac{\partial P_N}{\partial p_n} = 0$*. Then the Hicksian virtual price of good* n *is that smallest* p_n*, and it depends only on the other prices of group* N*.*

(c) *Let* $P_N^R = P_N(p_{N\setminus n}, p_n^V)$ *be the group index without the new good. Then*

$$\ln \frac{P_N^R}{P_N} = \int_{p_n}^{p_n^V} \frac{w_{n|N}(p_{N\setminus n}, t)}{t}\, \mathrm{d}t, \tag{10.15}$$

$$CV = E(p_{-N}, P_N^R, u^1) - E(p_{-N}, P_N, u^1) = \int_{P_N}^{P_N^R} H_N(p_{-N}, \tau, u^1)\, \mathrm{d}\tau, \tag{10.16}$$

where $H_N = \frac{\partial E}{\partial P_N}$ *is the Hicksian demand for the composite good.*

Proof. (a) Fix u and minimize cost in two steps. Given a level Q_N of the composite, the cheapest bundle with $\phi(q_N) \geq Q_N$ costs $P_N(p_N)\, Q_N$, because ϕ is homogeneous of degree one. The consumer then chooses q_{-N} and Q_N to minimize $p_{-N}^{\top} q_{-N} + P_N Q_N$ subject to $F(q_{-N}, Q_N) \geq u$. The value of this problem is $E(p_{-N}, P_N, u)$.

(b) By Shephard's lemma and the chain rule,

$$h_n(p,u) = \frac{\partial E}{\partial P_N} \cdot \frac{\partial P_N}{\partial p_n} = H_N(p_{-N}, P_N, u)\, \frac{\partial P_N}{\partial p_n}.$$

By hypothesis $H_N > 0$ below the first zero of $\frac{\partial P_N}{\partial p_n}$, so $h_n > 0$ there. At that zero $h_n = 0$. The virtual price is therefore the first zero of $\frac{\partial P_N}{\partial p_n}$, a condition on p_N alone.

(c) Shephard's lemma applied to the unit cost gives $\frac{\partial \ln P_N}{\partial p_n} = \frac{w_{n|N}}{p_n}$. Integrating in p_n from p_n to p_n^V with the other group prices fixed gives (10.15). For (10.16), (10.7) and part (a) give $CV = E(p_{-N}, P_N^R, u^1) - E(p_{-N}, P_N, u^1)$. Shephard's lemma for E and the fundamental theorem of calculus give the integral. □

The proposition splits the calculation into two stages. The change in the group index needs only the new good's within-group share as a function of its own price, at the observed prices of the other goods in the group. In that sense Hausman's claim holds. Part (b) needs its positivity condition. If the whole group can leave consumption, H_N can reach zero before $\frac{\partial P_N}{\partial p_n}$ does. The Hicksian virtual price is then the lower price at which H_N vanishes, and it can depend on u and on prices outside the group. Part (c) still holds if we evaluate P_N^R at the first zero of $\frac{\partial P_N}{\partial p_n}$, because E does not change with P_N once $H_N = 0$. Converting the group index change into money needs the demand for the group as a whole. If compensated group spending X_N stays roughly constant over the relevant range, then $CV \approx X_N \ln \frac{P_N^R}{P_N}$. The index used at the upper stage must be the exact group index with the virtual price inserted for the period before the introduction. A Stone or matched-model index of the old goods records no change. Hausman (1997, p. 221) rejects homotheticity of brand choice in his cereal data. For groups that are not homothetic, two-stage budgeting holds only approximately or under the generalized Gorman polar form of Definition 5.35. Gorman (1959) gives the conditions.

Deaton and Muellbauer (1980b, Section 5.2, pp. 128–133) give a textbook account of these conditions. The upper stage allocates income across groups G through group cost functions $c_G(u_G, p_G)$, subject to $\sum_G c_G(u_G, p_G) = y$ (their eqs. 2.11–2.14, p. 130). Gorman's first case has group cost functions of the form $\theta_G(u_G)\, b_G(p_G)$, which is Assumption 10.14 (eq. 2.15, p. 130). His second case is the generalized polar form with utility additive across groups (eqs. 2.16–2.17, pp. 130–131). Weak separability also restricts substitution across groups. For good n in group N and good j in another group H, the compensated cross-price effect is

$$\frac{\partial h_n}{\partial p_j} = m_{NH}\, \frac{\partial q_n}{\partial y}\, \frac{\partial q_j}{\partial y},$$

where the scalar m_{NH} depends only on the two groups (eq. 2.8, p. 128). A new good therefore reaches the demand for a good in another group only through the expenditure allocated to that group.

10.2.7 The CES variety-adjusted price index

Constant elasticity of substitution (CES) preferences give the best known correction of a price index for new varieties (Feenstra, 1994). Let $\mathcal{I}_t$ be the set of varieties available in period t, with taste parameters $a_j > 0$. The CES unit expenditure function is

$$c(p; \mathcal{I}) = \Big(\sum_{j \in \mathcal{I}} a_j p_j^{1-\eta} \Big)^{\frac{1}{1-\eta}}, \qquad \eta > 1, \tag{10.17}$$

and preferences are homothetic, so $e(p, u) = c(p; \mathcal{I})\, u$. Here η is the elasticity of substitution. Hausman (1997) writes the CES utility function with a parameter ρ, and $\eta = \frac{1}{1-\rho}$. Chapter 5 writes σ for η, a symbol this chapter keeps for the nesting parameter.

Shephard's lemma gives the expenditure shares. Differentiating (10.17),

$$\frac{\partial c}{\partial p_j} = \frac{1}{1-\eta} \Big(\sum_k a_k p_k^{1-\eta} \Big)^{\frac{1}{1-\eta}-1} (1-\eta) a_j p_j^{-\eta} = c^{\eta} a_j p_j^{-\eta}.$$

The share of variety j is therefore

$$w_j = \frac{p_j}{c} \frac{\partial c}{\partial p_j} = a_j \Big(\frac{p_j}{c} \Big)^{1-\eta} = \frac{a_j p_j^{1-\eta}}{\sum_{k \in \mathcal{I}} a_k p_k^{1-\eta}}. \tag{10.18}$$

The first step handles a fixed set of varieties. For two positive numbers let $\mathcal{L}(a, b) = \frac{a-b}{\ln a - \ln b}$ if $a \neq b$ and $\mathcal{L}(a, a) = a$. This is the *logarithmic mean*.

Lemma 10.16 (Sato-Vartia index, Sato, 1976; Vartia, 1976)**.** *Let $\mathcal{I}$ be a set of varieties available in periods $t-1$ and t, with the same a_j in both periods. Let $\tilde{w}_{jt}$ be the share of variety j in period-t spending on $\mathcal{I}$. Then*

$$\frac{c(p_t; \mathcal{I})}{c(p_{t-1}; \mathcal{I})} = P_{\mathcal{I}}^{SV} \equiv \prod_{j \in \mathcal{I}} \Big(\frac{p_{jt}}{p_{j,t-1}} \Big)^{\omega_j}, \qquad \omega_j = \frac{\mathcal{L}(\tilde{w}_{jt}, \tilde{w}_{j,t-1})}{\sum_{k \in \mathcal{I}} \mathcal{L}(\tilde{w}_{kt}, \tilde{w}_{k,t-1})}. \tag{10.19}$$

Proof. Write $c_t = c(p_t; \mathcal{I})$. Taking logs of (10.18) for the set $\mathcal{I}$ gives $\ln \tilde{w}_{jt} = \ln a_j + (1-\eta)(\ln p_{jt} - \ln c_t)$. Differencing over time removes $\ln a_j$:

$$\Delta \ln \tilde{w}_j = (1-\eta)\big(\Delta \ln p_j - \Delta \ln c\big), \qquad j \in \mathcal{I}.$$

Solving for the change in the unit cost gives, for every j,

$$\Delta \ln c = \Delta \ln p_j - \frac{1}{1-\eta}\Delta \ln \tilde{w}_j.$$

Multiply by ω_j and sum over j. The weights sum to one, so

$$\Delta \ln c = \sum_{j \in \mathcal{I}} \omega_j \Delta \ln p_j - \frac{1}{1-\eta} \sum_{j \in \mathcal{I}} \omega_j \Delta \ln \tilde{w}_j.$$

By the definition of the logarithmic mean, $\mathcal{L}(\tilde{w}_{jt}, \tilde{w}_{j,t-1})\Delta \ln \tilde{w}_j = \tilde{w}_{jt} - \tilde{w}_{j,t-1}$. The shares sum to one in each period, so $\sum_j \omega_j \Delta \ln \tilde{w}_j$ is proportional to $\sum_j (\tilde{w}_{jt} - \tilde{w}_{j,t-1}) = 0$. The second term vanishes, and exponentiating gives (10.19). □

The Sato-Vartia index uses only observed prices and quantities, and it is exact for CES preferences without knowledge of η. New varieties enter through a second factor. Let $\mathcal{I} \subseteq \mathcal{I}_{t-1} \cap \mathcal{I}_t$ be a nonempty set of varieties sold in both periods, with unchanged a_j. Let λ_t be the share of period-t spending that goes to $\mathcal{I}$, and λ_{t-1} the corresponding share in period $t-1$:

$$\lambda_t = \frac{\sum_{j \in \mathcal{I}} p_{jt} q_{jt}}{\sum_{j \in \mathcal{I}_t} p_{jt} q_{jt}}, \qquad \lambda_{t-1} = \frac{\sum_{j \in \mathcal{I}} p_{j,t-1} q_{j,t-1}}{\sum_{j \in \mathcal{I}_{t-1}} p_{j,t-1} q_{j,t-1}}.$$

Proposition 10.17 (CES index with changing varieties, Feenstra, 1994)**.** *Under CES preferences* (10.17),

$$\frac{c(p_t; \mathcal{I}_t)}{c(p_{t-1}; \mathcal{I}_{t-1})} = P_{\mathcal{I}}^{SV} \left(\frac{\lambda_t}{\lambda_{t-1}}\right)^{\frac{1}{\eta-1}}. \tag{10.20}$$

Proof. By (10.17), $\sum_{j \in \mathcal{I}} a_j p_{jt}^{1-\eta} = c(p_t; \mathcal{I})^{1-\eta}$ and $\sum_{j \in \mathcal{I}_t} a_j p_{jt}^{1-\eta} = c(p_t; \mathcal{I}_t)^{1-\eta}$. Summing (10.18) over $j \in \mathcal{I}$ gives the share of the common varieties,

$$\lambda_t = \frac{c(p_t; \mathcal{I})^{1-\eta}}{c(p_t; \mathcal{I}_t)^{1-\eta}}.$$

Solving for the full unit cost,

$$c(p_t; \mathcal{I}_t) = c(p_t; \mathcal{I})\, \lambda_t^{-\frac{1}{1-\eta}} = c(p_t; \mathcal{I})\, \lambda_t^{\frac{1}{\eta-1}}.$$

The same steps hold in period $t-1$. Taking the ratio of the two periods,

$$\frac{c(p_t; \mathcal{I}_t)}{c(p_{t-1}; \mathcal{I}_{t-1})} = \frac{c(p_t; \mathcal{I})}{c(p_{t-1}; \mathcal{I})} \left(\frac{\lambda_t}{\lambda_{t-1}}\right)^{\frac{1}{\eta-1}}.$$

Lemma 10.16 replaces the first ratio by $P_{\mathcal{I}}^{SV}$. □

A matched-model index computed on the common varieties is $P_{\mathcal{I}}^{SV}$. The second factor is the correction for changing variety. When new varieties take a larger share of spending than the varieties that disappear, $\lambda_t < \lambda_{t-1}$, and the correction lowers the index. The correction needs one parameter, η. A low elasticity of substitution means a large correction, because the new varieties are then poor substitutes for the old ones.

Corollary 10.18 (One new variety)**.** *Suppose $\mathcal{I}_t = \mathcal{I}_{t-1} \cup \{n\}$, the other prices do not change, and the new variety takes the share w_n of period-t spending. Then*

$$\frac{c(p_t;\mathcal{I}_t)}{c(p_{t-1};\mathcal{I}_{t-1})} = (1-w_n)^{\frac{1}{\eta-1}}, \qquad \frac{CV}{y} = (1-w_n)^{-\frac{1}{\eta-1}} - 1, \qquad \frac{EV}{y} = 1-(1-w_n)^{\frac{1}{\eta-1}}. \tag{10.21}$$

For small w_n both measures are close to $\frac{w_n}{\eta-1}$.

Proof. Take $\mathcal{I} = \mathcal{I}_{t-1}$. Unchanged prices give $P_{\mathcal{I}}^{SV} = 1$, and $\lambda_{t-1} = 1$ and $\lambda_t = 1 - w_n$. Equation (10.20) gives the first formula. Write $c_0 = c(p_{t-1};\mathcal{I}_{t-1})$ and $c_1 = c(p_t;\mathcal{I}_t)$. Period-$t$ income is $y = c_1 u^1$, and the consumer would need $c_0 u^1$ to reach u^1 without the new variety. Hence $\frac{CV}{y} = \frac{c_0 u^1 - c_1 u^1}{c_1 u^1} = \frac{c_0}{c_1} - 1$. Similarly, $y = c_0 u^0$ and $\frac{EV}{y} = \frac{c_0 u^0 - c_1 u^0}{c_0 u^0} = 1 - \frac{c_1}{c_0}$. The approximation is the first-order expansion of $(1-w_n)^{\pm\frac{1}{\eta-1}}$ around $w_n = 0$. □

The formula for CV is the removal formula of Proposition 5.48(a) read in reverse. Two features stand out. First, CES demand is positive at every price, so the virtual price of the new variety is infinite. The gain is nonetheless finite, because the CES demand curve approaches the price axis fast enough. Second, the gain depends only on the new variety's share and on η. Nothing in the formula measures how close the new variety is to particular old ones. Hausman (1997, p. 230) draws the conclusion that the CES, like the logit, "will tend to overvalue variety" because it treats all goods symmetrically.

Remark 10.19 (CES and logit). The parallel with the logit model is exact. Section 10.7 shows that adding a product with post-introduction share s_n to a logit market raises expected consumer surplus by $-\frac{1}{\alpha}\ln(1-s_n)$ per consumer. This is again a function of one share and one parameter (Small and Rosen, 1981; McFadden, 1981). Anderson et al. (1992) explain why, and Hausman (1997, n. 29) cites them. Suppose each consumer buys one variety and spends all income on it, with conditional indirect utility $\ln y - \ln p_j + \theta_j + \mu\epsilon_{ij}$ and type-I extreme value ϵ_{ij}. The logit choice probability is $\mathbb{P}_j = \frac{e^{\frac{\theta_j}{\mu}} p_j^{-\frac{1}{\mu}}}{\sum_k e^{\frac{\theta_k}{\mu}} p_k^{-\frac{1}{\mu}}}$. Each buyer of j purchases $\frac{y}{p_j}$ units, so expected demand per consumer is

$$\frac{y\mathbb{P}_j}{p_j} = \frac{y\, e^{\frac{\theta_j}{\mu}} p_j^{-\frac{1}{\mu}-1}}{\sum_k e^{\frac{\theta_k}{\mu}} p_k^{-\frac{1}{\mu}}}.$$

This is the CES demand $\frac{y\, a_j p_j^{-\eta}}{\sum_k a_k p_k^{1-\eta}}$ implied by (10.18), with $\eta = 1 + \frac{1}{\mu}$ and $a_j = e^{\frac{\theta_j}{\mu}}$. Expected maximum utility is $\ln y + \mu \ln \sum_k a_k p_k^{-\frac{1}{\mu}}$ plus a constant. Since $\mu(1-\eta) = -1$, this equals $\ln y - \ln c(p;\mathcal{I})$ plus a constant, the CES indirect utility in logs. In both models each variety carries its own taste shock, and the value of variety is built into the functional form.

As an illustration, take two numbers from Hausman (1997). His reported CES elasticity is $\eta = 2.13$ (p. 231). His printed $\hat{\rho} = 0.580$ would imply 2.38, an inconsistency that Section 10.5.9 discusses. In addition, Apple-Cinnamon Cheerios had a 6.19 percent share of the family segment of ready-to-eat cereal in 1992 (Table 5.2). Treat the segment as a CES group. Corollary 10.18 then gives our computation $(1 - 0.0619)^{\frac{1}{1.13}} = 0.945$. The introduction lowers the segment's cost of living by 5.5 percent, and the compensating variation is 5.8 percent of segment spending. Hausman reports that his own CES specification gives a consumer surplus about three times as large as his preferred estimate (p. 231). Section 10.5 returns to the comparison.

10.3 Functional form, extrapolation and bounds

The exact measures of Section 10.2 integrate the compensated demand curve from the observed price to the virtual price. This section asks how much of that integral the data can deliver. We show that the answer depends on the shape assumed beyond the data, and we compare three standard shapes. We then explain how to recover the exact measure from an estimated Marshallian demand curve and derive a lower bound that needs only convexity.

10.3.1 The extrapolation problem

Prices in a sample vary within a band around the observed price. In Hausman's cereal data the variation is on the order of 50 percent, and prices as high as the estimated virtual price are never observed (Hausman, 1997, p. 228). His virtual price is about twice the actual price. The part of the area in Figure 10.1 that lies above the highest observed price is then pinned down by the functional form alone.

Berry and Pakes (2007, Section 1) make the general point. We rarely see demand for a new product at prices high enough to estimate the reservation prices of many consumers without parametric assumptions. A demand system in product space obtains the gains of inframarginal buyers by extending the curve estimated at low prices into a higher price range. That extension can be very sensitive to the model. A demand system in characteristics space also uses the price variation of products with similar characteristics. It therefore uses more information, but similar problems arise. Section 10.7 develops the characteristics approach.

The problem can be stated as a question of identification. Suppose the data reveal $h_n(p_{-n}, t, u^1)$ for $t \in [p_n, \bar{p}]$, with $\bar{p}$ the highest observed price and $h_n(p_{-n}, \bar{p}, u^1) > 0$. Split the compensating variation at $\bar{p}$:

$$CV = \underbrace{\int_{p_n}^{\bar{p}} h_n(p_{-n}, t, u^1)\, \mathrm{d}t}_{\text{supported by data}} + \underbrace{\int_{\bar{p}}^{p_n^V} h_n(p_{-n}, t, u^1)\, \mathrm{d}t}_{\text{extrapolated}}. \tag{10.22}$$

Any nonincreasing extension of the demand curve beyond $\bar{p}$ agrees with the data. A curve that stays flat at $h_n(p_{-n}, \bar{p}, u^1)$ over a long interval before dropping to zero makes the second term as large as we like. Without restrictions on shape, the data identify only the lower bound given by the first term. Bounds that are more useful need restrictions, and point estimates need a functional form.

10.3.2 Three canonical shapes

Fix an observed point (p, q) on the demand curve for good n. Let $\varepsilon = -\frac{p\,q'(p)}{q} > 0$ be the elasticity of demand at that point, written as a positive number as in the rest of the book. We compare three demand curves that share the point and the slope. To keep the formulas transparent we integrate the demand curve as drawn, and write CS for the area.

Linear demand. Let $q(t) = a - bt$. Matching the slope gives $b = \frac{\varepsilon q}{p}$, and matching the point gives $a = q + bp$. Demand reaches zero at

$$p^V = \frac{a}{b} = p + \frac{q}{b} = p\Big(1 + \frac{1}{\varepsilon}\Big).$$

The area is a triangle with height $p^V - p = \frac{q}{b}$ and base q:

$$CS = \int_p^{\frac{a}{b}} (a - bt)\,\mathrm{d}t = \frac{(a - bp)^2}{2b} = \frac{q^2}{2b} = \frac{pq}{2\varepsilon}.$$

AIDS demand with $\beta_n = 0$. In the almost ideal demand system the budget share of good n is linear in log prices. With $\beta_n = 0$ and the other prices fixed, $w(t) = w + \gamma \ln \frac{t}{p}$, where w is the observed share and $\gamma = \gamma_{nn}$ (Section 5.3). Quantity is $q(t) = \frac{y\,w(t)}{t}$. The budget share does not depend on income, but quantity has income elasticity one. Since $\ln q = \ln y + \ln w(t) - \ln t$, the elasticity at p is $\varepsilon = 1 - \frac{\gamma}{w}$. Hence $\gamma = -w(\varepsilon - 1)$, which is negative when $\varepsilon > 1$. The share reaches zero where $\ln \frac{p^V}{p} = \frac{w}{-\gamma}$, so

$$p^V = p\,\exp\Big(\frac{1}{\varepsilon - 1}\Big).$$

Substituting $x = \ln \frac{t}{p}$ and writing $x^V = \ln \frac{p^V}{p} = \frac{w}{-\gamma}$, the area is

$$CS = \int_p^{p^V} \frac{y\,w(t)}{t}\,\mathrm{d}t = y\int_0^{x^V} (w + \gamma x)\,\mathrm{d}x = y\Big(w\,x^V + \frac{\gamma\,(x^V)^2}{2}\Big) = \frac{y\,w^2}{2(-\gamma)} = \frac{pq}{2(\varepsilon - 1)}.$$

The last step uses $yw = pq$ and $-\gamma = w(\varepsilon - 1)$. With $\beta_n = 0$ the area also gives the exact measure through $\ln(1 + \frac{CV}{y}) = \frac{CS}{y}$, which is Proposition 5.48(c).

Constant-elasticity demand. Let $q(t) = At^{-\varepsilon}$ with $A = qp^{\varepsilon}$. Demand is positive at every price, so $p^V = \infty$. For $\varepsilon > 1$,

$$CS = \int_p^{\infty} At^{-\varepsilon}\,\mathrm{d}t = \frac{Ap^{1-\varepsilon}}{\varepsilon - 1} = \frac{pq}{\varepsilon - 1}.$$

For $\varepsilon \le 1$ the integral diverges.

Table 10.1 and Figure 10.2 collect the three cases. Three lessons follow. First, curves that agree on the level and slope of demand at the observed price give very different values. At $\varepsilon = 2$ the constant-elasticity value is four times the linear one. Second, an infinite virtual price does not imply an infinite gain. Third, both the AIDS and the constant-elasticity values explode as ε approaches one, while the linear value stays finite. The ratio of the constant-elasticity value to the AIDS value is two at every elasticity. Hausman (1997, p. 231) finds a ratio of about three between his CES and AIDS estimates.

Table 10.1: Three demand curves through the same point

	General point (p, q), elasticity ε		$p = q = 1$, $\varepsilon = 2$	
Demand curve	Virtual price	Area CS	Virtual price	Area CS
Linear	$p\left(1 + \frac{1}{\varepsilon}\right)$	$\frac{pq}{2\varepsilon}$	1.50	0.25
AIDS with $\beta_n = 0$	$p \exp\left(\frac{1}{\varepsilon - 1}\right)$	$\frac{pq}{2(\varepsilon - 1)}$	2.72	0.50
Constant elasticity	∞	$\frac{pq}{\varepsilon - 1}$	∞	1.00

Notes: Each curve passes through the observed point (p, q) with own-price elasticity $\varepsilon > 1$, written as a positive number. The area is the integral of the demand curve from p to the virtual price. The AIDS and constant-elasticity formulas require $\varepsilon > 1$. Derivations are in Section 10.3.2, and the numbers come from `figures/ch10/src/part1_checks.py`.

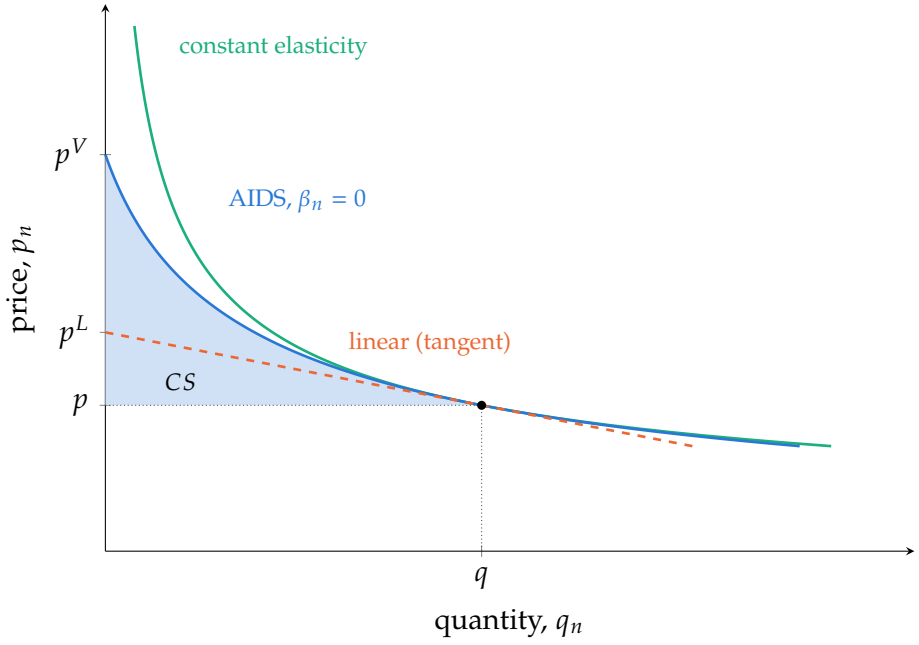

Figure 10.2: Extrapolating demand beyond the data. All three curves pass through the observed point $(p, q) = (1, 1)$ with own-price elasticity 2. The linear curve is the tangent at the observed point and reaches zero at $p^L = 1.5$. The AIDS curve with $\beta_n = 0$ is convex and reaches zero at $p^V = e \approx 2.72$. The constant-elasticity curve never reaches the price axis. The areas from p upward are 0.25, 0.50 (shaded) and 1.00. Because the AIDS curve is convex, the tangent reaches zero below its virtual price, the bound of Proposition 10.21.

With $\beta_n \neq 0$ the budget share of good n varies with income, and the virtual price no longer has the closed form above. The translog price index is quadratic in $\ln p_n$, so the zero-share condition is a quadratic equation in the log virtual price (5.112). The Hicksian condition (5.114) needs a one-dimensional root finder, and the compensating variation then follows from the closed form (5.100). The AIDS represents preferences only where all shares are nonnegative, so the formulas apply up to the virtual price and no further (Section 5.7.2).

10.3.3 Exact surplus from Marshallian demand*

Estimated demand systems are usually written in Marshallian form, with income as a regressor. Hausman (1981) shows how to recover the expenditure function from them. Along an indifference curve, Shephard's lemma and the duality identity (10.1) give

$$\frac{\partial e(p,u)}{\partial p_n} = h_n(p,u) = q_n\big(p, e(p,u)\big). \tag{10.23}$$

With the other prices fixed, this is an ordinary differential equation in p_n for the function $p_n \mapsto e(p,u)$. The constant of integration indexes utility, and the boundary condition $e(p^1,u^1) = y$ selects the period-1 indifference curve. Hausman (1997, p. 212 and n. 6) describes this step as solving the differential equation that arises from Roy's identity.

Example 10.20 (Linear demand with income effects)**.** Let $q_n = a + bp_n + cy$ with $b < 0$ and $c \neq 0$, and suppress the other prices. Then (10.23) becomes

$$\frac{\mathrm{d}e}{\mathrm{d}p} - c\,e = a + bp.$$

Multiplying by the integrating factor e^{-cp} turns the left side into an exact derivative:

$$\frac{\mathrm{d}}{\mathrm{d}p}\big(e^{-cp}e\big) = (a+bp)e^{-cp}.$$

An antiderivative of the right side is $-\frac{a+bp}{c}e^{-cp} - \frac{b}{c^2}e^{-cp}$. Differentiating it gives $-\frac{b}{c}e^{-cp} + (a+bp)e^{-cp} + \frac{b}{c}e^{-cp} = (a+bp)e^{-cp}$, as required. Integrating, with the constant of integration u as the utility index,

$$e(p,u) = u\,e^{cp} - \frac{1}{c}\Big(bp + \frac{b}{c} + a\Big). \tag{10.24}$$

We verify (10.24) directly. Its derivative is $\frac{\partial e}{\partial p} = cu\,e^{cp} - \frac{b}{c}$. Substituting (10.24) into demand gives

$$a + bp + c\,e(p,u) = a + bp + cu\,e^{cp} - bp - \frac{b}{c} - a = cu\,e^{cp} - \frac{b}{c},$$

which equals the derivative. Setting $e(p,u) = y$ and solving gives the indirect utility function $v(p,y) = e^{-cp}\big[y + \frac{1}{c}(bp + \frac{b}{c} + a)\big]$. Roy's identity returns $a + bp + cy$.

The Hicksian demand is $h(p,u) = cu\,e^{cp} - \frac{b}{c}$. Its slope is $c^2u\,e^{cp} = c\big(h + \frac{b}{c}\big) = b + ch$, the Slutsky term $b + cq$ evaluated at $q = h$. We assume it negative, so in this normalization the utility index u is negative. At the observed point (p^1, q^1) the identity $h(p^1,u^1) = q^1$ gives $cu^1e^{cp^1} = q^1 + \frac{b}{c}$. The Hicksian virtual price solves $cu^1e^{cp^V} = \frac{b}{c}$. Dividing the second condition by the first,

$$e^{c(p^V - p^1)} = \frac{b}{b + cq^1}, \qquad \text{so} \qquad p^V - p^1 = -\frac{1}{c}\ln\Big(1 + \frac{cq^1}{b}\Big).$$

At the virtual price demand is zero, so $a + bp^V + c\,e(p^V, u^1) = 0$ and $e(p^V, u^1) = -\frac{a+bp^V}{c}$. The compensating variation is therefore

$$CV = e(p^V, u^1) - y = -\frac{a + bp^V + cy}{c} = -\frac{q^1 + b(p^V - p^1)}{c}. \tag{10.25}$$

The Marshallian choke price is $p^M = -\frac{a+cy}{b}$, so $p^M - p^1 = \frac{q^1}{-b}$, and the Marshallian surplus is the triangle $CS = \frac{(q^1)^2}{2(-b)}$. Expanding the logarithm for small c gives $CV = \frac{(q^1)^2}{2(-b)} + \frac{c\,(q^1)^3}{3b^2}$ plus terms of order c^2. The second term is the income-effect correction, positive for a normal good.

For numbers, take $p^1 = 1$, $y = 100$, $q^1 = 2$, $b = -2$ and $c = 0.02$, so $a = 2$ and the Slutsky term is -1.96. The Marshallian choke price is 2.000 and $CS = 1.000$. The Hicksian virtual price is 2.010, and (10.25) gives $CV = 1.0135$. The equivalent variation, computed in the same way at the period-0 utility, is 0.9934. The income elasticity at the observed point is $\frac{cy}{q^1} = 1$, so Willig's approximation of Remark 10.9 would suggest a gap of 0.5 percent between CV and CS. The exact gap is 1.35 percent, because the income elasticity rises without bound as the quantity falls to zero.

The same logic works without a parametric form. Hausman and Newey (1995) estimate demand nonparametrically and solve (10.23) numerically, and they derive standard errors for the resulting exact surplus. Hausman (1997, n. 24) uses their method for his estimates of exact consumer surplus and its asymptotic standard error.

10.3.4 A lower bound from convexity

Hausman (1997, p. 228) proposes a bound that does not depend on the shape of demand near the price axis. Draw the tangent to the demand curve at the observed price and see where it meets the price axis. If demand is convex, the tangent lies below the curve, so it meets the axis below the virtual price.

Proposition 10.21 (Tangent bound)**.** *Let $q(t)$ be a demand curve for good n (Marshallian at fixed income or Hicksian at fixed utility), with $q(p) = q > 0$, differentiable at p with $q'(p) < 0$, and convex on $[p, \infty)$. Let $\varepsilon = -\frac{p\,q'(p)}{q}$ and*

$$p^L = p + \frac{q}{-q'(p)} = p\left(1 + \frac{1}{\varepsilon}\right). \tag{10.26}$$

Then (a) $p^L \le p^V$, and (b) the area $CS = \int_p^{p^V} q(t)\,\mathrm{d}t$ satisfies

$$CS \ge \frac{1}{2} q\,(p^L - p) = \frac{pq}{2\varepsilon}. \tag{10.27}$$

If in addition p^V is finite, Corollary 10.12 gives $CS \le \frac{1}{2} q\,(p^V - p)$.

Proof. A convex function lies above its tangent lines. For every $t \ge p$,

$$q(t) \ge \ell(t) \equiv q + q'(p)(t - p),$$

and $\ell(p^L) = 0$ by (10.26).

(a) Suppose $p^V < p^L$. Then $\ell(p^V) > 0 = q(p^V)$, which contradicts $q(t) \ge \ell(t)$. Hence $p^L \le p^V$.

(b) Demand is nonnegative, so $q(t) \geq \max\{\ell(t), 0\}$ for every $t \geq p$. Integrating over $[p, p^L]$ and using $p^L \leq p^V$,

$$CS \geq \int_p^{p^L} q(t)\,\mathrm{d}t \geq \int_p^{p^L} \ell(t)\,\mathrm{d}t = \frac{1}{2} q\,(p^L - p) = \frac{1}{2} q\,\frac{q}{-q'(p)} = \frac{pq}{2\varepsilon}.$$

□

The bound uses only the observed price, quantity and slope, and one shape restriction. The restriction is weaker than a functional form, but it is still a restriction. Many common demand curves satisfy it. A linear curve equals its tangent, so the bound is exact. A constant-elasticity curve has $q''(t) = \varepsilon(\varepsilon+1)At^{-\varepsilon-2} > 0$. For the AIDS with $\beta_n = 0$, differentiating $q(t) = \frac{y\,w(t)}{t}$ twice gives

$$q'(t) = \frac{y\,(\gamma - w(t))}{t^2}, \qquad q''(t) = \frac{y\,(2w(t) - 3\gamma)}{t^3},$$

which is positive wherever $w(t) \geq 0$ and $\gamma < 0$. The demand curves that Hausman plots for his new brand from his estimated AIDS are convex as well (his Figures 5.1 and 5.2). If demand were concave beyond the data, the tangent would lie above the curve and would overstate the virtual price.

No convex curve through the observed point with the observed slope gives a smaller area, because every such curve lies above the tangent line. In Table 10.1 the bound is the linear row, half the AIDS value at $\varepsilon = 2$. Combined with Corollary 10.12, convexity brackets the area between two triangles. The lower one uses the tangent choke price p^L, and the upper one uses the true virtual price. Hausman (1997, p. 228) applies the tangent construction to Apple-Cinnamon Cheerios and obtains lower-bound virtual prices between about \$5.55 and \$5.94, about 65 percent above the average price of \$3.48. Section 10.5 examines these numbers.

10.4 New goods under imperfect competition

The classical theory of Section 10.2 assumes perfect competition. The prices of the other goods stay at marginal cost when the new good arrives (Hausman, 1997, p. 213). In differentiated-product markets this assumption fails in two ways. A firm that already sells close substitutes may reprice them once it owns the new product. Rival firms face a new competitor and reprice their own products. Hausman notes the first effect and quantifies it. Bresnahan (1997) argues that the second effect is generally the more important one. This section builds the welfare accounting that covers both, then studies each price response in turn.

10.4.1 Welfare accounting with equilibrium prices

Let $\mathcal{J}^1 = \mathcal{J}^0 \cup \{n\}$ be the set of products in period 1. Firm f owns the products in $\mathcal{J}_f$, and firm f^* introduces product n. Marginal costs mc_j are constant, and the introduction requires a fixed cost F_n. Market shares $s_j(p)$ come from a demand model with market size M, and firms set prices in a Bertrand-Nash equilibrium. Let $\Delta(p)$ be the Jacobian of shares, the matrix with (j, r) element $\frac{\partial s_j(p)}{\partial p_r}$, and let Ω be the ownership matrix. The first-order conditions are

$$s_j(p) + \sum_{r \in \mathcal{J}_f} (p_r - mc_r)\frac{\partial s_r(p)}{\partial p_j} = 0, \quad j \in \mathcal{J}_f, \qquad \text{or} \qquad s(p) + (\Omega \odot \Delta(p))^\top (p - mc) = 0. \tag{10.28}$$

This is the markup system of Chapter 4, solved as $p - mc = -[(\Omega \odot \Delta)^\top]^{-1} s$ as in (8.71).

Evaluating the welfare effect of an introduction that has already happened requires a counterfactual, because the data show the market only with the new good. Petrin (2002, eqs. 1–3) uses the following steps.

(i) Estimate demand on data from the market with the new product, at observed prices p^1.

(ii) Recover marginal costs from (10.28) at p^1: $mc = p^1 + [(\Omega \odot \Delta(p^1))^\top]^{-1} s(p^1)$.

(iii) Solve (10.28) for the choice set $\mathcal{J}^0$, without product n, to obtain the counterfactual prices p^0 of the remaining products.

(iv) Compute the compensating variation and the change in each firm's variable profit.

In logit-type models, removing product n is the same as raising its price to infinity, its virtual price. In product-space systems, removal sets p_n at its virtual price, which itself moves with the other prices. The elasticities of the remaining products then follow (5.122).

The compensating variation now has two parts. With u^1 the period-1 utility, add and subtract $e^R(p^1_{-n}, u^1)$:

$$\begin{aligned} CV &= e^R(p^0_{-n}, u^1) - e(p^1, u^1) \\ &= \underbrace{e^R(p^0_{-n}, u^1) - e^R(p^1_{-n}, u^1)}_{\text{price effect}} + \underbrace{e^R(p^1_{-n}, u^1) - e(p^1, u^1)}_{\text{variety effect}}. \end{aligned} \tag{10.29}$$

The variety effect is the area of Proposition 10.7, evaluated at the period-1 prices of the other goods:

$$e^R(p^1_{-n}, u^1) - e(p^1, u^1) = \int_{p^1_n}^{p^V_n(p^1_{-n}, u^1)} h_n(p^1_{-n}, t, u^1)\, \mathrm{d}t.$$

The price effect values the change in the other prices for a consumer who cannot buy good n. The rationed expenditure function is an ordinary expenditure function over the remaining goods, so Shephard's lemma applies to it with the rationed Hicksian demands h^R_k. To first order,

$$e^R(p^0_{-n}, u^1) - e^R(p^1_{-n}, u^1) \approx \sum_{k \neq n} h^R_k(p^1_{-n}, u^1)\,(p^0_k - p^1_k). \tag{10.30}$$

The price effect is positive when the introduction lowers the other prices ($p^0_k > p^1_k$), and negative when it raises them. The decomposition is sequential, so its terms depend on the order in which the two changes are made. Equation (5.126) gives the analogous three-way decomposition of Chaudhuri et al. (2006) for product withdrawals.

The change in total welfare adds the change in profits and subtracts the fixed cost:

$$\Delta W = CV + \sum_f \left(\Pi^1_f - \Pi^0_f\right) - F_n, \qquad \Pi^t_f = M \sum_{j \in \mathcal{J}_f} (p^t_j - mc_j)\, s_j(p^t). \tag{10.31}$$

With heterogeneous consumers, CV is the sum of the individual compensating variations. With quasi-linear utility it equals the change in consumer surplus, and ΔW is the change in total surplus.

Both of the empirical studies of imperfect competition in this chapter fit this framework. Hausman (1997, p. 234) starts from a variety effect of about \$32,000 per city and week. He then subtracts \$4,605, a first-order price effect from the price increases of two existing Cheerios brands. Petrin (2002, p. 720) computes the counterfactual equilibrium without minivans. In

1984, gains to buyers of other vehicles from increased price competition account for almost 43 percent of total consumer benefits. These gains are part of the price effect in (10.29). Sections 10.5 and 10.9 develop both studies.

10.4.2 Private and social returns

A firm introduces a product when the introduction raises its own profit. The social value of the introduction is ΔW in (10.31). The two differ, and the gap governs whether markets supply too many or too few products.

Definition 10.22 (Private and social returns)**.** The *private return* of the introduction is the change in the introducer's profit net of the fixed cost, $G = \Pi^1_{f^*} - \Pi^0_{f^*} - F_n$. The *social return* is ΔW.

Subtracting the definitions gives the general wedge,

$$\Delta W - G = CV + \sum_{f \neq f^*} \left(\Pi^1_f - \Pi^0_f\right). \tag{10.32}$$

The introducer ignores the gain of consumers and the change in its rivals' profits. The next proposition isolates the two terms when prices do not respond.

Proposition 10.23 (The wedge at fixed prices)**.** *Suppose utility is quasi-linear in income and the prices of all existing products are the same with and without product n. Hicksian demand then does not depend on utility, and we write the variety effect as $V_n = \int_{p_n}^{p_n^V} h_n(p_{-n}, t)\,\mathrm{d}t$, where h_n is market Hicksian demand, the sum of the M consumers' demands. Then*

$$G = M(p_n - mc_n)s^1_n - M \sum_{k \in \mathcal{J}_{f^*} \setminus \{n\}} (p_k - mc_k)(s^0_k - s^1_k) - F_n, \tag{10.33}$$

$$\Delta W - G = V_n - M \sum_{k \notin \mathcal{J}_{f^*}} (p_k - mc_k)(s^0_k - s^1_k). \tag{10.34}$$

Proof. With prices fixed, each firm's profit changes only through its shares: $\Pi^1_f - \Pi^0_f = M \sum_{k \in \mathcal{J}_f} (p_k - mc_k)(s^1_k - s^0_k)$, with $s^0_n = 0$. For the introducer, split off product n and subtract F_n to obtain (10.33). The price effect in (10.29) is zero, so $CV = V_n$. Substituting $CV = V_n$ and the rivals' profit changes into (10.32) gives (10.34). □

The wedge has two terms of opposite sign. The variety effect V_n is surplus the introducer cannot appropriate without perfect price discrimination, and it pushes toward too few products. The second term is *business stealing*: margins that rivals lose when their customers switch to the new product. It pushes toward too many products. Cannibalization of the introducer's own products enters both the private and the social return, so it is not part of the wedge at fixed prices. Spence (1976) analyzes the two forces in models of monopolistic competition. Mankiw and Whinston (1986) show that business stealing alone produces excessive entry under free entry in a homogeneous-good market, apart from the integer constraint. They also show that product diversity can reverse the result (Chapter 2). Bresnahan (1997, p. 237, n. 1) quotes Eaton and Lipsey (1989), who conclude that "we do not even know the nature of the bias" between equilibrium and optimal product diversity. The answer is empirical, and it needs estimates of both V_n and the diversion of customers from rivals.

Remark 10.24 (Steep demand means large surplus and large rents). Bresnahan (1997, p. 243) observes that the condition for a large consumer gain, a steep demand curve for the new product, is also the condition for a profitable single-product monopoly. A linear example makes this exact. Let demand for the new product be $q = k(p^V - p)$, and let its seller have constant marginal cost $mc_n < p^V$. The profit-maximizing price is $p^* = \frac{p^V + mc_n}{2}$, and the quantity is $q^* = \frac{k(p^V - mc_n)}{2}$. Profit and consumer surplus at the optimum are

$$\pi^* = (p^* - mc_n)q^* = \frac{k(p^V - mc_n)^2}{4}, \qquad CS^* = \frac{1}{2}(p^V - p^*)q^* = \frac{k(p^V - mc_n)^2}{8} = \frac{\pi^*}{2}.$$

At the seller's optimum, consumer surplus and profit move in proportion. A demand estimate that implies a large consumer gain also implies a large private return.

Bresnahan (1997, pp. 245–246) organizes the effects of a new product under imperfect competition in a two-by-two classification, reproduced in Table 10.2. Columns give the channel, through the introducer's other products or through competitors' products. Rows give the welfare criterion, the social return or the inventor's private return. Bresnahan shades the price-discrimination cell, where Hausman's analysis lies. He argues that the competition cell is generally far more important for the social return.

Table 10.2: Imperfect competition and new goods

	Effect through the introducer's other products	Effect through competitors' products
Social return	*Price discrimination.* The introducer reprices its existing products now that it also owns the new one. Consumers of those products gain or lose. This is the cell Hausman quantifies.	*Competition.* Rivals' residual demands become more elastic, and their prices typically fall. Consumers of rival products gain.
Inventor's private return	*Cannibalization.* Part of the new product's sales comes from the introducer's own products. The private return falls short of the new product's profit.	*Creative destruction.* Part of the new product's profit is taken from rivals' rents. It is a private gain without a matching social gain.

Notes: The cell labels are those of Bresnahan (1997, Figure 5C.2), who shades the price-discrimination cell. The descriptions are our reading of the labels, consistent with his text. The competition and creative-destruction cells correspond to the price effect on rival products in (10.29) and to the business-stealing term in (10.34).

10.4.3 Multiproduct pricing in elasticity form

Product-space demand systems deliver elasticities, so Hausman (1997) writes the first-order conditions in elasticity form. In this subsection $\varepsilon_{kj} = \frac{\partial q_k}{\partial p_j}\frac{p_j}{q_k}$ is the signed elasticity of q_k with respect to p_j. Own elasticities ε_{jj} are negative, unlike the positive scalar ε of Section 10.3. Let E be the matrix with (k, j) element ε_{kj}.

A firm sells products $1, \ldots, K$ at constant marginal costs and maximizes $\pi = \sum_{k=1}^{K}(p_k -$

$mc_k)q_k(p)$. The derivative with respect to p_j is

$$\frac{\partial \pi}{\partial p_j} = q_j + \sum_{k=1}^{K} (p_k - mc_k)\frac{\partial q_k}{\partial p_j}.$$

Let $R = \sum_k p_k q_k$ be the firm's revenue, $w_k = \frac{p_k q_k}{R}$ the revenue share of product k, and $L_k = \frac{p_k - mc_k}{p_k}$ its Lerner index. Multiply the derivative by $\frac{p_j}{R}$. The first term becomes w_j. Each term of the sum becomes

$$(p_k - mc_k)\frac{\partial q_k}{\partial p_j}\frac{p_j}{R} = \frac{p_k - mc_k}{p_k} \cdot \frac{p_k q_k}{R} \cdot \frac{\partial q_k}{\partial p_j}\frac{p_j}{q_k} = L_k\, w_k\, \varepsilon_{kj}.$$

Setting the derivative to zero gives equation (13) of Hausman (1997):

$$\frac{p_j}{R}\frac{\partial \pi}{\partial p_j} = w_j + \sum_{k=1}^{K} L_k\, w_k\, \varepsilon_{kj} = 0, \qquad j = 1, \ldots, K. \tag{10.35}$$

For a single-product firm the condition reduces to $L_1 = -\frac{1}{\varepsilon_{11}}$, his equation (12). Let $m_k = L_k w_k$ be the share-weighted margin and stack the conditions. In matrix form,

$$w + E^{\top} m = 0, \qquad m = -\left(E^{\top}\right)^{-1} w, \tag{10.36}$$

which are his equations (14) and (15) with his s renamed w and his w renamed m. The system is (5.116) in the notation of Chapter 5.

The elasticity form is the single-firm block of (10.28). With one owner, $\Omega_{jr} = 1$ for all products of the firm. Multiplying row j of (10.28) by $\frac{M p_j}{R}$ and using $\frac{\partial s_r}{\partial p_j} = \varepsilon_{rj}\frac{s_r}{p_j}$ gives $\frac{p_j q_j}{R} + \sum_r \frac{p_r - mc_r}{p_r}\frac{p_r q_r}{R}\varepsilon_{rj} = 0$, which is (10.35).

Once margins are known with and without a product, constant marginal cost converts them into prices. From $L_k = \frac{p_k - mc_k}{p_k}$ we get $p_k = \frac{mc_k}{1 - L_k}$, and therefore

$$\frac{p_k^{\text{with}}}{p_k^{\text{without}}} = \frac{1 - L_k^{\text{without}}}{1 - L_k^{\text{with}}}. \tag{10.37}$$

Section 10.5 applies this formula to Hausman's Table 5.7. Bresnahan (1997, p. 241, n. 7) notes that pricing equations of this kind imply an upward-sloping supply relation, which matters for the validity of Hausman's instruments (Section 10.6).

10.4.4 The introducer's other prices

Hausman (1997, p. 231) gives the intuition for a price increase. Once the firm sells the new brand, part of the demand it would lose by raising the price of an existing brand goes to the new brand instead of to rivals. Bresnahan (1997, pp. 244–245) replies that (10.35) changes in three ways when product $K + 1$ is added. First, a new positive term enters the sum,

$$\frac{p_{K+1} - mc_{K+1}}{p_{K+1}}\, w_{K+1}\, \varepsilon_{K+1,j} > 0,$$

which raises the marginal return to increasing p_j. Second, w_j falls because the new product cannibalizes product j. Third, w_k falls for the firm's other existing products, which shrinks

each positive cross term $L_k w_k \varepsilon_{kj}$ with $k \neq j$. At fixed elasticities, the first effect pushes p_j up. Bresnahan treats the second and third, the falls in the shares, as the offsetting effects. At fixed margins and elasticities only the third works this way. The terms in w_j combine to $w_j(1 + L_j \varepsilon_{jj})$, which is negative at the optimum when the firm's products are substitutes, so a smaller w_j also pushes p_j up. The net effect on p_j is ambiguous. Bresnahan adds that with linear demand and a two-product firm the effects offset exactly. The next proposition proves this and extends it to any number of products.

Proposition 10.25 (Linear demand: no repricing, Bresnahan, 1997)**.** *A firm sells the products in $O = \{1, \dots, K\}$ and can add product n. Demand for the $K+1$ products is $q = a - Bp$, with B symmetric and positive definite, and marginal costs mc are constant. The prices of other firms are held fixed and absorbed into a. Before the introduction, demand for the products in O is the rationed demand obtained by setting p_n at its virtual price $p_n^V(p_O) = \frac{a_n - B_{nO} p_O}{b_{nn}}$. Then the profit-maximizing prices of the products in O are the same with and without product n. In the two-product case with $B = \left(\begin{smallmatrix} b & -d \\ -d & b \end{smallmatrix}\right)$, $b > d > 0$, the price of product 1 is in both cases*

$$p_1 = \frac{1}{2}\left[\frac{b a_1 + d a_2}{b^2 - d^2} + mc_1\right]. \tag{10.38}$$

Proof. We compute the optimal prices before and after the introduction and compare them.

Before the introduction, substitute the virtual price into the demand for O:

$$q_O = a_O - B_{OO} p_O - B_{On} \frac{a_n - B_{nO} p_O}{b_{nn}} = \tilde{a} - \tilde{B} p_O,$$

with

$$\tilde{a} = a_O - \frac{B_{On} a_n}{b_{nn}}, \qquad \tilde{B} = B_{OO} - \frac{B_{On} B_{nO}}{b_{nn}}.$$

The matrix $\tilde{B}$ is the Schur complement of b_{nn} in B, so it is symmetric and positive definite. Profit is $(p_O - mc_O)^\top(\tilde{a} - \tilde{B} p_O)$, a strictly concave quadratic. Its gradient is $\tilde{a} - \tilde{B} p_O - \tilde{B}^\top(p_O - mc_O)$. Setting it to zero and using symmetry gives $2\tilde{B} p_O = \tilde{a} + \tilde{B} mc_O$, so

$$p_O^{\text{without}} = \frac{1}{2}\left(\tilde{B}^{-1}\tilde{a} + mc_O\right).$$

After the introduction, the same steps with a and B give $p^{\text{with}} = \frac{1}{2}(B^{-1}a + mc)$.

The partitioned-inverse formula for a symmetric matrix gives the blocks of B^{-1} in the rows of O:

$$(B^{-1})_{OO} = \tilde{B}^{-1}, \qquad (B^{-1})_{On} = -\frac{\tilde{B}^{-1} B_{On}}{b_{nn}}.$$

Hence

$$(B^{-1}a)_O = \tilde{B}^{-1} a_O - \frac{\tilde{B}^{-1} B_{On} a_n}{b_{nn}} = \tilde{B}^{-1}\tilde{a},$$

and $p_O^{\text{with}} = p_O^{\text{without}}$.

In the two-product case, $B^{-1} = \frac{1}{b^2 - d^2}\left(\begin{smallmatrix} b & d \\ d & b \end{smallmatrix}\right)$, so the first row of $\frac{1}{2}(B^{-1}a + mc)$ is (10.38). Directly, the virtual price is $p_2^V = \frac{a_2 + d p_1}{b}$, and residual demand for product 1 is $q_1 = \frac{b a_1 + d a_2}{b} - \frac{b^2 - d^2}{b} p_1$. The monopoly price for this demand is half the sum of its choke price $\frac{b a_1 + d a_2}{b^2 - d^2}$ and mc_1, which is again (10.38). ∎

The result does not depend on the new product's intercept or marginal cost, which affect only whether it is worth selling. The introduction is relevant when $q_n > 0$ at the optimal prices. With linear demand the recapture effect is exactly offset by the cannibalization effects. The firm leaves its existing prices unchanged, and the consumer gain from the introduction is the pure variety effect. Since rivals' prices are held fixed in the proposition, the conclusion also applies to Hausman's own experiment. In a correctly computed counterfactual, his price increases for existing Cheerios brands would have to come from the curvature of his demand system. Section 10.5.10 shows that his calculation instead keeps the post-launch shares, so it captures only the first of the three effects. Bresnahan puts it this way: any tendency of one effect to dominate comes from "higher-order derivatives," and the paper contains no evidence on them (Bresnahan, 1997, p. 245).

Remark 10.26 (Logit demand: the existing prices rise). Curvature can push either way, and in the logit model it pushes prices up. Let firm f sell the products in $\mathcal{J}_f$ with logit demand and common price coefficient α. With $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$ and $\frac{\partial s_k}{\partial p_j} = \alpha s_k s_j$, the first-order condition (10.28) for p_j becomes

$$s_j\left[1 - \alpha(p_j - mc_j) + \alpha \sum_{k \in \mathcal{J}_f} (p_k - mc_k)s_k\right] = 0.$$

The bracket depends on j only through $p_j - mc_j$. All the firm's products therefore carry the same markup $\bar{m}$, and $\bar{m} = \frac{1}{\alpha(1-S_f)}$ with S_f the firm's total share. Write $A_f = \sum_{k \in \mathcal{J}_f} e^{x_k\beta + \xi_k - \alpha mc_k}$ and let R be the sum of e^{δ_k} over rival products, held fixed. Then $1 - S_f = \frac{1+R}{1+R+A_f e^{-\alpha\bar{m}}}$, and the markup solves

$$\alpha\bar{m}\,(1 + R) = 1 + R + A_f e^{-\alpha\bar{m}}.$$

The left side rises with $\bar{m}$ and the right side falls, so the solution is unique. Adding a product raises A_f, which raises the right side and hence the solution. Holding rivals' prices fixed, a logit firm raises the prices of its existing products when it adds a product. For example, with $\alpha = 1$ and a single product with $e^{x\beta + \xi - \alpha mc} = e^2$, a monopolist's markup is 2.00. Adding a second product with $e^{1.5}$ raises the markup on both products to 2.25 (our computation). Hausman's direction holds here, the linear case gives zero, and no general theorem signs the effect.

10.4.5 Rivals' prices

Analyses of entry often hold rivals' prices fixed, and Bresnahan (1997, p. 244) argues that this is an error (Section 10.6.4). The Bertrand concept has firms maximize profits taking one another's post-entry prices as given. The analyst who evaluates entry must instead compute the new equilibrium, and in it rivals' prices typically fall. Hausman's claim that his calculation gives a lower bound on the price changes, absent new entry by competitors (Hausman, 1997, p. 233), fails for this reason. The next proposition makes the competition effect precise for single-product firms with logit demand.

Proposition 10.27 (Entry lowers rivals' prices under logit)**.** *Consider single-product firms with logit demand* $s_j(p) = \frac{e^{v_j - \alpha p_j}}{1 + \sum_k e^{v_k - \alpha p_k}}$, *with* $v_j = x_j\beta + \xi_j$, *constant marginal costs* mc_j *and* $\alpha > 0$.

(a) Each firm's best response is unique, satisfies $(p_j - mc_j)\,\alpha\,(1 - s_j) = 1$, *and is increasing in every rival's price.*

(b) *Let p^0 be an equilibrium without product n. Then the market with product n has an equilibrium in which every incumbent's price is strictly below its value in p^0. If the equilibrium with product n is unique, all incumbents' prices fall.*

(c) *In the symmetric case $v_j = v$ and $mc_j = mc$ for all J products, the symmetric equilibrium markup is $p - mc = \frac{1}{\alpha(1-s)}$, where s is each product's share. The markup and the share both fall as J rises, and the markup converges to $\frac{1}{\alpha}$ as $J \to \infty$.*

Proof. (a) Fix the rivals' prices and let $A_{-j} = 1 + \sum_{k \neq j} e^{v_k - \alpha p_k}$. Write the markup as $m_j = p_j - mc_j$ and let $z_j = \frac{e^{v_j - \alpha mc_j} e^{-\alpha m_j}}{A_{-j}}$, so that $s_j = \frac{z_j}{1+z_j}$ and $1 - s_j = \frac{1}{1+z_j}$. Profit is $M m_j s_j$, and the logit derivative $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$ gives

$$\frac{\partial (M m_j s_j)}{\partial p_j} = M s_j \big[1 - \alpha m_j (1 - s_j)\big] = M s_j \Big[1 - \frac{\alpha m_j}{1 + z_j}\Big].$$

The ratio $\frac{\alpha m_j}{1+z_j}$ is zero at $m_j = 0$ and strictly increasing in m_j, because z_j falls with m_j. The bracket therefore changes sign once, from positive to negative, and profit has a unique maximum where

$$\alpha m_j = 1 + z_j = 1 + \frac{e^{v_j - \alpha mc_j} e^{-\alpha m_j}}{A_{-j}},$$

which is $(p_j - mc_j)\alpha(1 - s_j) = 1$. The left side increases in m_j and the right side decreases. A higher A_{-j} lowers the right side and therefore lowers the solution. Since A_{-j} falls when any rival raises its price, the best response rises with every rival's price. The solution also satisfies $m_j > \frac{1}{\alpha}$.

(b) Adding product n adds the positive term $e^{v_n - \alpha p_n}$ to every incumbent's A_{-j}. Let Φ be the best-response map of the market with product n, and start from $x^0 = (p^0, \Phi_n(p^0))$, the old prices together with the entrant's best response to them. At x^0, each incumbent's A_{-j} exceeds its value at p^0 in the old market. By part (a), $\Phi_j(x^0) < p^0_j$ for every incumbent. Define $x^{t+1} = \Phi(x^t)$. In the first step the incumbents' prices fall, while the entrant's price is unchanged because $x^1_n = \Phi_n(p^0) = x^0_n$. Hence $x^1 \leq x^0$ componentwise. Because Φ is increasing, $x^t \leq x^{t-1}$ implies $x^{t+1} = \Phi(x^t) \leq \Phi(x^{t-1}) = x^t$. The sequence is therefore decreasing, and it is bounded below by $mc + \frac{1}{\alpha}$. It converges to a limit x^*, which is a fixed point of Φ by continuity, so x^* is an equilibrium. For every incumbent, $x^*_j \leq x^1_j < p^0_j$. If the equilibrium is unique, it is x^*.

(c) With symmetric products and a common markup m, let $x = e^{v - \alpha mc - \alpha m}$. Then $s = \frac{x}{1+Jx}$, and part (a) gives $m = \frac{1}{\alpha(1-s)}$. Define $g(m, J) = \alpha m(1 - s(m, J)) - 1$. Differentiating s,

$$\frac{\partial s}{\partial m} = -\frac{\alpha x}{(1 + Jx)^2} < 0, \qquad \frac{\partial s}{\partial J} = -\frac{x^2}{(1 + Jx)^2} < 0.$$

Hence $\frac{\partial g}{\partial m} = \alpha(1 - s) - \alpha m \frac{\partial s}{\partial m} > 0$ and $\frac{\partial g}{\partial J} = -\alpha m \frac{\partial s}{\partial J} > 0$. Since $g(0, J) = -1$ and $g \to \infty$ as $m \to \infty$, the equation $g = 0$ has a unique root $m(J)$. The implicit function theorem gives $\frac{\mathrm{d}m}{\mathrm{d}J} = -\big(\frac{\partial g}{\partial m}\big)^{-1} \frac{\partial g}{\partial J} < 0$. The markup $\frac{1}{\alpha(1-s)}$ increases in s, so the equilibrium share falls as well. Finally $Js < 1$, so $s \to 0$ and $m(J) \to \frac{1}{\alpha}$ as $J \to \infty$. □

Table 10.3 illustrates part (c) with $\alpha = 1$ and $v - \alpha mc = 2$. A single product carries a markup of 2.00. With ten products the markup is 1.11, and it approaches the floor $\frac{1}{\alpha} = 1$ slowly.

The floor reflects the idiosyncratic logit taste shocks, which give every product a set of loyal buyers, a feature Section 10.7 examines. Part (b) does not need symmetry. In an example with three incumbents, $v = (2.0, 1.5, 1.0)$ and $mc = (1.0, 0.8, 0.5)$, the equilibrium prices are $(2.344, 2.060, 1.715)$. Adding a fourth product with $v_n = 1.2$ and $mc_n = 0.7$ lowers them to $(2.287, 2.016, 1.678)$ (our computation).

Table 10.3: Symmetric logit equilibrium as the number of products grows

Number of products J	1	2	3	5	10	20	50
Share of each product s	0.500	0.375	0.282	0.183	0.096	0.049	0.020
Total inside share Js	0.500	0.749	0.846	0.916	0.961	0.981	0.993
Markup $p - mc$	2.000	1.599	1.393	1.224	1.106	1.052	1.020

Notes: Single-product firms with logit demand, $\alpha = 1$ and $v - \alpha mc = 2$ for every product. The markup solves $p - mc = \frac{1}{\alpha(1-s)}$ (Proposition 10.27). Our computation, `figures/ch10/src/part1_checks.py`.

The proof of part (b) also shows how the effect builds up. The first step of the iteration is the direct response of each incumbent to the entrant. Later steps add the responses to the other incumbents' price cuts, which push prices down further. Bresnahan (1997, p. 244, n. 13) makes this point: under Bertrand competition the indirect effects of an introduction reinforce the direct effects. The monotone argument is an instance of the theory of games with strategic complementarities (Milgrom and Roberts, 1990). Uniqueness of the single-product logit equilibrium follows from the conditions of Caplin and Nalebuff (1991), discussed in Chapter 4.

The logit model makes the competition effect unambiguous. Its own-price elasticity $-\alpha p_j(1 - s_j)$ rises in magnitude whenever entry lowers s_j. Other demand systems allow exceptions. Bresnahan (1997, p. 243, n. 12) notes that peculiar elasticities can reverse the result, for example when the new good makes the demand curve for an old good steeper. One mechanism is a shift in the mix of buyers. If the entrant draws away an incumbent's most price-sensitive customers, the remaining customers are less elastic, and the incumbent's price can rise. Hausman (1997, p. 231, n. 32) concedes the counteracting effect. He writes that the new brand can lower other firms' prices by raising the own-price elasticity of existing brands, and that these interactions were beyond the reach of existing theory. Random-coefficient models permit both outcomes. In Petrin (2002, p. 720), station wagons have the largest percentage price decreases after the minivan enters, and large family sedans the largest dollar decreases, of $100 to $150 (Section 10.9).

The value of a new good under imperfect competition is therefore the variety effect at the new prices plus the price effects on all other products. The effect through the introducer's own products has no general sign. It is zero with linear demand, positive with logit demand, and determined in any application by the curvature of the estimated demand system. The effect through rivals' products usually benefits consumers, and it can be large. The case studies that follow measure these effects with actual data. The first, Hausman's valuation of a new breakfast cereal, applies every tool of Sections 10.2 and 10.3 and the multiproduct pricing of this section. The critique of Bresnahan (1997) then turns on the competition effect and on the instruments behind the demand estimates.

10.5 Case study: Apple-Cinnamon Cheerios (Hausman 1997)

Hausman (1997) is an early study that values a single new brand with an estimated demand system for differentiated products. It applies the virtual-price theory of Section 10.2 to the ready-to-eat (RTE) cereal industry. It then adds the multiproduct pricing adjustment that Section 10.4 analyzes in general form. We take the paper in the order question, setting, data, model, identification, results, robustness, interpretation and critique.[2] Section 10.6 then examines the comment by Bresnahan (1997), published with the paper, which disputes both the instruments and the treatment of competition. Table 10.10 at the end of this section maps the study.

The paper uses several symbols that this book reserves for other objects, so we rename them. Hausman's revenue share s becomes w, and his margin-weighted share w becomes m. His cost coefficient δ_j becomes κ_j, and his segment price coefficients δ_k become b_{mg}. His segment price indexes π_{knt} become P_{gnt}, his virtual price p_n^* becomes p_n^V, and his elasticity e_{kj} becomes ε_{kj}. As in Section 10.4, elasticities in this section are signed, so own-price elasticities are negative.

10.5.1 The question

Hausman asks three questions (pp. 209–210). How much consumer surplus does one incremental brand create? By how much does the consumer price index (CPI) overstate cereal inflation because it ignores new brands? How does multiproduct pricing by the introducing firm change the answer?

The second question motivates the first. The Bureau of Labor Statistics includes a new good in the CPI only after it has been on sale for some time (fn. 1). The index then tracks the good's later price changes but never records the gain from its arrival. In the terms of Section 10.2, the exact index values the new good in the base period at its virtual price, while the CPI drops the good from the base-period comparison. Hausman quotes the agency's own warning that a systematic measurement error of this kind would bias the measured rate of price change (p. 210, quoting Fixler, 1993).

The question also matters for the economics of product differentiation. Hausman notes that differentiation is one of the two basic business strategies (p. 209). He calls RTE cereal "perhaps the foremost industry in the introduction of new goods" (p. 213). Some economists read cereal brand proliferation as wasteful or as a device to deter entry (Schmalensee, 1978). If new brands create little surplus, the advertising spent to launch them is mostly a private transfer. If they create large surplus, official price indexes miss a real gain. Hausman chooses a demanding test case. Apple-Cinnamon Cheerios (ACC), introduced by General Mills in 1989, sits next to two established brands of the same firm, Cheerios and Honey-Nut Cheerios. Whether consumers value a product that may already be "spanned by existing brands" is an empirical question (p. 216).

10.5.2 The setting: brand proliferation in ready-to-eat cereal

The industry introduces many brands (pp. 213–215). From 1980 to 1992 about 190 new brands entered a pool of about 160 existing ones. More than 95 of the new brands were discontinued. Of the 27 brands introduced in 1989, 14 had been withdrawn by 1993. Only 2 of the 190 reached a pound share above 1 percent. Even so, about 25 percent of RTE consumption came from

[2] The NBER page of the volume is dated January 1996, so the paper is sometimes cited as Hausman (1996). Page numbers below are those of the published volume, pp. 209–237.

brands introduced within the previous ten years. Hausman notes that about 80 percent of new consumer products fail in general (fn. 9).

The industry is concentrated at the firm level and fragmented at the brand level. Six firms together accounted for 94 percent or more of dollar sales over 1982–92 (p. 214). Kellogg's share ranged from 37.3 to 41.5 percent, General Mills' from 23.0 to 29.0 percent and General Foods' (Post) from 10.4 to 15.8 percent. Quaker, Ralston and Nabisco each held about 3.0 to 8.9 percent, and Malt-O-Meal was the only other firm above 1 percent. Individual brands are small. In 1993 the largest General Mills brand, Cheerios, had 5.3 percent, and the largest Kellogg brands, Frosted Flakes and Corn Flakes, had 5.0 and 4.99 percent (p. 214).

No significant manufacturer had entered successfully in fifty years. Entrants of the 1970s, such as Pillsbury, Pet and Colgate, did not last, although real revenue grew by 6.7 percent a year over 1982–92 (p. 215). Launching a brand cost $20–40 million in advertising and promotion in the first year, and the spending typically continued for one or two more years. A 1 percent share counts as "a great success" (p. 215). The only outside competition of note came from private labels, which doubled their share from about 4 to 8 percent over five to ten years. Ralston manufactured most of them.

Hausman rejects the view that proliferation deters entry. The Federal Trade Commission had argued this "shared monopoly" theory against the leading firms and lost (fn. 10). Judd (1985) showed that proliferation is a credible preemption device only if exit costs are high, and withdrawing a brand is cheap. Hausman instead sees sunk advertising as the main barrier to entry, in the spirit of Sutton (1991). The success of private labels, which advertise little and copy existing brands, supports this reading (pp. 215–216). The welfare question remains open under either view. Many economists doubt the social value of brands that mostly fail, and ACC is a natural test.

10.5.3 Data

The data are Nielsen Scantrak scanner data (p. 220). The time series has 137 weekly observations from January 1990 to August 1992. The cross section has seven metropolitan areas: Boston, Chicago, Detroit, Los Angeles, New York, Philadelphia and San Francisco. In each area Nielsen samples supermarkets by stratified random sampling, and the sample covers most cereal sold. Sales are recorded for each stock-keeping unit (each package size of each brand) at a weekly average price. Hausman aggregates packages to weekly pounds of each brand and an average price per pound. The panel thus has $7 \times 137 = 959$ city-week observations for each brand. Prices vary by about 50 percent over the sample, mostly through promotions and coupons (pp. 216 and 228).

Brands are grouped into three segments used by industry marketing analysts (Table 5.1). The adult segment contains Shredded Wheat Squares, Special K, Fruit Wheats, Shredded Wheat, Shredded Wheat and Bran, Spoon-Size Shredded Wheat and Grape Nuts. The child segment contains Trix, Kix, Frosted Flakes and Froot Loops. The family segment contains the nine brands of Table 10.4, ACC among them. The family segment accounts for about 26.4 percent of RTE sales (p. 220). Hausman reports that his specification tests do not reject the segmentation (fn. 22).

The three Cheerios brands hold 42.84 percent of the family segment, or about 11.3 percent of all cereal sales (p. 221). ACC holds 6.19 percent of the segment, about 1.6 percent of all cereal. By the standards of Section 10.5.2 the brand is a large success, since almost no new brand reaches 1 percent.

Table 10.4: The family segment of ready-to-eat cereal, 1992

Brand	Company	Average price ($ per pound)	Segment share (percent)
Cheerios	General Mills	2.644	21.62
Honey-Nut Cheerios	General Mills	3.605	15.03
Apple-Cinnamon Cheerios	General Mills	3.480	6.19
Corn Flakes	Kellogg	1.866	14.24
Raisin Bran	Kellogg	3.214	13.11
Rice Krispies	Kellogg	2.475	13.54
Frosted Mini-Wheats	Kellogg	3.420	9.07
Frosted Wheat Squares	Nabisco	3.262	1.48
Raisin Bran	Post	3.046	5.72

Notes: Reproduced in full from Hausman (1997, Table 5.2). Shares are shares of family-segment sales. The three Cheerios brands together hold 42.84 percent of the segment.

10.5.4 A three-level demand system

Hausman estimates demand with the multistage budgeting structure of Section 5.5, drawn in Figure 5.4(a). The top level is total cereal demand. The middle level allocates cereal spending across segments. The bottom level allocates segment spending across brands. Estimation proceeds from the bottom up, and the price indexes of each level feed the level above (pp. 216–218). We index segments by m and g, brands by i and j, cities by $n = 1, \ldots, N$ and weeks by $t = 1, \ldots, T$. In this section $N = 7$ counts cities, not firms, and M counts segments, not consumers. The subscript n on p_n^V and w_n still denotes the new good.

Bottom level. For brand i in segment m, the share equation is an almost ideal demand system (AIDS) in segment expenditure (Deaton and Muellbauer, 1980a),

$$w_{int} = \alpha_{in} + \beta_i \ln \frac{Y_{mnt}}{P_{mnt}} + \sum_{j \in m} \gamma_{ij} \ln p_{jnt} + \xi_{int} \tag{10.39}$$

(Hausman's eq. 5). Here w_{int} is the revenue share of brand i in segment spending Y_{mnt}, and P_{mnt} is the segment price index. The price per pound of brand j is p_{jnt}, and ξ_{int} is the demand error. The intercept α_{in} is a brand-city effect. Table 5.3 shows that the equations also include a quadratic time trend and a display variable $\ln(DISP + 1)$. Adding up across the brands of the segment requires $\sum_i \alpha_{in} = 1$, $\sum_i \beta_i = 0$ and $\sum_i \gamma_{ij} = 0$. Homogeneity requires $\sum_j \gamma_{ij} = 0$, and Slutsky symmetry requires $\gamma_{ij} = \gamma_{ji}$.

Three features of (10.39) carry the analysis. First, the γ_{ij} are unrestricted apart from symmetry and homogeneity. With nine brands that leaves $\frac{9 \times 8}{2} = 36$ free price coefficients, and no equal-cross-elasticity assumption constrains substitution within the segment. Second, a test of $\beta_i = 0$ for all i is a test of *segment homotheticity*, the hypothesis that brand shares do not depend on segment spending. Third, the expenditure variable is segment spending. Using total spending "is inconsistent with the economic theory of multistage budgeting" and gives worse results (p. 217).

The *conditional elasticities* hold segment spending fixed. With the translog index of the AIDS, Shephard's lemma gives $\frac{\partial \ln P_m}{\partial \ln p_j} = w_{j|m} - \beta_j \ln \frac{Y_m}{P_m}$, where $w_{j|m}$ is brand j's share of the segment. Since $q_i = \frac{w_{i|m} Y_m}{p_i}$, we have $\ln q_i = \ln w_{i|m} + \ln Y_m - \ln p_i$. Differentiating with respect to $\ln p_j$ at

fixed Y_m,

$$\varepsilon^c_{ij} = -\mathbf{1}\{i=j\} + \frac{1}{w_{i|m}}\frac{\partial w_{i|m}}{\partial \ln p_j} = -\mathbf{1}\{i=j\} + \frac{\gamma_{ij} - \beta_i\left(w_{j|m} - \beta_j \ln \frac{Y_m}{P_m}\right)}{w_{i|m}}. \tag{10.40}$$

Differentiating instead with respect to $\ln Y_m$ gives the conditional expenditure elasticity $\phi_{i|m} = 1 + \frac{\beta_i}{w_{i|m}}$. These are the AIDS formulas of Section 5.3.6, written with within-segment shares.

Middle level. Segment quantities follow a log-log system,

$$\ln q_{mnt} = \alpha_{mn} + \phi_m \ln Y_{nt} + \sum_{g=1}^{M} b_{mg} \ln P_{gnt} + \xi_{mnt}, \qquad m = 1, \ldots, M \tag{10.41}$$

(Hausman's eq. 6). Here q_{mnt} is the pound volume of segment m, Y_{nt} is total cereal spending in the city-week, and P_{gnt} is the price index of segment g. Because cereal spending is held fixed, ϕ_m is the segment's expenditure elasticity and b_{mg} are price elasticities conditional on cereal spending. Hausman uses Stone indexes at this level (p. 221) and states that the choice between exact and Stone indexes typically matters little (p. 218). Exact two-stage budgeting requires additive separability at the level above, and the AIDS is a generalized Gorman polar form, so Gorman's theorem applies (Hausman, 1997, fn. 17). A less restrictive middle level, not consistent with exact two-stage budgeting, gives similar results (fn. 17). The log-log system is second-order flexible, and Slutsky restrictions are not imposed on it (fn. 18).

Top level. Total cereal consumption Q_t satisfies

$$\ln Q_t = a_0 + a_1 \ln y_t + \varepsilon_U \ln \Pi_t + Z_t \psi + \xi_t \tag{10.42}$$

(Hausman's eq. 7), where y_t is real disposable income, Π_t is the real cereal price index and Z_t holds demographic and monthly seasonal variables. A longer period than store data provide helps to estimate this elasticity, so Hausman fits (10.42) to sixteen years of national monthly data from the Bureau of Labor Statistics. He uses instrumental variables, with cost shifters for ingredients, packaging and labor as instruments (p. 218). The coefficient ε_U is the price elasticity of total cereal demand.

Combining the levels. Pricing and welfare calculations need *unconditional* elasticities, which let segment and cereal spending respond to prices. The next result writes them in terms of the three levels. It is the formula of (5.130) for beer, restated in this section's notation with Stone indexes. We restate it because its rank-one structure matters for reading Hausman's tables.

Proposition 10.28 (Unconditional elasticities in a three-level system)**.** *Let brand i belong to segment m and brand j to segment g. Assume the following.*

(i) The demand q_i depends on prices only through the prices of segment m and on spending only through Y_m, with elasticities ε^c_{ij} and $\phi_{i|m}$.

(ii) Segment spending is $Y_m = P_m q_m$, with a Stone index satisfying $\frac{\partial \ln P_g}{\partial \ln p_j} = w_{j|g}$.

(iii) Segment quantities follow (10.41).

(iv) Cereal spending is $Y = \Pi Q$*, with* $\ln \Pi = \sum_g w_g \ln P_g$ *and* w_g *segment* g*'s share of cereal spending. Cereal volume* Q *follows* (10.42) *at fixed income.*

Then

$$\varepsilon_{ij} = \mathbf{1}\{m = g\}\, \varepsilon^c_{ij} + \phi_{i|m}\, w_{j|g} \big[\mathbf{1}\{m = g\} + b_{mg} + \phi_m (1 + \varepsilon_U) w_g\big]. \tag{10.43}$$

Proof. Write $q_i = q_i^c(p_m, Y_m)$. The price p_j moves q_i directly if j is in segment m, and indirectly through Y_m. By the chain rule,

$$\varepsilon_{ij} = \mathbf{1}\{m = g\}\, \varepsilon^c_{ij} + \phi_{i|m} \frac{\mathrm{d} \ln Y_m}{\mathrm{d} \ln p_j}.$$

By (ii), $\ln Y_m = \ln P_m + \ln q_m$. The index P_m responds to p_j only if $m = g$, so

$$\frac{\mathrm{d} \ln Y_m}{\mathrm{d} \ln p_j} = \mathbf{1}\{m = g\}\, w_{j|g} + \frac{\mathrm{d} \ln q_m}{\mathrm{d} \ln p_j}.$$

By (iii), q_m responds to p_j through the index P_g and through cereal spending Y:

$$\frac{\mathrm{d} \ln q_m}{\mathrm{d} \ln p_j} = b_{mg}\, w_{j|g} + \phi_m \frac{\mathrm{d} \ln Y}{\mathrm{d} \ln p_j}.$$

By (iv), $\ln Y = \ln \Pi + \ln Q$ and $\frac{\partial \ln \Pi}{\partial \ln p_j} = w_g\, w_{j|g}$. With income fixed, $\frac{\mathrm{d} \ln Q}{\mathrm{d} \ln p_j} = \varepsilon_U\, w_g\, w_{j|g}$, so

$$\frac{\mathrm{d} \ln Y}{\mathrm{d} \ln p_j} = (1 + \varepsilon_U)\, w_g\, w_{j|g}.$$

Substituting the last display into the one before it, and that into the second display,

$$\frac{\mathrm{d} \ln Y_m}{\mathrm{d} \ln p_j} = w_{j|g} \big[\mathbf{1}\{m = g\} + b_{mg} + \phi_m (1 + \varepsilon_U) w_g\big].$$

Inserting this into the first display gives (10.43). □

Two implications follow. Within a segment ($m = g$), the gap between unconditional and conditional elasticities is $\phi_{i|m}\, w_{j|m}\, B_m$, with a common factor $B_m = 1 + b_{mm} + \phi_m (1 + \varepsilon_U) w_m$. The matrix of gaps is therefore the outer product of the vector of expenditure elasticities and the vector of shares, a matrix of rank one. Across segments only the expenditure channel remains, so all brand-specific substitution between segments is ruled out. For the family segment, Table 5.4 gives $b_{FF} = -1.829$ and $\phi_F = 0.999$. With $\varepsilon_U = -0.90$ and $w_F = 0.264$ the factor is $B_F = 1 - 1.829 + 0.999 \times 0.10 \times 0.264 = -0.80$. A higher price of any family brand raises the segment index, and because segment demand is elastic, family spending falls.

10.5.5 Identification and estimation

Prices in (10.39) are endogenous if retailers or manufacturers set them knowing local demand. The usual remedy, input prices excluded from demand, fails here. There may be too few input prices, and they are rarely observed weekly (p. 219). Hausman exploits the panel structure instead. He models the price of brand j in city n and week t as

$$\ln p_{jnt} = \kappa_j \ln c_{jt} + \mu_{jn} + \omega_{jnt} \tag{10.44}$$

(Hausman's eq. 8). The cost c_{jt} has no city-specific time variation, consistent with national shipping and national advertising. The effect μ_{jn} captures city-specific transport costs and wages. The shock ω_{jnt} has mean zero and captures local promotions. Section 5.8.4 writes the same model as (5.131) for the beer study of Hausman et al. (1994).

Assumption 10.29 (Independence across cities)**.** After brand-city effects are removed, the following hold.

(i) The shocks ω_{jnt} are independent across cities. They may be correlated across brands within a city (Hausman, 1997, fn. 19).

(ii) The demand errors ξ_{int} are uncorrelated with the cost component c_{jt} and with the price shocks $\omega_{j\ell t}$ of every other city $\ell \neq n$.

Let a tilde denote the deviation from the brand-city mean. Under Assumption 10.29 the prices of every segment brand in other cities are valid instruments,

$$\mathbb{E}\big[\widetilde{\ln p}_{j\ell t}\,\tilde{\xi}_{int}\big] = 0, \qquad i, j \in m,\ \ell \neq n. \tag{10.45}$$

Relevance comes from the common cost. By (10.44), $\operatorname{Cov}(\widetilde{\ln p}_{j\ell t}, \widetilde{\ln p}_{jnt}) = \kappa_j^2 \operatorname{Var}(\widetilde{\ln c}_{jt})$, which is positive whenever national costs vary over time. In Hausman's words, prices in one city, "after elimination of city- and brand-specific effects", are driven by underlying costs (p. 219). This is the logic of Hausman and Taylor (1981) and Breusch et al. (1989): after unit effects are removed, variation shared with other units serves as an instrument. With more than two cities the model is overidentified, and the restrictions can be tested (fn. 20). Instruments of this kind are now called *Hausman instruments*. Section 5.8.4 discusses them in general, and Chapter 8 uses them in random-coefficient models.

Hausman offers a second interpretation (p. 219). Suppose supermarkets set weekly prices under constant short-run marginal cost and do not adjust them to clear the market. Then prices are predetermined with respect to the demand errors, and instruments are unnecessary for prices. Segment spending Y_{mnt} may still need instruments, because it responds to the same demand shocks. The choice between the two views can be tested with the specification test of Hausman (1978).

Estimator. Stack the share equations of the segment, dropping one by adding up (Post Raisin Bran in Table 5.3). For city n and week t let $\xi_{nt}(\theta)$ be the vector of residuals of the remaining eight equations and Z_{nt} the vector of instruments: the exogenous regressors and the other-city prices. The estimator combines seemingly unrelated regression with instruments (p. 221). In generalized method of moments form it solves

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{n,t} \xi_{nt}(\theta) \otimes Z_{nt}\right]^{\top} \left[\hat{\Sigma} \otimes \sum_{n,t} Z_{nt} Z_{nt}^{\top}\right]^{-1} \left[\sum_{n,t} \xi_{nt}(\theta) \otimes Z_{nt}\right] \tag{10.46}$$

subject to symmetry, with $\hat{\Sigma}$ a first-step estimate of the covariance matrix of the eight errors. This is a form of three-stage least squares, and Appendix A develops the general theory. Hausman tests and imposes symmetry, which is not rejected, and tests homotheticity, which is rejected (p. 221). The paper does not report the instrument list in full, the first-stage fit, or the outcome of the overidentification and Hausman tests.

The source of identifying variation deserves emphasis. After brand-city effects are removed, the slope of each brand's demand curve is identified by the weekly co-movement of that brand's

price across the seven cities. Hausman attributes this co-movement to national costs. Any national demand shock that also moves prices in all cities in the same week contaminates it. Section 10.6 works out the consequences.

10.5.6 Estimates

Table 10.5 reproduces the price, expenditure and display coefficients of the bottom level. Own-price coefficients are large and precise. Most cross-price coefficients are positive, as substitution suggests. The three Cheerios brands are substitutes for each other: $\gamma_{12} = 0.02087$, $\gamma_{13} = 0.00842$ and $\gamma_{23} = 0.01849$, each more than two standard errors from zero. A few cross coefficients are negative, such as $\gamma_{56} = -0.00791$ between Kellogg's Raisin Bran and Rice Krispies. The expenditure coefficients show that homotheticity fails. ACC's $\beta_3 = -0.00854$ implies an expenditure elasticity within the segment of $1 + \frac{-0.00854}{0.06193} = 0.86$. Corn Flakes and Rice Krispies, with positive β_i, have elasticities above one. Display coefficients are positive for all brands and significant for all but Rice Krispies.

Table 10.5: Bottom-level AIDS estimates for the family segment (selected coefficients)

Notes: From Hausman (1997, Table 5.3). Columns are share equations, rows are regressors. Asymptotic standard errors in parentheses. Brands 1 to 3 are Cheerios, Honey-Nut and Apple-Cinnamon Cheerios. The row "Own price" gives γ_{ii} for equations 4 to 8 (for equations 1 to 3 it appears in the rows above). Symmetry $\gamma_{ij} = \gamma_{ji}$ is imposed, so row $\ln p_k$ of column i equals γ_{ik}. Estimation is seemingly unrelated regression with other-city price instruments on 959 city-week observations. All equations also include a constant, a quadratic trend and city effects. The Post Raisin Bran equation is dropped by adding up. Cross coefficients among brands 4 to 8 are in the paper.

Table 10.6 reproduces the middle level. Expenditure elasticities are below one for adult cereals (0.73), above one for child cereals (1.19) and indistinguishable from one for family cereals (1.00). Own-price elasticities are large, about −2.0, and cross elasticities are large and significant (p. 221). For example, a 1 percent rise in the family price index raises child-segment volume by 1.04 percent. The top level gives a price elasticity of total cereal demand of $\varepsilon_U = -0.90$, with an asymptotic standard error of 0.10 (p. 224). Cereal as a whole is inelastic, while each segment and each brand is elastic.

Table 10.7 reports the elasticities that matter for ACC. Conditional own elasticities in the family segment range from −1.74 (Cheerios) to −3.16 (Frosted Wheat Squares), with ACC at −2.12. The Cheerios brands compete with each other, "consistent with the 'cannibalization' fears of brand managers" (p. 221). A 1 percent rise in the Honey-Nut price raises ACC's volume

Table 10.6: Middle-level segment demand

	(0.00365)	(0.00401)	(0.00221)

Notes: From Hausman (1997, Table 5.4). The dependent variable is segment sales in pounds, and columns are segment equations. Asymptotic standard errors in parentheses. Each equation also includes a constant, a quadratic trend and six city dummies. Price indexes are Stone indexes.

by 0.35 percent at fixed segment spending, and a rise in the Cheerios price raises it by 0.24 percent. The responses of the larger brands to ACC's price are smaller (0.14 for Honey-Nut, 0.07 for Cheerios). Slutsky symmetry predicts this asymmetry. With small income effects, $\frac{\varepsilon_{ij}}{\varepsilon_{ji}}$ is close to $\frac{w_j}{w_i}$, and indeed $\frac{0.349}{0.142} = 2.5$ while $\frac{0.150}{0.062} = 2.4$. The overall elasticities add the segment and cereal spending responses of Proposition 10.28. ACC's overall own elasticity is −2.17.

Remark 10.30 (Reading Tables 5.5 and 5.6). Hausman does not say whether rows of his elasticity tables index quantities or prices. The estimates themselves settle the question. Our computations below use only numbers printed in the paper.

(a) Table 5.5 can be rebuilt from Table 5.3 with (10.40). The shares are the mean shares printed under Table 5.5, and the Post Raisin Bran coefficients follow from adding up and homogeneity. One constant is not reported, the mean of $\ln \frac{Y_m}{P_m}$. Fitting it by least squares gives 13.87, and then all 81 entries match the printed table to within 0.0006. Only the reading "row i is the quantity" fits, because the denominator $w_{i|m}$ belongs to the quantity.[3]

(b) By Proposition 10.28, overall minus conditional elasticities should form a rank-one matrix with typical entry $\phi_{i|m} w_{j|m} B_F$. Table 5.6 minus Table 5.5 is far from rank one. Table 5.6 transposed minus Table 5.5 is rank one up to rounding. Each of its 81 entries divided by $\phi_{i|m} w_{j|m}$ equals −1.054, with a standard deviation of 0.0001. Hence Table 5.6 prints in row r and column c the elasticity of brand c's quantity with respect to brand r's price. The standard errors agree. Frosted Wheat Squares, the smallest and least precisely estimated brand, has large standard errors in its row of Table 5.5 and in its column of Table 5.6.

(c) The common factor in Hausman's table, −1.054, differs from the value $B_F = -0.80$ that (10.43) gives with his estimates. The printed factor equals $1 + b_{FF} + \phi_F \varepsilon_U w_F$ with

[3]These are our computations. The Stone-index version of (10.40) misses by up to 0.48. The value $e^{13.87}$ is about \$1.05 million, close to the family-segment spending per city-week implied by Hausman's pound volumes and prices (about \$1.14 million), if the price index is normalized near one.

Table 10.7: Elasticities of the Cheerios brands: rows are quantities, columns are prices

	Price of

	(0.07505)	(0.06808)	(0.07525)	(0.06503)	(0.07011)	(0.05384)

Notes: From Hausman (1997, Tables 5.5 and 5.6), asymptotic standard errors in parentheses. Entry (i, j) is the signed elasticity of the quantity of brand i with respect to the price of brand j. The conditional panel copies rows 1 to 3 of Table 5.5. The overall panel takes entry (i, j) from row j, column i of Table 5.6, because Table 5.6 is printed with rows indexing prices (Remark 10.30). The other three family brands are omitted.

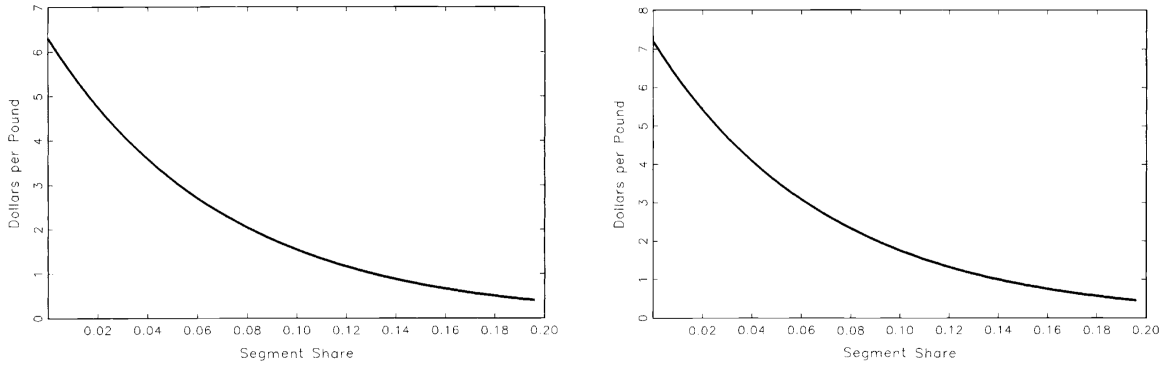
$w_F = 0.250$. That is the formula with ε_U in place of $1 + \varepsilon_U$, which would be right if the top-level elasticity referred to cereal spending rather than cereal volume. The paper does not state its formula, so we cannot tell which reading is intended. The difference matters little for own elasticities (−2.173 against −2.160 for ACC). It matters more for cross elasticities between brands with small conditional cross effects.

The rearranged overall elasticities explain the negative cross elasticities in Table 5.6. Take the response of Post Raisin Bran's volume to the Cheerios price, printed as −0.51 in the Cheerios row. Its conditional value is −0.105, small and imprecise (standard error 0.124). Post Raisin Bran's expenditure elasticity is $1 + \frac{0.04466}{0.05722} = 1.78$, the largest in the segment, with $\beta_9 = 0.04466$ implied by adding up. The segment-spending term is $1.78 \times 0.216 \times (-1.054) = -0.41$, and the sum is −0.51. A higher Cheerios price shrinks family spending, and the brand most sensitive to segment spending loses the most. Unconditionally, brands of the same segment can be gross complements. The negative values are thus a mechanical consequence of an elastic segment and imprecise conditional cross effects. They are not evidence that consumers eat these cereals together.

10.5.7 The virtual price and consumer surplus

The virtual price of ACC is the price at which its predicted share falls to zero. By the separability argument of Section 10.2, only the conditional demand curve of the new brand is needed (fn. 7). Hausman computes it from the bottom level in two ways (fn. 23). Method 1 evaluates the demand system at the average of the right-hand-side variables over the 959 observations and solves for the price that sets ACC's share to zero. Method 2 solves for the virtual price in each of the 959 city-weeks and averages the solutions. The methods differ because the system is nonlinear. Figure 10.3 shows the resulting demand curves, in the plane of segment share

and price per pound. Both are convex and meet the price axis at a finite price, about $6.30 for method 1 and about $7.20 for method 2.



(a) Method 1: demand at average regressors

(b) Method 2: average of 959 city-week curves

Figure 10.3: Estimated AIDS demand curves for Apple-Cinnamon Cheerios. The horizontal axis is ACC's share of family-segment spending and the vertical axis is the price in dollars per pound. The intercept on the price axis is the virtual price. Source: Hausman (1997), Figures 5.1 and 5.2.

Virtual price. City virtual prices range from about $6.00 to about $7.50. Hausman's best estimate of the aggregate virtual price is $7.14, with an asymptotic standard error of $1.33 (p. 227). The lower end of an approximate 95 percent confidence interval is $4.75. Hausman describes it as 35 percent above ACC's average price of $3.48 (36.5 percent by our computation).[4] The virtual price is about twice the actual price. Hausman finds this reasonable given an own elasticity of about −2.2 (p. 228).

Exact consumer surplus. The exact compensating variation is computed from the expenditure function, by the method of Hausman and Newey (1995) (fn. 24). It is close to the area under the demand curve above $3.48. The estimate is $32,268 per city per week, with an asymptotic standard error of $3,384 (p. 228). For the United States it amounts to about $78.1 million per year, or about $0.3136 per person per year. Hausman anticipates the objection that his method yields small elasticities. The same technique gives own-price elasticities for beer brands between about −4.0 and −6.2 in Hausman et al. (1994) (fn. 25).

A bound robust to extrapolation. Observed prices never come near the virtual price, so $7.14 rests on the shape of the estimated curve far outside the data. Hausman addresses this with a supporting line. If demand is convex, the tangent at the observed point lies below the curve and meets the price axis below the true intercept. This is the logic of Proposition 10.21. Drawing the tangent to the curves of Figure 10.3 at $3.48 gives lower bounds between $5.55 and $5.94, with a standard error of about $0.15 (p. 228). The bounds lie about 65 percent above the average price.[5]

Two consistency checks. Two checks of our own relate these numbers to the theory of Section 10.2. Hausman's pound volumes and prices imply family-segment spending of about $1.14 million

[4] A symmetric normal interval would give $7.14 - 1.96 \times 1.33 = \$4.53$ (our computation). Hausman does not say how he computes $4.75.

[5] The tangents are drawn in the share-price plane of the figures. In the quantity-price plane, Proposition 10.21 with ACC's overall elasticity of −2.173 gives $3.48\left(1 + \frac{1}{2.173}\right) = \$5.08$ (our computation). Convexity in one plane does not imply convexity in the other, since the share is proportional to price times quantity.

per city-week, so ACC sells about 20,300 pounds a week in a typical city.[6] First, the Paasche rectangle of Proposition 10.11 is $(7.14 - 3.48) \times 20{,}300 \approx \$74{,}200$. The exact surplus, \$32,268, is 43 percent of it. A linear Hicksian curve would give exactly half, and a convex curve lies below the chord, so the share below one half is what convexity predicts. Second, the rectangle is about 1.7 percent of cereal spending, which matches the index effect Hausman reports below.

Table 10.8: Welfare effects of Apple-Cinnamon Cheerios

Quantity	Estimate	Page
Perfect competition (AIDS)		
Virtual price, aggregate	\$7.14 (1.33)	227
Virtual price, range across cities	\$6.00 to \$7.50	227
Lower end of approximate 95% interval	\$4.75	227
Tangent lower bound on virtual price	\$5.55 to \$5.94 (about 0.15)	228
Consumer surplus per city per week	\$32,268 (3,384)	228
Consumer surplus, United States, per year	\$78.1 million	228
Consumer surplus per person per year	\$0.3136	228
Alternative specification		
CES virtual price	infinite	231
CES consumer surplus	about 3× AIDS	231
Imperfect competition (rivals' prices fixed)		
Loss from higher Cheerios prices, city-week	\$890 + \$3,715 = \$4,605	234
Net gain per city-week	\$27,395 (85.6% of \$32,000)	234
Net gain, United States, per year	\$66.8 million, \$0.268 per person	234
Cereal price index		
Overstatement, perfect competition	about 25%	229
Overstatement, imperfect competition	about 20%	234

Notes: Compiled from the text of Hausman (1997), pp. 227–234. Asymptotic standard errors in parentheses. The net gain uses a rounded perfect-competition surplus of \$32,000. The index overstatements refer to the cumulative effect of brands introduced over ten years.

Table 10.8 collects the welfare results of the paper.

10.5.8 Implications for the cereal price index

Hausman translates the surplus into a price-index correction (pp. 228–229). Treating ACC as part of Honey-Nut Cheerios would show almost no effect, beyond ACC's slightly lower price. Suppose instead, contrary to fact, that all of ACC's share came from Honey-Nut. With ACC valued at its virtual price before the introduction, the price index of the two brands falls from about \$4.60 to about \$3.57, or 22 percent. The family-segment index falls from \$3.10 to \$2.88, or 7.1 percent. The overall cereal index falls by about 0.017, or \$0.052, about 1.7 percent. These figures are share-weighted average prices with ACC valued at \$7.14 in the base period.[7]

[6] We compute these figures from Table 5.2 and p. 234. Cheerios sells 93,738 pounds at \$2.644 with a segment share of 0.216, and Honey-Nut sells 47,215 pounds at \$3.605 with a share of 0.150. The two imply segment spending of \$1.147 and \$1.133 million. ACC's volume is $\frac{0.0619 \times 1.14 \text{ million}}{3.48}$.

[7] We approximately reproduce these figures from Table 5.2. The Honey-Nut and ACC composite is $\frac{15.03 \times 3.605 + 6.19 \times 7.14}{21.22} = \$4.64$ before and $\frac{15.03 \times 3.605 + 6.19 \times 3.48}{21.22} = \$3.57$ after, a fall of 23 percent. The family index is \$2.88 with ACC at \$3.48 and \$3.11 with ACC at \$7.14. The small gaps from Hausman's \$4.60, 22 percent and

Hausman then states a rule of thumb. The change in the overall index is approximately ACC's share of cereal spending, 1.6 percent, times the gap between the virtual and the actual price relative to the actual price. If the virtual price is twice the actual price, the index change roughly equals the new brand's share. About 25 percent of cereal demand comes from brands introduced in the previous ten years. Suppose these brands sell at about the same prices as old ones and have virtual prices twice their actual prices. Then the cereal index that ignores them is too high by about their share, 25 percent (p. 229). Exits reduce the gain, but brands are withdrawn only when their shares are tiny, so the correction is small and could not be estimated (fn. 26).

The rule of thumb is the Paasche rectangle of Proposition 10.11, expressed as a share of spending: $w_n\left(\frac{p_n^V}{p_n} - 1\right)$. The proposition shows that this rectangle exceeds the exact gain for any downward-sloping Hicksian curve. Hausman's own surplus estimate is 43 percent of the rectangle, about 0.75 percent of cereal spending against the 1.7 percent of the rule. Applying the same ratio to his extrapolation would cut the 25 percent figure to about 11 percent, and the imperfect-competition figure of 20 percent to about 9 percent.[8] The correction remains large by the standards of price measurement. The main conclusion survives, but the rectangle overstates the exact effect by a factor of about two.

10.5.9 Alternative specifications: attributes, logit and CES*

Section 5.5 of the paper explains why Hausman prefers a flexible product-space system. Attribute models in the Hotelling, Gorman and Lancaster tradition describe a product by its characteristics and predict demand for new products from them (Hausman, 1997, fn. 27, citing Pakes et al., 1993). Hausman argues that ACC cannot be described by attributes, "perhaps the volume of apples and cinnamon" (p. 229). He adds that no metric measures how close attributes are and no aggregator combines them. The right measure of closeness, in his view, is the cross-price elasticity. His experience with probit models of French champagne makes the point: "the bubble content could never be made to come in significant" (fn. 28, on the models of Hausman and Wise, 1978). The logit model has the independence of irrelevant alternatives (IIA) property, which "typically leads to a vast overestimate" of the surplus from a new good (p. 230). The nested logit still has IIA within each nest. Section 10.7 takes up the case for characteristics models.

CES demand. Hausman compares his estimates with the constant elasticity of substitution (CES) model of Dixit and Stiglitz (1977), which treats all goods symmetrically. Utility is

$$U(x_1, \ldots, x_n) = \left(\sum_{i=1}^{n} x_i^{\rho} \right)^{\frac{1}{\rho}}, \qquad 0 < \rho < 1 \tag{10.47}$$

(Hausman's eq. 9). Write $\eta = \frac{1}{1-\rho}$ for the elasticity of substitution, so that $1 - \eta = -\frac{\rho}{1-\rho}$. Maximizing (10.47) subject to $\sum_i p_i x_i = y$ gives the Marshallian demand implied by (10.18) with equal taste parameters,

$$x_k = \frac{y\, p_k^{-\eta}}{\sum_{i=1}^{n} p_i^{1-\eta}}. \tag{10.48}$$

$3.10 presumably reflect rounding.

[8] We compute $0.435 \times 25 = 10.9$ and $0.435 \times 0.856 \times 25 = 9.3$. The extrapolation also assumes that every new brand of the decade resembles ACC, a strong assumption that Hausman calls "perhaps unrealistic" (p. 229).

Hausman's eq. 10 writes the compensated version. The unit expenditure function is $c(p) = \left(\sum_i p_i^{1-\eta}\right)^{\frac{1}{1-\eta}}$, and Hicksian demand is $x_k = U\left(\frac{p_k}{c(p)}\right)^{-\eta} = U\, p_k^{-\eta}\left(\sum_i p_i^{1-\eta}\right)^{-\frac{\eta}{\eta-1}}$. Since $\frac{\eta}{\eta-1} = \frac{1}{\rho}$, this equals $\left[\frac{\sum_i x_i^{\rho}}{\sum_i p_i^{-\frac{\rho}{1-\rho}}}\right]^{\frac{1}{\rho}} p_k^{-\frac{1}{1-\rho}}$, which is eq. 10 without its error term. Taking logs of (10.48), $\ln x_k = \ln y - \eta \ln p_k - \ln \sum_i p_i^{1-\eta}$. Differentiating with respect to $\ln p_j$ and writing $w_j = \frac{p_j^{1-\eta}}{\sum_i p_i^{1-\eta}}$ for the spending share,

$$\varepsilon_{kj} = -\eta\, \mathbf{1}\{k = j\} + (\eta - 1) w_j. \tag{10.49}$$

Every product has the same cross elasticity with respect to p_j, which is Hausman's eq. 11. Own elasticities depend only on the share and on η, "a property without any empirical foundation" (p. 231). Demand (10.48) is positive at every finite price, so the CES virtual price is infinite.

Estimates. Hausman estimates the CES model by nonlinear two-stage least squares (p. 231). He reports $\hat{\rho} = 0.580$ with an asymptotic standard error of 0.00001 and an elasticity of substitution of 2.13. The two printed numbers are inconsistent, since $\frac{1}{1-0.580} = 2.38$, while 2.13 corresponds to $\rho = 0.53$. We cannot tell which is the typographical error. Figure 10.4 shows the estimated CES curve. It rises steeply as the share approaches zero and never meets the price axis. The consumer surplus, the area under this curve above the price, is "about three times as high" as the AIDS estimate of $78.1 million a year (p. 231).

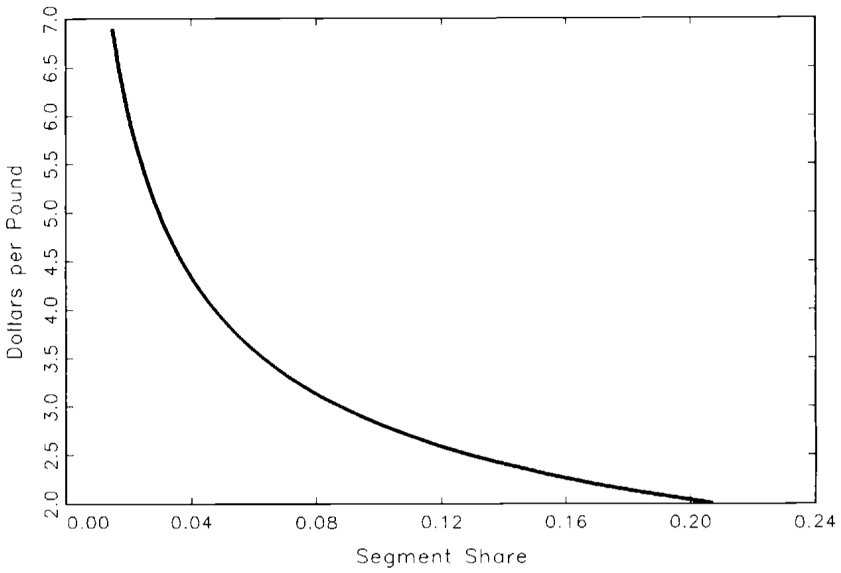


Figure 10.4: Estimated CES demand curve for family-segment brands. The horizontal axis is the segment share and the vertical axis the price in dollars per pound. The curve never meets the price axis, so the virtual price is infinite. Source: Hausman (1997), Figure 5.3.

The comparison teaches a lesson about functional form. At ACC's segment share of 0.0619, (10.49) gives an own elasticity of $-2.13 + 1.13 \times 0.0619 = -2.06$ with $\eta = 2.13$. This is close to the AIDS value of -2.12. The two systems thus give similar own elasticities at the data and diverge mainly in the extrapolation to zero quantity. The share-only CES formula of Corollary 10.18 implies, as computed in Section 10.2.7, that ACC lowers the cost of living of the family segment by 5.5 percent. The equivalent variation is then 5.5 percent of family-segment spending, about $63,000 per city-week, and the compensating variation is 5.8 percent. Both are about twice the

AIDS surplus. With $\eta = 2.38$ the fall in the cost of living is 4.5 percent.[9] In the CES and the logit, the value of variety is built into the functional form. The AIDS lets the data choose a finite virtual price, at the cost of relying on the curvature of the estimated curve.

10.5.10 Imperfect competition

The classical analysis assumes that other prices stay at marginal cost when the new good arrives. Hausman notes that most new brands come from multiproduct firms (p. 231). When General Mills raises the price of Cheerios, some of the lost buyers now switch to ACC instead of a rival brand. The firm keeps that demand, so the introduction lets it raise the prices of its existing brands. This effect lowers the consumer gain.

Pricing equations. Section 10.4.3 derives Hausman's pricing equations in the notation of this chapter. A single-product firm under Nash-Bertrand pricing sets $\frac{p_1 - mc_1}{p_1} = -\frac{1}{\varepsilon_{11}}$ (Hausman's eq. 12). A firm selling brands $k = 1, \ldots, K$ satisfies the elasticity form (10.35) of its first-order conditions (his eq. 13), with w_k the revenue share of brand k in the firm's sales. In matrix form these are (10.36), $w + E^{\top} m = 0$ and $m = -(E^{\top})^{-1} w$ (his eqs. 14 and 15), where $m_k = \frac{p_k - mc_k}{p_k} w_k$. Dividing each m_k by w_k gives the Lerner index of brand k.

The calculation. Hausman solves (10.36) for the General Mills family brands with ACC and without it. He holds marginal costs constant and assumes that "other firms, such as Kellogg, will not change their prices in response to the introduction" (p. 234). He claims that the resulting price changes are "a lower bound on expected price changes, absent new entry by competitors" (p. 233). Table 10.9 reproduces the results.

Table 10.9: Nash-Bertrand price-cost margins of the General Mills family brands

	Cheerios	Honey-Nut Cheerios
Price-cost margin	0.5268	0.5203
Price-cost margin without Apple-Cinnamon Cheerios	0.5251	0.5096
Price-cost margin if brand were independent	0.5193	0.5050

Notes: Reproduced in full from Hausman (1997, Table 5.7). Margins are Lerner indexes $\frac{p - mc}{p}$ from (10.36). The last row is $-\frac{1}{\varepsilon_{jj}}$ with the overall own elasticities of Table 5.6: $\frac{1}{1.92572} = 0.5193$ and $\frac{1}{1.98037} = 0.5050$. Rivals' prices and marginal costs are held fixed.

The margins rise when ACC joins the line, and they exceed the single-product margins of the last row. With constant marginal cost, (10.37) converts the margins into the ratio $r_k = \frac{p_k^{\text{with}}}{p_k^{\text{without}}}$ of the prices with and without ACC. The 1992 prices of Table 5.2 are observed with ACC on the market. The price without ACC is therefore $\frac{p_k^{\text{with}}}{r_k}$, and the price increase is $p_k^{\text{with}} - \frac{p_k^{\text{with}}}{r_k} = p_k^{\text{with}}\left(1 - \frac{1}{r_k}\right)$. For Cheerios, the ratio is $\frac{1-0.5251}{1-0.5268} = \frac{0.4749}{0.4732} = 1.0036$. At the 1992 price of \$2.644 the increase is $2.644 \times \left(1 - \frac{0.4732}{0.4749}\right) = \$0.0095$. For Honey-Nut, the ratio is $\frac{0.4904}{0.4797} = 1.0223$, and at \$3.605 the increase is $3.605 \times \left(1 - \frac{0.4797}{0.4904}\right) = \$0.0787$. Both are the figures

[9] These are our computations, using segment spending of \$1.14 million per city-week. Hausman's "three times" integrates his estimated CES curve, so the two comparisons are not identical. Both put the CES valuation at a multiple of the AIDS valuation.

Hausman reports.[10] The larger effect on Honey-Nut is expected, since ACC is a closer substitute for Honey-Nut than for Cheerios.

Welfare. Average weekly sales per city are 93,738 pounds of Cheerios and 47,215 pounds of Honey-Nut (p. 234). To first order, the price increases cost consumers $0.0095 \times 93{,}738 = \$890$ and $0.0787 \times 47{,}215 = \$3{,}715$ per city-week, a total of \$4,605. Hausman compares this loss with "the \$32,000–44,000 consumer's surplus estimates". The net gain is $\$32{,}000 - \$4{,}605 = \$27{,}395$, which is 85.6 percent of the Hicksian gain (p. 234). Per year the gain is \$66.8 million, or \$0.268 per person. The overstatement of the cereal CPI falls from about 25 percent to about 20 percent. Hausman notes that his data begin after ACC's launch, so he cannot compare prices before and after it directly. He leaves such a study for future research (p. 234).

What the calculation holds fixed. Reproducing Table 5.7 shows exactly what the counterfactual changes. The "without" row deletes ACC's row and column from the elasticity matrix and ACC's entry from the share vector. It keeps the shares and elasticities of Cheerios and Honey-Nut at their values with ACC present.[11] In the language of Section 10.4, the calculation captures only the new term that ACC adds to the first-order conditions. Before the launch, Cheerios and Honey-Nut had larger shares. The fall in their shares is the source of the two offsetting effects that Bresnahan (1997) stresses, and the calculation omits it. Rivals' prices are held fixed as well. Section 10.6.4 returns to both points.

Remark 10.31 (The orientation of the elasticity matrix in Table 5.7). Table 5.7 is reproduced exactly when Table 5.6 is read with rows as quantities, the layout that (10.36) requires. Remark 10.30 shows that Table 5.6 is printed with rows as prices. The two facts together imply that the margins were computed with ε_{jk} where (10.35) requires ε_{kj}. Recomputing with the layout implied by Remark 10.30, and changing nothing else, gives margins with ACC of 0.5250 (Cheerios), 0.5402 (Honey-Nut) and 0.5251 (ACC), and without ACC of 0.5215 and 0.5169. Relative to the prices without ACC, the implied increases are 0.7 percent for Cheerios and 5.1 percent for Honey-Nut. In dollars, $p_k^{\text{with}}\left(1 - \frac{1}{r_k}\right)$ gives \$0.0192 and \$0.1739 per pound. The first-order loss becomes \$10,004 per city-week, and the net gain 68.7 percent of \$32,000.[12] The direction is intuitive. In Honey-Nut's first-order condition the relevant cross effect is the response of ACC's volume to Honey-Nut's price, which is 0.21. The printed layout uses instead the response of Honey-Nut's volume to ACC's price, which is 0.08. We offer this as a reproduction exercise, since the paper itself does not confirm our reading of Table 5.6. It shows that the imperfect-competition adjustment is sensitive to a detail that papers rarely state, the layout of the elasticity matrix.

10.5.11 Robustness*

The paper reports several robustness checks, mostly in footnotes. Monthly data give elasticities similar to the weekly estimates, with less precision (fn. 21). The segmentation is not rejected by specification tests (fn. 22). A middle level that does not impose exact two-stage budgeting gives similar results (fn. 17). The choice between exact and Stone segment indexes "does not

[10] This is our computation. The implied prices without ACC are \$2.635 and \$3.526. The paper also reports markup increases of 0.32 and 3.0 percent. The first is the ratio of the Cheerios margins, $\frac{0.5268}{0.5251} = 1.0032$. The same ratio for Honey-Nut is 1.021.

[11] This is our computation. We solve (10.36) with the mean revenue shares of Table 5.5 and the Cheerios block of Table 5.6. The solution reproduces the four margins in the first two rows of Table 5.7 to four decimals.

[12] We computed these values with `figures/ch10/src/hausman_reproduction.py`. With the printed layout, the same program gives ACC's own margin as 0.6201, a value the paper does not report.

typically have much influence" (p. 218). The two aggregation methods for the virtual price give intercepts of about $6.30 and $7.20. The tangent bound limits the role of extrapolation, and the CES comparison shows the direction of functional-form bias.

Other checks are missing. The paper reports no estimates with alternative instruments, no first-stage statistics and no outcome of the overidentification tests that fn. 20 mentions. It reports no test of the independence of demand shocks across cities, the assumption on which identification rests. Table 5.7 has no standard errors, and the imperfect-competition calculation fixes rivals' prices without a sensitivity analysis. Section 10.6 shows why the first omission matters most.

10.5.12 Interpretation, critiques and contribution

Taken at face value, the estimates say that consumers value even a close variant of existing brands highly. ACC's demand curve is steep relative to its volume. The virtual price is twice the actual price, and the surplus is about 46 percent of ACC's revenue.[13] If incremental brands are typical, official price indexes for branded consumer goods understate real income growth.

Four lines of critique follow from the theory of this chapter. First, the estimates rest on instruments that fail if national demand shocks move prices in all cities at once (Section 10.6.3). Second, the virtual price is an extrapolation, and the surplus depends on the curvature of the AIDS curve beyond the data (Section 10.3). The tangent bound helps, but it requires convexity. Third, the imperfect-competition adjustment holds rivals' prices fixed and keeps post-launch shares in the counterfactual (Section 10.6.4). Fourth, the price-index extrapolation uses the Paasche rectangle, which exceeds the exact gain, and assumes that all new brands resemble ACC (Section 10.5.8).

The paper made several contributions. It showed how to compute the exact value of a new brand from scanner data. It combined the virtual price of Hicks (1940) and Rothbarth (1941) with the exact surplus methods of Hausman (1981) and Hausman and Newey (1995). Together with Hausman et al. (1994), it made multistage budgeting with an unrestricted bottom level a practical tool. The two papers also introduced prices in other markets as instruments, now a standard device in demand estimation (Nevo, 2001). Finally, it raised the question of how market power changes the value of a new good. The answer it gave was incomplete, as the next section explains, but the question has shaped the literature since, including the work of Petrin (2002) in Section 10.9.

10.6 Bresnahan's Comment: instruments and competition

Bresnahan (1997) accepts the importance of the question and much of the specification. He disputes the instruments and the treatment of competition. His comment opens with a statistic: *Brandweek* counted over 22,000 new-product introductions in 1994 (p. 237). Theory cannot say whether markets supply too many or too few varieties (fn. 1, quoting Eaton and Lipsey, 1989, as discussed in Section 10.4.2). So the value of incremental variety is an empirical question, and Hausman's paper is an important attempt to answer it. This section develops Bresnahan's four points in turn, with the formal analysis that he sketches in his appendix.

[13] By our computation, the surplus of $32,268 compares with revenue of about $70,600 per city-week.

Table 10.10: Identification and counterfactual map of Hausman (1997)

Observed data	Weekly Nielsen scanner prices and pounds sold of cereal brands in seven cities, January 1990 to August 1992, which gives 959 city-weeks per brand. Segment and total cereal spending.
Latent objects	City-week demand shocks, the national cost component c_{jt}, local promotion shocks, marginal costs, and the virtual price of Apple-Cinnamon Cheerios.
Estimated parameters	Bottom-level AIDS coefficients for the nine family-segment brands, segment and total cereal elasticities, and brand-city effects.
Identifying variation	Weekly co-movement of a brand's price across the seven cities after brand-city effects are removed, attributed to national costs (Assumption 10.29).
Maintained assumptions	Separable three-level budgeting with marketing segments, no national demand shocks, AIDS curvature up to the virtual price, and Nash-Bertrand pricing with constant marginal cost for the imperfect-competition adjustment.
Counterfactual and what it holds fixed	Removal of the new brand by raising its price to the virtual price of \$7.14. The adjustment re-prices General Mills' other brands and holds rivals' prices and all marginal costs fixed.
Conclusion	Consumer surplus is about \$78.1 million a year, or \$66.8 million net of the price effects. Hausman extrapolates that the cereal CPI is too high by about 20 to 25 percent. The level rests on the instruments.
One limitation	National demand shocks would bias the price slopes toward zero and inflate the surplus (Proposition 10.32).
Source and our additions	The tables and surplus figures are Hausman's. Our formalization of Bresnahan's critique in Proposition 10.32, the checks of the confidence interval and the price index, and the recomputed prices and margins are ours.
Tools in the appendices	Sections A.2, A.3 and B.4.

10.6.1 Why a steep single-product demand curve means large value

Bresnahan frames the issue with Figure 10.5. The steep curve DD is market demand. The flatter curve dd is the demand for one product when the prices of its substitutes are held fixed. The flat line $dd(-\infty)$ is the demand for a product that is a perfect substitute for others. Introducing a product at price P_1 creates the shaded triangle between dd, the price axis and the line at P_1. Before the introduction the product was in effect priced at P_0, where dd meets the price axis. This is the virtual price of Section 10.2.

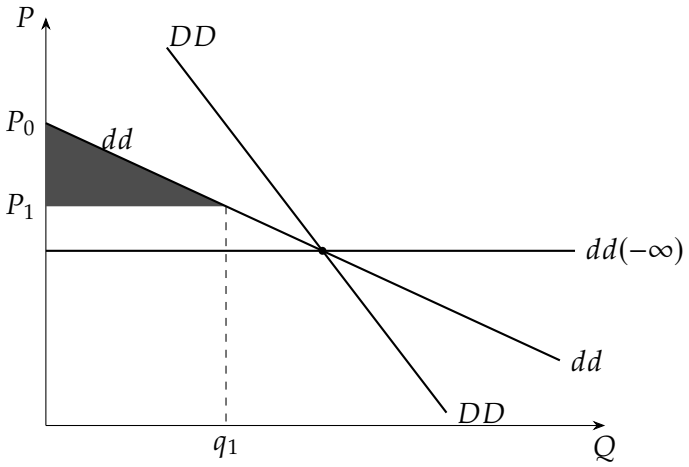

Figure 10.5: Consumers' gain from a new product. DD is market demand, dd the demand for a single product at fixed prices of its substitutes, and $dd(-\infty)$ the demand for a perfect substitute. Selling the product at P_1 instead of its choke price P_0 yields the shaded surplus. The steeper is dd, the larger the triangle for a given volume q_1. Source: redrawn after Bresnahan (1997), Figure 5C.1.

The area of the triangle makes the point precise. Let dd be linear with slope $-s$ in the (Q, P) plane, where $s > 0$ measures its steepness. A product sold at P_1 in volume q_1 then has choke price $P_0 = P_1 + s\, q_1$. Its surplus is

$$CS = \frac{1}{2}(P_0 - P_1)\, q_1 = \frac{s}{2}\, q_1^2. \tag{10.50}$$

For a given volume the surplus is proportional to the steepness s, and it vanishes as dd flattens to $dd(-\infty)$. Treating new goods as perfect substitutes, as hedonic quality adjustment implicitly does, therefore sets their value to zero. Linking a new good into a price index late treats it as irrelevant in its early life, and the later the link, the larger the error (p. 238). Both practices understate the value of new goods. Bresnahan notes a converse in fn. 2. If a new good is a perfect substitute, the law of one price holds, and late linking does no harm.

Hausman's finding is a steep dd for ACC. Trajtenberg (1989), whose work Section 10.8 studies, conjectured that the distance of a new good from existing products in characteristics space governs the slope of dd (fn. 3). The same steepness has a second implication, developed in Section 10.6.4. A product with a steep dd that is sold by one firm carries market power. Consumer surplus and imperfect competition are therefore linked from the start.

10.6.2 Is the large surplus an artifact of the specification?

Bresnahan concludes that it is not (pp. 239–240). A skeptic might suspect that existing Cheerios products already satisfy "pretty much any palate". Hausman's large surplus must then come

from finding poor substitutability between ACC and the other family brands. Within the segment, the AIDS imposes almost no structure on own and cross elasticities, so the finding comes from the data. The more restrictive CES gives an even larger surplus (fn. 4).

The segment structure is an assumption, which Bresnahan does not find worrying. It is not interesting to ask whether two children's cereals substitute more closely than a children's cereal and Special K. The segments come from marketing research based on richer data, including consumer microdata. Bresnahan adds a caution for other industries (fn. 5). In automobiles, brand names and country reputations compete with size classes as principles of grouping, and in many consumer goods private labels form a further group. The simple structure of cereal is the exception.

10.6.3 Instruments and national demand shocks

The treatment of price endogeneity is the other place where the conclusion might have been "accidentally assumed" (p. 240). Hausman's identifying assumption is that the shocks ω_{jnt} in (10.44) are independent across cities. This rules out every national shock to the demand for one brand relative to another. In Bresnahan's words, "there can be no successful nationwide advertising campaigns which shift the demand for individual brands or products" (p. 241). There can be no national fads and no slow national acceptance of new brands. Including advertising in the demand system does not solve the problem, because the econometrician does not observe which campaigns succeed (fn. 6).

Hausman's fallback is that prices are predetermined. Economically, this requires that national demand shocks cannot be foreseen when prices are set. Bresnahan finds this unlikely for shocks such as advertising campaigns, which manufacturers plan and communicate to retailers in advance. If national shocks exist and are reflected in prices, and if supply slopes up, prices in other cities are correlated with the demand error. Supply slopes up in the one-week run because inventories cannot adjust or because of market power (fn. 7). Hausman's own pricing equations imply an upward-sloping supply relation.

The model. We formalize the argument with one product, following Bresnahan's simple case: linear demand, single-product Bertrand pricing and constant marginal cost (p. 241). In city n and week t,

$$q_{nt} = d_n - b\,p_{nt} + \xi_{nt}, \qquad b > 0, \tag{10.51}$$

where d_n is a city effect. Marginal cost is $c_{nt} = c_n + k_t + v_{nt}$. The national cost component k_t has variance σ_k^2, and the local component v_{nt} has variance σ_v^2. The demand error has a national and a local part, $\xi_{nt} = \chi_t + e_{nt}$. Each part splits into a component that is anticipated when prices are set and one that is not: $\chi_t = \chi_t^a + \chi_t^u$ and $e_{nt} = e_{nt}^a + e_{nt}^u$, with variances $\sigma_{\chi a}^2$, $\sigma_{\chi u}^2$, σ_{ea}^2 and σ_{eu}^2. All components have mean zero and are mutually independent. Local components are independent across cities. City effects are removed by the within transformation, so we treat d_n and c_n as known.

Pricing. The firm sets p_{nt} to maximize expected profit $\mathbb{E}[(p - c_{nt})(d_n - bp + \xi_{nt}) \mid \mathcal{I}_{nt}]$, where the information set $\mathcal{I}_{nt}$ contains costs and the anticipated shocks. The first-order condition is

$$d_n - 2b\,p_{nt} + \mathbb{E}[\xi_{nt} \mid \mathcal{I}_{nt}] + b\,c_{nt} = 0.$$

Solving for the price,

$$p_{nt} = \frac{1}{2}\Big(c_{nt} + \frac{d_n + \chi_t^a + e_{nt}^a}{b}\Big). \tag{10.52}$$

Equivalently $p_{nt} = c_{nt} + \frac{\mathbb{E}[q_{nt}|\mathcal{I}_{nt}]}{b}$, the expected-quantity version of Bresnahan's supply relation $P = Q(-\gamma_{jj})^{-1} + c$. With fully anticipated shocks this is his model, and with no anticipated shocks prices are predetermined in Hausman's sense.

Estimators. The Hausman estimator of $-b$ is the instrumental-variables (IV) estimator that uses $p_{\ell t}$, the price in another city $\ell \neq n$, as the instrument for p_{nt}. Averaging over several other cities, as our simulation does, has the same probability limit. Ordinary least squares (OLS) regresses q_{nt} on p_{nt}. Both use within-city deviations.

Proposition 10.32 (Hausman instruments with national demand shocks)**.** *In the model given by* (10.51) *and* (10.52)*, define*

$$\lambda = \frac{\sigma_{\chi a}^2}{b^2\sigma_k^2 + \sigma_{\chi a}^2}, \qquad \lambda_{OLS} = \frac{\sigma_{\chi a}^2 + \sigma_{ea}^2}{b^2(\sigma_k^2 + \sigma_v^2) + \sigma_{\chi a}^2 + \sigma_{ea}^2}.$$

Then, as the number of weeks grows,

$$\operatorname{plim} \hat{b}_{IV} = b(1 - 2\lambda), \qquad \operatorname{plim} \hat{b}_{OLS} = b(1 - 2\lambda_{OLS}). \tag{10.53}$$

Consequently, the following hold.

(a) The IV estimator is consistent if and only if there are no anticipated national demand shocks, $\sigma_{\chi a}^2 = 0$. Local shocks, anticipated or not, cause no bias.

(b) If $\sigma_{\chi a}^2 > 0$, the estimated demand curve is too steep. If $\sigma_{\chi a}^2 > b^2\sigma_k^2$, the estimated slope has the wrong sign.

(c) Let $\lambda < \frac{1}{2}$, and take linear demand through the observed point (p, q). The implied consumer surplus $\frac{q^2}{2\hat{b}}$ and the implied gap $\frac{q}{\hat{b}}$ between the virtual and the actual price are both overstated by the factor $\frac{1}{1-2\lambda}$.

(d) The IV estimator is less biased than OLS if and only if $\lambda < \lambda_{OLS}$.

Proof. Work with within-city deviations, so that d_n and c_n drop out. From (10.52), the deviation of the price is

$$\tilde{p}_{nt} = \frac{1}{2}\left(k_t + v_{nt} + \frac{\chi_t^a + e_{nt}^a}{b}\right).$$

Substituting into (10.51), the IV and OLS estimators of the coefficient $-b$ converge to

$$-b + \frac{\operatorname{Cov}(\tilde{p}_{\ell t}, \xi_{nt})}{\operatorname{Cov}(\tilde{p}_{\ell t}, \tilde{p}_{nt})} \qquad \text{and} \qquad -b + \frac{\operatorname{Cov}(\tilde{p}_{nt}, \xi_{nt})}{\operatorname{Var}(\tilde{p}_{nt})}.$$

For the IV estimator take $\ell \neq n$. The price in city ℓ shares only the national components k_t and χ_t^a with city n. Of these, only χ_t^a is correlated with ξ_{nt}. Hence

$$\operatorname{Cov}(\tilde{p}_{\ell t}, \xi_{nt}) = \frac{1}{2b}\operatorname{Cov}(\chi_t^a, \chi_t) = \frac{\sigma_{\chi a}^2}{2b},$$

$$\operatorname{Cov}(\tilde{p}_{\ell t}, \tilde{p}_{nt}) = \frac{1}{4}\left(\sigma_k^2 + \frac{\sigma_{\chi a}^2}{b^2}\right) = \frac{b^2\sigma_k^2 + \sigma_{\chi a}^2}{4b^2}.$$

The ratio of the two is

$$\frac{\sigma_{\chi a}^2}{2b} \cdot \frac{4b^2}{b^2\sigma_k^2 + \sigma_{\chi a}^2} = 2b\lambda.$$

So the IV estimate of $-b$ converges to $-b + 2b\lambda$, and $\operatorname{plim} \hat{b}_{IV} = b - 2b\lambda = b(1 - 2\lambda)$. For OLS the same steps apply with all anticipated components:

$$\operatorname{Cov}(\tilde{p}_{nt}, \xi_{nt}) = \frac{\sigma^2_{\chi a} + \sigma^2_{ea}}{2b}, \qquad \operatorname{Var}(\tilde{p}_{nt}) = \frac{b^2(\sigma^2_k + \sigma^2_v) + \sigma^2_{\chi a} + \sigma^2_{ea}}{4b^2},$$

and the ratio is $2b\lambda_{OLS}$, which gives $\operatorname{plim} \hat{b}_{OLS} = b(1 - 2\lambda_{OLS})$.

Part (a) follows because $\lambda = 0$ if and only if $\sigma^2_{\chi a} = 0$, and λ does not depend on σ^2_{ea} or σ^2_{eu}. For part (b), $\lambda > 0$ gives $\operatorname{plim} \hat{b}_{IV} < b$, and $1 - 2\lambda < 0$ if and only if $\lambda > \frac{1}{2}$, which is equivalent to $\sigma^2_{\chi a} > b^2\sigma^2_k$. For part (c), linear demand through (p, q) with slope $-\hat{b}$ meets the price axis at $p + \frac{q}{\hat{b}}$, and the triangle above p has area $\frac{q^2}{2\hat{b}}$. Both are proportional to $\frac{1}{\hat{b}}$, so their ratios to the true values converge to $\frac{b}{\operatorname{plim} \hat{b}_{IV}} = \frac{1}{1-2\lambda}$. Part (d) compares the two biases $2b\lambda$ and $2b\lambda_{OLS}$. □

The weight λ has a direct interpretation. The common price component shared by all cities is $\frac{1}{2}(k_t + \frac{\chi^a_t}{b})$. Its variance is $\frac{1}{4}(\sigma^2_k + \frac{\sigma^2_{\chi a}}{b^2})$, and λ is the share of that variance due to national demand shocks. The proposition thus says that the Hausman estimator is a weighted average of the demand slope and the supply slope. With weight $1 - \lambda$ the common price variation traces out demand, as Hausman assumes. With weight λ it traces out the supply relation $q = b(p - c)$, whose slope is $+b$. This is Bresnahan's remark that with national demand shocks the estimator "is like doing ordinary least squares on a supply and demand system" (p. 242). Section 5.8.5 derives the same weight in (5.133). Our version adds the distinction between anticipated and unanticipated shocks, the OLS comparison and the welfare consequences.

The welfare consequence is large even for modest violations. Suppose anticipated national demand shocks account for one quarter of the common price variation, so $\lambda = 0.25$. Then the estimated slope is half the true slope and the surplus is overstated by a factor of two. A share of 10 percent overstates the surplus by 25 percent. Part (c) is stated for linear demand. For the convex AIDS curves of Figure 10.3 the mapping is only approximate. A curve that is too steep at the data still implies too large a surplus.

Part (a) also clarifies the debate about predetermined prices. If no national shock is anticipated, both estimators are consistent when local shocks are unanticipated as well. IV then adds nothing, as Hausman's second interpretation says. Bresnahan's objection is that the national shocks most likely to matter, such as advertising campaigns and promotions, are planned in advance. Planned shocks are precisely the anticipated component that enters λ. Neither the data nor the paper distinguish the two cases.

Many products. Bresnahan's appendix treats J products. Write demand as $q_{nt} = d + A\, p_{nt} + \xi_{nt}$, with $a_{jk} = \frac{\partial q_j}{\partial p_k}$ (his γ), and single-product Bertrand pricing as $p_{nt} = c_{nt} + D^{-1} q_{nt}$ with $D = \operatorname{diag}(-a_{11}, \ldots, -a_{JJ})$. Multiplying the pricing equation by D and substituting demand gives $Dp_{nt} = Dc_{nt} + d + Ap_{nt} + \xi_{nt}$, so the prices solve $p_{nt} = (D - A)^{-1}(d + Dc_{nt} + \xi_{nt})$. Bresnahan states that the sign and size of the bias are governed by $\Sigma^{\text{nat}}[\operatorname{diag}(-\gamma) - \gamma]^{-1}$, where Σ^{nat} is the covariance matrix of the national demand shocks. This is the covariance between other-city prices and demand errors. For two products whose national shocks have correlation ϱ, his appendix reports that the on-diagonal bias has the sign of $-2\gamma_{22} + \varrho\gamma_{12}$ and the off-diagonal bias the sign of $\gamma_{12} - 2\varrho\gamma_{11}$ (p. 247). At $\varrho = 0$ both signs are positive when the goods are substitutes ($\gamma_{12} > 0$). Bresnahan reads them as a bias of own-price coefficients toward zero and of cross-price coefficients away from zero. These are signs of the covariance between instruments and demand errors. With several endogenous prices the bias also involves the

inverse of the instrument-price covariance, so the signs need not carry over. Bresnahan notes that the cross-price claim depends on the correlation of national shocks across products (fn. 9). Proposition 5.55 gives the exact probability limit, $\operatorname{plim} \hat{A} = (I - \Lambda)A + \Lambda D$ with $\Lambda = \Sigma^{\text{nat}}(D\Sigma_c D + \Sigma^{\text{nat}})^{-1}$ and Σ_c the covariance matrix of national cost shocks. Section 5.8.5 also documents typographical slips in the printed appendix.

The estimate mixes demand slopes with supply slopes. Suppose national demand and cost shocks are uncorrelated across products, and write $\sigma^2_{\chi j}$ and σ^2_{cj} for the diagonal elements of Σ^{nat} and Σ_c. Then Λ is diagonal with $\lambda_j = \frac{\sigma^2_{\chi j}}{a^2_{jj}\sigma^2_{cj} + \sigma^2_{\chi j}}$, so $\operatorname{plim} \hat{a}_{jj} = (1 - 2\lambda_j)a_{jj}$ and $\operatorname{plim} \hat{a}_{jk} = (1 - \lambda_j)a_{jk}$. Own slopes move toward zero and possibly beyond it, and cross slopes are attenuated. Bresnahan's cross-price reading therefore fails even at $\varrho = 0$. With correlated national shocks, Λ is no longer diagonal. Row j of the estimate then mixes in the demand and supply slopes of the other products. Cross slopes can be inflated, and even an own slope can be biased away from zero. For example, the matrices $A = \left(\begin{smallmatrix} -2 & 0.5 \\ 0.5 & -1.5 \end{smallmatrix}\right)$, $\Sigma_c = \operatorname{diag}(5, 0.01)$ and $\Sigma^{\text{nat}} = 0.4\left(\begin{smallmatrix} 1 & 0.95 \\ 0.95 & 1 \end{smallmatrix}\right)$ give $\operatorname{plim} \hat{a}_{11} = -2.44$, farther from zero than the true -2. The own-slope bias is the diagonal element $2\Lambda_{jj}|a_{jj}| - \sum_{k \neq j} \Lambda_{jk} a_{kj}$ of $\Lambda(D - A)$. The own-price bias toward zero that drives the surplus therefore holds when $2\Lambda_{jj}|a_{jj}| > \sum_{k \neq j} \Lambda_{jk} a_{kj}$, for example when national shocks are uncorrelated across products.

A Monte Carlo experiment. Figure 10.6 illustrates Proposition 10.32 in a panel shaped like Hausman's, with 7 cities and 137 weeks. All shocks are anticipated. The true slope is $b = 2$, demand shocks have total variance $\sigma^2_\chi + \sigma^2_e = 1$, and cost shocks have $\sigma_k = \sigma_v = 0.5$. The horizontal axis moves the national share of demand variance from 0 to 0.5 while holding the total fixed. The instrument is the average price of the product in the other six cities. Each point averages 500 replications. Without national shocks the IV estimator is centered on the truth, while OLS recovers only one third of the slope. As the national share rises, the IV estimate falls toward the OLS estimate. At a share of 0.2 it recovers two thirds of the slope and overstates the surplus by half. At a share of 0.5 it is no better than OLS, and the surplus is overstated threefold.

Two features of the experiment deserve comment. First, the instrument is strong throughout: the correlation between a city's price and the other-city average is about 0.5 to 0.65. A strong first stage is no protection against an invalid instrument. Second, week fixed effects cannot remove the problem for a single product. They would absorb the national cost shocks as well, and with them all identifying variation. In a system with many brands, week effects common to all brands absorb only aggregate shocks. Brand-specific national shocks, the kind Bresnahan describes, remain.

Evidence from later work. Nevo (2001) uses Hausman instruments for cereal in a random-coefficients model (Chapter 8). His instruments are regional quarterly average prices of the same brand, excluding the city being instrumented (p. 321). He discusses exactly Bresnahan's concern. A national demand shock, such as the discovery that fiber reduces the risk of cancer, would raise the valuation of fiber-rich brands in all cities and violate the assumption. He argues that the concern is weaker for well-established brands and that time dummies absorb aggregate shocks. He then compares the price coefficient across instrument sets in his logit regressions (Table V). With other-city prices it is -17.57 (0.50), and with proxies for local marginal cost it is -17.12 (0.49), against -7.26 (0.16) by OLS with brand dummies. The two instrument sets agree. Nevo notes, however, that regional demand shocks would invalidate both, and overidentification tests reject in all columns except the one with city fixed effects. The comparison is informative, but it cannot rule out brand-specific national shocks.

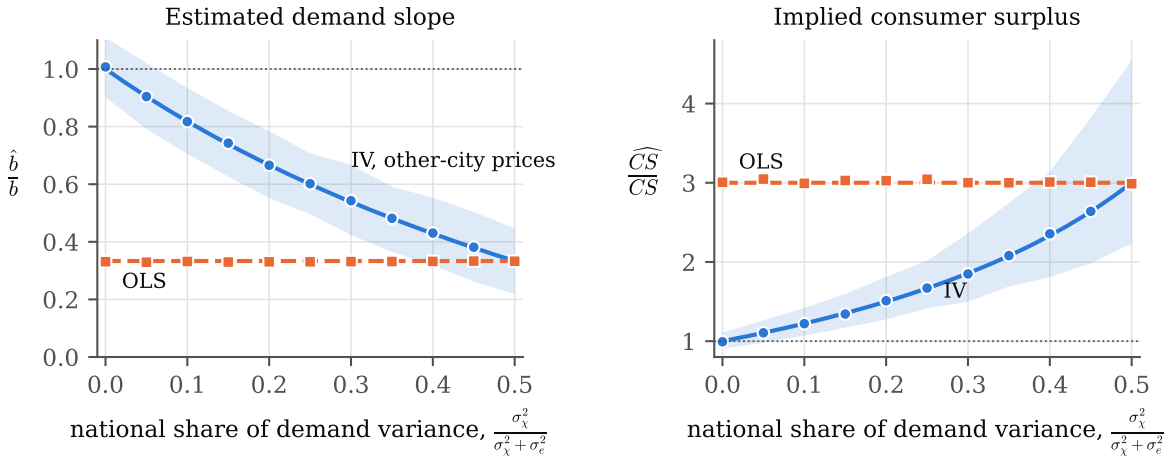

Figure 10.6: Hausman instruments with national demand shocks, a Monte Carlo experiment. The left panel shows the estimated demand slope relative to the truth. The right panel shows the implied consumer surplus with linear demand relative to the truth. Markers are Monte Carlo means (slope) or medians (surplus) over 500 replications. Lines are the probability limits of Proposition 10.32, solid for IV and dashed for OLS. The band shows the 10th to 90th percentiles of the IV estimates. The design has 7 cities, 137 weeks, $b = 2$, $\sigma_\chi^2 + \sigma_e^2 = 1$ and $\sigma_k = \sigma_v = 0.5$. All shocks are anticipated, and city fixed effects are removed. The script is `figures/ch10/src/hausman_iv_bias.py`.

10.6.4 Imperfect competition is "off point"

Bresnahan's second criticism concerns economic interpretation (pp. 243–246). Imperfect competition links new goods and market power in three ways. A new good can create market power for its inventor. It can destroy market power of competing products. And the transitory market power that results is a reward that motivates invention.

Private returns. The steep dd that implies a large consumer surplus also implies a large monopoly rent if one firm owns the product (p. 243). Remark 10.24 makes this exact for linear demand, where consumer surplus at the monopoly price is half the profit. Demand studies of new goods therefore speak to private returns to innovation as well as social returns. With multiproduct firms and competitive responses, the calculation needs the whole demand system and a supply model (p. 243).

Rivals' prices. Under imperfect competition among single-product firms, a new product lowers the market power of existing products and so lowers prices (p. 243). This is one of the classical benefits of competition. Section 10.4.5 develops the argument. It proves the result for logit demand (Proposition 10.27) and discusses Bresnahan's two qualifications, that unusual elasticities can reverse it (fn. 12) and that Bertrand competition reinforces the direct effects (fn. 13).

Hausman holds the prices of Kellogg and Post fixed. Bresnahan calls this "a common error among those who are new to models of imperfect competition, but an important one" (p. 244). The Bertrand solution concept has firms maximize post-entry profits taking each other's post-entry prices as given. The analyst who computes the effect of entry cannot take those prices as given, because entry changes the game. Typically the rivals' prices fall. By holding them fixed, Hausman solves the price-discrimination problem of General Mills as if it were a monopolist. His claim of a lower bound is therefore wrong, as Hausman's own fn. 32

partly concedes.

The multiproduct firm's own prices. Even for General Mills alone, the direction of the price change is ambiguous. Adding a brand changes the first-order condition (10.35) for an existing brand j in the three ways of Section 10.4.4 (pp. 244–245). The new brand's term favors a higher p_j, which is the effect Hausman stresses. Bresnahan counts the falls in the revenue shares of the existing brands, w_j among them, as the offsetting effects. At fixed margins and elasticities, only the cannibalization of the firm's other brands pushes the other way, because it shrinks the positive cross terms. Bresnahan states that with linear demand and a two-product firm the effects exactly offset, and Proposition 10.25 proves this for any number of products. Any dominance of one effect therefore comes "from higher-order derivatives", and the paper offers no evidence on them (p. 245). The reproduction of Table 5.7 in Section 10.5.10 makes the point concrete. Hausman's "without" margins keep the post-launch shares of Cheerios and Honey-Nut, so they include the first effect and omit the second and third.

Where the action is. Bresnahan summarizes the possibilities in the two-by-two classification of Table 10.2. Hausman's analysis sits in the price-discrimination cell. Bresnahan argues that if the social return is the object of interest, Hausman "has quantified the generally far less important effect" (p. 246). The competition cell, the effect of a new good on the pricing incentives of rival firms, must in general be much more important.

Conclusion. Bresnahan was left "unconvinced by key econometric assumptions" and found the imperfect-competition analysis "off point". To doubt the large single-product surplus may simply be to believe in nationwide brand-name demand shocks. "The puzzle of the value of this incremental product introduction remains unsolved" (p. 246).

10.6.5 Assessment

Each side of the exchange got something right. Hausman showed that the exact value of a new brand can be computed from estimated demand, and that a flexible system can deliver a finite virtual price. He also showed that the answer depends on market structure. Bresnahan showed that the identifying assumption is strong exactly where the conclusion is sensitive. Own-price slopes biased toward zero produce steep dd curves and large surplus. He also showed that holding rivals' prices fixed answers a monopoly question, and that the multiproduct effect itself is ambiguous.

Several kinds of evidence could settle the dispute. Price and quantity data spanning the launch would allow a direct before-and-after comparison, which Hausman lacked. Hausman and Leonard (2002) later made such a comparison for Kleenex Bath Tissue (KBT), which Kimberly-Clark rolled out across U.S. cities in waves.[14] They use weekly Nielsen scanner data on the seven largest brands in 30 cities from January 1992 to September 1995. KBT was already sold in 17 cities when the data begin. It entered three more in July 1993 and the last ten in May 1994. For each incumbent brand they estimate by ordinary least squares

$$\ln p_{ct} = \lambda_c + \omega_t + \beta_1 I_{ct} + \beta_2 M_{ct} + e_{ct}, \tag{10.54}$$

where c indexes cities and t weeks, and λ_c and ω_t are city and week fixed effects. The indicator I_{ct} equals one once KBT is sold in city c, and M_{ct} marks the third-wave cities in the weeks

[14] We checked the numbers in this paragraph against the authors' revised manuscript dated September 1999 (pp. 10–15 and 33–36, and Tables 2, 6 and 7), which thanks the journal's referees and editor. We did not check the published article, whose page and table numbers may differ.

between the second and third waves. The staggered entry separates β_1 from the common shocks absorbed by ω_t. All six estimated price effects are negative (Table 2). Cottonelle fell 8.2 percent (standard error 1.3), Charmin and Angel Soft 3.5 percent, private label 3.8 percent and Northern 2.3 percent. The economy brand ScotTissue fell only 0.6 percent (0.5). Kimberly-Clark had almost no prior share, so this is the competition cell of Bresnahan's classification, and the prices of rivals fell as he predicts. The authors also predict these changes from the post-entry demand system under Nash-Bertrand pricing. The predictions are close for four brands but well short for Cottonelle (−3.6 percent) and private label (−0.7 percent), where t-tests reject equality (Table 6). Because the comparison gives mixed support, they describe their evidence for Nash-Bertrand pricing as cautious. The authors put the total consumer gain at $69.2 million a year, 7.3 percent of bath tissue spending in the 30 cities (Table 7). About half of it comes from the lower prices of existing brands (p. 36). Residuals of the same brand in different cities and the same week can be tested for correlation, the most direct symptom of national shocks. Overidentification tests across cities, which fn. 20 of Hausman's paper proposes, could be reported. Instruments from observed local costs offer a comparison, as in Nevo (2001). Each check addresses a specific threat. None is a general proof of validity.

The broader literature moved in two directions. One kept product-space demand and looked for better instruments and data. The other moved to characteristics space (Berry, 1994; Berry et al., 1995). There the value of a new product depends on its location relative to existing products, and instruments come from the characteristics of rivals. That approach has its own extrapolation problem, the idiosyncratic taste shock that gives every product a positive value, which Section 10.7 analyzes. It also has its own instrument problem, the assumption that characteristics are exogenous (Chapter 6). Petrin (2002), studied in Section 10.9, combines characteristics-space demand with micro data and recomputes the full Bertrand equilibrium without the new product. His results quantify the competition cell of Bresnahan's classification, together with the price-discrimination cell.

10.7 Valuing new goods in characteristics space

The methods of Sections 10.2 and 10.3 value a new good in product space. They estimate the demand curve of the good itself and integrate under it up to the virtual price. This section treats a product as a bundle of characteristics instead, in the tradition of Lancaster (1966, 1971) and McFadden (1981). The change of viewpoint has three consequences for welfare measurement. First, a characteristics model can predict the demand for a product that has never been sold. Second, discrete-choice models deliver consumer surplus in closed form, so the value of a change in the choice set is a simple function of estimated parameters. Third, the functional forms that make these models tractable carry strong implicit assumptions about the value of variety. Most of the section makes those assumptions explicit and compares the models that impose them with models that do not.

Throughout the section a market has inside products $j = 1, \ldots, J$ and an outside good $j = 0$. Consumer i has income y_i, and we use the notation of Chapters 7 and 8 for mean utilities δ_j, deviations μ_{ij} and idiosyncratic shocks ϵ_{ij}. Where we discuss Trajtenberg (1989), we write $\mathcal{W}(S)$ for his surplus function over a choice set S. We also write z_j for the vector of characteristics of product j and $\tilde{p}_j$ for its residual price relative to a hedonic price function.

10.7.1 Predicting demand for products that have never been sold

A new product is a new point in characteristics space. Suppose a demand model has been estimated on existing products, and the new product combines characteristics that lie within the range spanned by them. The estimated tastes for characteristics then predict the new product's market share at any price, and the equilibrium pricing conditions of Chapter 4 predict its price. A product-space system cannot do this, because its parameters are indexed by products and the new product has none (Berry and Pakes, 2007, pp. 1–2). Berry and Pakes add a second advantage. The number of parameters of a characteristics model does not grow with the number of products. A log-linear product-space system for J products needs a number of parameters of the order of J^2. Berry et al. (2004a) use this property to simulate the demand for products before launch.

The same property disciplines the retrospective valuation of products that already exist. We never observe demand at prices high enough to reveal the reservation prices of most buyers. Every estimate of the surplus from a product therefore extrapolates beyond the data (Berry and Pakes, 2007, p. 2). A product-space system extrapolates the product's own demand curve to high prices, as in Section 10.3. A characteristics model uses slightly more information. It borrows the price variation of other products with similar characteristics, although the functional form still governs the extrapolation.

The approach has three limits. The first is an *entirely new characteristic*, one that no existing product possesses. Tastes for it cannot be learned from existing products. An electric car, for example, has a range, a charging time and no fuel cost, so its demand cannot be inferred from the demand for gasoline cars alone. The second limit is attributes that resist measurement, such as the plot of a book or the style of a film. When the relevant attributes cannot be coded as a short vector x_j, the approach loses its dimension reduction. The third limit is the *radical innovation*, a product that opens a new product class. Trajtenberg (1985, pp. 10–11)[15] argues that a welfare comparison requires a choice set and a surplus function defined before the innovation, and a radical innovation offers neither. He quotes Kuznets (1962, p. 28) on the point. For Kuznets, a rough estimate of the value of a new product "seems to be possible only if the new product can be treated as a substitute for the old one." Trajtenberg's response is to measure the improvements that follow the first commercial product, and to infer the value of the first product indirectly from the diffusion of the innovation (Section 10.8.9).

Hausman (1997, p. 229) pushes the first two limits further, as Section 10.5.9 reports. He describes each cereal brand by its own indicator variable and doubts that a brand such as Apple-Cinnamon Cheerios can be described by its attributes. For him the natural measure of distance between products is the cross-price elasticity. Bresnahan (1997, p. 238, n. 3) reads the characteristics approach more favorably. Trajtenberg used an address model of differentiation. This led him to conjecture that a new good's distance from existing products governs the slope of its demand curve dd, and hence its surplus (Figure 10.5). The propositions below make this conjecture precise for the logit, the nested logit and the vertical model.

Finally, the characteristics models used in this section assume that each consumer buys one unit of one product. Products can then only be substitutes. Complementarity between a new good and old goods requires a model of bundles, which we study in Section 10.10.

[15] We cite Trajtenberg (1989) through its working-paper version (Trajtenberg, 1985), the text available to us. Page, table and equation numbers for this study refer to the working paper, as explained in Section 10.8.

10.7.2 Consumer surplus in random utility models

We begin with the welfare theory that all characteristics-based valuations share. The key assumption is that income enters utility linearly, so that utility differences convert into money at a constant rate.

Assumption 10.33 (Quasi-linear random utility)**.** Consumer i's utility from product $j \in \{1, \dots, J\}$ and from the outside good are

$$u_{ij} = \alpha(y_i - p_j) + x_j\beta + \xi_j + \mu_{ij} + \epsilon_{ij}, \qquad u_{i0} = \alpha y_i + \epsilon_{i0}, \tag{10.55}$$

with $\alpha > 0$. Write $\delta_j = x_j\beta - \alpha p_j + \xi_j$ and set $\delta_0 = \mu_{i0} = 0$. The shocks $(\epsilon_{i0}, \dots, \epsilon_{iJ})$ are independent of (x, ξ, μ_i), have a joint density and a finite mean. In the logit case they are i.i.d. type-I extreme value.

The term αy_i is common to all alternatives, so it does not affect choices. For a consumer with deviations μ_i, define the *expected maximum utility* over a choice set $\mathcal{J}$ that contains the outside good,

$$G_i(\mathcal{J}) = \mathbb{E}\left[\max_{j \in \mathcal{J}} \left(\delta_j + \mu_{ij} + \epsilon_{ij}\right)\right], \tag{10.56}$$

where the expectation is over ϵ_i.

Lemma 10.34 (Compensating variation under quasi-linearity)**.** *Under Assumption 10.33, let the choice set and prices change from $(\mathcal{J}^0, p^0)$ to $(\mathcal{J}^1, p^1)$. Let CV_i be the extra income that consumer i would need, facing $(\mathcal{J}^0, p^0)$, to reach the utility she attains at $(\mathcal{J}^1, p^1)$, as in Definition 10.6. For every realization of ϵ_i,*

$$CV_i = \frac{1}{\alpha}\left[\max_{j \in \mathcal{J}^1}\left(\delta_j^1 + \mu_{ij} + \epsilon_{ij}\right) - \max_{j \in \mathcal{J}^0}\left(\delta_j^0 + \mu_{ij} + \epsilon_{ij}\right)\right], \tag{10.57}$$

and the expected compensating variation is $\mathbb{E}[CV_i] = \frac{1}{\alpha}\left[G_i^1(\mathcal{J}^1) - G_i^0(\mathcal{J}^0)\right]$, where G_i^t uses the mean utilities δ^t.

Proof. Adding c to income before the change raises the utility of every alternative by αc. The maximal utility before the change, with the extra income, is therefore

$$\alpha(y_i + c) + \max_{j \in \mathcal{J}^0}\left(\delta_j^0 + \mu_{ij} + \epsilon_{ij}\right).$$

After the change, maximal utility is $\alpha y_i + \max_{j \in \mathcal{J}^1}(\delta_j^1 + \mu_{ij} + \epsilon_{ij})$. Setting the two equal and solving for c gives (10.57). Taking expectations over ϵ_i gives the second statement. □

Because income effects are absent, the compensating and equivalent variations coincide here. Under quasi-linearity we therefore call $\frac{1}{\alpha}G_i(\mathcal{J})$, up to a constant, the *expected consumer surplus* $CS_i(\mathcal{J})$. This is the measure of Small and Rosen (1981) and McFadden (1981). The next lemma shows that it is the integral under the demand curves, so it is the discrete-choice counterpart of the Hicksian area in Proposition 10.7.

Lemma 10.35 (Williams-Daly-Zachary, McFadden, 1981)**.** *Let $\epsilon = (\epsilon_0, \dots, \epsilon_J)$ have a joint density and a finite mean, and let $G(\delta) = \mathbb{E}[\max_k(\delta_k + \epsilon_k)]$. Then G is differentiable and $\frac{\partial G}{\partial \delta_j} = \mathbb{P}\left(j = \arg\max_k(\delta_k + \epsilon_k)\right)$ for every j.*

The lemma restates part (ii) of Theorem 6.7 with $V = \delta$. The proof there bounds the difference quotient of the maximum by one and applies dominated convergence.

Two consequences follow. Since δ_j contains $-\alpha p_j$, the chain rule gives

$$\frac{\partial CS_i}{\partial p_j} = \frac{1}{\alpha}\frac{\partial G_i}{\partial \delta_j}(-\alpha) = -s_{ij}, \tag{10.58}$$

where s_{ij} is consumer i's choice probability. This is Roy's identity for discrete choice, and Trajtenberg (1985, p. 19, n. 18) uses it to verify his surplus function. Consumer surplus is thus the area under the probabilistic demand curves, and the change in CS_i from raising p_n to infinity is the area under product n's demand curve. The second consequence is a closed form in the logit case.

Lemma 10.36 (Log-sum formula)**.** *If $\epsilon_0, \dots, \epsilon_J$ are i.i.d. type-I extreme value, then $\max_k(\delta_k + \epsilon_k)$ is type-I extreme value with location $\ln \sum_{k=0}^{J} e^{\delta_k}$, and*

$$\mathbb{E}\left[\max_k(\delta_k + \epsilon_k)\right] = \ln \sum_{k=0}^{J} e^{\delta_k} + \gamma_E, \tag{10.59}$$

where $\gamma_E \approx 0.5772$ is Euler's constant.

The first statement is the max-stability of the Gumbel distribution (Lemma 6.9). The second is Proposition 6.13 with $V_{ik} = \delta_k$ and $\sigma_\epsilon = 1$.

With $\delta_0 = 0$, the logit consumer surplus is therefore

$$CS = \frac{1}{\alpha}\ln\left(1 + \sum_{k=1}^{J} e^{\delta_k}\right) + C, \tag{10.60}$$

where C collects income and γ_E and does not depend on the choice set. Section 6.3 derives the extreme value algebra and the logit shares. Trajtenberg's surplus function is the same object, $\mathcal{W}(S) = \frac{1}{\alpha}\ln \sum_{j \in S} e^{V_j}$, written for a choice set S of scanners without an outside good. We now use (10.60) to value an introduction.

Proposition 10.37 (Value of a new product in the logit model)**.** *In the logit model, add product n with mean utility δ_n to a market with products $1, \dots, J$, holding the other mean utilities fixed. Per consumer, consumer surplus rises by*

$$\Delta CS = \frac{1}{\alpha}\ln\left(1 + \frac{e^{\delta_n}}{1 + \sum_{k=1}^{J} e^{\delta_k}}\right) = -\frac{1}{\alpha}\ln(1 - s_n), \tag{10.61}$$

where s_n is the market share of product n after the introduction.

Proof. The introduction reverses the removal of n from the post-introduction market. By (7.83) in Corollary 7.31, that removal changes surplus by $\frac{1}{\alpha}\ln(1 - s_n)$, with s_n the share before the removal, which is the share after the introduction. The introduction therefore raises surplus by $-\frac{1}{\alpha}\ln(1 - s_n)$. For the first expression, let $A_0 = 1 + \sum_{k=1}^{J} e^{\delta_k}$ and $A_1 = A_0 + e^{\delta_n}$. Then $s_n = \frac{e^{\delta_n}}{A_1}$, so $1 - s_n = \frac{A_0}{A_1}$ and $-\ln(1 - s_n) = \ln\frac{A_1}{A_0} = \ln\left(1 + \frac{e^{\delta_n}}{A_0}\right)$. □

The proposition has a strong implication. The value of a new product depends only on its share and on the price coefficient. Two products with the same share are worth the same, whether one is a novel design and the other a near copy of an existing product. The characteristics of the new product matter only through the share they produce. The CES variety index of Corollary 10.18 has the same property, since it depends only on the new good's expenditure share and the elasticity of substitution. Remark 10.19 explains why the two results are close relatives: the CES demand system is the aggregate demand of logit consumers (Anderson et al., 1992).

The proposition also bounds the gain of the average buyer of the new product. For $s \in (0,1)$ we have $s \le -\ln(1-s) \le \frac{s}{1-s}$, by the series $-\ln(1-s) = \sum_{m\ge 1} \frac{s^m}{m}$. Dividing (10.61) by s_n therefore gives

$$\frac{1}{\alpha} \le \frac{\Delta CS}{s_n} \le \frac{1}{\alpha(1-s_n)}. \tag{10.62}$$

The upper bound is the markup of a single-product logit firm (Proposition 10.40 below). So in the logit model the average buyer of a new product gains at least $\frac{1}{\alpha}$ dollars, however close the product is to existing ones. She gains roughly as much as the firm earns per unit sold. For a small share, $\Delta CS \approx \frac{s_n}{\alpha}$. The market-level gain is $M\,\Delta CS$ for a market of size M. If the introduction also changes rivals' prices, as in Proposition 10.27, the formula measures the variety effect at the new prices, and the price effect must be added.

Nesting relaxes the result in the direction that Bresnahan (1997) and Trajtenberg anticipate. Partition the inside products into nests $g = 1, \dots, G$ and place the outside good in its own nest. In the nested logit of Chapter 7, with nesting parameter $\sigma \in [0,1)$, define the inclusive value sums $D_g = \sum_{j\in g} e^{\frac{\delta_j}{1-\sigma}}$. Shares and consumer surplus are

$$s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}, \qquad s_g = \frac{D_g^{1-\sigma}}{1+\sum_{h=1}^{G} D_h^{1-\sigma}}, \qquad CS = \frac{1}{\alpha}\ln\left(1+\sum_{h=1}^{G} D_h^{1-\sigma}\right) + C. \tag{10.63}$$

Proposition 10.38 (Value of a new product in the nested logit model)**.** *In the nested logit model* (10.63)*, add product n to nest g, holding the other mean utilities fixed. Per consumer, consumer surplus rises by*

$$\Delta CS = -\frac{1}{\alpha}\ln\left[1 - s_g + s_g\left(1 - s_{n|g}\right)^{1-\sigma}\right], \tag{10.64}$$

where s_g is the share of nest g and $s_{n|g}$ the within-nest share of product n, both after the introduction. For fixed post-introduction shares, ΔCS equals the logit value $-\frac{1}{\alpha}\ln(1-s_n)$ at $\sigma = 0$, falls strictly as σ rises, and tends to zero as $\sigma \to 1$.

Proof. Let primes denote post-introduction values. Only nest g changes: $D_g' = D_g + e^{\frac{\delta_n}{1-\sigma}}$. Since $s_{n|g} = \frac{e^{\frac{\delta_n}{1-\sigma}}}{D_g'}$, we have

$$D_g = D_g' - e^{\frac{\delta_n}{1-\sigma}} = D_g'\left(1 - s_{n|g}\right).$$

Write $A' = 1 + \sum_h D_h'^{1-\sigma}$ and $A = 1 + \sum_h D_h^{1-\sigma}$. Then

$$A = A' - D_g'^{1-\sigma} + D_g^{1-\sigma} = A' - D_g'^{1-\sigma} + D_g'^{1-\sigma}\left(1 - s_{n|g}\right)^{1-\sigma}.$$

Dividing by A' and using $s_g = \frac{D_g'^{1-\sigma}}{A'}$ gives

$$\frac{A}{A'} = 1 - s_g + s_g \left(1 - s_{n|g}\right)^{1-\sigma}.$$

Since $\Delta CS = \frac{1}{\alpha} \ln \frac{A'}{A} = -\frac{1}{\alpha} \ln \frac{A}{A'}$, (10.64) follows. At $\sigma = 0$ the bracket is $1 - s_g s_{n|g} = 1 - s_n$. Because $0 < 1 - s_{n|g} < 1$, the term $(1 - s_{n|g})^{1-\sigma}$ rises strictly with σ and tends to 1. The bracket therefore rises toward 1, and ΔCS falls toward zero. □

The nesting parameter measures how close the new product is to the other members of its nest. At $\sigma = 0$ every product is an equally distant substitute and the logit value applies. As $\sigma \to 1$ the products within a nest become perfect substitutes, and a new member of a crowded nest adds nothing. This is Bresnahan's point about the slope of dd in discrete-choice form. A new product that steals its share from close substitutes has a flat demand curve and little surplus. With $s_g = 0.3$ and $s_{n|g} = 0.1$, for example, the gain in units of $\frac{1}{\alpha}$ is 0.0305 at $\sigma = 0$, 0.0155 at $\sigma = 0.5$ and 0.0032 at $\sigma = 0.9$.

Trajtenberg writes the nested logit in a different but equivalent way, which matters for reading his estimates. His within-nest index is $V_j = \frac{\delta_j}{1-\sigma}$, so the within-nest shares are $s_{j|g} = \frac{e^{V_j}}{\sum_{k \in g} e^{V_k}}$. His nest-level parameter is $\lambda = 1 - \sigma$, and the inclusive value of nest g is $W_g = \ln \sum_{k \in g} e^{V_k}$. The nest shares are $s_g = \frac{e^{a_g + \lambda W_g}}{\sum_h e^{a_h + \lambda W_h}}$, where we have added nest constants a_g that his specification sets to zero. In a sequential estimator, the coefficients inside V_j are estimated in a first stage and then held fixed. Let $\alpha_V = \frac{\alpha}{\lambda}$ denote the price coefficient inside V_j. Differentiating $\ln s_j = V_j - W_g + a_g + \lambda W_g - \ln \sum_h e^{a_h + \lambda W_h}$ gives, for $j \in g$,

$$\frac{\partial \ln s_j}{\partial V_k} = \begin{cases} -s_{k|g} \left[1 - \lambda(1 - s_g)\right], & k \in g,\ k \neq j, \\ -\lambda\, s_k, & k \in h \neq g. \end{cases} \tag{10.65}$$

Holding the V's fixed, $\lambda \to 0$ drives the cross-nest effects to zero while the within-nest effects stay bounded away from zero. In this parameterization a small λ therefore means that the nests are separate markets, which is the reading Trajtenberg (1985, p. 43, n. 42) gives it. With δ_j held fixed instead, $\sigma \to 1$ makes products within a nest perfect substitutes. The two readings differ only in what is held fixed. The money value of a change in the inclusive values has a simple limit.

Corollary 10.39 (Separate markets)**.** *In the parameterization above, consumer surplus is* $CS = \frac{1}{\lambda \alpha_V} \ln \sum_h e^{a_h + \lambda W_h} + C$. *Let the inclusive values change from* W_h^0 *to* W_h^1, *and let* $s_h^0 = \frac{e^{a_h}}{\sum_m e^{a_m}}$. *Holding* α_V, *the* a_h *and the* W*'s fixed, as* $\lambda \to 0$

$$\Delta CS \;\to\; \sum_h s_h^0 \, \frac{W_h^1 - W_h^0}{\alpha_V}. \tag{10.66}$$

Proof. In the units of δ, the marginal utility of income is $\alpha = \lambda \alpha_V$, and nest-level consumer surplus is $\frac{1}{\alpha} \ln \sum_h e^{a_h + \lambda W_h}$ by the nested version of Lemma 10.36. Define $f(\lambda) = \ln \sum_h e^{a_h + \lambda W_h^1} - \ln \sum_h e^{a_h + \lambda W_h^0}$, so that $\Delta CS = \frac{f(\lambda)}{\lambda \alpha_V}$. Then $f(0) = 0$ and

$$f'(0) = \sum_h \frac{e^{a_h}}{\sum_m e^{a_m}} W_h^1 - \sum_h \frac{e^{a_h}}{\sum_m e^{a_m}} W_h^0 = \sum_h s_h^0 \left(W_h^1 - W_h^0\right).$$

By l'Hôpital's rule, $\frac{f(\lambda)}{\lambda} \to f'(0)$, which gives (10.66). □

When the nests are separate markets, the nest shares no longer respond to the products, and the value of a change is the share-weighted average of the within-nest log-sum changes. This is exactly how Trajtenberg aggregates the gains in head and body scanners (Section 10.8.7).

Random coefficients and income effects. With random coefficients the logit formula holds consumer by consumer. Conditional on (D_i, ν_i), the logit form gives $CS_i = \frac{1}{\alpha_i} \ln(1 + \sum_k e^{\delta_k + \mu_{ik}})$, and the market measure integrates this over the distribution of (D_i, ν_i), as in Chapter 8. Income effects break the log-sum formula. Petrin (2002) uses $\alpha_i \ln(y_i - p_j)$ in place of $\alpha(y_i - p_j)$, so the marginal utility of income varies with $y_i - p_j$. Let the introduction change the choice set from $\mathcal{J}^0$ at prices p^0 to $\mathcal{J}^1$ at prices p^1. With the standard of living after the introduction as the reference, as in Definition 10.6, the compensating variation of consumer i solves

$$\max_{j \in \mathcal{J}^0} u_{ij}\left(y_i + CV_i,\, p^0\right) = \max_{j \in \mathcal{J}^1} u_{ij}\left(y_i,\, p^1\right). \tag{10.67}$$

It depends on the realized tastes, and its average over consumers is computed by simulation.

1. Draw R simulated consumers. For each draw r, draw demographics D_r from their empirical distribution, taste shocks ν_r, and an extreme value shock ϵ_{rj} for every product in $\mathcal{J}^0 \cup \mathcal{J}^1$. Use the same ϵ_{rj} for a product in both choice sets.
2. Compute the new maximal utility $\bar{u}_r = \max_{j \in \mathcal{J}^1} u_{rj}(y_r, p^1)$.
3. Find CV_r by bisection on $c \mapsto \max_{j \in \mathcal{J}^0} u_{rj}(y_r + c, p^0) - \bar{u}_r$. This function is continuous and strictly increasing in c, because utility rises with income for every product.
4. Average: $\widehat{\mathbb{E}[CV]} = \frac{1}{R} \sum_r CV_r$. Multiply by the market size for the total.

For Petrin's logarithmic specification, step 3 even has a closed form, derived in Section 10.9.6. Other income specifications need the root finder. The average of the individual CV_r differs in general from the income change that equates expected maximal utilities. The two coincide under quasi-linearity, where CV_r is linear in the utility difference. Section 10.9 applies this algorithm to the minivan and splits the result into a part due to observed characteristics and a part due to the ϵ's.

10.7.3 The idiosyncratic-taste problem

Characteristics-based demand models fall into two families, and the difference between them drives the valuation of new goods. Let $f(y_i, p_j)$ be a function with $f_y > 0$, $f_p < 0$ and $f_{py} \geq 0$, so that utility rises with income, falls with price, and richer consumers are weakly less sensitive to price. The first family contains the *pure characteristics models*,

$$U_{ij} = f(y_i, p_j) + \delta_j + \sum_k \beta_k x_{jk} \nu_{ik} \qquad \text{or} \qquad U_{ij} = f(y_i, p_j) + \delta_j - \sum_k \tau_k \left(x_{jk} - \nu_{ik}\right)^2, \tag{10.68}$$

with $\tau_k > 0$. The first form is the pure hedonic model of Berry and Pakes (2007), in which ν_{ik} is a taste for characteristic k. The second is the ideal-type model of Anderson et al. (1992), in which ν_{ik} is consumer i's ideal level of characteristic k. The second family adds an idiosyncratic shock,

$$U_{ij} = f(y_i, p_j) + \delta_j + \sum_k \beta_k x_{jk} \nu_{ik} + \epsilon_{ij}, \tag{10.69}$$

as in Berry et al. (1995). The shocks ϵ_{ij} are drawn independently for every product and consumer. Berry and Pakes (2007) call the second family models with *tastes for products*, because

the ϵ_{ij} act like a separate characteristic for each product. Following Caplin and Nalebuff (1991), one can think of them as interactions between product-specific dummy variables and i.i.d. tastes for each dummy.

The ϵ_{ij} mean that the product space can never be exhausted. Each new product arrives with a fresh set of draws, so some consumers like it more than anything else on the market, whatever its observed characteristics. The following proposition collects the implications for the logit.

Proposition 10.40 (Clones in the logit model)**.** *In the logit model with $\delta_0 = 0$:*

(a) A clone *of product j, a new product with $\delta_n = \delta_j$, has a positive share and raises consumer surplus by*

$$\Delta CS = \frac{1}{\alpha} \ln \frac{1 + \sum_{k=1}^{J} e^{\delta_k} + e^{\delta_j}}{1 + \sum_{k=1}^{J} e^{\delta_k}} = \frac{1}{\alpha} \ln \left(1 + s_j^0\right) > 0, \tag{10.70}$$

where s_j^0 is product j's share before the clone enters.

(b) With J identical products of mean utility δ, $CS(J) = \frac{1}{\alpha}\ln(1+Je^{\delta})+C$, and $CS(J)-\frac{1}{\alpha}\ln J \to \frac{\delta}{\alpha}+C$. Consumer surplus grows like $\frac{1}{\alpha}\ln J$ without bound.

(c) The equilibrium markup of a single-product firm satisfies $p_j - mc_j = \frac{1}{\alpha(1-s_j)} \geq \frac{1}{\alpha}$, however many products crowd the market.

(d) Every product with finite δ_j has a positive share, so the model cannot rationalize a product with a zero share.

Proof. (a) Apply (10.60) with $A_0 = 1 + \sum_k e^{\delta_k}$ and $A_1 = A_0 + e^{\delta_j}$. Then $\frac{A_1}{A_0} = 1 + \frac{e^{\delta_j}}{A_0} = 1 + s_j^0$, which exceeds 1. (b) With J identical products, $\sum_k e^{\delta_k} = Je^{\delta}$. Then

$$\frac{1}{\alpha}\ln(1 + Je^{\delta}) - \frac{1}{\alpha}\ln J = \frac{1}{\alpha}\ln\left(\frac{1}{J} + e^{\delta}\right) \to \frac{\delta}{\alpha}.$$

(c) Firm j maximizes $(p_j - mc_j)Ms_j$. The logit share derivative is $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$. The first-order condition is

$$s_j - (p_j - mc_j)\,\alpha s_j(1 - s_j) = 0,$$

so $p_j - mc_j = \frac{1}{\alpha(1-s_j)}$. Since $0 < s_j < 1$, the markup exceeds $\frac{1}{\alpha}$. (d) $s_j = \frac{e^{\delta_j}}{1+\sum_k e^{\delta_k}} > 0$ for finite δ_j. □

Each part is unrealistic in some markets. Part (a) is the red bus and blue bus problem of Chapter 7 viewed from the welfare side. Adding a blue bus identical to a red bus creates surplus in the logit, although nothing new is offered. Part (b) says that proliferating near-identical brands raises welfare without bound. Part (c) says that markups do not fall toward marginal cost as the product space fills. In a pure characteristics model, by contrast, a clone is a perfect substitute for the original. At given prices it adds no variety value. If a rival sells it, Bertrand competition drives both prices to cost, and consumers gain only through this price effect. If the original's owner sells it, nothing changes. Part (d) is the mirror image of the others. The model must assign every product a positive share, so it cannot use the information in products that sell nothing, and the inversion $\ln s_j - \ln s_0 = \delta_j$ breaks down at zero shares. The same mechanism biases estimated markups and the estimated welfare gains from new goods upward.

Trajtenberg (1985, p. 18) noticed the welfare side of this problem in 1985. He decomposed his surplus function into a part due to observed utility and a part due to dispersion.

Proposition 10.41 (Entropy decomposition)**.** *Let $s_j = \frac{e^{V_j}}{\sum_k e^{V_k}}$ be logit choice probabilities over a finite choice set. Then*

(a) $\ln \sum_j e^{V_j} = \sum_j s_j V_j + \mathcal{H}(s)$*, where* $\mathcal{H}(s) = -\sum_j s_j \ln s_j$ *is the* entropy *of the choice probabilities.*

(b) Conditional on choosing j, the maximal utility $V_j + \epsilon_j$ is type-I extreme value with location $\ln \sum_k e^{V_k}$, for every j. Hence

$$\mathbb{E}[\epsilon_j \mid j \text{ chosen}] = \gamma_E - \ln s_j \qquad \text{and} \qquad \mathcal{H}(s) = \sum_j s_j \left(\mathbb{E}[\epsilon_j \mid j \text{ chosen}] - \gamma_E\right).$$

Proof. (a) For every j, $\ln s_j = V_j - \ln \sum_k e^{V_k}$, so $\ln \sum_k e^{V_k} = V_j - \ln s_j$. Multiply by s_j and sum over j. Since $\sum_j s_j = 1$,

$$\ln \sum_k e^{V_k} = \sum_j s_j V_j - \sum_j s_j \ln s_j.$$

(b) Let f and F be the type-I extreme value density and CDF, and let $A = \sum_k e^{V_k - V_j} = \frac{1}{s_j}$. The event that j is chosen and its utility is at most m has probability

$$\int_{-\infty}^{m-V_j} f(e) \prod_{k \neq j} F(V_j + e - V_k)\, de = \int_{-\infty}^{m-V_j} e^{-e} \exp\left(-e^{-e} A\right) de.$$

Substitute $t = e^{-e}$, so $dt = -e^{-e} de$. The integral becomes

$$\int_{e^{-(m-V_j)}}^{\infty} e^{-tA}\, dt = \frac{1}{A} \exp\left(-A e^{-(m-V_j)}\right) = s_j \exp\left(-e^{-\left(m - \ln \sum_k e^{V_k}\right)}\right).$$

Dividing by $\mathbb{P}(j \text{ chosen}) = s_j$ gives the conditional CDF, which does not depend on j. Its mean is $\ln \sum_k e^{V_k} + \gamma_E$, so $\mathbb{E}[\epsilon_j \mid j] = \ln \sum_k e^{V_k} - V_j + \gamma_E = \gamma_E - \ln s_j$. Multiplying by s_j and summing gives the last identity. □

Part (a) is Trajtenberg's equation (11), and part (b) explains what the entropy term measures. The surplus function equals the share-weighted observed utility $\sum_j s_j V_j$ plus the average idiosyncratic taste that consumers realize on the products they choose. With J identical products and no outside good, $\sum_j s_j V_j = V$ and $\mathcal{H} = \ln J$, so the entire gain from proliferation is entropy. Trajtenberg traces this taste for "horizontal variety" to the independence of irrelevant alternatives. He notes that it rewards "the proliferation of seemingly identical brands that may differ only in their unobserved (and thus presumably less important) attributes" (Trajtenberg, 1985, p. 19). For some purposes he suggests netting out the change in entropy and using $\Delta\mathcal{W} - \frac{1}{\alpha}\Delta\mathcal{H}$. The net measure is not a clean fix. The entropy term also contains the real value of matching heterogeneous buyers to different products, which a model with random coefficients would attribute to observed characteristics.

Whether the ϵ's should count at all depends on what they represent. Four interpretations are common. They may be tastes for unobserved product attributes, measurement error, approximation error in the utility function, or optimization mistakes. Only the first supports counting them as welfare. If consumers choose with errors, the log-sum formula counts the errors as utility.

How the value of variety grows. Figure 10.7 compares the growth of consumer surplus as identical or evenly spaced products are added, in four models. The two logit-based curves use Propositions 10.38 and 10.40. In the nested logit, J identical products in one nest give $D^{1-\sigma} = J^{1-\sigma}e^{\delta}$, so $CS(J) = \frac{1}{\alpha}\ln(1 + J^{1-\sigma}e^{\delta})$. Surplus still grows without bound, at the slower rate $\frac{1-\sigma}{\alpha}\ln J$.

The pure characteristics benchmark is a Hotelling line. Consumers are uniform on $[0,1]$ and each buys one unit at a common price p from the nearest of J products. The products sit at $\ell_k = \frac{2k-1}{2J}$, and a consumer at distance d from her product loses td^2. Each product serves an interval of length $\frac{1}{J}$, and within it the distance d is uniform on $\left[0, \frac{1}{2J}\right]$. The average loss is therefore

$$t\,\mathbb{E}[d^2] = t \cdot \frac{1}{3}\left(\frac{1}{2J}\right)^2 = \frac{t}{12J^2},$$

and with gross value v,

$$CS(J) = v - p - \frac{t}{12J^2}, \qquad CS(J) - CS(1) = \frac{t}{12}\left(1 - \frac{1}{J^2}\right) \le \frac{t}{12}. \tag{10.71}$$

The gain is bounded, and the increment from one more product, $\frac{t}{12}\left(\frac{1}{J^2} - \frac{1}{(J+1)^2}\right)$, falls to zero like $\frac{t}{6J^3}$. Adding logit errors with scale μ to the same line gives $CS(x) = \mu \ln \sum_k e^{-\frac{t(x-\ell_k)^2}{\mu}}$ for a consumer at x, up to a constant. The sum divided by J is a Riemann sum, so for large J the sum is close to $J\,I(x)$ with $I(x) = \int_0^1 e^{-\frac{t(x-\ell)^2}{\mu}}\,d\ell > 0$. Hence $CS(x) \approx \mu \ln J + \mu \ln I(x)$, and the gain grows like $\mu \ln J$. The integral $I(x)$ is close to the whole-line value $\sqrt{\frac{\pi\mu}{t}}$ only when both x and $1 - x$ are large relative to $\sqrt{\frac{\mu}{t}}$.

Ackerberg and Rysman (2005) propose a correction within the logit family. It lets the contribution of the idiosyncratic term depend on how crowded the product space is, so that additional products add less.

10.7.4 Pure characteristics and vertical models

Berry and Pakes (2007) develop the pure characteristics model for empirical work. Their utility is

$$u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j, \qquad u_{i0} = 0, \tag{10.72}$$

with random coefficients $\beta_{ik} = \beta_k + \sigma_k \nu_{ik}$ and $\alpha_i > 0$, after normalizing the coefficient on the single unobserved characteristic ξ_j to one. The model has no ϵ_{ij}. They show that the two families of models differ in two respects (pp. 2–3 and 6–7 of their text). With tastes for products, substitution between products is limited and markups stay bounded away from zero as similar products are added. Each consumer's utility also grows without bound as products are added, whatever their characteristics. In the pure characteristics model, the gain from a new product is limited by a smooth function of its distance from existing products. As the space fills, products become close substitutes, prices approach marginal cost, and the increment in welfare from each new product declines to zero.

The ϵ's have practical advantages, which explain their popularity. They make choice probabilities integrals with simple limits, and they keep every probability positive with smooth derivatives. They also allow the share inversion that turns ξ_j into a linear function of data

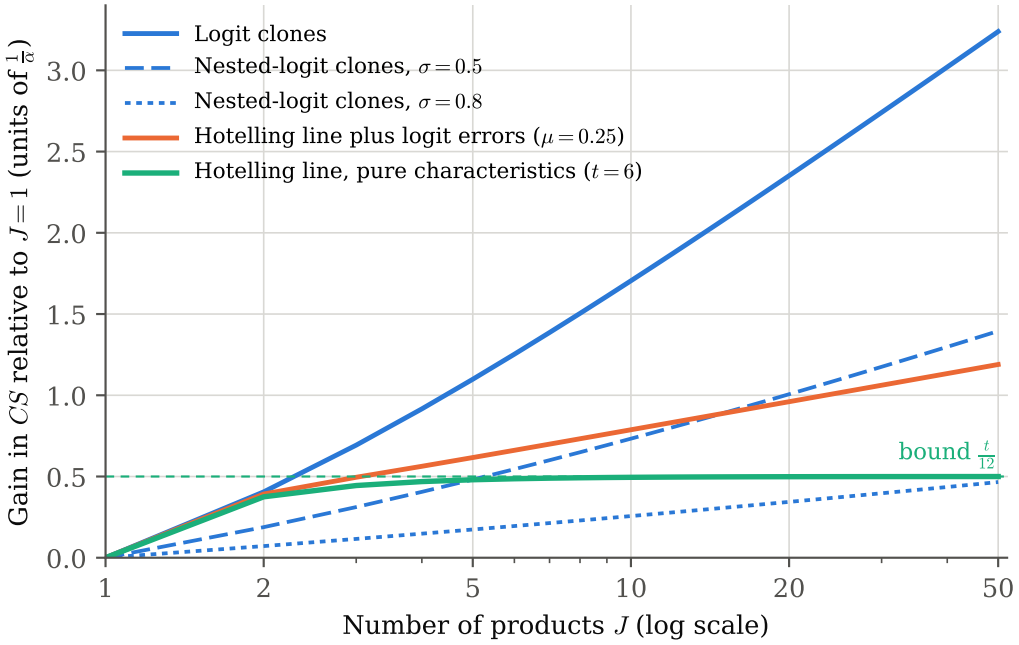

Figure 10.7: Gain in consumer surplus from adding products, relative to a market with one product, in units of $\frac{1}{\alpha}$. The logit and nested-logit curves add identical products with $\delta = 0$ in the presence of an outside good. The Hotelling curves place J products evenly on a line with uniform consumers, quadratic transport cost $t = 6$ and fixed equal prices. The orange curve adds logit errors with scale $\mu = 0.25$ to the Hotelling model. At $J = 50$ the gains are 3.24 (logit), 1.40 and 0.47 (nested logit with $\sigma = 0.5$ and 0.8), 1.19 (Hotelling with errors) and 0.50 (pure Hotelling). Only the models with idiosyncratic errors grow without bound. For the Hotelling curves we set $\alpha = 1$, so all curves are in the same units. Our computations.

and parameters (Berry, 1994; Berry et al., 1995). Without them the share function has kinks and the inversion is no longer a contraction. Berry and Pakes therefore propose to use the vertical model of Chapter 6 for the price coefficient, conditional on the other coefficients, and a homotopy method to compute the mean utilities. A *homotopy method* solves a hard system of equations by deforming an easy system into it and following the solution path. They also study a "modified BLP" model in which the logit term is scaled by $\frac{1}{\mu_\epsilon}$. The pure characteristics model is the limit as $\mu_\epsilon \to \infty$.

Welfare in a Monte Carlo experiment. The last experiment in Berry and Pakes (2007, Section 5.4) speaks to new goods. The data come from a pure characteristics model with three markets, structured as successive years of a market with improving characteristics. The number of products rises from 75 to 100 and then to 125. The characteristics are patterned on the megahertz of personal computers in 1995–97 (Pakes, 2003), and prices for given characteristics fall by roughly 30 percent a year. The welfare measure is the average gain per person, in dollars, from moving from the year-one choice set to the year-three choice set. Table 10.11 reports it.

Table 10.11: Welfare gain from the year-one to the year-three choice set in the Berry-Pakes Monte Carlo

Method	Gain
True (pure characteristics data-generating process)	266.1
Homotopy estimator of the pure characteristics model	265.3
Modified BLP, nominal scale $\mu_\epsilon = 10$, halved when needed	270.0
Modified BLP, scale μ_ϵ estimated	259.0
Modified BLP, μ_ϵ estimated, final homotopy contraction	272.1

Notes: Average per-person gain in dollars. One simulated data set with an average of 100 products per market. In the third row the scale starts at 10. Where a combination of parameter values and market caused numerical problems, Berry and Pakes halved it until the problems disappeared, in a few cases down to 2.5 (note to their Table 5). Their Table 7 labels this row $\mu_\epsilon = 10$. The estimated scale in the fourth row is 0.934 with standard error 6.680, and the estimated constant in mean utility is −6.455 against a true value of 2. Source: Berry and Pakes (2007), Tables 5 and 7.

All methods come within 3 percent of the truth. The modified BLP estimator with estimated scale does badly on parameters and elasticities. For the lowest-priced product its own-price elasticity is −1.8 against a true −11.0 (Berry and Pakes, 2007, Table 6). Yet its welfare gain is close to the truth. Berry and Pakes explain why. Because the contraction fits the shares exactly, the extra gain from the logit errors is offset by lower mean utilities δ, and the two roughly cancel. The estimated constant in δ falls below −6 to match the small shares with a large logit error. The lesson is double-edged. Fitting shares exactly protects welfare measures against part of the ϵ problem in this design, but it does so by distorting the parameters that govern substitution.

The hedonic approach. Bajari and Benkard (2005) take a different route to demand without ϵ_{ij}. Their method has two stages in the spirit of Rosen (1974). The first estimates a hedonic price function $p_j = \mathbf{p}(x_j, \xi_j)$ that allows one unobserved characteristic and a non-additive form, and recovers the ξ_j. They show that a hedonic price surface exists even with imperfect competition and finitely many products. The second stage recovers tastes from each consumer's first-order conditions. At the chosen product, the marginal utility of each continuous characteristic equals the marginal utility of money times the slope of the price surface,

$$\frac{\partial u_i}{\partial x_{jk}} = \alpha_i \frac{\partial \mathbf{p}}{\partial x_{jk}}. \tag{10.73}$$

With a continuum of products this inverts to each consumer's taste vector. With finitely many products the revealed-preference conditions place each consumer's tastes in a set, which shrinks as the number of products grows. The unobserved characteristic is essential. In their data on personal computers, 357 of 695 products are dominated by another product that is better in every observed dimension and cheaper (Benkard and Bajari, 2004, p. 2). They also note that the ϵ_{ij} amount to assuming an infinite-dimensional characteristics space, and that logit-type demand curves typically are hyperbolic, approaching both axes. The hedonic model imposes no shape beyond a downward slope, so the two families can predict quite different demand at prices outside the observed range. That range is exactly where new-good valuations live.

A vertical example. The vertical model of Chapter 6 makes the role of distance transparent. Utility is $U_{ij} = \delta_j - \nu_i p_j$, with $\nu_i > 0$ distributed with continuous density f on $(0, \infty)$. A consumer's marginal utility of money is ν_i, so a utility gain ΔU is worth $\frac{\Delta U}{\nu_i}$ dollars to her. Products that sell are ordered by price and quality, and consumer i buys j when ν_i lies between the cutoffs $c_{j,j+1} = \frac{\delta_{j+1} - \delta_j}{p_{j+1} - p_j}$ and $c_{j-1,j}$.

Proposition 10.42 (Value of a new product in the vertical model)**.** *Let j and $j+1$ be adjacent products with positive shares, $p_j < p_{j+1}$, and $c^* = c_{j,j+1} > 0$. Insert product n with $p_j < p_n < p_{j+1}$ and quality*

$$\delta_n = \delta_j + c^*(p_n - p_j) + d, \tag{10.74}$$

so that d is the vertical distance of the point (p_n, δ_n) above the chord joining (p_j, δ_j) and (p_{j+1}, δ_{j+1}). Hold all other prices fixed, and take d small enough that the new cutoffs stay inside $(c_{j+1,j+2},\ c_{j-1,j})$.

(a) If $d \le 0$, product n sells nothing and creates no surplus.

(b) If $d > 0$, exactly the consumers with $\nu \in (\nu_L, \nu_H)$ switch to n, where

$$\nu_L = c^* - \frac{d}{p_{j+1} - p_n}, \qquad \nu_H = c^* + \frac{d}{p_n - p_j}.$$

(c) The money-metric gain of consumer ν is $g(\nu) = \frac{1}{\nu}\left[U_n(\nu) - \max\{U_j(\nu), U_{j+1}(\nu)\}\right]^+$. It is positive on (ν_L, ν_H) and equals $\frac{d}{c^*}$ at $\nu = c^*$.

(d) The total gain $\mathcal{G} = \int g(\nu) f(\nu)\, d\nu$ satisfies the first expansion below. If in addition $f(c^*) > 0$, the share s_n is first order in d and the gain per buyer satisfies the second,

$$\mathcal{G} = \frac{f(c^*)}{2c^*} \frac{p_{j+1} - p_j}{(p_n - p_j)(p_{j+1} - p_n)} d^2 + o(d^2), \qquad \frac{\mathcal{G}}{s_n} = \frac{d}{2c^*} + o(d). \tag{10.75}$$

Proof. At $\nu = c^*$ the old products give equal utility, $U_j(c^*) = U_{j+1}(c^*)$. Using (10.74),

$$U_n(c^*) - U_j(c^*) = \delta_n - \delta_j - c^*(p_n - p_j) = d.$$

For $\nu > c^*$ the relevant rival is j, and $U_n(\nu) - U_j(\nu) = d - (\nu - c^*)(p_n - p_j)$. This difference vanishes at ν_H. For $\nu < c^*$ the rival is $j+1$, and $U_n(\nu) - U_{j+1}(\nu) = d + (c^* - \nu)(p_n - p_{j+1})$, which vanishes at ν_L. Both differences are linear in ν with peak d at c^*.

(a) If $d \le 0$, $U_n(\nu) \le \max\{U_j(\nu), U_{j+1}(\nu)\}$ for every ν, by the two linear expressions. No consumer strictly prefers n.

(b) and (c) For $d > 0$, n beats the better of j and $j+1$ exactly on (ν_L, ν_H). The bound on d ensures that products other than j and $j+1$ remain worse for these consumers. Dividing the utility gain by ν gives $g(\nu)$, which equals $\frac{d}{c^*}$ at c^*.

(d) Let $h(v) = vg(v)$ denote the utility gain. It is a triangle with height d and base $v_H - v_L$, where

$$v_H - v_L = d\left(\frac{1}{p_n - p_j} + \frac{1}{p_{j+1} - p_n}\right) = d\,\frac{p_{j+1} - p_j}{(p_n - p_j)(p_{j+1} - p_n)}.$$

Its area is $\frac{1}{2}d(v_H - v_L)$. Since $\frac{f(v)}{v}$ is continuous at $c^* > 0$ and the interval shrinks to c^*, $\frac{f(v)}{v} = \frac{f(c^*)}{c^*} + o(1)$ uniformly on it. Therefore

$$\mathcal{G} = \int_{v_L}^{v_H} h(v)\frac{f(v)}{v}\,dv = \left(\frac{f(c^*)}{c^*} + o(1)\right)\frac{d}{2}(v_H - v_L),$$

which is the first part of (10.75). This step holds also when $f(c^*) = 0$, and the coefficient on d^2 is then zero. The share is $s_n = F(v_H) - F(v_L) = (f(c^*) + o(1))(v_H - v_L)$. When $f(c^*) > 0$, the factor $f(c^*) + o(1)$ is bounded away from zero for small d. Dividing the two expressions then gives $\frac{\mathcal{G}}{s_n} = \frac{d}{2c^*} + o(d)$. □

The condition $f(c^*) > 0$ matters for the per-buyer formula. Take the density $f(v) = (v-1)^2 e^{-v}$, old products $(p, \delta) = (1, 2)$ and $(3, 4)$, an outside utility of zero and the new product $(2, 3 + d)$. Then $c^* = 1$ and $f(c^*) = 0$. Our computation gives $s_n = \frac{2e^{-1}d^3}{3} + o(d^3)$ and $\mathcal{G} = \frac{e^{-1}d^4}{6} + o(d^4)$, so that $\frac{\mathcal{G}}{s_n} = \frac{d}{4} + o(d)$. This is half the value $\frac{d}{2c^*} = \frac{d}{2}$ of (10.75).

Figure 10.8 draws the construction. When $f(c^*) > 0$, the gain is second order in the distance d. The share of the new product is then first order in d, and the gain per buyer, $\frac{d}{2c^*}$, vanishes as the new product approaches the chord. The quantity $\frac{d}{c^*}$ is the dollar value of the new product's quality premium at the margin between its neighbors, and the average switcher gets half of it, as in any triangle. Compare (10.62). In the logit the gain per buyer is at least $\frac{1}{\alpha}$ for any product, including a product on or below the chord. A numerical check with $f(v) = e^{-v}$ and the prices of Figure 10.8 confirms (10.75). The exact gain differs from the approximation by 1.7 percent at $d = 0.2$ and by 0.1 percent at $d = 0.05$.

10.7.5 Hedonic methods, quality change and changing tastes

Statistical agencies often handle new varieties with hedonic methods, and the vertical example shows what these methods assume. A *hedonic price function* $\mathbf{p}(z)$ relates the prices of products to their characteristics z (Griliches, 1971; Rosen, 1974). We write

$$p_j = \mathbf{p}(z_j) + \tilde{p}_j, \tag{10.76}$$

where $\tilde{p}_j$ is the *residual price*, the deviation of product j's price from the surface. In Rosen's model with a continuum of products, the hedonic function is an equilibrium locus. A consumer with utility $\alpha[y - \mathbf{p}(z)] + \phi(z)$ chooses z to satisfy $\mathbf{p}'(z) = \frac{\phi'(z)}{\alpha}$. A new variety priced on the surface offers nothing that consumers could not already buy, so it adds no surplus. Hedonic quality adjustment therefore treats a new variety as a perfect substitute for a combination of existing ones. This is the flat curve $dd(-\infty)$ of Figure 10.5, which Bresnahan (1997, p. 238) identifies as an understatement of the value of new goods. In the vertical model the chord between neighbors plays the role of the hedonic surface. A product priced on it has $d = 0$ and adds nothing, while a product above it adds a gain of order d^2. When the product space is sparse, the surface has wide gaps and the understatement can be large.

Quality as repackaging. Deaton and Muellbauer (1980b, Section 10.3, pp. 262–266) derive the most common hedonic regression from a model in which quality repackages quantity. The

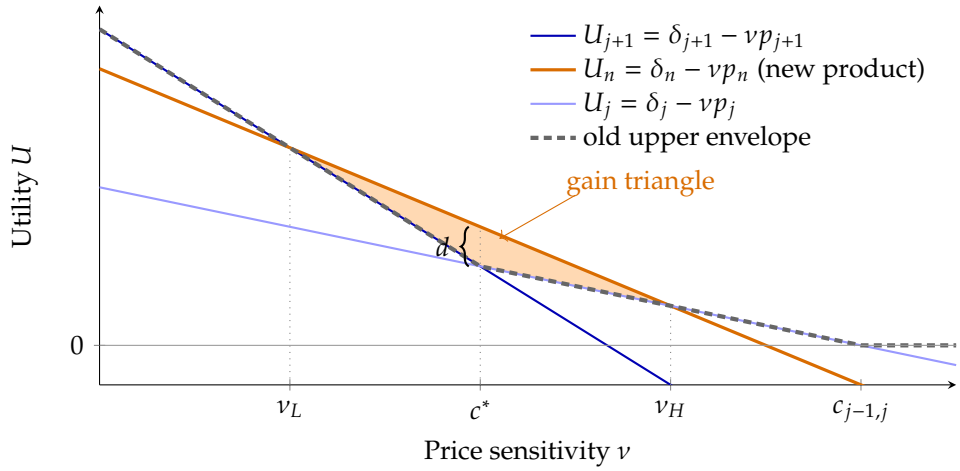

Figure 10.8: The vertical model with a product inserted between two neighbors. Each line is the utility $\delta - vp$ of one product as a function of price sensitivity v. The dashed line is the upper envelope before the introduction, and the outside good gives utility zero. Product n lies a distance d above the chord joining its neighbors and wins the consumers with $v \in (v_L, v_H)$. The shaded triangle is their utility gain, so the welfare gain is of order d^2. The parameters are $(p_j, p_n, p_{j+1}) = (1, 2, 3)$ and $(\delta_j, \delta_n, \delta_{j+1}) = (2, 3.5, 4)$, so $c^* = 1$ and $d = 0.5$.

varieties j of a good are perfect substitutes once each is weighted by a quality index $\zeta_j > 0$. Utility is $v\big(h(\sum_j \zeta_j q_j), q_{\text{other}}\big)$, where q_{other} collects the other goods (their eq. 3.7). A consumer then buys only the varieties with the lowest price per unit of quality, $\frac{p_{jt}}{\zeta_j}$. Suppose all consumers share the weights and every variety sells. The prices per unit of quality must then be equal, $p_{jt} = \zeta_j P_t$, where P_t is the price of a unit of quality in period t. With $\ln \zeta_j = f(z_j)$, taking logs gives

$$\ln p_{jt} = \ln P_t + f(z_j) \tag{10.77}$$

(their eq. 3.8). A disturbance and a log-linear f give the *time-dummy hedonic regression*. It pools all periods and adds a zero-one dummy for each period except a reference period (p. 263). The coefficients on the period dummies estimate $\ln P_t$, a quality-corrected price index. A new variety priced on this surface sells quality at the going price P_t, so it adds no surplus. Their Table 10.1 (p. 264) fits such a regression to 150 British used-car models, aged one to three years, from nine manufacturers in the late 1950s and the 1960s. A 1 percent increase in brake horsepower raises the price by 0.370 percent (standard error 0.023). The implied quality-corrected price of cars was about 8 percent lower in 1969 than in 1958 (p. 263). The coefficients on miles per gallon, −0.064 (0.041), and interior size, −0.146 (0.094), are negative and imprecise. Deaton and Muellbauer suggest that, with length and width held fixed, a large interior may signal restricted luggage space (p. 264). An F-test rejects a common price function across manufacturers. The statistic is 9, and 1.2 suffices to reject at the 5 percent level (p. 265). Deaton and Muellbauer read this as evidence of *market segmentation*, in which products made for different types of consumers carry different shadow prices of characteristics (p. 259). A single price surface ignores it. When consumers' weights differ, the surface is instead an envelope of their *bid functions*. A consumer's bid function gives the most she would pay for one unit of a variety with characteristics z, at her utility level (pp. 265–266). The marginal condition $\frac{\partial \ln \mathbf{p}(z)}{\partial z_k} = \frac{\partial \ln \zeta(z)}{\partial z_k}$ then holds for each consumer at her chosen variety, as in Rosen (1974) (eq. 3.10, pp. 265–266).

Changing tastes: ex ante and ex post measures. Applications over long periods face a further problem. If the estimated taste parameters change from year to year, the value of moving from choice set S_t to S_{t+1} depends on which year's tastes are used. Write $\mathcal{W}^t$ for the surplus function evaluated with the parameters estimated for year t. Trajtenberg (1985, pp. 56–58) defines

$$\Delta\mathcal{W}^a = \mathcal{W}^t(S_{t+1}) - \mathcal{W}^t(S_t), \qquad \Delta\mathcal{W}^p = \mathcal{W}^{t+1}(S_{t+1}) - \mathcal{W}^{t+1}(S_t). \tag{10.78}$$

The *ex ante* measure $\Delta\mathcal{W}^a$ asks what a consumer with today's tastes would pay to face next year's choice set. The *ex post* measure $\Delta\mathcal{W}^p$ asks how much income could be taken from a consumer with next year's tastes, leaving her indifferent between next year's and this year's sets. The distinction resembles the one between compensating and equivalent variation, but it has a different source. Compensating and equivalent variation hold tastes fixed and differ in the reference utility level, and they coincide without income effects. Here utility is quasi-linear, and the ambiguity comes from the change in the taste parameters themselves. The hybrid $\mathcal{W}^{t+1}(S_{t+1}) - \mathcal{W}^t(S_t)$ compares utilities under two different preference structures, which is an interpersonal comparison and has no welfare meaning.

Trajtenberg expects the ex ante measure to exceed the ex post one. His argument is a *dual inducement* mechanism. Strong tastes for an attribute induce firms to improve that attribute, and the improvement then lowers its marginal valuation next year. Judged by the original tastes, an improvement is therefore worth more. He also considers a Divisia-like alternative that estimates adjacent years jointly. It yields a unique measure, but only by suppressing the taste differences that create the problem.

10.8 Case study: CT scanners (Trajtenberg 1989)

Trajtenberg (1989) was the first study to measure a product innovation by the welfare it creates, using an estimated discrete-choice demand system in characteristics space. The application is computed tomography (CT) scanners in the United States from their introduction in 1973 to 1982. The paper is also an early study of how innovation, diffusion and returns to research interact. The PDF available to us is the working-paper version (Trajtenberg, 1985). All numbers below come from it, and page numbers refer to its typed pages. The published version may number its tables differently, and some of its numbers may differ. Trajtenberg indexes products by i and characteristics by j. We index scanners by j and characteristics by k, consistent with the rest of the book. Table 10.20 at the end of the section maps the study.

10.8.1 The question

The output of innovative activity does not come in countable units. Patent counts vary enormously in significance, and sales of new products confound innovation with market size. Trajtenberg therefore argues that a quantitative measure of innovation can only be defined in value terms (Trajtenberg, 1985, pp. 2–3). How much product innovation occurred in a field over a period is the additional social surplus that the innovations generated. Other measures can at best serve as proxies.

A product is a pair (z_j, p_j), with $z_j = (z_{j1}, \dots, z_{jK})$ its characteristics and p_j its price. Trajtenberg writes s_j for this pair, a symbol we keep for market shares. The choice set in year t is S_t, and product innovation is the change $S_t - S_{t-1}$. It includes improvements in existing products, the addition of new ones and the exit of old ones. The magnitude of innovation is

$$\Delta\mathcal{W}_t = \mathcal{W}(S_t) - \mathcal{W}(S_{t-1}), \tag{10.79}$$

for a surplus function $\mathcal{W}$ (equation 1 of the paper, p. 7). The measure includes the effect of price changes. Trajtenberg defends this broad definition on practical grounds. With nonlinear surplus functions the effects of characteristics and prices cannot be separated, and new products have no earlier price to compare with (pp. 8–9).

What counts as a product innovation needs a definition, and Trajtenberg provides one through the nature of characteristics (pp. 4–6).

Definition 10.43 (Concatenable characteristics)**.** Let x_j be the quantity of product j that a consumer buys. Characteristic k is *concatenable* if the amount of it available to the consumer is $z_{jk} = f^k(x_j)$ with $\frac{\partial z_{jk}}{\partial x_j} \neq 0$. Examples are the protein in a food or the carrying capacity of vehicles. It is *non-concatenable* if $z_{jk} = g^k(\theta_j)$ for the product's natural unit θ_j, with $\frac{\partial z_{jk}}{\partial x_j} = 0$ for $x_j > \theta_j$. Examples are the speed of a vehicle or the aperture of a camera.

Product innovation requires at least one non-concatenable characteristic. Suppose all characteristics were concatenable and linear in quantity. Then a change from (z_j, p_j) to $(\kappa z_j, \kappa p_j)$ with $\kappa > 1$ would leave the indirect utility unchanged, $V(z_j, p_j, y) = V(\kappa z_j, \kappa p_j, y)$. Buying κ units of the old product delivers the same bundle at the same cost. Such a change could not count as an innovation. A product innovation therefore presupposes a quality dimension that can be changed only by switching products. CT scanners satisfy this. Speed and image resolution are properties of the machine. Buying more machines does not change them.

Scope. The surplus function is in principle total surplus. Trajtenberg argues that profits pose no special measurement problem beyond accounting, so the difficulty lies in consumer surplus. He measures the gains that are not appropriated by the innovating firms and passed on to buyers (pp. 9–10). He states two limitations. Radical innovations, which open new product classes, cannot be measured directly (Section 10.7.1). The measure also ignores spillovers to other product classes, so it is a lower bound on the social gain (pp. 11–12). Trajtenberg proposes an indirect estimate of the gain from the first scanner, based on diffusion (Section 10.8.9).

The question matters for three reasons. Product innovation is a large part of technical change, and official price and productivity statistics do not capture it (p. 1). Social returns to research cannot be computed without a measure of benefits. And the interaction between innovation and diffusion cannot be studied without a measure of innovation.

10.8.2 Setting

Research on computed tomography began in 1967 at the British electronics company EMI. The first operational prototype was installed in a London hospital in 1971, and the first commercial system, the EMI Scanner, was installed in the United States in June 1973 (p. 25). In 1974–77 nearly 20 firms entered. They ranged from electronics companies (General Electric, Siemens, Hitachi, Philips) to pharmaceutical companies (Pfizer, Searle, Syntex) and specialized firms (AS&E, Elscint), and they competed mainly through product performance (p. 26). Diffusion among U.S. hospitals was fast, the fifth fastest among twenty innovations for which diffusion studies existed (p. 26, n. 23). Mounting concern about health-care costs led to Certificate of Need regulation, which required approval for large hospital investments. Its full impact in 1978–79 produced a sharp downturn and the exit of many firms, including EMI. The market then recovered and settled at 10–15 percent annual growth, with General Electric holding about 50 percent of the U.S. market and some ten firms sharing the rest (p. 26). The two pioneers of CT received the Nobel Prize in Medicine in 1979.

Characteristics. A CT scanner takes cross-sectional images of the body. Trajtenberg measures three performance characteristics (pp. 27–30). SPEED is the minimum scan time in seconds. The first scanner took five minutes per scan, which restricted it to the brain, a motion-free organ. Scan times of twenty seconds and less opened other organs, and the fastest systems of the early 1980s scanned in about one second. RESOL is spatial resolution in millimeters, the size of the smallest object visible in high-contrast regions. Trajtenberg had constructed a fuller image-quality index from experimental data, but it was unavailable for most of the roughly 50 systems marketed. RTIME is reconstruction time in seconds, the time the computer takes to produce the image. A fourth attribute, gantry tilt, proved insignificant and was dropped. All three characteristics are defined so that less is better. Scanners come in two types. *Head scanners* can image only the brain, while *body scanners* can image almost any organ.

10.8.3 Data

Trajtenberg assembled his own data bank, covering the period from the announcement of the innovation in 1972 to 1981, with some series extending to 1983 (pp. 30–32). It has four parts. The first gives the technical characteristics and prices of all CT scanners marketed up to 1982, by year, which is the sequence of choice sets S_t. The second records every installation in the United States, with the identity of the hospital or clinic, the dates of order and installation, and the model bought. It has more than 2,000 observations, including upgrades, and Trajtenberg estimates that it covers about 98 percent of U.S. installations up to July 1981. The third describes the hospitals and the fourth the manufacturers, including their research and development spending on CT. The main source is a questionnaire to all manufacturers, with follow-up contacts. Others are the radiology and medical-physics literature, trade journals and consulting reports. Public sources include the Food and Drug Administration, the Office of Technology Assessment, the Patent Office and the American Hospital Association, and Trajtenberg also ran a telephone survey of hospitals. All but two firms active in 1981 answered the questionnaire. The two were CGR and Philips, and Philips was excluded for lack of reliable information. Little is lost, since it had sold fewer than twenty scanners in the United States by 1981.

A year in the data runs from November 1 of the previous year to October 31. Most new scanners are introduced at the annual meeting of the Radiological Society of North America in November, so this *radiological year* matches the timing of choice sets. Data for 1981 cover only the first half of that year (p. 33, n. 28). Table 10.12 reproduces Tables 1 and 2 of the paper.

The two types followed opposite paths (pp. 32–33). Head scanners became simpler and cheaper, and their price fell from \$379K in 1975 to \$150K by 1981. Body scanners improved quickly, with average scan time falling from 195 seconds in 1975 to 2.6 seconds in 1982, and their price rose from \$365K to \$850K. By most indicators competition peaked in 1977. Fourteen new scanners were introduced that year, the number of firms reached 12, and the Herfindahl index reached its low of 0.23. Sales to new adopters fell from 97.7 percent of sales in 1975 to 50.0 percent in 1981 as diffusion leveled off and replacement purchases grew.

10.8.4 The model

Demand and the surplus function. A buyer chooses one scanner from S. She spends the rest of income y on a composite outside good m with unit price (pp. 15–17),

$$\max_{j,m} \; U(z_j, m; D) + \epsilon_j \qquad \text{subject to} \qquad p_j + m = y, \quad j \in S, \tag{10.80}$$

Table 10.12: CT scanners in the United States, 1973–1982

Panel A. Prices and average characteristics

	Price ($K)		SPEED (s)		RESOL (mm)		RTIME (s)	
Year	Head	Body	Head	Body	Head	Body	Head	Body
1973	310	–	300	–	3.1	–	300	–
1974	370	–	300	–	1.7	–	30	–
1975	379	365	285	195.0	1.8	1.6	20	8
1976	374	471	105	63.0	1.7	1.5	60	83
1977	354	573	95	19.0	1.7	1.3	54	38
1978	167	620	96	7.1	1.6	1.2	29	30
1979	154	667	150	6.6	1.5	1.1	19	29
1980	154	739	115	5.5	1.5	1.0	27	31
1981	150	827	115	4.9	1.5	0.8	27	32
1982	150	850	115	2.6	1.5	0.7	27	27

Panel B. Market indicators

Year	Units sold	Sales ($M)	Body (% sales)	New adopters (%)	Firms	Models	HHI
1973	16	5	0	100.0	1	1	1.00
1974	74	27	0	98.7	1	1	1.00
1975	221	82	44.8	97.7	4	5	0.43
1976	374	167	76.2	84.8	9	14	0.38
1977	385	208	84.9	84.1	12	23	0.23
1978	248	122	72.4	84.4	10	23	0.28
1979	273	141	70.2	76.0	9	22	0.26
1980	270	169	80.4	65.3	8	17	0.32
1981	392	302	91.6	50.0	8	14	0.31
1982	428	344	93.5	n.a.	8	16	0.30

Notes: Radiological years (November to October), U.S. market. Price is the sales-weighted average price of all scanners of each type. The characteristics are simple averages, and smaller values are better. "Body" is the share of body scanners in unit sales and "New adopters" the share of sales to first-time buyers. HHI is the Herfindahl index. In 1974 and 1977–80 the units sold differ from the counts that Trajtenberg uses in his Table 11 (Table 10.18). Source: Trajtenberg (1985), Tables 1 and 2.

where D is a vector of buyer attributes. Substituting $m = y - p_j$ gives the conditional indirect utility $V(z_j, y - p_j; D) + \epsilon_j$. With i.i.d. type-I extreme value shocks and quasi-linear utility $\alpha(y - p_j) + \phi(z_j; D) + \epsilon_j$, income cancels and the choice probabilities are

$$s_j = \frac{e^{-\alpha p_j + \phi(z_j; D)}}{\sum_{k \in S} e^{-\alpha p_k + \phi(z_k; D)}}, \qquad j \in S. \tag{10.81}$$

There is no outside good. The model describes the choice among scanners by buyers who buy one, and the decision to adopt is modeled separately (Section 10.8.9). By Lemmas 10.34 and 10.36 the surplus function is

$$\mathcal{W}(S; D) = \frac{1}{\alpha} \ln \sum_{j \in S} e^{-\alpha p_j + \phi(z_j; D)}, \tag{10.82}$$

which is equation (10) of the paper (p. 18), and its entropy decomposition is Proposition 10.41. Trajtenberg notes that the surplus function treats the buyer as if she bought a fraction s_j of every product. Every change in the set therefore registers, whichever product a buyer ends up with. He rejected the probit because his choice sets had up to twenty alternatives, and the computers of the time could handle a probit with only four or five.

Hedonic prices and the collinearity problem. In markets for differentiated products, prices are closely related to characteristics through the hedonic function (10.76). Entering both p_j and z_j in (10.81) creates severe collinearity, and their separate coefficients cannot be estimated with precision (pp. 19–20). Trajtenberg argues that the problem is conceptual. In Rosen's continuous model the consumer cannot choose z and p independently, because choosing z determines p. With

$$\max_{z} \; \alpha[y - \mathbf{p}(z)] + \phi(z) \qquad \Longrightarrow \qquad \mathbf{p}'(z) = \frac{\phi'(z)}{\alpha}, \tag{10.83}$$

only the characteristics enter the demand analysis (p. 21). In the discrete case the hedonic function is a stochastic budget constraint. Substituting (10.76) into utility gives

$$V_j = \phi(z_j) - \alpha\, \mathbf{p}(z_j) - \alpha \tilde{p}_j = V^n(z_j) - \alpha \tilde{p}_j, \qquad V^n(z) \equiv \phi(z) - \alpha\, \mathbf{p}(z). \tag{10.84}$$

The term $V^n(z)$ is the *net utility* of characteristics, net of their expected cost. The residual price $\tilde{p}_j$ is a random extra charge or discount relative to the market's valuation of the characteristics. Choices depend on z_j and $\tilde{p}_j$, the part of price orthogonal to the characteristics. The next proposition supplies the functional form for V^n (p. 22).

Proposition 10.44 (Quadratic approximation of net utility)**.** *Let V^n be twice continuously differentiable with an interior point z^* at which*

$$\frac{\partial V^n(z^*)}{\partial z_k} = \frac{\partial \phi(z^*)}{\partial z_k} - \alpha \frac{\partial \mathbf{p}(z^*)}{\partial z_k} = 0, \qquad k = 1, \ldots, K,$$

and let the Hessian $H = \nabla^2 V^n(z^*)$ be negative definite. Then

$$V^n(z) = c_0 + z^\top \beta + z^\top G z + o\left(\|z - z^*\|^2\right), \qquad G = \frac{1}{2} H, \quad \beta = -H z^*, \tag{10.85}$$

where $c_0 = V^n(z^*) + \frac{1}{2} z^{*\top} H z^*$ does not depend on z. If ϕ is concave and $\mathbf{p}$ is convex near z^*, and $\nabla^2 \phi(z^*)$ or $\nabla^2 \mathbf{p}(z^*)$ is definite, then H is negative definite.

Proof. A second-order Taylor expansion about z^* gives

$$V^n(z) = V^n(z^*) + \nabla V^n(z^*)^\top (z - z^*) + \frac{1}{2}(z - z^*)^\top H (z - z^*) + o\left(\|z - z^*\|^2\right).$$

The gradient term vanishes by assumption. Expanding the quadratic form with H symmetric,

$$\frac{1}{2}(z - z^*)^\top H (z - z^*) = \frac{1}{2} z^\top H z - z^\top H z^* + \frac{1}{2} z^{*\top} H z^*.$$

Collecting terms gives (10.85). Finally $H = \nabla^2 \phi(z^*) - \alpha \nabla^2 \mathbf{p}(z^*)$ is the sum of two negative semidefinite matrices, one of which is negative definite, so H is negative definite. □

The constant c_0 drops out of the logit probabilities. In a discrete market tangency is not required, and z^* is the expected optimum. Actual choices scatter around it. Products near z^* are more likely to be chosen than products far from it (p. 23). Figure 10.9 redraws the paper's Figure 1. Trajtenberg adds that $\mathbf{p}$ may be concave and the conditions still hold, provided it is less concave than ϕ (p. 22, n. 21). Otherwise the expected optimum is a corner, the approximation is poor, and estimated coefficients may take the wrong signs.

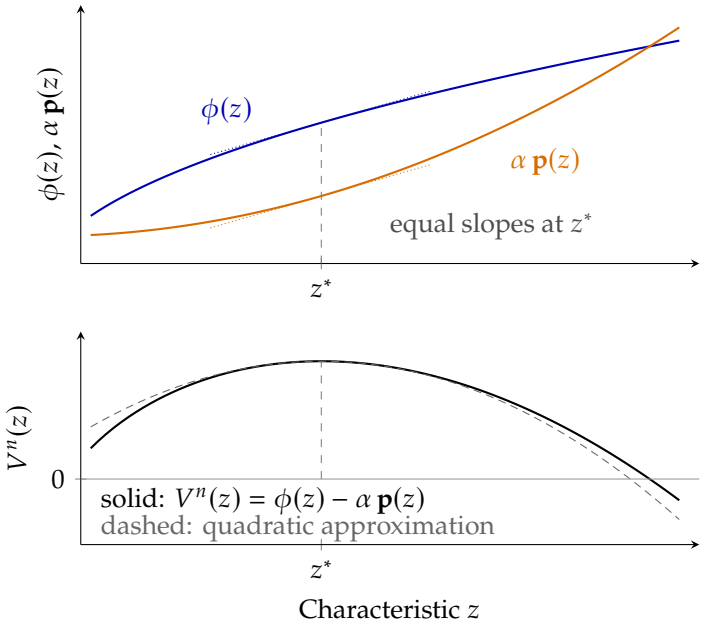

Figure 10.9: Net utility and its quadratic approximation. The top panel shows a concave utility of characteristics $\phi(z)$ and a convex hedonic cost $\alpha\,\mathbf{p}(z)$, with equal slopes at the expected optimum z^*. The bottom panel shows that net utility $V^n(z) = \phi(z) - \alpha\,\mathbf{p}(z)$ has an interior maximum at z^*. Its dashed curve is the second-order expansion of Proposition 10.44. Illustrative functions $\phi(z) = 2\sqrt{z} + 0.5$ and $\alpha\,\mathbf{p}(z) = 0.3z^2 + 1.2$. Redrawn after Trajtenberg (1985), Figure 1.

The separable specification. Trajtenberg simplifies further (p. 38). Suppose utility is additively separable in characteristics, $\phi(z) = \sum_k f^k(z_k)$ with each f^k quasi-concave, and the hedonic function is linear in logs, $\mathbf{p}(z) = h_0 + \sum_k h_k \ln z_k$. Then net utility is separable too,

$$V^n(z) = \sum_k \left[f^k(z_k) - \alpha h_k \ln z_k \right] - \alpha h_0 \approx \sum_k \left(\beta_k z_k + \gamma_k z_k^2 \right) + \text{const}, \tag{10.86}$$

because the Hessian of a separable function is diagonal and the cross terms of (10.85) vanish. The saving of $\frac{K(K-1)}{2}$ parameters matters here. A multinomial logit (MNL) with characteristics that vary only across products, and not across buyers, can include at most $|S|-1$ such variables. Here $|S|$ is the number of alternatives in the choice set S (p. 38, n. 36). The separability of the hedonic function in $\ln z_k$ is what licenses the simplification. A double-log or semi-log hedonic function would reintroduce cross terms (p. 39, n. 36).

The estimating equation. Combining (10.84) and (10.86), the model estimated for each year is

$$s_j = \frac{e^{V_j}}{\sum_{k \in S_t} e^{V_k}}, \qquad V_j = \sum_{k=1}^{K} \left(\beta_k z_{jk} + \gamma_k z_{jk}^2 \right) + \vartheta \, \tilde{p}_j, \qquad \tilde{p}_j = p_j - \hat{\mathbf{p}}(z_j), \tag{10.87}$$

with $K = 3$ characteristics. If the residual price measured only the price, ϑ would equal $-\alpha$. Section 10.8.6 explains why Trajtenberg allows otherwise. The procedure has two steps. The first estimates the hedonic function and computes the residual prices. The second estimates the MNL by maximum likelihood with $\tilde{p}_j$ as a regressor (p. 23). Trajtenberg abstracts from simultaneity. His working assumption is that each choice set and its hedonic function are fixed before the year begins and do not change during it, which matches the annual introduction cycle (p. 24). He also warns that the residual price may be correlated with omitted attributes that affect choice, which would bias its coefficient (p. 24).

10.8.5 Estimation and specification tests

Step 1: hedonic regressions. Trajtenberg compares three forms (pp. 35–37). They are the double-log $\ln p_j = h_0 + \sum_k h_k \ln z_{jk} + e_j$, the semi-log $\ln p_j = h_0 + \sum_k h_k z_{jk} + e_j$, and the linear-log

$$p_j = h_0 + \sum_k h_k \ln z_{jk} + e_j. \tag{10.88}$$

As far as Trajtenberg knew, the linear-log form had not been used for hedonic prices before. When more of a characteristic is better, $h_k > 0$ and the form is concave, which is implausible. Here less is better, so $h_k < 0$, and $\frac{\partial^2}{\partial z_k^2} h_k \ln z_k = -\frac{h_k}{z_k^2} > 0$ makes the function convex. The forms were estimated for 1976–81 on two samples, all scanners with a head dummy and body scanners alone, which gives twelve cases. The *Box-Cox transformation* $\frac{p^\lambda - 1}{\lambda}$ gives the linear form at $\lambda = 1$ and the log form as $\lambda \to 0$, so its likelihood puts the forms on a common scale. Box-Cox comparisons of fit ranked the linear-log first in half the cases, second in a third, and last in a sixth. The double-log ranked first in a quarter, second in seven twelfths and third in a sixth (p. 37, n. 33). The linear-log has two further advantages. Its residuals are in price units and enter the MNL directly, and it justifies the separable form (10.86). Table 10.13 reproduces the body-scanner regressions. The R^2 hovers around 0.85 and most coefficients are significant, so the characteristics explain most of the variation in price. Including price and characteristics together in the MNL would have produced the collinearity Trajtenberg feared.

Step 2: multinomial logit by year. The MNL is estimated separately for each year from 1975 to 1981, by type of scanner, without buyer attributes except in 1975 (pp. 33–34). With about 300 purchases a year, computing the surplus for every buyer and integrating over attributes would have multiplied the burden by an order of magnitude. The estimates therefore describe a representative buyer, hospital or private clinic. Trajtenberg also leaves out firm variables such

Degrees of freedom	4	11	12	12	11	7

Notes: Dependent variable is price in thousands of dollars. t-statistics in parentheses. For the pooled sample of head and body scanners with a head dummy, the R^2 are 0.653, 0.895, 0.855, 0.937, 0.912 and 0.916 for 1976–81. Source: Trajtenberg (1985), Table 3, panels (b) and (a).

as reputation or advertising, which improve the fit but have no clear welfare interpretation (p. 34, n. 30). Choice sets changed within years. The software allowed buyers to face expanding sets, so entries during the year were handled exactly, but exits were not (pp. 38–40). Fit is summarized by $\rho^2 = 1 - \frac{L(\hat{\beta})}{L(0)}$, with $L(0)$ the log likelihood when all alternatives are equally likely, and by the correlation between predicted and actual shares.

Head scanners offered few models, so their MNL could be estimated only for 1976–79, in linear form with the actual price, and without RTIME in 1979 (p. 45). Body scanners use the quadratic form (10.87) with the residual price. Table 10.14 reproduces both tables. The coefficients on the characteristics change substantially from year to year. Trajtenberg attributes this to the dual inducement mechanism of Section 10.7.5. Since the quadratic form makes individual coefficients hard to read, he measures relative preferences by average derivatives of the choice probabilities (p. 45, n. 46). The price coefficients of head scanners are negative and fairly stable, between −0.71 and −0.89. The residual-price coefficients of body scanners are positive in every year except 1981.

Testing independence of irrelevant alternatives. Should head and body scanners form one choice set? Under IIA the cross-price elasticities of all products with respect to the price of product k are equal. A body scanner and a head scanner would then be equally good substitutes for any third scanner (p. 41). Trajtenberg applies the test of Hausman and McFadden (1984). Let $\hat{\beta}_f$ be the MNL estimate on the full set of head and body scanners. Let $\hat{\beta}_r$ be the estimate on the restricted set of body scanners, using the buyers who chose from it. Under the null hypothesis that IIA holds on the full set, both estimators are consistent and $\hat{\beta}_f$ is efficient. The statistic is

$$S = \left(\hat{\beta}_r - \hat{\beta}_f\right)^{\top} \left(\widehat{V}_r - \widehat{V}_f\right)^{-1} \left(\hat{\beta}_r - \hat{\beta}_f\right) \xrightarrow{d} \chi^2_m, \tag{10.89}$$

with m the rank of $\widehat{V}_r - \widehat{V}_f$ (p. 42). The variance of the difference is the difference of the variances by the argument of Hausman (1978). An efficient estimator must be uncorrelated with its difference from any other consistent estimator. Otherwise a linear combination of the two would be consistent with smaller variance. Appendix A gives the general Hausman test.

Trajtenberg computes the test for 1977 and 1981. He chose years far apart, with similar ratios of head to body models, so that the results would not depend on the relative number

Notes: Asymptotic t-statistics in parentheses. Prices are in hundreds of thousands of dollars. RPRICE is the residual price from the year's hedonic regression. The correlations between predicted and actual shares are 0.999, 0.910, 0.993 and 0.998 for head scanners and 0.999, 0.877, 0.900, 0.870, 0.722 and 0.547 for body scanners. The 1981 data cover the first half of the year. Source: Trajtenberg (1985), Tables 4 and 5.

of alternatives dropped (p. 42, n. 40). The statistics are $S(1977) = 21.83$ and $S(1981) = 27.77$, against a 1 percent cutoff of 18.5. IIA is rejected for the full set. This cutoff is the 0.99 quantile of a χ^2 with seven degrees of freedom, consistent with the seven coefficients of the body-scanner specification. He notes that the test is an omnibus test, with power only against large departures from the MNL. Its advantage is that it needs no model beyond the MNL.

The nested logit. Trajtenberg next estimates a nested logit with a head branch H and a body branch B (pp. 43–47), in the parameterization of (10.65) with no nest constants:

$$s_j = s_{j|g}\, s_g, \qquad s_{j|g} = \frac{e^{V_j}}{\sum_{k\in g} e^{V_k}}, \qquad s_g = \frac{e^{\lambda W_g}}{e^{\lambda W_H} + e^{\lambda W_B}}, \qquad W_g = \ln \sum_{k\in g} e^{V_k}. \tag{10.90}$$

At $\lambda = 1$ the model collapses to the MNL on the full set. At $\lambda = 0$ the cross elasticities between branches are zero, the branch shares no longer depend on the products, and each branch is a separate market. With branch constants chosen to reproduce the observed branch shares, the surplus function is then $\mathcal{W} = \sum_g s_g W_g$ in utility units, which is Corollary 10.39 (equation 23 of the paper, p. 44). Estimation is sequential. The first stage is the branch MNLs of Table 10.14. The inclusive values are computed from them, and the second stage estimates λ in the branch-choice model. The second-stage standard errors are not corrected for the first stage, so Trajtenberg does not test $\lambda = 0$ formally (p. 47, n. 47).

Table 10.15 reports the second stage. Except in 1978, $\hat{\lambda}$ is between 0.02 and 0.08. Trajtenberg concludes that the cross elasticities between head and body scanners are nil, so the two types form separate markets. He reads the negative estimate for 1978 as a local failure of the conditions for a generalized extreme value model, since λ must lie in the unit interval. A negative λ would even suggest complementarity. The conclusion agrees with the divergent technological paths of the two types. Trajtenberg stresses a broader lesson. Estimating λ offers a way to draw market boundaries in empirical studies (p. 47).

Table 10.15: Nested logit, second stage, and a reinterpretation

	Inclusive values		Second stage			Reinterpretation	
Year	W_B	W_H	$\hat{\lambda}$	(s.e.)	ρ^2	Body share	Implied λ
1976	47.704	−9.102	0.0205	(0.00214)	0.21	0.762	0.0205
1977	11.989	−10.410	0.0784	(0.00646)	0.40	0.849	0.0771
1978	−14.428	−10.340	−0.2120	(0.03510)	0.12	0.724	−0.2359
1979	−4.728	−15.806	0.0706	(0.01211)	0.10	0.702	0.0773

Notes: $W_g = \ln \sum_{k\in g} e^{V_k}$ from the first-stage MNLs. The body share is the share of body scanners in unit sales (Table 10.12, Panel B). The implied λ is $\frac{1}{W_B - W_H} \ln \frac{s_B}{1-s_B}$, the value at which the branch model reproduces the observed body share. Hausman-McFadden statistics for the full versus body-only choice set are 21.83 (1977) and 27.77 (1981), against a 1 percent cutoff of 18.5. Source: Trajtenberg (1985), Table 6 and pp. 41–42. The implied λ is our computation.

The last two columns of Table 10.15 suggest a more cautious reading, which is ours and not the paper's. In the second stage each buyer chooses a branch, and the only regressor is $W_B - W_H$. If all buyers in a year face the same choice set, this regressor is the same for every buyer. The score of the binary logit likelihood is then

$$\sum_i \left[\mathbf{1}\{i \text{ buys body}\} - \Lambda\left(\lambda(W_B - W_H)\right)\right](W_B - W_H) = 0,$$

with Λ the logistic CDF. The estimate sets the predicted body share equal to the observed one, so

$$\hat{\lambda} = \frac{1}{W_B - W_H} \ln \frac{s_B}{1 - s_B}. \tag{10.91}$$

Within-year entry makes choice sets differ slightly across buyers, so the formula holds only approximately. It reproduces the 1976 estimate exactly and the others closely. The magnitude of $\hat{\lambda}$ is therefore the log odds of the body share divided by the gap between the inclusive values. That gap has an arbitrary location. Each branch MNL is invariant to adding a constant to all its V's, and the two branches use different functional forms with no intercepts. A branch constant would fit the shares exactly for any λ. The 1978 sign, for instance, arises because $W_B < W_H$ that year while body scanners outsold head scanners. On this reading the second stage carries little information about substitution between the branches. Trajtenberg's conclusion that the two types were separate markets may still be right, given the evidence from technology, prices and use. It does not, however, rest on the estimated λ.

The first year with a choice. In 1973 and 1974 only the EMI head scanner was sold, so there was nothing to estimate (p. 33, n. 28). In 1975 the first two body scanners and a second head scanner entered. At that stage the two types were still similar in characteristics and price, and the effective choice set had four alternatives (pp. 47–48). With room for only three variables that vary across products alone, Trajtenberg estimated a hybrid specification on hospitals only. He interacted resolution with a hospital attribute, which makes it vary across buyers and bypasses the limit. In his Table 7 the residual-price coefficient is 10.183 ($t = 4.3$) and the interaction of a head dummy with price is -2.875 ($t = -6.0$). The coefficients are -0.165 for SPEED ($t = -0.8$) and -6.338 for RESOL times RAD ($t = -4.8$), with $\rho^2 = 0.24$ from 181 purchases. RAD is the average of three dummy variables for the availability of x-ray, cobalt and radium therapy at the hospital. It lets resolution matter more to hospitals with a wider range of radiation therapy, and the RESOL coefficient at the mean of RAD is -4.183.

10.8.6 Positive price coefficients and signaling

A positive residual-price coefficient cannot be read as a negative marginal utility of income, and the surplus function needs α to convert utility into money. Nor is it clear whether $\vartheta \tilde{p}_j$ belongs in the utility used for welfare (pp. 48–49). Trajtenberg addresses both questions with a model of price, quality and quantity interdependence in the tradition of Spence. Demand q depends on price and on perceived quality ψ, which may in turn depend on price and quantity,

$$q = q(p, \psi), \qquad \psi = \Psi(p, q). \tag{10.92}$$

The observed demand curve is $q = q(p, \Psi(p, q))$. Totally differentiating the two equations gives

$$\begin{aligned} dq &= q_p \, dp + q_\psi \, d\psi, \\ d\psi &= \Psi_p \, dp + \Psi_q \, dq. \end{aligned}$$

Substituting the second into the first,

$$dq \left(1 - q_\psi \Psi_q\right) = \left(q_p + q_\psi \Psi_p\right) dp,$$

so

$$\frac{dq}{dp} = \frac{q_p + q_\psi \Psi_p}{1 - q_\psi \Psi_q} \tag{10.93}$$

(equation 28, p. 50). With $\Psi_q = 0$ and $\Psi_p > 0$, perceived quality rises with price, and the observed demand curve slopes up whenever $q_\psi \Psi_p > -q_p$. In econometric terms this is the bias from omitting a quality variable correlated with price (p. 51).

Trajtenberg argues that the observed characteristics are only partly informative about a scanner's performance, for buyers as well as for the econometrician. Prices can then signal quality. He postulates that expected quality depends on the part of price not explained by the observed characteristics, $\psi^e = \Psi(p - \mathbf{p}(z)) = \Psi(\tilde{p})$ (equation 30, p. 52). He then asks whether a signaling equilibrium, in which expected and realized quality agree on average, is plausible. A firm could price above its true quality and exit once the bluff is called. Trajtenberg argues that this "quick kill" was unlikely in CT. Reputation mattered in medical equipment, most firms operated in many related markets, and research and marketing costs were persistently high (pp. 52–53).

In a signaling equilibrium the expected quality is a real quality dimension and belongs in utility (p. 53):

$$V_j = V^1(z_j) + V^2(\psi^e_j) - \alpha p_j.$$

Take $V^2(\psi^e) = b_\psi \psi^e$ and $\psi^e_j = a_\psi \tilde{p}_j$, and write $\beta_0 = a_\psi b_\psi$ for the marginal utility of a dollar of residual price through the signal. Substituting $p_j = \mathbf{p}(z_j) + \tilde{p}_j$,

$$V_j = \left[V^1(z_j) - \alpha\, \mathbf{p}(z_j)\right] + (\beta_0 - \alpha)\tilde{p}_j, \qquad \vartheta = \beta_0 - \alpha \tag{10.94}$$

(equations 32 and 33). The estimated coefficient is positive when the signaling effect exceeds the price effect, $\beta_0 > \alpha$. Two implications follow (p. 54). The estimated $\vartheta \tilde{p}_j$ should stay in V_j when computing $\mathcal{W}(S_t)$, because the signaled quality is real. But the conversion to money requires α itself. Dividing by ϑ in the surplus function would be meaningless.

To identify α Trajtenberg uses the contrast between the two types (pp. 54–55). Signaling should matter more for products that are complex, new to users and changing fast, and it should fade as a product matures. Head scanners were introduced first, kept the same application, and after early improvements became simpler and cheaper. Body scanners grew steadily more sophisticated, with large jumps in the first years. Trajtenberg therefore treats the head-scanner price coefficients for 1976–79 as unbiased estimates of α. The head scanner had been on the market for three years by 1976, which he takes as long enough for signaling to vanish (p. 55, n. 53). He uses the 1976 coefficient for earlier years and the 1979 coefficient for later ones (p. 56). The difference between the body and head coefficients then measures the signaling effect.

The signaling interpretation deserves scrutiny. The more natural reading of a positive price coefficient is omitted quality correlated with price, the endogeneity problem later handled with instruments by Berry (1994) and Berry et al. (1995). Petrin (2002, p. 708) cites Trajtenberg as an example of a price coefficient biased toward zero by omitted characteristics. In these data the two readings are observationally equivalent. Both imply that the residual price proxies real quality, so both support keeping $\vartheta \tilde{p}_j$ in V_j. They differ on whether a clean α is available. Importing α from head scanners assumes that buyers of the two types have the same marginal utility of income, an assumption the data cannot test. The head coefficients are also imprecise, with t-statistics of -1.5 and -1.9 in 1976 and 1977. Finally, the 1981 body coefficient is -0.277. If signaling had vanished by then, this coefficient should be near the head value of about -0.8. Its smaller magnitude suggests that a positive bias remained.

10.8.7 Welfare computations

Trajtenberg computes both measures of (10.78) (pp. 58–60). The residual prices must come from the hedonic function of the reference year, since $\mathbf{p}(z)$ is added back to the quadratic approximation to recover utility. For the ex ante measure the year-t hedonic function generates the residuals of both years, and for the ex post measure the year-$(t+1)$ function does. Because the IIA test rejected a common tree from 1976 on, the gains are computed separately for head and body scanners for 1976–82. For 1973–76 they are computed for the joint set with the 1975 parameters. The 1973 and 1974 sets contain one head scanner each.

The computation for body scanners has three steps (p. 59). The first computes the change in the log-sum,

$$\Delta\widetilde{\mathcal{W}}_{t,t+1} = \ln \sum_{j \in S_{t+1}} e^{V_j} - \ln \sum_{j \in S_t} e^{V_j}. \tag{10.95}$$

The second divides by the absolute value of α and multiplies by 100, because prices were measured in hundreds of thousands of dollars. The result is the gain in thousands of dollars per buyer. The third deflates by the producer price index for capital equipment (1982 = 1.00). Table 10.16 reproduces Table 8. The arithmetic of the table reveals a detail the text does not state. The ex ante column divides by the year-t coefficient, the value printed in column (2), while the ex post column divides by the year-$(t+1)$ coefficient. For 1977–78, for example, $\frac{-0.419}{0.893} \times 100 = -46.9$, which uses the 1978 coefficient.

Table 10.16: Welfare gains from innovation in body scanners, 1976–1982

	(1) $\Delta\widetilde{\mathcal{W}}_B$		(2)	(3) Gain ($K)		(4)	(5) Real gain ($K)	
Period	Ex ante	Ex post	$\lvert\alpha\rvert$	Ex ante	Ex post	PPI	Ex ante	Ex post
1975–76	14.715[a]	2.930	0.748	1,967.2	391.7	0.620	3,173.0	631.8
1976–77	5.416	0.764	0.748	724.1	107.8	0.660	1,097.1	163.3
1977–78	0.110	−0.419	0.709	15.5	−46.9	0.712	21.8	−65.9
1978–79	1.413	0.349	0.893	158.2	42.7	0.774	204.4	55.1
1979–80	0.681	0.377	0.818	83.3	46.1	0.858	97.0	53.7
1980–81	1.551	−0.073	0.818	189.6	−8.9	0.945	200.6	−9.4
1981–82	1.709	–	0.818	208.9	–	1.00	208.9	–

Notes: Column (1) is the change in the log-sum (10.95). Column (2) is the head-scanner price coefficient used for the ex ante measure. The ex post measure uses the coefficient of the following year. Column (3) is $\frac{(1)}{(2)} \times 100$, and column (5) is $\frac{(3)}{(4)}$, where (4) is the producer price index for capital equipment with 1982 = 1.00. [a] Imputed value. In real terms it equals the joint 1975–76 ex ante gain of Table 10.17 times the body scanners' share of the 1975–76 ex post gains, $\frac{0.6318}{0.3191+0.6318} \times 4.7758 = 3.173$ (our reading). The last digit of the ex post entry for 1975–76 in column (5) is faint in the source and equals $\frac{391.7}{0.620}$. Source: Trajtenberg (1985), Table 8.

Table 9 of the paper, reproduced as Table 10.17, brings the two types together. The overall gain in each period is the share-weighted average

$$\Delta\mathcal{W} = s_H \, \Delta\mathcal{W}_H + s_B \, \Delta\mathcal{W}_B, \tag{10.96}$$

where s_g is the fraction of buyers who bought type g. This is (10.66) applied to separate markets, with branch constants that reproduce the observed shares. The 1975–76 ex ante gain, computed for the joint set with the 1975 parameters, is entered for both types. Ex ante and ex post pairs overlap for four periods, 1975–76 to 1978–79. In those periods the ex ante gain exceeds the ex post gain by a fairly constant factor, as the dual inducement argument predicts.

The mean ratio is 7.24 with standard deviation 1.34 (p. 60). Trajtenberg uses this ratio to impute the ex ante gains of 1973–74 and 1974–75 and the ex post gains of 1979–82. The incremental gains are the $\Delta \mathcal{W}_t$, and their running sums are the cumulative gains.

Table 10.17: Welfare gains by scanner type, incremental and cumulative overall gains ($M per buyer)

	Head scanners			Body scanners			Incremental		Cumulative	
Period	$\Delta \mathcal{W}_H^a$	$\Delta \mathcal{W}_H^p$	s_H	$\Delta \mathcal{W}_B^a$	$\Delta \mathcal{W}_B^p$	s_B	Ex ante	Ex post	Ex ante	Ex post

Notes: Millions of 1982 dollars per representative buyer. s_g is the share of buyers choosing type g. *Computed with the mean ratio of ex ante to ex post gains for 1976–79. For 1973–74 and 1974–75 the paper enters the joint ex post gain in both type columns. Every overall entry satisfies (10.96) to four decimals, and the cumulative columns are running sums. Source: Trajtenberg (1985), Table 9.

Interpretation. The cumulative ex ante gain to 1982 is $16.6 million per buyer, and the ex post gain $2.2 million. Most of it accrues before 1977. The largest single increment, $8.71 million ex ante in 1973–74, comes from the second EMI model, discussed in Section 10.8.9. It is imputed from the ex post gain with the mean ratio. These per-buyer gains are large. In 1975–76 the ex ante gain of $4.78 million is several times the price of a body scanner in Table 10.12, even allowing for the deflation to 1982 dollars. Large gains are possible for a revolutionary technology, since buyers can value an early improvement far above its price. But two features of the estimates suggest that the functional form also plays a role. The ex ante measure exceeds the ex post measure by a factor of seven. And the logit adds an entropy term for every new model (Proposition 10.41), while the quadratic utility extrapolates the value of large changes in characteristics.

10.8.8 Who is the consumer?

The buyers of CT scanners are hospitals and clinics, which buy them as capital inputs and sell diagnostic services to patients (pp. 60–63). This does not by itself invalidate the welfare measure. Under perfect competition, the surplus from the derived demand for an input equals the surplus from the final demand for the output. The firm is then a redundant intermediary (p. 61, n. 56). Regulation affects the surplus that is realized, but the measure still captures it.

Trajtenberg locates the difficulty in the behavior of hospitals. He compares two ideal types and the patient. Let $q(z)$ be the price of a procedure performed with a scanner of quality z. The operating cost per procedure is $C[z, \mathbf{p}(z)]$, which rises with quality and with the scanner's price. A profit-maximizing, price-taking hospital solves

$$\max_z \; q(z) - C[z, \mathbf{p}(z)] \qquad \Longrightarrow \qquad q_z = C_z .$$

A hospital that maximizes a utility $v^h(z)$ of the quality of its diagnostic services instead sets

$v_z^h = C_z$. A patient with utility $v^c(z) + y^c - q(z)$ chooses $v_z^c = q_z$. Under perfect competition

$$v_z^c = q_z = C_z = v_z^h, \tag{10.97}$$

and the hospitals' demand for scanners, which is what the MNL estimates, reflects the patients' valuation. Trajtenberg doubts that $v_z^h = v_z^c$. Physicians may value diagnostic technology above patients do, because of rivalry between hospitals, long-range scientific goals, status and prestige. If so, the measured gains overstate the social gains (p. 62). A deeper problem is that v_z^c is hardly defined. Patients cannot evaluate the medical value of diagnostic procedures, so the size of the principal-agent problem cannot be gauged (p. 63). Trajtenberg proceeds on the assumption that extraneous motives are not the main driver of hospitals' choices. Insurance adds a further wedge that the paper does not model. Insured patients do not face the full price of a procedure, so neither their demand nor the hospital's derived demand measures willingness to pay at the margin.

10.8.9 Diffusion, total gains and social returns

The $\Delta\mathcal{W}_t$ are gains per representative buyer. Total gains require the number of buyers who benefit from each year's innovations, and this depends on the dynamics of adoption (pp. 63–67). Trajtenberg contrasts two polar views of diffusion. In the first, diffusion traces the distribution of reservation prices among potential adopters. Each innovation lowers the quality-adjusted price, triggers adoption by the buyers just at the margin, and benefits only those who buy in the year it appears. Total gains are then

$$TW_t = \Delta\mathcal{W}_t \, n_t, \tag{10.98}$$

where n_t is the number of buyers in year t. In the second view diffusion is driven entirely by demonstration effects, such as learning, emulation and rivalry. Today's innovations then benefit all future adopters too. With N potential adopters, adoption-time density f, CDF F and discount rate r,

$$TW_t = \Delta\mathcal{W}_t \, N \int_t^\infty f(\tau) e^{-r(\tau - t)} \, d\tau. \tag{10.99}$$

Ignoring discounting, $TW_t = \Delta\mathcal{W}_t N[1 - F(t)] = \Delta\mathcal{W}_t(n_t + n_t^f)$, with $n_t^f = N[1 - F(t+1)]$ the number of future adopters. The demonstration view gives larger totals.

The diffusion equation. To find out which view fits, Trajtenberg estimates a logistic diffusion curve whose ceiling rises with the cumulative gains from innovation, $CW_t = \sum_{\tau \le t} \Delta\mathcal{W}_\tau$ (pp. 67–68):

$$F(t) = \frac{K_0 + k \, CW_t}{1 + \exp(a_0 - a_1 t)}. \tag{10.100}$$

Time captures demonstration effects, and the cumulative gains act as a quality-adjusted price index that shifts the distribution of reservation prices. A linear ceiling corresponds to uniformly distributed reservation prices. Trajtenberg also tried a concave ceiling, corresponding to exponentially distributed ones, with very similar results. The equation cannot be linearized by taking log odds, so it is estimated by nonlinear least squares. Time is measured in months from November 1972 to July 1981, and $F(t)$ is the fraction of the $N = 3{,}457$ potential adopters that have bought a first scanner. The population consists of the 3,078 community hospitals with more than 100 beds and the 379 private clinics that had bought a scanner by July 1981 (p. 68, n. 65). The series CW_t is the ex ante cumulative gain of Table 10.17.

Table 10 of the paper reports two specifications, with asymptotic standard errors in parentheses. The traditional logistic with a free ceiling gives $K_0 = 0.459$ (0.004), $a_0 = 4.053$ (0.076), $a_1 = 0.071$ (0.002) and a residual sum of squares of 0.013. With the innovation term, $K_0 = 0.074$ (0.003), $k = 0.025$ (0.002), $a_0 = 3.443$ (0.07) and $a_1 = 0.06$ (0.001), and the residual sum of squares falls to 0.006. Both time and innovation matter, and the traditional model that ignores innovation fits much worse (p. 68). The estimate $k = 0.025$ means that each million dollars of improvement per buyer raises the eventual adoption rate by 2.5 percentage points. Had technical change stopped after the first scanner, only 7.4 percent of potential adopters would have adopted. With $CW_{82} = 16.65$, the ceiling reached $0.074 + 0.025 \times 16.65 = 0.49$ by 1982 (p. 69, n. 66). Trajtenberg also allowed the incremental gains $\Delta \mathcal{W}_t$ to shift the speed of diffusion, and found that effect significant but very small (p. 68, n. 64).

The value of the first scanner. The diffusion equation yields an indirect estimate of the gain from the first scanner, the radical innovation that the surplus function cannot value. If the behavior behind the equation is stable, the first scanner must have been worth enough to generate the initial ceiling K_0. Its gain therefore satisfies $k\,\Delta \mathcal{W}_{73} = K_0$, so

$$\Delta \mathcal{W}_{73} = \frac{K_0}{k} = \frac{0.074}{0.025} = 2.99$$

million dollars per buyer (p. 69). With the rounded estimates the ratio is 2.96, so the paper's 2.99 presumably uses more digits. Trajtenberg cautions that this figure is computed in a very different and probably less precise way than the others.

Total gains. Trajtenberg combines the two views (p. 70). Current buyers receive the incremental gain, and so do the future adopters attracted by the higher ceiling, discounted at 5 percent a year (0.0041 a month):

$$TW_t = \Delta \mathcal{W}_t \left[n_t + N\,(K_0 + k\,CW_t) \int_{t+1}^{\infty} f(\tau) e^{-r(\tau - t - 1)}\, d\tau \right]. \tag{10.101}$$

The integral has no closed form and is computed numerically. Repeat purchases, which include second scanners and replacements, are credited only with the incremental gain of their year. This is a lower bound, since the upper bound would credit all gains since the buyer's previous purchase (p. 70, n. 67). Upgrades of installed scanners are ignored, although nearly a quarter of the scanners installed by mid-1981 had been upgraded. The only source of upward bias is the implicit assumption that adopters are just at the margin when they adopt, so that they receive the incremental gain in full. Buyers who delay adoption in anticipation of further improvements would offset this bias (pp. 70–71). Table 10.18 reproduces the computation. Total gains are \$6.9 billion in 1974 and \$6.0 billion in 1976, and they fall below \$100 million a year from 1978 on.

Research and development and the social rate of return. Trajtenberg collected research and development spending on CT for almost all firms active in the field (pp. 71–72). Table 10.19 reproduces the annual totals. He does not show the breakdown by firm, which was confidential. Since the benefits are measured for U.S. buyers while the innovations came from U.S. and foreign firms, he computes returns both to U.S. research and to total research. He reads them as upper and lower bounds on the true rate.

The return is computed as a capitalized benefit-cost ratio (Griliches, 1958). With $r = 0.05$ and all values discounted to 1973,

$$\mathcal{R} = r\, \frac{\sum_{\tau=1973}^{1982} TW_\tau (1+r)^{-(\tau - 1973)}}{\sum_{\tau=1968}^{1981} RD_\tau (1+r)^{-(\tau - 1973)}}, \tag{10.102}$$

Table 10.18: Computation of total ex ante gains ($M)

Year	(1) ΔW_t	(2) $K(CW_t)$	(3) $1 - F(t)$	(4) Discounted	(5) n_t^f	(6) $\tilde{n}_t^f$	(7) n_t	(8) $n_t + \tilde{n}_t^f$	(9) TW_t

Notes: (1) Incremental ex ante gain per buyer, with the 1973 entry equal to $\frac{K_0}{k}$. (2) $K(CW_t) = 0.074 + 0.025\,CW_t$. (3) Share of the logistic adoption distribution after year t, and (4) the same share discounted to year $t+1$ at 5 percent a year. (5) $n_t^f = (2) \times (3) \times N$ and (6) $\tilde{n}_t^f = (2) \times (4) \times N$, with $N = 3{,}457$. (7) Scanners sold in year t. (9) $TW_t = (1) \times (8)$. Column (7) differs from the unit sales of Trajtenberg's Table 2 (Table 10.12) in 1974 (43 against 74) and in 1977–80 (390, 250, 275 and 271 against 385, 248, 273 and 270). Both tables describe the series as scanners sold in the year, and the paper does not reconcile them. We reproduce each table as printed. With the Table 2 count, the 1974 total would be about $7.2 billion (our computation). Source: Trajtenberg (1985), Table 11 and its notes.

Table 10.19: Research and development spending on CT scanners (constant 1982 $M)

Year	U.S. firms	Total	Firms	Per firm
1968–71	–	6.22	1	1.55
1972	0.22	5.42	2	2.71
1973	0.82	9.00	3	3.00
1974	7.79	22.62	8	2.83
1975	28.63	59.68	12	4.97
1976	58.18	96.08	13	7.39
1977	46.64	79.68	14	5.69
1978	37.03	64.33	11	5.85
1979	33.70	56.05	9	6.23
1980	29.58	46.40	8	5.80
1981	22.58	37.94	8	4.74
Total	265.17	483.42		
Mean, 1974–81	33.02	57.85	10	5.44

Notes: Deflated with a research and development price deflator. CGR, Hitachi and Philips are not included in the total. The 1968–71 per-firm figure is an average for the period. Source: Trajtenberg (1985), Table 12.

where RD_τ is research and development spending. The numerator is a present value B. A perpetuity with present value B pays rB a year, so $\mathcal{R}$ is the annual return in perpetuity per dollar of research. Trajtenberg finds (p. 73)

$$\mathcal{R}_{\text{U.S.}} = 0.05 \times \frac{14{,}813}{214} = 3.46, \qquad \mathcal{R}_{\text{total}} = 0.05 \times \frac{14{,}813}{397} = 1.87.$$

A dollar of CT research thus returned $3.5 a year in perpetuity counting only U.S. research, and $1.9 counting foreign research as well. Taking the average, Trajtenberg concludes that the social rate of return was about 270 percent. The inputs reproduce from the tables. Discounting the total gains of Table 10.18 at 5 percent gives 14,813. Discounting the series of Table 10.19 gives 214 and 397, with the 1968–71 total spread evenly over its four years. Profits are omitted from the benefits. Even profits of 50 percent of revenue over the whole period would barely change the result, because total gains exceed revenues by orders of magnitude (p. 73).

Few studies exist for comparison (pp. 74–75). Griliches (1958) estimated a social return of about 700 percent for hybrid corn, a process innovation. Most of the difference is methodological. In Griliches's study the benefits of hybrid corn continue forever at the diffusion ceiling, whereas Trajtenberg's benefits end when diffusion ends, because later purchases confer no further gain. Recomputing the hybrid-corn return without benefits after 1955, from Griliches's Table 2, Trajtenberg obtains $0.05 \times \frac{4{,}405}{63} = 3.5$, close to his own upper bound of 3.46. Mansfield et al. (1977) found a median social rate of return of 56 percent across 17 innovations, with a maximum of 307 percent. Their internal rates of return are not directly comparable with benefit-cost ratios (p. 74, n. 73).

The time profile. Figure 10.10 plots the incremental gains, total gains and research spending by year. Trajtenberg draws three conclusions (pp. 75–81). First, the gains of the first half of the period dwarf those of the second. The years 1973–77 account for about 98 percent of the total gains of 1973–82. The stylized profile starts high, rises further, then declines quickly and leaves a long, low tail. Trajtenberg explains it by increasing returns followed by sharply diminishing returns in three dimensions at once. In research, early improvements are easy and later ones costly. In utility, a threshold effect makes early improvements valuable, and diminishing marginal utility then sets in. Cutting scan time from 60 to 10 seconds was worth far more than cutting it from 12 to 2. In market size, the number of future beneficiaries eventually shrinks. With $K_0 = 0$ in (10.101), $n_t^f = NkCW_t[1 - F(t)]$, so that

$$\frac{d \ln n_t^f}{dt} = \frac{d \ln CW_t}{dt} - h(t), \qquad h(t) = \frac{f(t)}{1 - F(t)}, \tag{10.103}$$

where F is now the logistic adoption distribution and h its hazard rate. For the logistic, $h(t) = a_1 F(t)$ rises over time. With cumulative gains growing at a non-increasing rate, n_t^f eventually falls, so total gains decline even if innovation proceeds at a constant pace.

Second, the single largest gain came from the second scanner model, the EMI CT 1000 of 1974. Its design was almost identical to the first EMI scanner, except that its resolution was almost doubled. The improvement transformed CT from a demonstration of feasibility into a widely useful diagnostic tool (p. 78). Trajtenberg calls the early appearance of such a big winner the "Ford-T effect," after the Model T. Third, research spending tracked the level of activity in the field with a one-year lead, but it was not closely related to the gains. The ratio of gains to research was about 80 to 1 for 1968–77, with research taken up to 1976. It

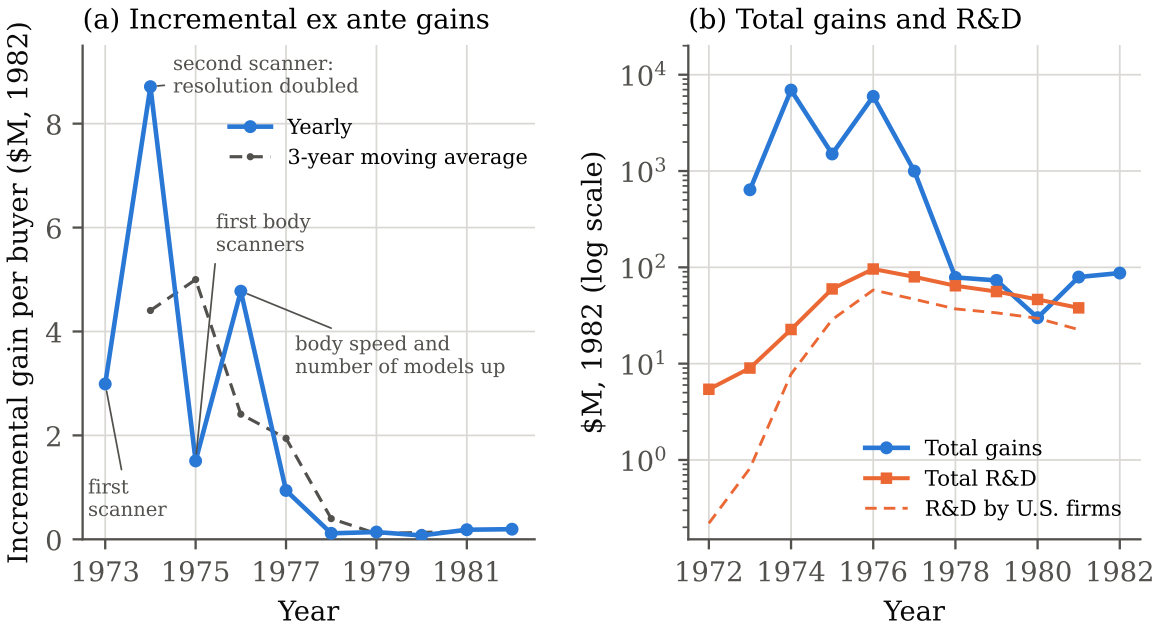

Figure 10.10: The time profile of the gains from innovation in CT scanners. Panel (a) shows the incremental ex ante gain per buyer, with the 1973 value equal to the indirect estimate $\frac{K_0}{k}$, and its centered three-year moving average, which is our computation. Panel (b) shows total gains TW_t and research and development spending on a logarithmic scale. The 1968–71 research total is a four-year aggregate and is omitted. Source: Trajtenberg (1985), Tables 9, 11 and 12.

was 1.4 for 1978–82, and in 1980 research spending exceeded the benefits (p. 80).[16] Average returns are therefore a poor guide to policy. The question is less whether public support for research is warranted than until when it should last. In CT, support was socially valuable in the early stages but not after 1976. Trajtenberg notes that the British Department of Health supported the construction of the first prototype at EMI in 1970–72. An American neurologist, W. H. Oldendorf, had independently developed a similar device but could not pursue it for lack of support (p. 80, n. 80). He presents the profile as evidence, from one case, that innovation can follow a wave-like pattern.

10.8.10 Robustness*

Trajtenberg checks several of his choices, mostly in footnotes. The checks are scattered through the preceding subsections, and we gather them here. The hedonic function was estimated in three forms, and Box-Cox comparisons ranked the linear-log form first in half of the twelve cases (p. 37, n. 33). In the diffusion equation, a concave ceiling gave very similar results to the linear one (pp. 67–68). The concave ceiling corresponds to exponentially distributed reservation prices. Letting the incremental gains shift the speed of diffusion gave an effect that was significant but very small (p. 68, n. 64). Repeat purchases are credited only with the incremental gain of their year, so total gains are a lower bound in this respect (p. 70, n. 67). Adding profits of up to half of revenue to the benefits would barely change the rate of return

[16] The first ratio reproduces from Tables 11 and 12. Total gains of $16,023.7 million in 1973–77 against total research of $199.02 million in 1968–76 give 80.5. With the same one-year research lead and no discounting, the two tables give $\frac{348.3}{284.40} = 1.22$ for 1978–82. The paper does not state the definition behind its figure of 1.4 (our computation).

(p. 73). Returns to U.S. research and to total research serve as upper and lower bounds on the true rate (pp. 71–72). Finally, the ex ante and ex post welfare measures are both reported, and they differ by a factor of about seven (Section 10.8.7).

10.8.11 Interpretation, critiques and contribution

Trajtenberg's study established that the magnitude of a product innovation can be measured by the consumer surplus it creates, computed from an estimated discrete-choice model in characteristics space. Each step of the later literature appears here in early form. Welfare comes from a log-sum surplus function. The nested logit is used to draw market boundaries. Prices are related to characteristics through a hedonic function, and the per-buyer gains are linked to diffusion and to research spending. Petrin (2002) builds on the template. Bresnahan (1997, p. 238) writes that Hausman takes on the question of the slope of dd "following Trajtenberg (1989)."

The limitations are of three kinds. The first concerns identification of price sensitivity. There are no instruments, the residual-price coefficients have the wrong sign, and α is imported from another segment (Section 10.8.6). Because the money value of every gain divides by α, the welfare numbers inherit this uncertainty in full. The second concerns functional form. The MNL imposes IIA within branches, buyer heterogeneity is absent after 1975, and the logit adds an entropy term for every new model (Propositions 10.40 and 10.41). The quadratic net utility extrapolates the value of large changes in characteristics. The estimated tastes change from year to year, and the choice between ex ante and ex post measures changes the answer by a factor of seven. The second-stage estimate of λ carries little information about substitution between branches, as (10.91) shows. The third concerns interpretation. The buyers are hospitals, whose valuations may diverge from those of patients (Section 10.8.8). The total gains rest on a reduced-form diffusion equation, and the value of the first scanner is an indirect extrapolation from it.

These limitations do not overturn the qualitative conclusions. Early innovations in CT created large value relative to their cost, gains concentrated in a few improvements, and returns to research fell sharply as the technology matured. The precise numbers are less secure. The next case study, Petrin's minivan, addresses several of the weaknesses at once. It uses instruments for price, random coefficients disciplined by micro data, and a supply side that lets rivals' prices respond. It also decomposes the welfare gain into the parts due to observed characteristics and to the logit errors.

10.9 Case study: the minivan (Petrin 2002)

Petrin (2002) measures the welfare created by the minivan, a vehicle that Chrysler introduced in 1984 and that its rivals imitated within two years. The paper answers two questions. The first is substantive. How large were the gains to consumers and to each producer, and how were they shared? The second is methodological. How can a researcher who has only market-level data discipline the random coefficients that govern substitution, and therefore welfare? Petrin's answer to the second question, the use of *micro moments*, is now a standard part of demand estimation (Section 8.8.3). Table 10.30 at the end of the section maps the study. We follow the paper from its question to its contribution, as in Section 10.5.[17]

[17] Petrin writes γ_k for the scale of the random coefficient on characteristic k, γ_{mi}, γ_{sw}, γ_{su} and γ_{pv} for the family-vehicle interactions, and τ for the cost parameters. In his text the income-group price coefficients are α_0, α_1

Table 10.20: Identification and counterfactual map of Trajtenberg (1989)

Observed data	Prices and technical characteristics of all CT scanners marketed in the United States up to 1982, and more than 2,000 installations by hospital, date and model. Manufacturers' spending on research and development.
Latent objects	Buyers' net utility from characteristics, the logit taste shocks, and the adoption dates of potential buyers.
Estimated parameters	Hedonic price functions, the coefficients of a quadratic net utility in characteristics and of the residual price in multinomial and nested logit models, and a diffusion equation.
Identifying variation	Choices among the scanners available each year as the choice set expands. There are no price instruments, and the price coefficient α is imported from head scanners.
Maintained assumptions	Quasi-linear utility with i.i.d. extreme value errors, a representative buyer after 1975, the linear-log hedonic function, and a reduced-form diffusion process.
Counterfactual and what it holds fixed	The yearly change in the log-sum surplus as the choice set changes, at observed prices. Supply and the responses of existing prices are not modeled.
Conclusion	Early innovations created large gains relative to their cost, and the social rate of return to research was about 270 percent. Returns fell sharply as the technology matured.
One limitation	Every money value divides by a price coefficient that the scanner choices themselves do not identify.
Source and our additions	All numbers come from the working paper (Trajtenberg, 1985). Proposition 10.41, the implied nesting parameter and the recomputed totals are ours.
Tools in the appendices	Sections A.6 and B.5.

10.9.1 The question

New products improve the standard of living, and firms introduce them to earn the temporary market power of a first mover (p. 705). Petrin estimates three objects for the minivan. The first is the compensating variation of consumers, including the gains of households that bought other vehicles whose prices fell when the minivan arrived. The second is the change in producer surplus. It combines Chrysler's first-mover profits, the cannibalization of its own station wagons, and the losses imposed on Ford and General Motors (GM). The third is the profit that the imitators dissipated when they entered.

The question matters for the theory of Section 10.4. There we saw that a new good changes welfare through the surplus of its own buyers and through the prices of existing goods. Table 10.2 called the second channel "Competition," and Section 10.6 criticized Hausman (1997) for holding rivals' prices fixed. Petrin re-solves the pricing equilibrium of the whole automobile market with and without minivans. His estimates therefore measure the Competition cell, together with Chrysler's repricing of its own wagons, in one equilibrium calculation.

The method matters as much as the answer. Random coefficients are imprecisely estimated from market shares alone (Section 8.6). Welfare numbers inherit that imprecision, and they inherit the dependence on the idiosyncratic logit shock described in Section 10.7. Petrin's abstract states the main finding in these terms. Models estimated without micro data yield much larger welfare numbers, "primarily because the micro data appear to free the model from a heavy dependence on the idiosyncratic logit 'taste' error" (p. 705).

10.9.2 The minivan innovation

Ford proposed a vehicle called the "Mini/Max" in the early 1970s (p. 707). It was a boxlike vehicle that obtained interior space from its height, with front-wheel drive that lowered the passenger floor. Ford's management gave the idea little support because it feared cannibalizing the firm's strong station wagon sales. This is the private incentive problem of Section 10.4 in its purest form. A firm that owns close substitutes values a new product only net of the profits it diverts from them.

The financially troubled Chrysler Corporation introduced the Dodge Caravan in 1984. It sold 170,000 units in its first year. GM introduced the Astro and Safari in 1985, and Ford introduced the Aerostar in 1986. Both rivals were unprepared for the Caravan's success. They built their minivans on truck platforms with rear-wheel drive, so these vehicles handled more like downsized full-size vans than like passenger cars. Chrysler kept its lead by adding a larger engine and a second sliding door. Fourteen years after the introduction, six firms sold 13 minivans, and Chrysler held 44 percent of a market of 1.16 million vehicles. Station wagon sales peaked at 950,000 in 1984 and fell to 300,000 over the next seven years (p. 707).

Table 3 of the paper shows the substitution in shares of total vehicle sales. Minivans rose from 1.58 percent in 1984 to 9.93 percent in 1993. Station wagons held about 10 percent in 1981–83 (10.51, 10.27 and 10.32 percent), fell to 8.90 percent in 1984, and reached 3.02 percent in 1993. The combined share of minivans and wagons stayed between 9.65 and 12.95 percent over 1981–93. Petrin reads this negative comovement as evidence of a positive covariance in the tastes for the two vehicle types (p. 718). The demand model is built to capture that covariance.

---

and α_2, while his Table 4 labels them α_1, α_2 and α_3. We write σ_k, π_{mv}, π_{sw}, π_{su}, π_{pv} and γ, and we follow the table for the price coefficients. Page and table numbers in this section refer to the journal article.

10.9.3 Data

The paper combines two data sets (pp. 712–713). The market data cover all 2,407 nameplates sold in the United States from 1981 to 1993 with annual sales above 1,000 vehicles. They come from the *Automotive News Market Data Book* and *Ward's Automotive Yearbook*. The characteristics are acceleration (horsepower per unit of curb weight), size (length times width times height), drive type, fuel efficiency (miles per dollar), and a luxury proxy (air conditioning standard). Quantity and list price refer to the base model. Nameplates in adjacent years whose horsepower, wheelbase, width and length change by less than 10 percent are treated as the same model. This rule leaves 916 independent observations, and the standard errors allow arbitrary correlation of the errors of the same model over time (p. 716, n. 11).

The consumer data come from the Consumer Expenditure Survey (CEX) for 1987–92. Almost 30,000 household records approximate the joint distribution of demographics in the United States. The CEX automobile supplement links the demographics of 2,660 new-vehicle buyers to the vehicles they bought. Among them are 120 minivan buyers, 63 station wagon buyers, 131 sport-utility buyers and 23 full-size van buyers. These samples are too small for a consumer-level choice model, since about 200 kinds of vehicles are sold each year but only about 400 purchases are recorded annually (p. 713, n. 8). They are large enough to estimate a few averages precisely. Other annual inputs are the number of households M, gasoline prices and the growth of gross national product. The random coefficients model without micro data also uses a lognormal income distribution estimated from the March Current Population Survey (p. 713, n. 9).

Table 10.21 reproduces the demographic averages of Table 2 of the paper. They are the targets of the micro moments. New-vehicle buyers had a mean income of $36,113, about $13,000 above the U.S. mean of $23,728 (incomes in 1982–84 dollars). Minivan buyers had the largest families of all buyer groups, 3.86 members against 2.58 in the population. They also had the highest share of household heads aged 30 to 60, 78 percent against 55 percent. Table 1 of the paper adds that minivans were larger than the average vehicle (size 0.87 against 0.71). Of them, 78 percent had air conditioning as standard (27 percent of all vehicles), and their mean list price was $10,060 against $9,867 for all vehicles. Chrysler accounted almost entirely for the 63 percent of minivan sales with front-wheel drive (p. 716).

Table 10.21: Demographics of the U.S. population and of new-vehicle buyers, 1987–92

	United States		Buyers of				
	Mean	Std. dev.	New vehicles	Minivans	Wagons	Sport-utilities	Full-size vans
Income ($)	23,728	21,255	36,113	39,476	40,196	41,569	31,164
Family size	2.58	1.53	2.87	3.86	3.17	2.97	3.47
Midage	0.55	0.49	0.64	0.78	0.73	0.74	0.65

Source: Petrin (2002, Table 2), from the Consumer Expenditure Survey. Income is in 1982–84 CPI-adjusted dollars. Family size is the number of household members. Midage is an indicator for a household head aged between 30 and 60 inclusive.

10.9.4 The demand model

Consumers are households i with income y_i, family size fs_i, an indicator mid_i for a head aged 30 to 60, and unobserved tastes. Each household buys one new vehicle $j \in \{1, \ldots, J\}$ in a year

or buys none ($j = 0$). Petrin specifies the conditional indirect utility (p. 710)

$$u_{ij} = \alpha_i \ln(y_i - p_j) + x_j\beta + \sum_k \sigma_k \nu_{ik} x_{jk} + \ln(f s_i)\, \nu_{i,\text{fv}} \sum_{g \in \mathcal{G}} \pi_g d_{jg} + \xi_j + \epsilon_{ij}, \qquad j = 1, \ldots, J. \tag{10.104}$$

The first term is the utility of the composite good bought with the income left after the vehicle. The row vector x_j holds a constant, the five characteristics, four vehicle-type dummies, the percentage change in gross national product and a quadratic time trend (Table 4, note). The set $\mathcal{G} = \{\text{mv}, \text{sw}, \text{su}, \text{pv}\}$ collects the four *family vehicle* types: minivans, station wagons, sport-utility vehicles and full-size passenger vans. The dummy d_{jg} equals one when vehicle j is of type g. The unobserved product quality is ξ_j, and ϵ_{ij} is type-I extreme value.

Three features of (10.104) carry the economics.

Income effects. The marginal utility of income varies across the three income terciles,

$$\alpha_i = \begin{cases} \alpha_1 & \text{if } y_i < \bar{y}_1, \\ \alpha_2 & \text{if } \bar{y}_1 \le y_i < \bar{y}_2, \\ \alpha_3 & \text{if } y_i \ge \bar{y}_2, \end{cases}$$

where $\bar{y}_1$ and $\bar{y}_2$ split the population into three equal groups. The utility cost of a higher price is

$$\frac{\partial u_{ij}}{\partial p_j} = -\frac{\alpha_i}{y_i - p_j}, \tag{10.105}$$

so price sensitivity falls with income within a group, and the three α_g let the curvature differ across groups. This is the Cobb-Douglas income specification of Berry et al. (1995) studied in Section 8.1.3, with group-specific coefficients. Conditional on all tastes, the logit formulas give the individual share derivatives

$$\frac{\partial s_{ij}}{\partial p_j} = -\frac{\alpha_i}{y_i - p_j} s_{ij}(1 - s_{ij}), \qquad \frac{\partial s_{ij}}{\partial p_k} = \frac{\alpha_i}{y_i - p_k} s_{ij} s_{ik} \quad (k \neq j).$$

Market derivatives integrate these over households.

Random tastes for characteristics. Household i draws a taste ν_{ik} for each characteristic k, scaled by σ_k. Petrin draws the ν_{ik} independently from a $\chi^2(3)$ distribution truncated at its 95th percentile (p. 711). He gives two reasons. The distribution is bounded above and below, and it skews heterogeneity in the direction of positive taste. Taken as written, the draws lie between 0 and 7.81, with mean about 2.63 and standard deviation about 1.83 (our computation). The paper does not say whether the draws are *centered*, that is, whether their mean is subtracted before they enter utility. The random coefficient on the constant makes the value of buying any new vehicle, relative to the outside option, heterogeneous across households.

Demographic tastes for family vehicles. The taste of household i for a family vehicle of type g is $\pi_g \ln(f s_i)\, \nu_{i,\text{fv}}$. The draw $\nu_{i,\text{fv}}$ is common to all four types, and family size scales it. Conditional on family size, the covariance between the tastes for minivans and for station wagons is

$$\text{Cov}\big(\pi_{\text{mv}} \ln(f s_i)\nu_{i,\text{fv}},\ \pi_{\text{sw}} \ln(f s_i)\nu_{i,\text{fv}} \,\big|\, f s_i\big) = \pi_{\text{mv}}\pi_{\text{sw}} \left(\ln f s_i\right)^2 \text{Var}(\nu_{i,\text{fv}}). \tag{10.106}$$

It rises with π_{mv} and π_{sw} and with family size. Substitution between minivans and wagons can therefore arise for two reasons (p. 710). Large families prefer both types, or the two types share other observed characteristics such as size.

The outside option is to buy no new vehicle. We write its utility as $u_{i0} = \alpha_i \ln y_i + \epsilon_{i0}$, the normalization of Section 8.1.3. Conditional on the household's demographics $D_i = (y_i, fs_i, mid_i)$ and tastes ν_i, the probability of buying j is the logit formula (p. 711)

$$s_{ij} = \frac{\exp V_{ij}}{\exp(\alpha_i \ln y_i) + \sum_{l=1}^{J} \exp V_{il}}, \qquad V_{ij} = \alpha_i \ln(y_i - p_j) + \delta_j + \mu_{ij}, \tag{10.107}$$

with base utility $\delta_j = x_j\beta + \xi_j$ and household-specific term

$$\mu_{ij} = \sum_k \sigma_k \nu_{ik} x_{jk} + \ln(fs_i)\, \nu_{i,\text{fv}} \sum_g \pi_g d_{jg}.$$

Price is not part of δ_j. It enters only through the income term, so the α_g are nonlinear parameters, as in Section 8.1.3. The market share is $s_j = \int s_{ij}\, \mathrm{d}P(D_i, \nu_i)$, where D_i follows the empirical distribution of the CEX and ν_i the truncated $\chi^2(3)$ distribution. Petrin calls the elements of β *base coefficients* (Table 4). If the draws are centered, μ_{ij} has mean zero and δ_j is the mean utility of product j, net of the income term. Otherwise δ_j is that utility for a household whose draws are all zero, and the mean taste for characteristic k is $\beta_k + 2.63\,\sigma_k$.

The demand side has 24 parameters: three price coefficients, eleven base coefficients, six random-coefficient scales and four family-vehicle interactions. Eleven of them describe family vehicles and income effects: the three α_g, the four type dummies and the four π_g. The micro moments speak most directly to these eleven.

10.9.5 Supply and the counterfactual equilibrium

The supply side follows Berry et al. (1995) (pp. 711–712). Multiproduct firms $f = 1, \dots, F$ set prices in a static Bertrand-Nash equilibrium. Marginal cost is log-linear in observed cost characteristics W_j and an unobserved component ω_j,

$$\ln mc_j = W_j\gamma + \omega_j. \tag{10.108}$$

Firm f earns $\Pi_f = M \sum_{j \in \mathcal{J}_f} (p_j - mc_j)\, s_j(p, x; \theta)$, and the first-order conditions are

$$s_j(p, x; \theta) + \sum_{r \in \mathcal{J}_f} (p_r - mc_r) \frac{\partial s_r(p, x; \theta)}{\partial p_j} = 0, \qquad j \in \mathcal{J}_f. \tag{10.109}$$

In matrix form these are (8.70), and inverting them gives the markup formula (8.71), $p - mc = -[(\Omega \odot \Delta)^\top]^{-1} s$. Given demand estimates and observed prices, this formula recovers each mc_j (Petrin, 2002, eq. 3).

A rearrangement of (10.109) is useful for reading the counterfactual. Separate the own-product term and divide by $-\frac{\partial s_j}{\partial p_j} > 0$:

$$0 = s_j + (p_j - mc_j)\frac{\partial s_j}{\partial p_j} + \sum_{r \in \mathcal{J}_f, r \neq j} (p_r - mc_r)\frac{\partial s_r}{\partial p_j},$$

$$p_j - mc_j = \frac{s_j}{-\frac{\partial s_j}{\partial p_j}} + \sum_{r \in \mathcal{J}_f, r \neq j} (p_r - mc_r)\, D_{jr}, \qquad D_{jr} = \frac{\frac{\partial s_r}{\partial p_j}}{-\frac{\partial s_j}{\partial p_j}}. \tag{10.110}$$

Here D_{jr} is the diversion ratio from j to r (Chapter 4). The markup on j is a single-product markup plus the margins the firm earns on the sales that a higher p_j diverts to its other products. When Chrysler adds a minivan m that is a substitute for its station wagons, a new positive term $(p_m - mc_m)D_{jm}$ appears in the markup of each Chrysler wagon j. Other things equal, Chrysler raises the prices of its wagons. Rival firms gain no term for the minivan. Their markups change through the first term, which falls when entry makes their demand more elastic, and through changes in diversion among their own products.

The counterfactual removes all minivans from the choice set and solves (10.109) for the remaining products, holding marginal costs, characteristics and ξ_j fixed (p. 712). Call the solution p^{cf} and the observed prices p^0. The change in the variable profit of firm f due to the minivan is $\Pi_f(p^0, mc) - \Pi_f(p^{cf}, mc)$, and summing over firms gives the change in producer surplus. A second counterfactual removes only the Ford and GM minivans, which measures how much of Chrysler's profit the imitators dissipated. The profit function ignores the 25 percent tariff on Japanese minivans, which made up a small part of minivan sales (p. 712, n. 6).

10.9.6 Compensating variation with income effects

Petrin measures consumer welfare by a compensating variation whose benchmark is the standard of living attained with minivans (p. 720). The counterfactual environment has no minivans, and the other vehicles sell at p^{cf}. For a household with all tastes (D_i, ν_i, ϵ_i) held fixed, let $\mathcal{J}^1$ be the choice set with minivans and $\mathcal{J}^0$ the set without them. The household's compensation CV_i solves

$$\max_{j \in \mathcal{J}^0 \cup \{0\}} u_{ij}\big(y_i + CV_i,\, p^{cf}\big) = \max_{j \in \mathcal{J}^1 \cup \{0\}} u_{ij}\big(y_i,\, p^0\big) \equiv U_i^1. \tag{10.111}$$

This is the compensating variation of removing the minivans, which equals the equivalent variation of introducing them. It is the measure (10.67) of Section 10.7.2, and the discrete-choice analog of Proposition 10.7, whose reference utility is also the one attained with the new good.

With the utility (10.104) the compensation has a closed form. Write $v_{ij} = \delta_j + \mu_{ij} + \epsilon_{ij}$ for the part of utility that does not involve money, with $p_0 = 0$ and $v_{i0} = \epsilon_{i0}$. For each alternative $j \in \mathcal{J}^0 \cup \{0\}$, define the compensation that would make j alone reach U_i^1:

$$\begin{aligned} \alpha_i \ln\big(y_i + c_{ij} - p_j^{cf}\big) + v_{ij} &= U_i^1, \\ y_i + c_{ij} - p_j^{cf} &= \exp\Big(\frac{U_i^1 - v_{ij}}{\alpha_i}\Big), \\ c_{ij} &= p_j^{cf} - y_i + \exp\Big(\frac{U_i^1 - v_{ij}}{\alpha_i}\Big). \end{aligned}$$

The left side of (10.111) increases in CV_i, and it first reaches U_i^1 when the cheapest of these compensations is paid. Hence

$$CV_i = \min_{j \in \mathcal{J}^0 \cup \{0\}} \Big\{ p_j^{cf} - y_i + \exp\Big(\frac{U_i^1 - v_{ij}}{\alpha_i}\Big) \Big\}. \tag{10.112}$$

The formula has a useful implication for households that did not buy a minivan. If household i chose $j \in \mathcal{J}^0$ at p^0, then $U_i^1 = \alpha_i \ln(y_i - p_j^0) + v_{ij}$, and the term for j in (10.112) equals

$$p_j^{cf} - y_i + \exp\Big(\frac{\alpha_i \ln(y_i - p_j^0)}{\alpha_i}\Big) = p_j^{cf} - y_i + (y_i - p_j^0) = p_j^{cf} - p_j^0.$$

A non-buyer's compensation is therefore at most the price change of the vehicle she chose. It equals that change if and only if her vehicle remains a best choice at prices p^{cf} and the compensated income $y_i + p_j^{cf} - p_j^0$. At that income vehicle j yields exactly U_i^1, so the condition says that no alternative reaches U_i^1 with less compensation. Remaining best at the original income y_i does not suffice, because income enters utility through $\ln(y_i - p_k)$. Extra income then raises the utility of expensive vehicles more than that of cheap ones. For these households, as Petrin notes (p. 720), compensation is determined entirely by the price changes that the minivan caused. Averaging CV_i over simulated households and multiplying by M gives the aggregate measure.

Petrin also splits the compensation of minivan buyers into two parts (Table 8). Suppose utility were quasi-linear, $u_{ij} = \delta_j - \alpha p_j + \mu_{ij} + \epsilon_{ij}$. Let j be the buyer's minivan and k her best alternative in $\mathcal{J}^0$ at p^{cf}. Then

$$CV_i = \underbrace{\frac{(\delta_j - \alpha p_j^0 + \mu_{ij}) - (\delta_k - \alpha p_k^{cf} + \mu_{ik})}{\alpha}}_{\text{observed characteristics}} + \underbrace{\frac{\epsilon_{ij} - \epsilon_{ik}}{\alpha}}_{\text{logit error}}. \tag{10.113}$$

The first part is the value of the minivan's observed characteristics and price relative to the second choice. The second part is the value of the idiosyncratic logit draws. With income effects the split is approximate (p. 722, n. 13).

The logit benchmark explains why the second part can dominate. The next result, which we derive, extends Proposition 10.37 from the aggregate gain to the gain of the buyers of the new good.

Proposition 10.45 (Who gains in a logit model)**.** *Let $u_{ij} = V_j + \epsilon_{ij}$ with $V_j = \delta_j - \alpha p_j$ and ϵ_{ij} independent type-I extreme value. Remove a set $\mathcal{N}$ of products whose total share is $s_{\mathcal{N}}$, holding all other prices fixed. Then*

(a) A consumer whose chosen product is not in $\mathcal{N}$ has $CV_i = 0$.

(b) The mean compensation of consumers who chose a product in $\mathcal{N}$ is $\frac{1}{\alpha}\frac{-\ln(1-s_{\mathcal{N}})}{s_{\mathcal{N}}} \geq \frac{1}{\alpha}$.

Proof. (a) The consumer's chosen product remains available at the same price, and her utilities are unchanged. Her maximum utility is the same in both choice sets, so $CV_i = 0$.

(b) By Lemma 10.34, $CV_i = \frac{1}{\alpha}\big(\max_j u_{ij} - \max_{j \notin \mathcal{N}} u_{ij}\big)$. By Lemma 10.36, the expected maximum of $V_j + \epsilon_{ij}$ over a set S is $\ln \sum_{j \in S} e^{V_j} + \gamma_E$. Therefore, as in the proof of Proposition 10.37,

$$\mathbb{E}[CV_i] = \frac{1}{\alpha}\left(\ln \sum_j e^{V_j} - \ln \sum_{j \notin \mathcal{N}} e^{V_j}\right) = -\frac{1}{\alpha} \ln \frac{\sum_{j \notin \mathcal{N}} e^{V_j}}{\sum_j e^{V_j}} = -\frac{1}{\alpha} \ln(1 - s_{\mathcal{N}}).$$

By part (a), $\mathbb{E}[CV_i] = s_{\mathcal{N}}\, \mathbb{E}[CV_i \mid \text{chose in } \mathcal{N}]$. Dividing by $s_{\mathcal{N}}$ gives the formula. The inequality follows from $-\ln(1-s) \geq s$ for $s \in [0, 1)$, as in (10.62). □

Part (b) says that in a logit model the buyers of a product with a small share gain on average about $\frac{1}{\alpha}$ dollars, whatever the product is. Part (b) of Proposition 10.41 says why. For every product n,

$$\mathbb{E}[\epsilon_{in} \mid i \text{ chooses } n] = \gamma_E - \ln s_n,$$

so a product with a small share is bought by consumers with large draws of ϵ_{in}, and the model credits the purchase to those draws. Its mean utility V_n is low, so the observed component

in (10.113) tends to be negative while the logit component is large. The markup has the same scale. Remark 10.26 showed that a multiproduct logit firm charges a common markup on all its products, $m_f = \frac{1}{\alpha(1-S_f)}$, where $S_f = \sum_{r \in \mathcal{J}_f} s_r$ is the firm's total share. Since each firm's share of all households is small, every logit markup is close to $\frac{1}{\alpha}$. We return to both implications when we read Petrin's Tables 8 and 9.

10.9.7 Estimation: market moments plus micro moments

The estimator is the generalized method of moments (GMM) estimator of Berry et al. (1995), augmented by moments from the CEX (pp. 713–716). The idea comes from Imbens and Lancaster (1994), who show that aggregate information on the averages of micro variables can sharpen the estimates of a micro model.

Micro moments. Petrin uses three sets of moments (p. 714). Let $P_{ig}(\theta) = \int \sum_{j \in g} s_{ij}(\theta)\, \mathrm{d}P(\nu_i)$ be the probability that a household with demographics D_i buys a vehicle of type g, and let $P_i(\theta) = \int \sum_{j \geq 1} s_{ij}(\theta)\, \mathrm{d}P(\nu_i)$ be its probability of buying any new vehicle. The first set matches the purchase probability in each income group $h \in \{1, 2, 3\}$:

$$\mathbb{E}\big[\mathbf{1}\{i \text{ buys a new vehicle}\} \,\big|\, y_i \in h\big] = \frac{\int \mathbf{1}\{y_i \in h\}\, P_i(\theta)\, \mathrm{d}P(D_i)}{\int \mathbf{1}\{y_i \in h\}\, \mathrm{d}P(D_i)}. \tag{10.114}$$

The second set matches the mean family size of the buyers of each family vehicle type $g \in \mathcal{G}$:

$$\mathbb{E}\big[f s_i \,\big|\, i \text{ buys type } g\big] = \frac{\int f s_i\, P_{ig}(\theta)\, \mathrm{d}P(D_i)}{\int P_{ig}(\theta)\, \mathrm{d}P(D_i)}. \tag{10.115}$$

The third set matches $\mathbb{E}[mid_i \mid i \text{ buys type } g]$, the probability that the household head is aged 30 to 60, in the same way. The left sides are CEX sample averages and the right sides are model predictions. There are $3 + 4 + 4 = 11$ micro moments. Equation (10.115) is Bayes' rule applied to the purchase probability, as in (8.91).

A simple identity shows what the family-size moments identify.

Lemma 10.46 (What a conditional-mean moment measures)**.** *For any demographic D and purchase probability P_{ig} with $\mathbb{E}[P_{ig}] > 0$,*

$$\mathbb{E}\big[D_i \,\big|\, i \text{ buys type } g\big] = \mathbb{E}[D_i] + \frac{\operatorname{Cov}(D_i, P_{ig})}{\mathbb{E}[P_{ig}]}.$$

Proof. By (10.115) the conditional mean is $\frac{\mathbb{E}[D_i P_{ig}]}{\mathbb{E}[P_{ig}]}$. Write $\mathbb{E}[D_i P_{ig}] = \mathbb{E}[D_i]\mathbb{E}[P_{ig}] + \operatorname{Cov}(D_i, P_{ig})$ and divide by $\mathbb{E}[P_{ig}]$. □

The CEX gives $\mathbb{E}[f s_i] = 2.58$ and $\mathbb{E}[f s_i \mid \text{minivan}] = 3.86$, so the model must produce $\frac{\operatorname{Cov}(f s_i, P_{i,\text{mv}})}{\mathbb{E}[P_{i,\text{mv}}]} = 1.28$. In (10.104) family size enters the minivan's utility only through $\pi_{\text{mv}} \ln(f s_i) \nu_{i,\text{fv}}$, apart from its correlation with income. The moment therefore pins down π_{mv}, and the other three moments pin down the other π_g. Likewise, the purchase probabilities by income group pin down how the α_g shift purchases across the income distribution. Market shares alone identify these parameters only through variation in choice sets and in demographics over time, which is weak in thirteen years of national data.

Market moments. The first set of market moments matches predicted and observed shares, $s_j(\delta, \theta) = s_j$ for every j. As in Section 8.4, this is equivalent to solving for the vector $\delta(\theta)$ that equates them (Berry, 1994). The second set states that the demand and cost unobservables are mean independent of the observed characteristics of all vehicles in the year (p. 715):

$$\mathbb{E}\big[\xi_j(\theta_0) \,\big|\, X, W\big] = \mathbb{E}\big[\omega_j(\theta_0) \,\big|\, X, W\big] = 0. \tag{10.116}$$

The instruments approximate the optimal ones in the manner of Berry et al. (1995). A product's own characteristics instrument for themselves. Cost variables excluded from demand instrument for price. So do the sums of each characteristic over the firm's other products, $\sum_{j \neq l,\, j \in \mathcal{J}_f} x_{jk}$, and over rivals' products, $\sum_{j \notin \mathcal{J}_f} x_{jk}$. These sums measure how crowded a product's neighborhood is, which shifts its markup through (10.110) (Bresnahan et al., 1997).

The objective and its variance. Stack the market moments $G_1(\theta)$ and the micro moments $G_2(\theta)$ in $G(\theta) = (G_1(\theta)^\top, G_2(\theta)^\top)^\top$, with $\mathbb{E}[G(\theta_0)] = 0$. Let $\hat{G}(\theta)$ be the sample analog and $a(\tilde{\theta})$ a consistent estimate of the "square root" of the inverse of the moments' asymptotic variance, computed at a preliminary estimate $\tilde{\theta}$. Following Hansen (1982), the two-step estimator is (p. 715)

$$\hat{\theta} = \arg\min_{\theta \in \Theta} \; \tilde{G}(\theta)^\top \tilde{G}(\theta), \qquad \tilde{G}(\theta) = a(\tilde{\theta})\, \hat{G}(\theta). \tag{10.117}$$

The two sets of moments come from independent samples, the vehicle market and the CEX. Let n be the size of the market sample, and suppose the CEX sample size n_2 satisfies $\frac{n_2}{n} \to \lambda \in (0, \infty)$. Write V_G for the asymptotic variance of $\sqrt{n}\, \hat{G}(\theta_0)$. Independence makes V_G block diagonal. Since $\sqrt{n}\, \hat{G}_2 = \sqrt{\frac{n}{n_2}}\, \sqrt{n_2}\, \hat{G}_2$, the micro block is $\frac{1}{\lambda}$ times the asymptotic variance of $\sqrt{n_2}\, \hat{G}_2(\theta_0)$. Let a and Γ be the probability limits of $a(\tilde{\theta})$ and $\frac{\partial \tilde{G}(\theta_0)}{\partial \theta}$. The scaled moments $\sqrt{n}\, \tilde{G}(\theta_0)$ then have asymptotic variance $V = a V_G a^\top$, and the asymptotic variance of $\sqrt{n}(\hat{\theta} - \theta_0)$ is

$$(\Gamma^\top \Gamma)^{-1} \Gamma^\top V \Gamma \, (\Gamma^\top \Gamma)^{-1}. \tag{10.118}$$

This is the usual sandwich for a GMM estimator with identity weight on the normalized moments (Appendix A). Petrin writes $V = \mathbb{E}[\tilde{G}(\theta_0)\tilde{G}(\theta_0)^\top]$ (p. 715). Read literally, that is the variance of a sample average, which is of order $\frac{1}{n}$, so the sandwich needs the factor n of our definition. If $a = V_G^{-\frac{1}{2}}$, then $V = I$ and (10.118) reduces to the efficient GMM variance $(\Gamma^\top \Gamma)^{-1}$. The micro block of V_G reflects CEX sampling error, which is large when a buyer group is small or the CEX sample is small relative to the market sample.

Computation. One evaluation of the objective proceeds as follows.

(i) Draw households from the CEX records and taste vectors ν_i from the truncated $\chi^2(3)$ distribution. Hold the draws fixed across evaluations.

(ii) For trial nonlinear parameters $(\alpha_g, \sigma_k, \pi_g)$, invert the shares to obtain $\delta(\theta)$ by the contraction of Section 8.4.

(iii) Recover $\xi_j = \delta_j - x_j \beta$, compute markups from (8.71), and recover $\omega_j = \ln(p_j - b_j) - W_j \gamma$, where b_j is the markup. The linear parameters (β, γ) can be concentrated out.

(iv) Compute the model's micro predictions, such as (10.114) and (10.115), from the same draws.

(v) Form (10.117) and search over the nonlinear parameters.

Because the micro moments only add terms to the objective, the method adds little computational burden to the BLP estimator (p. 706).

Identification. Petrin's footnote 5 (p. 709) explains how market data identify heterogeneity. Suppose three cars differ only in interior space, two of them spacious, and each has a third of the market. In a second market one spacious car is missing. If the remaining spacious car takes two-thirds of the market, its buyers substitute on space, which reveals a strong and heterogeneous taste for space. If the two remaining cars split the market, there is no evidence of heterogeneity. Identification of this kind requires large changes in choice sets. The micro moments supply a second source, the covariance between demographics and choices in Lemma 10.46.

Berry et al. (2004a) develop a third source, consumers' reported second choices, which measure substitution directly. They note that consumer attribute data, together with a changing choice set, are useful for explaining substitution and welfare for minivans. They find other automotive choices less closely tied to commonly observed attributes (Berry et al., 2004a, p. 70, n. 1). They also stress that second-choice data from one cross section cannot identify the level of price elasticities. Berry and Haile (2024) give the formal nonparametric identification argument for micro data (Section 8.8.5).

10.9.8 Results

Demand parameters. Tables 10.22 and 10.23 reproduce Tables 4 and 5 of the paper. Moving from the OLS logit to the instrumental variables (IV) logit almost doubles the price coefficient, from 0.07 to 0.13. Berry, Levinsohn and Pakes found the same pattern, and it shows that instrumenting matters (p. 719). Many random coefficients differ significantly from zero, so Wald tests reject both logit models in favor of the random coefficient models.

The random coefficients model estimated from market data alone (column 3 of Table 10.22 and column 1 of Table 10.23) is imprecise. The paper reports that only six of the 24 demand parameters have z-statistics above one, and that none of the eight family-vehicle coefficients does. Adding the micro moments changes the picture. Twenty-one of the 24 parameters then have z-statistics above one. The paper reports that all eleven coefficients related to family vehicles and income effects have z-statistics above three (p. 719).[18] The parameters closest to the added information gain the most precision. The standard error of π_{mv}, for example, falls from 2.62 to 0.10.

The estimates with micro data have an intuitive structure. The base coefficients on the four family-vehicle dummies are negative, while the four π_g are positive and precise. Relative to a car with the same observed characteristics, household i values a vehicle of type g at $\beta_g + \pi_g \ln(fs_i)\, \nu_{i,\text{fv}}$. A one-person household has $\ln fs_i = 0$, so it values type g at $\beta_g < 0$ whether or not the draws are centered. For a household with a positive draw, the taste rises with family size. The draw is independent of demographics (p. 710), so the average taste is $\beta_g + \pi_g \mathbb{E}[\ln fs_i]\, \mathbb{E}[\nu_{i,\text{fv}}]$. With centered draws it equals β_g. With uncentered draws $\mathbb{E}[\nu_{i,\text{fv}}] \approx 2.63$, and Jensen's inequality gives $\mathbb{E}[\ln fs_i] \leq \ln \mathbb{E}[fs_i] = \ln 2.58$, where 2.58 is the CEX mean family size for 1987–92 (Table 2, p. 717). The largest resulting bound, for station wagons, is $-1.31 + 0.28 \times 2.63 \times \ln 2.58 \approx -0.61$, and it stays negative for any mean family

[18] Counting from the printed estimates and standard errors, we find seven ratios above one in the model without micro data. The extra one is the front-wheel-drive coefficient, −5.24 (3.09), which Table 4 prints without a star. In the model with micro data, ten of the eleven family-vehicle and income ratios exceed three. The full-size van interaction, 0.42 (0.21), has a ratio of about two.

size below 5.9. Under either normalization the average household therefore values each family-vehicle type below a comparable car (our computation).

The scale of the random coefficient on miles per dollar is precisely estimated, at 2.58 (0.14). Since the draws of Section 10.9.4 have a standard deviation of about 1.83, the implied standard deviation of the taste for miles per dollar is about 4.7 (our computation). Tastes for fuel economy are therefore heterogeneous.

Table 10.22: Petrin's demand estimates: price and base coefficients

	OLS logit	IV logit	Random coefficients	Random coefficients and micro data
	(1)	(2)	(3)	(4)
A. Price coefficients				
α_1 (low income)	0.07 (0.01)**	0.13 (0.01)**	4.92 (9.78)	7.52 (1.24)**
α_2 (middle income)			11.89 (21.41)	31.13 (4.07)**
α_3 (high income)			37.92 (18.64)**	34.49 (2.56)**
B. Base coefficients				
Constant	−10.03 (0.32)**	−10.04 (0.34)**	−12.74 (5.65)**	−15.67 (4.39)**
Horsepower per weight	1.48 (0.34)**	3.78 (0.44)**	3.40 (39.79)	−2.83 (8.16)

Percent change in GNP	0.03 (0.01)**	0.03 (0.01)**	0.08 (0.02)**	0.24 (0.02)**

Source: Petrin (2002, Table 4). Standard errors in parentheses. * z-statistic above one. ** z-statistic above two (stars as printed). A quadratic time trend is included in all specifications. The logit models (columns 1–2) have one price coefficient and no income effects. In columns 3–4 the α_g multiply $\ln(y_i - p_j)$. In columns 1–2 the base coefficients are mean tastes. In columns 3–4 the coefficient on the change in GNP, which has no random term, is also a mean taste. The other base coefficients are mean tastes only if the taste draws are centered, which the paper does not state (Section 10.9.4). Estimation uses 2,407 nameplate-years (916 independent models), 1981–93.

Costs. Table 10.24 reproduces Table 6 of the paper. It regresses the log of estimated marginal cost on cost characteristics, which gives the parameters γ of (10.108). Petrin reports that the car characteristics enter with the expected sign and significant coefficients (p. 720). The front-wheel-drive coefficient, 0.01 (0.01), is an exception. The elasticities of marginal cost are 0.84 (0.03) with respect to horsepower per weight, 1.28 (0.04) with respect to weight and 0.23 (0.04) with respect to miles per gallon. Standard air conditioning raises log cost by 0.24 (0.01). Japanese and European production carry cost premia of 0.12 (0.01) and 0.47 (0.03) in logs. The coefficient on $\ln q$ is −0.05 (0.01), which indicates mild economies of scale.

Prices on entry. Panel A of Table 10.25 shows the vehicles whose prices fell most when the minivan entered in 1984. The Caravan's closest substitutes were top-selling large sedans and station wagons. Wagons had the largest percentage decreases, and large family sedans the largest dollar decreases ($100 to $150). Panel B shows that some prices rose. Two of the four largest increases are Chrysler's own wagons, the LeBaron ($297) and the Dodge Aries K ($170). This is the diversion term of (10.110): once Chrysler sells minivans, a lost wagon sale is partly recaptured as a minivan sale. The other two increases are rival wagons. Random

Table 10.23: Petrin's random coefficient estimates

	No micro data (1)	CEX micro data (2)
Scales σ_k of the random coefficients

Source: Petrin (2002, Table 6), where the parameters are called τ. The dependent variable is the log of estimated marginal cost. Standard errors in parentheses. Estimation uses the 2,407 nameplate-years of Table 10.22.

coefficients can produce such increases because entry removes the buyers most willing to switch, leaving a less elastic residual demand. The paper's note states that Bertrand-Nash pricing with random coefficients does not determine the signs of the price changes a priori. Compare Proposition 10.27, where symmetric logit demand forces all rivals' prices down.

Table 10.25: Equilibrium prices with and without the minivan, 1984 (selected vehicles)

	Price ($)			
Vehicle (segment)	With minivan	Without minivan	Δ price ($)	Δ price (%)
A. Largest decreases on entry				
GM Oldsmobile Toronado (large sedan)	15,502	15,643	−141	−0.90
GM Buick Riviera (large sedan)	15,379	15,519	−139	−0.89
GM Buick Electra (large sedan)	12,843	12,978	−135	−1.04
GM Chevrolet Celebrity (wagon)	8,304	8,431	−127	−1.51
GM Pontiac 6000 (wagon)	9,273	9,397	−123	−1.31
GM Oldsmobile Ciera (wagon)	9,591	9,714	−123	−1.27
GM Buick Century (wagon)	8,935	9,056	−121	−1.34
GM Oldsmobile Firenza (wagon)	7,595	7,699	−104	−1.35
B. Largest increases on entry				
Chrysler LeBaron (wagon)	9,869	9,572	297	3.10
Volkswagen Quattro (wagon)	13,263	13,079	184	1.41
Chrysler (Dodge) Aries K (wagon)	7,829	7,659	170	2.22
AMC Eagle (wagon)	10,178	10,069	109	1.08

Source: Petrin (2002, Table 7), model with micro data, 1982–84 CPI-adjusted dollars. The signs in the percentage column of Panel A are ours. The original prints magnitudes only. Panel A of the original also lists two Cadillac large sedans (−126 and −125 dollars), omitted here.

Consumer welfare in 1984. Gains from lower prices are large. In 1984 the households that did not buy a minivan received $157 million of the $367 million of consumer gains, almost 43 percent (pp. 720 and 727). Table 10.26 reproduces Table 8, which summarizes the compensation of minivan buyers under the four demand models.

The logit models imply mean compensations of $13,652 (OLS) and $7,414 (IV). Adding the price of the vehicle, the implied mean willingness to pay is $22,374 and $16,136 (p. 720). Petrin finds these values inconsistent with Chrysler's profit maximization and implausible given the many cheaper vehicles available. The decomposition shows the source. Minivan buyers would need $95,121 (OLS) or $51,663 (IV) for the loss of their idiosyncratic minivan taste, while they "strongly dislike" the minivan's observed characteristics relative to their second choice.

Proposition 10.45 predicts this pattern. By part (b), minivan buyers should gain on average about $\frac{1}{\alpha}$, since minivans were a small fraction of all households' choices in 1984. The paper does not state the units of price in the logit models. We infer that they are thousands of 1982–84 dollars, from two pieces of evidence. First, Petrin notes that the ratio of the two mean logit markups, $13,904 to $7,551, almost equals the ratio of the price coefficients (p. 723, n. 14). Second, the logit markup $\frac{1}{\alpha(1-S_f)}$ is close to $\frac{1}{\alpha}$ when firms' shares are small. With $\alpha = 0.07$ per thousand dollars, $\frac{1}{\alpha}$ is about $14,300, and Table 9 places the OLS logit markups between $13,647 and $14,297 (10th and 90th percentiles). The IV logit gives $\frac{1}{0.13}$, about $7,700, against markups between $7,413 and $7,765. Figure 1 reports compensating variation in thousands of the same dollars (p. 724), which fits this reading. The reported means lie slightly below these values, which the proposition gives as lower bounds at fixed prices. Rounding of α in Table 4

Table 10.26: Compensating variation of 1984 minivan buyers under four demand models

	OLS logit	IV logit	Random coefficients	Random coefficients and micro data
Compensating variation ($)				
Median	9,573	5,130	1,217	783
Mean	13,652	7,414	3,171	1,247
Welfare change from difference in ($)				
Observed characteristics ($\delta_j + \mu_{ij}$)	−81,469	−44,249	−820	851
Logit error (ϵ_{ij})	95,121	51,663	3,991	396
Income of minivan buyers ($)				
Estimate from model	23,728	23,728	99,018	36,091
Difference from actual (CEX)	−15,748	−15,748	59,542	−3,385

Source: Petrin (2002, Table 8), 1982–84 CPI-adjusted dollars. Compensating variation is evaluated at equilibrium prices without minivans. The decomposition is the average difference in the value of observed and unobserved characteristics between first and second choices, as in (10.113). In the logit models the purchase decision is independent of income, so the mean income of buyers is the mean U.S. household income. The two decomposition rows sum to the mean in every column, and the last row equals the model estimate minus the CEX mean of $39,476.

explains almost all of the gap, since coefficients printed as 0.07 and 0.13 may be as large as 0.0749 and 0.1349. By Proposition 10.41(b), the minivan's small share means that its buyers have large logit draws, so the observed component is negative.

The random coefficients model without micro data lowers the mean compensation to $3,171 and the logit component to $3,991. The observed component is still negative (−$820). This model also implies that only the wealthiest, least price-sensitive households buy new vehicles. The mean income of its minivan buyers is $99,018, almost $60,000 above the CEX value. With micro moments, the mean compensation falls to $1,247. The observed component becomes positive ($851) and the logit component falls to $396. The implied mean income of minivan buyers, $36,091, is about $3,000 below the CEX value of $39,476 (pp. 722–723).

Figure 10.11 shows the whole distribution of compensation. Under the IV logit, 10 percent of minivan buyers would need at least $20,000 (p. 723). With random coefficients, the tail is much thinner, but many buyers would still need thousands of dollars. Adding the micro moments removes most of the "extreme-tastes" tail. Petrin prefers the full model on the cumulative weight of this evidence.

Markups. Table 10.27 reproduces Table 9. The two logit models imply mean markups of $13,904 and $7,551. Their ratio is almost exactly the ratio of the price coefficients, as the logit markup formula $\frac{1}{\alpha(1-S_f)}$ implies (p. 723, n. 14). The same formula explains the tiny dispersion. The standard deviation is 1.85 percent of the mean in both logit columns, because firms' shares are small and identical across the two columns. A Yugo and a Cadillac then carry nearly the same dollar markup. Marginal cost, which is price minus this markup, is negative for 73.7 percent (OLS) and 22.6 percent (IV) of vehicles. Petrin notes that many logit own-price elasticities are below one, which is inconsistent with static profit maximization (p. 723, n. 15). The example shows how a bias in demand passes into the supply side. The random coefficient models imply only positive marginal costs. Their mean percentage markups are 40.7 percent without micro data and 16.7 percent with them. Both lie within the range of earlier estimates, 15 to 40 percent in Berry et al. (1995) and an average of 38 percent in Goldberg (1995) (p. 725, n. 16).

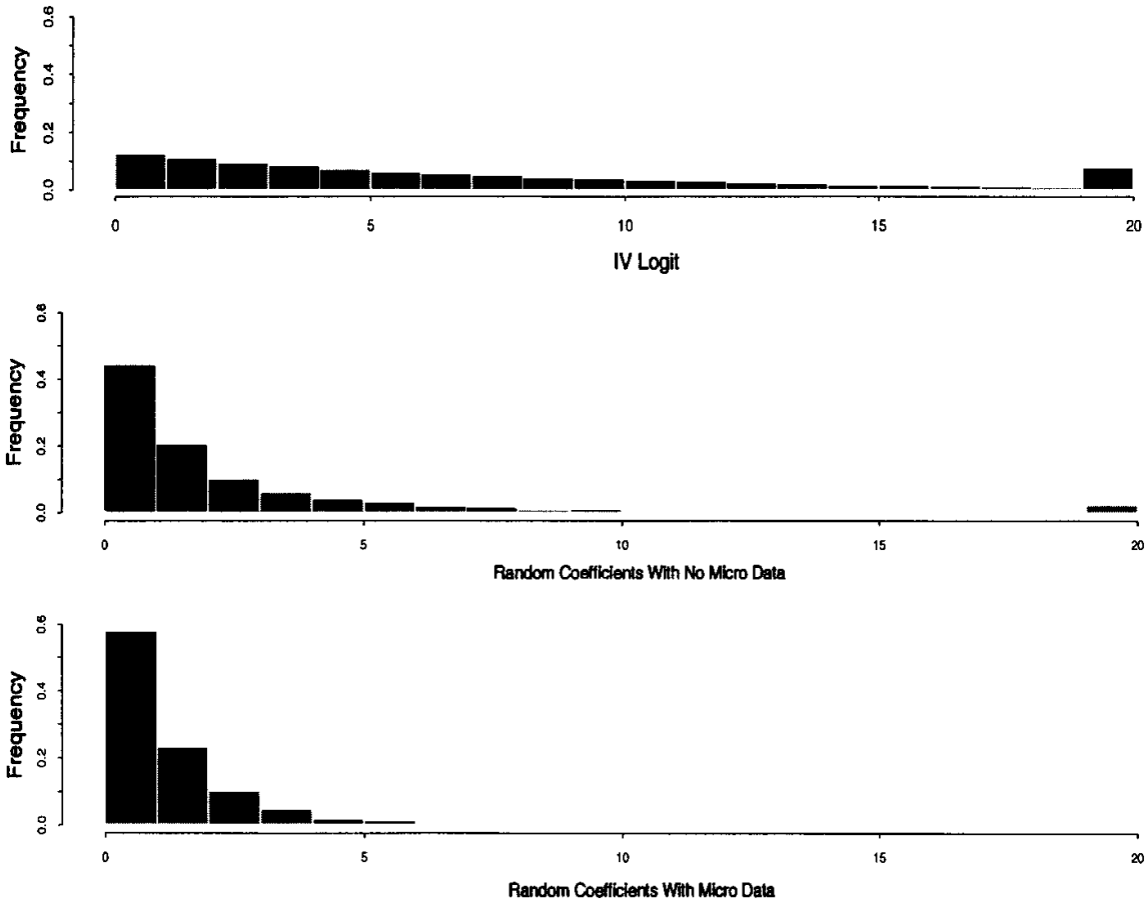

Figure 10.11: Distribution of compensating variation for 1984 minivan buyers, in thousands of 1982–84 dollars. The top panel is the IV logit model, the middle panel the random coefficients model without micro data, and the bottom panel the random coefficients model with micro data. The bar at 20 appears to collect the upper tail. Source: Petrin (2002), Figure 1.

Table 10.27: Implied markups under Bertrand-Nash pricing, 1981–93 (2,407 models)

	OLS logit	IV logit	Random coefficients		RC and micro data	
Statistic	($)	($)	($)	(%)	($)	(%)
Median	13,834	7,513	2,593	36.7	1,439	15.0
Mean	13,904	7,551	4,017	40.7	1,753	16.7
10th percentile	13,647	7,413	1,628	27.8	819	11.2
90th percentile	14,297	7,765	8,357	62.6	2,856	24.8
Standard deviation	257	140	4,089	14.0	1,229	6.2
Negative marginal costs (%)	73.7	22.6	0		0	

Source: Petrin (2002, Table 9), 1982–84 CPI-adjusted dollars. Percentage markups are markups divided by observed prices. They are not reported for the logit models because estimated marginal costs are negative for many vehicles.

Table 10 of the paper follows sales-weighted percentage markups by segment for 1983–87, using the model with micro data. Minivans earned the highest markups in every year they were sold (19.19 percent in 1984, 19.43 in 1985, 17.33 in 1986 and 16.31 in 1987). Station wagons earned less than minivans in every year. In four of the five years their markups also fell below those of the column for all other vehicles. The pairs are 18.27 against 18.85 percent in 1983, 16.81 against 17.12 in 1985, 15.82 against 16.43 in 1986 and 13.86 against 14.79 in 1987. In 1984 wagons were slightly above that column, at 17.83 against 17.72 percent. Petrin's text says that wagon markups "consistently fell below the market average" (p. 725), which his table does not bear out for 1984. Petrin attributes the minivan premium partly to its location in a less crowded region of product space. Overall, markups fell as the number of vehicle choices grew from 157 in 1983 to 198 in 1987 (p. 725).

Producer surplus and dissipation. Table 10.28 combines Tables 11 and 12. Chrysler's variable profits rose by $202.5 million, or 14.38 percent, in 1984 relative to a world without minivans. The gain grew to $504.1 million (32.50 percent) by 1988. Petrin states that by the end of 1987 Chrysler's minivans had generated almost $1.5 billion in profits, against a reported development cost of $700 million (p. 726).[19] Ford and GM were both hurt. The paper summarizes their losses as 1 to 2 percent of variable profits a year, which for high-volume GM amounted to more than $100 million in every year of Table 11. Ford's profit rose in 1986, the year its Aerostar arrived. The industry as a whole lost in 1984 and 1985, so ex post the industry would have been willing to pay Chrysler not to introduce the minivan (p. 727). Once Ford and GM sold minivans, they dissipated $126 million of Chrysler's profits over 1985–88, the profit on about 76,000 minivans. Chrysler's minivan was differentiated enough to keep much of its market power.

Table 10.28: Changes in variable profits due to the minivan, and Chrysler's losses to imitators

	Industry	Chrysler		Ford		GM		Chrysler, dissipation	
Year	(%)	($m)	(%)	($m)	(%)	($m)	(%)	($m)	(%)
1984	−0.21	202.5	14.38	−31.8	−1.16	−155.8	−1.50		
1985	−0.13	259.1	13.99	−37.4	−1.29	−171.0	−1.63	−6.06	−0.16
1986	0.14	201.1	12.42	54.7	1.84	−119.9	−1.09	−22.72	−1.99
1987	0.17	346.1	23.27	−22.8	−0.66	−174.5	−2.14	−42.35	−2.25
1988	0.65	504.1	32.50	−24.7	−0.70	−235.4	−2.90	−55.68	−2.63

Source: Petrin (2002, Tables 11 and 12), model with micro data, millions of 1982–84 dollars. The first eight columns compare profits with minivans to profits with all minivans removed. The last two compare Chrysler's profits with all minivans to its profits with the Ford and GM minivans removed.

Total welfare. Table 10.29 reproduces Table 13. Over 1984–88 the compensating variation sums to $2,804.55 million and producer profits rise by $105.54 million, for a welfare gain of $2,910.09 million. Producer profits fell in 1984 and 1985 and rose afterward. In every row the welfare change equals the compensating variation plus the change in producer profits. The gains to society far exceed both the cost of developing the vehicle and the innovator's private return (p. 727).

The 1984 numbers can be cross-checked against Table 8. Minivans took 1.58 percent of 10.66 million vehicle sales in 1984, or about 168,000 vehicles (Table 3). Minivan buyers received

[19] The Chrysler column of Table 11 sums to $1,008.8 million over 1984–87 and to $1,512.9 million over 1984–88. The paper does not show how its $1.5 billion figure is computed. The development cost was reported in *Time* on March 21, 1983. A $400 million retooling cost reported in *Fortune* is a lower bound on development costs (p. 726, n. 17).

Table 10.29: Change in U.S. welfare from the minivan, 1984–88 (millions of 1982–84 dollars)

Year	Compensating variation	Change in producer profits	Welfare change
1984	367.29	−36.68	330.61
1985	625.04	−25.07	599.97
1986	439.93	27.30	467.23
1987	596.59	29.75	626.34
1988	775.70	110.24	885.94
Total	2,804.55	105.54	2,910.09

Source: Petrin (2002, Table 13), model with micro data. Producer profits are the variable profits of all firms, from the equilibrium with and without minivans.

$367.29 million less the $157 million that went to other households. That leaves about $1,250 per minivan buyer, close to the mean of $1,247 in Table 8.

10.9.9 Robustness*

The paper's main robustness check is the comparison across its four demand models, and we gather its results here. Instrumenting almost doubles the logit price coefficient (p. 719). Wald tests reject both logit models in favor of the random coefficients models (p. 719). Without micro data only 6 of the 24 demand parameters have z-statistics above one, and with them 21 of the 24 do (p. 719). Across the four models the mean compensation of 1984 minivan buyers falls from $13,652 to $7,414, $3,171 and $1,247 (Table 10.26). Two further checks discriminate among the models. The logit models imply negative marginal costs for many vehicles (Table 10.27). The random coefficients model without micro data predicts a mean income of minivan buyers far above the CEX value, while the full model comes close (Table 10.26). The paper reports no estimates under other taste distributions. The tail of compensation in Figure 10.11 therefore rests on the truncated $\chi^2(3)$ assumption, which Section 10.9.10 discusses.

10.9.10 Interpretation, limitations and critiques

The paper's central lesson concerns the logit error. Its share in the welfare of minivan buyers is a diagnostic of how much the answer rests on the functional form. That share falls from about 700 percent of the mean (the observed part being negative) under the OLS logit to 32 percent with micro data ($396 of $1,247). Even the preferred model credits a third of the buyers' gain to the ϵ_{ij} draws. A pure characteristics model would remove that component entirely (Berry and Pakes, 2007), and Section 10.7 showed that such models value close substitutes much less. Ackerberg and Rysman (2005) propose a related correction that lets the variance of the logit error shrink as the product space fills.

Several assumptions shape the level of the estimates. The income term $\alpha_i \ln(y_i - p_j)$ fixes how compensation scales with income, and the truncated $\chi^2(3)$ distribution fixes the tails of taste heterogeneity. Since compensation is a nonlinear function of tastes, Figure 10.11 depends on these tails. The market size is the number of U.S. households, so the outside option absorbs all households that buy no new vehicle. The counterfactual holds the characteristics and the ξ_j of the other vehicles fixed. Ford and GM might have repositioned their wagons or introduced their own minivans earlier in a world in which Chrysler did not. The model is static, so welfare covers only 1984–88 and is not discounted. Prices are list prices of base models, without rebates or options.

The counterfactual also defines the object being valued. It removes all minivans, including the Ford and GM models, so the $2.9 billion values the minivan as a class of vehicle. The value of any single firm's minivan is a narrower question. The dissipation counterfactual of Table 12 answers it for the imitators.

Finally, the minivan dummy carries much of the new good's value. A minivan is a new combination of height, size and front-wheel drive. Its mean taste and the dispersion of that taste (π_{mv}) are identified from minivan sales and from the CEX buyer averages. They are not predicted from tastes for existing characteristics. The analysis is therefore an ex post valuation, which differs from the ex ante prediction that characteristics models promise in Section 10.7.

10.9.11 Contribution

The paper made two contributions. The first is the micro-moment technique. It brings aggregate information about buyers into the BLP estimator at almost no computational cost, and it showed that such moments sharpen exactly the parameters that matter for welfare. Micro moments are now routine in demand estimation (Section 8.8). The second is the welfare accounting of a new good under oligopoly. Petrin measured how much of the consumer gain came through competition (43 percent in 1984), how much the innovator earned, and how much the imitators dissipated. He concludes that large improvements in consumers' standard of living arise from competition among firms that seek temporary market power through new goods (p. 728).

Table 10.30: Identification and counterfactual map of Petrin (2002)

Observed data	Prices, sales and characteristics of 2,407 U.S. nameplate-years, 1981–1993. CEX averages of the demographics of new-vehicle buyers, 1987–1992, and the CPS income distribution.
Latent objects	Product quality ξ_j, cost shocks ω_j, household tastes and incomes, and marginal costs.
Estimated parameters	Price coefficients for three income groups, random-coefficient scales σ_k, family-vehicle interactions π, mean tastes and the cost coefficients γ.
Identifying variation	Characteristics-based instruments for prices, as in BLP, plus micro moments that match purchase probabilities by income group and the family size and age of the buyers of each vehicle type.
Maintained assumptions	Static multiproduct Bertrand-Nash pricing, log-linear marginal cost, the income term $\alpha_i \ln(y_i - p_j)$, exogenous characteristics, and a market size equal to the number of households.
Counterfactual and what it holds fixed	Removal of all minivans, with the prices of the other vehicles re-solved. Marginal costs, characteristics and ξ_j are held fixed. A second counterfactual removes only the Ford and GM minivans.
Conclusion	The compensating variation is $2,804.55 million over 1984–1988, and about 43 percent of the consumer gain in 1984 came through lower prices of other vehicles. Micro moments shrink the share of the logit errors in buyers' gains.
One limitation	Rivals cannot reposition their products in the counterfactual, although they might have done so in a world without Chrysler's minivan.
Source and our additions	The tables are Petrin's. Proposition 10.45 and Lemma 10.46 and the diversion form (10.110) are ours.

10.10 Case study: complementarity and online news (Gentzkow 2007)

Every discrete choice model of this chapter so far assumes that a consumer chooses one product. In those models the new good can only draw consumers away from existing goods. The continuous demand systems of the chapter, such as the AIDS system of Section 10.5, are different, since they let spending spread over many brands. Gentzkow (2007) builds a discrete choice model in which consumers may choose several goods at once, and in which the data decide whether goods are substitutes or complements. He applies it to the *Washington Post*, its online edition (the post.com) and the competing daily *Washington Times*. We follow the paper from its question to its contribution, and Table 10.39 at the end of the section maps it.[20]

10.10.1 The question

Do new goods crowd out existing goods or complement them? Gentzkow opens with examples in which the answer surprised the industry (p. 713). Record companies in the 1920s believed that radio broadcasts crowded out record sales, until radio airplay turned out to raise them. A widely cited forecast predicted that computers would create a "paperless office," yet information technology sharply increased paper consumption. Newspaper executives in the early 2000s debated whether free online editions siphon readers from print (p. 714, n. 4).

The answer matters for three reasons (pp. 713–714). It drives firms' decisions on entry, positioning and pricing. It determines the welfare value of the new good and hence the bias of price indexes. It informs policy, such as rules on cross-media mergers. Standard discrete choice models cannot answer the question. They assume that each consumer chooses exactly one product, so all goods are perfect substitutes at the individual level (p. 714). The single-unit assumption is reasonable for cars, and it is the main limitation of characteristics models for goods consumed together. Gentzkow's model removes it.

A second difficulty is empirical. Frequent online readers are also frequent print readers. The pattern could mean that the goods are complements. It could also mean that some consumers simply have a stronger taste for news. Separating true complementarity from correlated tastes is the central identification problem of the paper (p. 714).

10.10.2 A two-good model of bundles

Consider two goods, A and B. Each consumer buys at most one unit of each, so she chooses one of four *bundles*: nothing (0), A only, B only, or both (AB). Income not spent on the goods buys a composite good whose utility is α per dollar. Let u_r be the utility of bundle r relative to the empty bundle. Gentzkow specifies (p. 717, eq. 1)

$$u_0 = 0, \qquad u_A = \delta_A - \alpha p_A + \nu_A, \qquad u_B = \delta_B - \alpha p_B + \nu_B, \qquad u_{AB} = u_A + u_B + \Gamma_{AB}. \quad (10.119)$$

Here δ_A and δ_B are mean utilities, and (ν_A, ν_B) are unobserved tastes. The parameters δ_A, δ_B and Γ_{AB} are common to all consumers. The term $-\alpha p_j$ is the utility of the composite good forgone, $\alpha(y - p_j) - \alpha y$. The *interaction term*

$$\Gamma_{AB} = (u_{AB} - u_B) - (u_A - u_0)$$

[20] Gentzkow writes σ for the correlation of the unobservables in his two-good model and Γ for the interaction term. He writes γ for the probability of a news-day shock, λ for the number of readers per copy, κ for the transaction cost of online payment and Ψ for the fixed cost. We write ρ, Γ_{AB} (or Γ_r for bundle r), ω, κ, χ and F^{fix}. Page and table numbers in this section refer to the journal article.

is the discrete analog of a cross-partial derivative of utility. It measures how much the added utility of A rises when B is consumed as well. Gentzkow assumes that (v_A, v_B) is bivariate normal with unit variances and correlation ρ. One unit variance is a normalization of scale. The other only simplifies exposition.

Demand per consumer is $Q_A = P_A + P_{AB}$ for good A and $Q_B = P_B + P_{AB}$ for good B, where P_r is the probability of choosing bundle r. Because utility is quasi-linear, income effects are absent, and compensated and uncompensated cross-price derivatives coincide. The standard definition of complements (Samuelson, 1974) then reads as follows (p. 717, Definition 1).

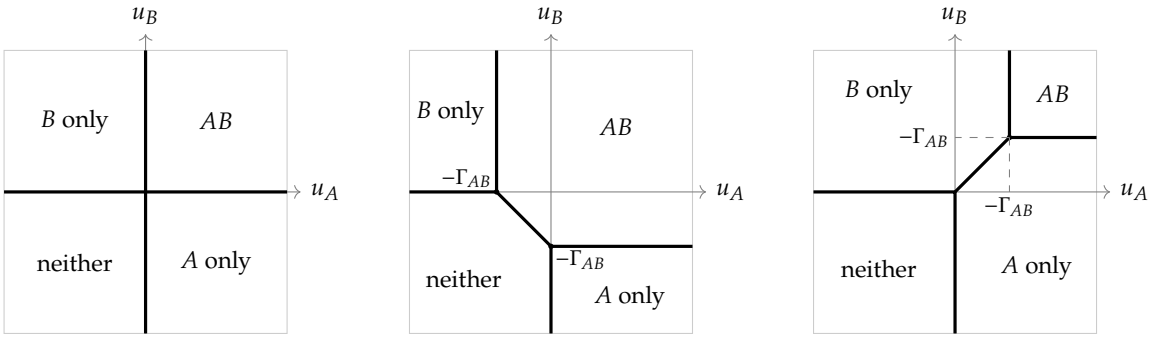
Definition 10.47 (Substitutes and complements)**.** Goods A and B are *substitutes* if $\frac{\partial Q_A}{\partial p_B} > 0$, *independent* if $\frac{\partial Q_A}{\partial p_B} = 0$, and *complements* if $\frac{\partial Q_A}{\partial p_B} < 0$.

Choice regions. The consumer picks the bundle with the highest utility. Comparing the four utilities pairwise gives the regions of the (u_A, u_B) plane shown in Figure 10.12. Bundle AB beats A when $u_B + \Gamma_{AB} \geq 0$, beats B when $u_A + \Gamma_{AB} \geq 0$, and beats 0 when $u_A + u_B + \Gamma_{AB} \geq 0$. Bundle A beats 0 when $u_A \geq 0$ and beats B when $u_A \geq u_B$. Three cases follow.

If $\Gamma_{AB} = 0$, the comparisons separate. The consumer buys A if and only if $u_A \geq 0$, and B if and only if $u_B \geq 0$. The boundaries are the two axes.

If $\Gamma_{AB} > 0$, the consumer buys AB when $u_A \geq -\Gamma_{AB}$, $u_B \geq -\Gamma_{AB}$ and $u_A + u_B \geq -\Gamma_{AB}$. She buys A alone when $u_A \geq 0$ and $u_B \leq -\Gamma_{AB}$, and B alone in the mirror case. She buys nothing when $u_A \leq 0$, $u_B \leq 0$ and $u_A + u_B \leq -\Gamma_{AB}$. The boundary between AB and 0 is the segment of the anti-diagonal line $u_A + u_B = -\Gamma_{AB}$ with both coordinates in $[-\Gamma_{AB}, 0]$. Consumers on that segment are indifferent between buying both goods and buying neither.

If $\Gamma_{AB} < 0$, the consumer buys AB when $u_A \geq -\Gamma_{AB}$ and $u_B \geq -\Gamma_{AB}$. She buys A alone when $u_A \geq 0$, $u_A \geq u_B$ and $u_B \leq -\Gamma_{AB}$, and B alone in the mirror case. She buys nothing when both utilities are negative. The boundary between A alone and B alone is the segment of the diagonal $u_A = u_B$ with both coordinates in $[0, -\Gamma_{AB}]$. Consumers on it are indifferent between the two goods.



(a) $\Gamma_{AB} = 0$ **(b)** $\Gamma_{AB} > 0$ (complements) **(c)** $\Gamma_{AB} < 0$ (substitutes)

Figure 10.12: Choice regions of the two-good bundle model in the plane of (u_A, u_B), the utilities of A and B relative to buying nothing. Thick lines are indifference boundaries. In panel (b) the anti-diagonal segment $u_A + u_B = -\Gamma_{AB}$ separates buying both goods from buying neither. In panel (c) the diagonal segment $u_A = u_B$ separates buying A alone from buying B alone. A rise in p_B shifts probability mass downward. Only consumers on the diagonal segments change their consumption of A. Drawn from the boundaries derived in the text. Compare Gentzkow (2007, Figure 1).

Why the interaction term decides. A rise in p_B lowers u_B for every consumer and moves probability mass down in Figure 10.12. In panel (a), consumers who move from AB to A alone and from

B alone to nothing leave the demand for A unchanged. In panel (b), some consumers on the anti-diagonal segment move from AB to nothing, so they stop buying A. In panel (c), consumers on the diagonal segment move from B alone to A alone, so they start buying A (pp. 718–719). The following result makes the argument exact.

Proposition 10.48 (The interaction term signs the cross-price effect)**.** *In the model of* (10.119)*, let* $\alpha > 0$ *and let* (v_A, v_B) *have a continuous joint density that is positive on* $\mathbb{R}^2$*. Write* f_u *for the implied density of* (u_A, u_B)*. Then*

$$\frac{\partial Q_A}{\partial p_B} = \begin{cases} \alpha \displaystyle\int_0^{-\Gamma_{AB}} f_u(t,t)\,\mathrm{d}t > 0 & \text{if } \Gamma_{AB} < 0, \\ 0 & \text{if } \Gamma_{AB} = 0, \\ -\alpha \displaystyle\int_{-\Gamma_{AB}}^{0} f_u(-\Gamma_{AB} - t,\, t)\,\mathrm{d}t < 0 & \text{if } \Gamma_{AB} > 0. \end{cases} \tag{10.120}$$

Hence A and B are substitutes if $\Gamma_{AB} < 0$, independent if $\Gamma_{AB} = 0$ and complements if $\Gamma_{AB} > 0$ (Gentzkow, 2007, Proposition 1).

Proof. Step 1: the condition for consuming A. Ties have probability zero. The consumer consumes A when her best bundle containing A beats her best bundle without it:

$$\begin{aligned} \max\{u_A,\ u_A + u_B + \Gamma_{AB}\} &\geq \max\{0,\ u_B\}, \\ u_A + \max\{0,\ u_B + \Gamma_{AB}\} &\geq \max\{0,\ u_B\}, \\ u_A &\geq g(u_B), \qquad g(b) \equiv \max\{0, b\} - \max\{0, b + \Gamma_{AB}\}. \end{aligned}$$

Step 2: the shape of g. If $\Gamma_{AB} = 0$, then $g \equiv 0$. If $\Gamma_{AB} > 0$, then $g(b) = 0$ for $b \leq -\Gamma_{AB}$, $g(b) = -\Gamma_{AB} - b$ for $-\Gamma_{AB} < b < 0$, and $g(b) = -\Gamma_{AB}$ for $b \geq 0$. So g is nonincreasing with slope -1 on $(-\Gamma_{AB}, 0)$. If $\Gamma_{AB} < 0$, then $g(b) = 0$ for $b \leq 0$, $g(b) = b$ for $0 < b < -\Gamma_{AB}$, and $g(b) = -\Gamma_{AB}$ for $b \geq -\Gamma_{AB}$. So g is nondecreasing with slope $+1$ on $(0, -\Gamma_{AB})$. Outside these intervals $g' = 0$.

Step 3: differentiate demand. Write $c_A = \delta_A - \alpha p_A$ and $c_B = \delta_B - \alpha p_B$, so that $u_A = c_A + v_A$ and $u_B = c_B + v_B$. Let f be the density of (v_A, v_B). Then

$$Q_A = \mathbb{P}\big(v_A \geq g(c_B + v_B) - c_A\big) = \int_{-\infty}^{\infty} \int_{g(c_B+v_B)-c_A}^{\infty} f(v_A, v_B)\,\mathrm{d}v_A\,\mathrm{d}v_B.$$

The function g is piecewise linear, so we may differentiate under the outer integral:

$$\frac{\partial Q_A}{\partial c_B} = -\int_{-\infty}^{\infty} f\big(g(c_B + v_B) - c_A,\ v_B\big)\, g'(c_B + v_B)\,\mathrm{d}v_B = -\int_{-\infty}^{\infty} f_u\big(g(t),\ t\big)\, g'(t)\,\mathrm{d}t,$$

where the second equality substitutes $t = c_B + v_B$ and uses $f_u(a, b) = f(a - c_A, b - c_B)$. Since $\frac{\partial c_B}{\partial p_B} = -\alpha$,

$$\frac{\partial Q_A}{\partial p_B} = \alpha \int_{-\infty}^{\infty} f_u\big(g(t),\ t\big)\, g'(t)\,\mathrm{d}t.$$

Step 4: evaluate. If $\Gamma_{AB} = 0$, then $g' \equiv 0$ and the derivative is zero. If $\Gamma_{AB} < 0$, then $g(t) = t$ and $g'(t) = 1$ on $(0, -\Gamma_{AB})$, which gives the first line of (10.120). If $\Gamma_{AB} > 0$, then $g(t) = -\Gamma_{AB} - t$ and $g'(t) = -1$ on $(-\Gamma_{AB}, 0)$, which gives the third line. The density is positive, so both integrals are strictly positive. □

The two integrals run along the diagonal segments of Figure 10.12. Gentzkow's equation (3) writes them as line integrals with indicator functions (p. 719). The magnitude of the cross effect depends on the length $|\Gamma_{AB}|$ of the segment and on the density of consumers along it. The proposition also covers nonprice shifters. Suppose a variable z raises u_B by ζz and leaves u_A unchanged. Then $\frac{\partial Q_A}{\partial z} = \zeta \frac{\partial Q_A}{\partial c_B} = -\frac{\zeta}{\alpha} \frac{\partial Q_A}{\partial p_B}$. Improving the connection speed of an online paper works like cutting its price, and its effect on print demand has the sign of Γ_{AB} (p. 719). This is how Gentzkow's excluded variables reveal substitution without any price variation.

10.10.3 What the data can and cannot identify

A counting problem. Choice data in the two-good model give three probabilities, P_A, P_B and P_{AB}. The model has five parameters: δ_A, δ_B, Γ_{AB}, ρ and α (p. 720). The price coefficient is identified from choices only if prices vary, because the probabilities depend on $(\delta_A, \delta_B, \alpha)$ only through $\delta_A - \alpha p_A$ and $\delta_B - \alpha p_B$. Without price variation, α needs another moment. Gentzkow takes it from a firm's pricing condition (Section 10.10.8).

The harder problem is to separate Γ_{AB} from ρ. The marginal probabilities Q_A and Q_B identify the two mean utilities. One moment remains, how often the goods are consumed together. A high P_{AB} relative to P_A and P_B can come from a large Γ_{AB} or from a large ρ, and nothing else in the data separates them (p. 720). By Proposition 10.48, the same data could be fit by near-perfect substitutes with highly correlated tastes, or by near-perfect complements with weakly correlated tastes. A model that fixes one of the two parameters by assumption fixes the answer to the substitution question.

Exclusion restrictions. Suppose a variable x enters the utility of A only. Observing choices at a second value of x adds three moments, P_A, P_B and P_{AB} at the new value, and one parameter, the new mean utility of A (p. 721). The model becomes formally identified. The intuition is direct. If joint consumption reflects a high Γ_{AB}, then shifting up the utility of A raises the probability of consuming B. If it reflects correlated tastes, the probability of consuming B stays unchanged. Keane (1992) gives Monte Carlo evidence that exclusion restrictions sharpen the covariance estimates of multinomial probit models, which nest the model of (10.119) when defined over bundles (p. 721, n. 11).

Panel data. Split each taste into a consumer random effect, constant over time, and a shock that is i.i.d. across goods and days. With choices observed at two dates there are $4^2 = 16$ joint outcomes, hence 15 moments instead of 3 (p. 721, n. 12). The argument is the usual one for random effects. Correlated random effects make some consumers likely to consume both goods and others likely to consume neither. Conditional on a consumer's average propensities, her day-to-day variation is then uncorrelated across goods. A high Γ_{AB} instead makes the day-to-day variation strongly correlated. The consumer reads both papers on some days and neither on others, and rarely reads only one.

Gentzkow's data are a limited panel. Respondents report what they read in the last 24 hours and in the last five weekdays. For consumers who read nothing in the last 24 hours, the five-day report shows which papers they read on the other four weekdays. Whether they were less likely to read then identifies the variance of the random effects. Consumers who read one paper in the last 24 hours identify the correlation. If the random effects are positively correlated, a consumer who read only A yesterday is more likely to have read B earlier in the week (p. 722).

Unobserved goods. The outside option has a different meaning when bundles are allowed.

Every choice in the model includes an implicit maximization over goods the econometrician does not see, such as cable news (p. 719). Suppose watching CNN destroys the value of the post.com and raises the value of the print *Post*. Then the *Post* and the post.com are never read together, and the model estimates them as strong substitutes. Gentzkow argues that this answer is correct for the market as it is. Raising the price of the *Post* would reduce CNN viewing as well and raise post.com reading (p. 720). The estimates are conditional on the set and the prices of the unobserved goods, a limitation all discrete choice models share (Samuelson, 1974).

Relation to earlier models. The model of (10.119) nests the earlier approaches as restrictions (pp. 722–723). The multiple-discrete choice model of Hendel (1999) aggregates many "tasks," such as the computing needs of each employee of a firm. Hendel's model lets a buyer choose several units of several brands, and he estimates it by the method of simulated moments on micro data for personal computer purchases by firms. Each task uses one good, so the task-level model fixes $\Gamma_{AB} = -\infty$, and the goods are restricted to be substitutes (Chapter 7). A multivariate probit, with one equation per good and correlated errors, sets $\Gamma_{AB} = 0$ and forces independence. A logit or nested logit over bundles (Manski and Sherman, 1980; Train et al., 1987) can estimate Γ_{AB} freely. Its unobservables, however, are uncorrelated or follow the nest structure, so it would read correlated tastes as complementarity. Gentzkow's model frees both terms and relies on exclusions and panel information to separate them.

10.10.4 Setting and data

The data come from a Scarborough Research survey of 16,179 adults in the Washington, DC, Designated Market Area (DMA), conducted between March 2000 and February 2003 (p. 723). The survey lists the local print newspapers each respondent read in the last 24 hours and in the last five weekdays. It records the readership of the major local online newspapers over the same windows, and many household characteristics. The *Post* dominated the market, with an average daily readership of 1.8 million against 256,000 for the *Times*. The post.com had 406,000 area readers per day. The *Times*'s own website had only 373 readers in the sample and is omitted (p. 723, n. 16). The goods are the daily editions of the *Post*, the *Times* and the post.com. The outside option includes all other news sources and not reading news at all.

The survey is about a 0.4 percent sample and broadly representative. It overrepresents older, more educated and wealthier residents and underrepresents minorities (p. 724). Estimation uses the unweighted data, and the policy simulations use the sampling weights. About 6 percent of records were filled in by Scarborough from matched respondents. Gentzkow drops them in estimation and keeps them in the simulations (p. 724, n. 17).

The aggregate time series are suggestive but inconclusive (p. 724). Post.com readership grew rapidly after its introduction in 1996 while *Post* readership fell. A regression of *Post* readership since 1984 on post.com readership and a trend implies that four post.com readers displace one *Post* reader. Yet the decline began in 1994, two years before the post.com, and did not accelerate afterward. Readership was falling nationally, and the *Post* raised its subscription price several times. Time series alone cannot separate these forces.

The micro data show that reading several papers is common (p. 725). Forty-eight percent of respondents read at least one of the three papers in the last 24 hours. Of these, 18 percent read two and 1 percent read all three. Over five days, 65 percent read at least one, and of these 27 percent read two and 3 percent all three. Panel A of Table 10.31 cross-tabulates *Post* and post.com readership. Among post.com readers the share who also read the *Post* is higher than among non-readers. Panel B reports raw and partial correlations. The partial correlations

control for age, sex, education, occupation, employment status, income, political party, survey date, location and the number of missing answers. Controls cut the *Post*-post.com correlation by about two-thirds, but it stays significantly positive. The *Post*-*Times* correlation is positive in the raw data and vanishes or turns negative with controls.

Table 10.31: Joint readership of the *Post*, the post.com and the *Times*

A. Cross-tabulation of Post and post.com readership (number of respondents)				
	Last 24 hours		Last 5 weekdays	
	No post.com	Read post.com	No post.com	Read post.com
Did not read *Post*	8,771	622	6,012	680
Read *Post*	5,829	877	7,203	2,204
B. Correlation coefficients of readership indicators				
	Last 24 hours		Last 5 weekdays	
	Raw	Partial	Raw	Partial
Post and post.com	0.0989**	0.0364**	0.1579**	0.0673**
Post and *Times*	0.0632**	0.0035	0.0450**	−0.0623**
Times and post.com	0.0146	0.0090	0.0184	0.0066

Source: Gentzkow (2007, Tables 2 and 3), Scarborough survey, Washington, DC, DMA, 2000–03. Partial correlations are correlations of the residuals from regressions of each readership indicator on the controls listed in the text. Panel B drops respondents for whom print or online papers are not in the choice set. ** significant at 1 percent.

10.10.5 Reduced-form evidence

To separate complementarity from correlated tastes, Gentzkow uses four variables that shift the utility of reading online but not, directly, the utility of reading print (pp. 725–726). They are indicators for Internet access at work, use of the Internet for work-related tasks, use of the Internet for education-related tasks, and a high-speed connection at home. Access at work lowers the time cost of reading online. The two use variables indicate familiarity with the Internet and time spent at a computer. A fast connection raises the utility of online reading. Collect them in a vector z_i. No variable shifts the *Post* without shifting the *Times*, so print-print substitution is less well identified than print-online substitution (p. 726).

A linear probability model shows the exclusion restrictions at work. Let R_i^p indicate that respondent i read the *Post* in the last five weekdays and R_i^w that she read the post.com. Gentzkow estimates

$$R_i^p = b\, R_i^w + x_i\varphi + e_i, \tag{10.121}$$

first by OLS and then by two-stage least squares (2SLS) with z_i as instruments for R_i^w. The controls x_i are those of the partial correlations, plus *Times* readership. The 2SLS coefficient has a simple interpretation in terms of Proposition 10.48. Each instrument moves only the utility of the post.com, so it acts like a change in the post.com's price. The 2SLS coefficient is the ratio of the instrument's effect on *Post* reading to its effect on post.com reading. In the language of Chapter 4, it estimates minus the diversion ratio from the post.com to the *Post*, averaged over the respondents whom the instruments move.

Table 10.32 reproduces Table 4. OLS gives a positive coefficient, 0.0464 (0.0090), which mirrors the raw correlation. 2SLS gives −0.4132 (0.107). Taken literally, a respondent assigned to read the online paper at zero time cost would be about 41 percentage points less likely to read

the print paper. Gentzkow describes this as "40 percent less likely" (p. 726). The coefficient on a binary regressor in a linear probability model is a change in the probability itself. A relative decline would require dividing by a baseline probability of reading the print paper. Gentzkow warns that the linear probability model limits how far this magnitude can be trusted. The first-stage F-statistic on the instruments is 33.05, so weak instruments are not a concern. The overidentification statistic is $\chi^2 = 3.65$ with a p-value of 0.302, so the test does not reject the validity of the instruments.

Table 10.32: Linear probability model of *Post* readership in the last five weekdays

	OLS	2SLS		
		(1)	(2)	(3)
Read post.com last 5 days	0.0464**	−0.4132**	−0.4579**	−0.4381**
	(0.0090)	(0.107)	(0.119)	(0.141)
Other Internet news				0.0244
				(0.0195)
Industry and occupation controls			Yes	
Overidentification p-value		0.302	0.431	0.219
R^2	0.333	0.214	0.207	0.202
N	14,313	14,313	14,313	14,313

Source: Gentzkow (2007, Table 4). Robust standard errors in parentheses. The instruments are indicators for Internet access at work, a fast Internet connection, and use of the Internet for research or education and for work. The overidentification test is a Sargan test. Industry controls are 12 categories and occupation controls 11. All regressions include the controls listed in the text and omit respondents without print papers in the choice set. ** significant at 1 percent.

The main threat is that the instruments correlate with unmeasured tastes for print (pp. 727–728). People who like reading may select into jobs with Internet access, and news enthusiasts may buy fast connections. Gentzkow offers three checks. Adding 12 industry and 11 occupation categories, which should absorb part of any omitted job characteristic, strengthens the 2SLS coefficient slightly to −0.4579 (Altonji et al., 2005). Restricting the sample to residents of more than ten years, whose job choices largely predate online news, leaves the estimates nearly unchanged (p. 727, n. 19). Controlling for other Internet news use raises the coefficient's magnitude slightly (−0.4381), so the instruments do not appear to work through other online news sources. The structural robustness checks below also drop the broadband exclusion.

10.10.6 The empirical model

Index days by t, consumers by i, goods by $j \in \{1, \dots, J\}$ with $J = 3$, and bundles by $r \in \{0, 1, \dots, 2^J - 1\}$, where $r = 0$ is the empty bundle (p. 728). The utility of consumer i from good j alone on day t is

$$\tilde{u}_{ijt} = \delta_j - \alpha p_j + x_i \beta_j + \nu_{ij} + \tau_{it}. \tag{10.122}$$

The vector x_i holds age, sex, education, occupation, employment status, political party, location within the DMA, the number of missing survey answers, six-month time dummies and log income. For the post.com it also holds the four excluded variables z_i, which are absent from the print utilities. The time dummies absorb changes in the quality of the goods and their substitutes. Log income proxies for unobservables correlated with income, since the budget effect of income differences out (p. 729).

The two unobservables play different roles. The vector $\nu_i = (\nu_{i1}, \ldots, \nu_{iJ})$ is constant over the survey week. It captures a general taste for news, loyalty to a paper and subscription status. It is multivariate normal with a free covariance matrix, whose scale is pinned down by the logit errors below (p. 729, n. 21). The day shock τ_{it} raises the utility of all papers equally. It equals $\hat{\tau} > 0$ with probability ϖ and zero otherwise, a stylized description of major news days and of day-to-day variation in the cost of time. Price does not vary enough to estimate α from demand, so the first two terms are combined into $\bar{\delta}_j = \delta_j - \alpha p_j$.

The utility of bundle r adds the base utilities of its goods, an interaction term and a bundle-specific shock (p. 729, eq. 4):

$$u_{irt} = \begin{cases} \epsilon_{irt} & \text{if } r = 0, \\ \sum_{j \in r} \tilde{u}_{ijt} + \Gamma_r + \epsilon_{irt} & \text{if } r > 0. \end{cases} \tag{10.123}$$

Here $\Gamma_r = 0$ for single-good bundles, and ϵ_{irt} is i.i.d. type-I extreme value. With three goods there are three pairwise interactions and one triple interaction, which is estimated but not reported (Table 6, note). On a major news day the bundle r gains $|r|\hat{\tau}$, where $|r|$ is its number of goods. The interaction terms and the price coefficient are common to all consumers. Gentzkow reports that letting Γ_r vary with observables did not change the results substantially (p. 729).

Proposition 10.48 does not apply unchanged to this model. Label the goods A, B and C. With three goods, a change in p_B also moves consumers into and out of the bundles that contain C. The triple interaction and the bundle-specific logit errors then enter the cross-price effect, and a negative Γ_{AB} no longer signs it. Our computation gives an example with ν_i and τ_{it} set to zero. Let every $\bar{\delta}_j + x_i\beta_j$ be zero, $\alpha = 1$, $\Gamma_{AB} = -1$, $\Gamma_{AC} = \Gamma_{BC} = 0$, and $\Gamma_r = 10$ for the bundle r of all three goods. With r_i the bundle that consumer i chooses, the logit form gives $\frac{\partial Q_A}{\partial p_B} = -\alpha \operatorname{Cov}\big(\mathbf{1}\{A \in r_i\}, \mathbf{1}\{B \in r_i\}\big) \approx -0.00009$. So A and B are complements although $\Gamma_{AB} < 0$, because almost every consumer buys all three goods. A small positive variance of ν_i preserves the sign. In the empirical model the two-good result is therefore an intuition, and the substitution patterns must be read from the cross-price derivatives of the full model.

Two dummies define choice sets. About 10 percent of respondents say they look at no newspaper sections, and print papers are removed from their choice set. Respondents who did not use the Internet in the last 30 days have no online paper. Each dummy also enters, as a control, the utility of the goods it does not exclude (p. 729). Choice-set variation therefore does not identify substitution, which seems prudent because it is unlikely to be exogenous (n. 25).

Choice probabilities and the likelihood. Integrating over the ϵ_{irt} gives the logit probability of bundle r on a day with shock τ:

$$Q_r(x_i, \nu_i, \tau; \theta) = \frac{\exp\Big[\sum_{j \in r}(\bar{\delta}_j + x_i\beta_j + \nu_{ij} + \tau) + \Gamma_r\Big]}{1 + \sum_{r'=1}^{2^J-1} \exp\Big[\sum_{j \in r'}(\bar{\delta}_j + x_i\beta_j + \nu_{ij} + \tau) + \Gamma_{r'}\Big]}. \tag{10.124}$$

The data report, for each good, whether it was read in the last 24 hours and whether it was read in the last five weekdays. Let $\tilde{q} \in \{0, \ldots, 2^J - 1\}^5$ list the bundles chosen on the five weekdays. Let q be a reported outcome and $\Omega(q)$ the set of daily sequences consistent with it. Since τ_{it} and ϵ_{irt} are independent across days, the probability of report q given ν_i is (p. 730)

$$P_q(x_i, \nu_i; \theta) = \sum_{\tilde{q} \in \Omega(q)} \prod_{t=1}^{5} \Big[\varpi\, Q_{\tilde{q}_t}(x_i, \nu_i, \hat{\tau}; \theta) + (1 - \varpi)\, Q_{\tilde{q}_t}(x_i, \nu_i, 0; \theta)\Big]. \tag{10.125}$$

The log-likelihood integrates over the random effects:

$$L(X, q, \theta) = \sum_i \ln \int P_{q_i}(x_i, \nu; \theta)\, \mathrm{d}F(\nu; \theta), \tag{10.126}$$

where $F(\nu; \theta)$ is the multivariate normal distribution of ν (p. 732, eq. 6).

Identification in the empirical model. The two-good intuition carries over (p. 730). The combination of 24-hour and 5-day reports pins down the covariance matrix of ν_i. Choices on earlier days are more correlated with the choice in the last 24 hours, conditional on observables, the larger the variance of the random effects. The exclusion restrictions then pin down the distribution of the common day shock τ_{it} and the interaction terms. If same-day joint reading of print and online papers is driven by τ_{it}, Internet access at work should not change the probability of reading print. If it is driven by complementarity, those with access should read print more. Gentzkow stresses three limitations. The partial panel identifies the random effects less well than a true panel. The excluded variables shift only the online paper. And without price variation, functional forms carry more weight than in richer data sets.

10.10.7 Simulated maximum likelihood

The integral in (10.126) has no closed form. Gentzkow replaces it with a simulator and maximizes the simulated likelihood (p. 732, eq. 7):

$$\hat{\theta}^{SML} = \arg\max_\theta \sum_i \ln\Big[\frac{1}{S}\sum_{s=1}^{S} P_{q_i}(x_i, \nu_{is}; \theta)\Big], \tag{10.127}$$

with $S = 300$ draws per consumer. The leading alternative is the method of simulated moments (MSM) of McFadden (1989) and Pakes and Pollard (1989). MSM is consistent for a fixed number of draws. Simulated maximum likelihood (SML), introduced by Lerman and Manski (1981), needs the number of draws to grow with the sample (Gourieroux and Monfort, 1996). But efficient MSM requires optimal instruments, which perform poorly when the preliminary estimate is inaccurate, and it requires the probabilities of all possible reports. With many reported outcomes this is expensive. In preliminary tests the two estimators gave similar parameters, and MSM took 10 to 20 times longer, so Gentzkow uses SML (p. 732).

Importance sampling. Draws from the unconditional distribution of ν waste effort on values that make the observed report unlikely. Gentzkow instead draws from the distribution of ν conditional on the observed report, computed at a preliminary estimate $\tilde{\theta}$ (p. 732, n. 31). The logic is clearest when the draws are standardized shocks $\eta \sim N(0, I)$ with density ϕ, and $\nu = C(\theta)\eta$. (In this subsection η and ϕ denote these shocks and their density, not the CES elasticity of Section 10.2.7.) Write $P_i(\eta; \theta) \equiv P_{q_i}(x_i, C(\theta)\eta; \theta)$ for the probability of i's report given the shocks. Let $\bar{P}_i(\tilde{\theta}) = \int P_i(\eta; \tilde{\theta})\phi(\eta)\, \mathrm{d}\eta$, computed once with many draws. The importance density is

$$h_i(\eta) = \frac{P_i(\eta; \tilde{\theta})\, \phi(\eta)}{\bar{P}_i(\tilde{\theta})},$$

which is the posterior density of η given the report. The weighted simulator

$$\tilde{P}_i(\theta) = \frac{1}{S}\sum_{s=1}^{S} P_i(\eta_s; \theta)\, W_{is}, \qquad W_{is} = \frac{\bar{P}_i(\tilde{\theta})}{P_i(\eta_s; \tilde{\theta})}, \qquad \eta_s \sim h_i,$$

is unbiased for every θ:

$$\mathbb{E}_h\big[P_i(\eta;\theta)\,W_i\big] = \int P_i(\eta;\theta)\,\frac{\bar{P}_i(\tilde{\theta})}{P_i(\eta;\tilde{\theta})}\,\frac{P_i(\eta;\tilde{\theta})\,\phi(\eta)}{\bar{P}_i(\tilde{\theta})}\,\mathrm{d}\eta = \int P_i(\eta;\theta)\,\phi(\eta)\,\mathrm{d}\eta.$$

Draws from h_i are taken by acceptance and rejection, since h_i is the distribution of the shocks conditional on the observed report. *Acceptance and rejection* draws η from ϕ and keeps each draw with probability proportional to $P_i(\eta;\tilde{\theta})$, so the kept draws follow h_i. Gentzkow writes the same simulator in terms of ν (his eqs. 13–14). The general treatment of importance sampling is in Section 8.3.4.

Bias correction. SML is biased in finite samples because the logarithm is concave (p. 732, n. 32). Let $\tilde{f}$ be an unbiased simulator of a choice probability f, so $\mathbb{E}\tilde{f} = f$. A second-order expansion of $\ln\tilde{f}$ around f gives

$$\ln\tilde{f} = \ln f + \frac{\tilde{f}-f}{f} - \frac{(\tilde{f}-f)^2}{2f^2} + O\big(|\tilde{f}-f|^3\big),$$
$$\mathbb{E}\ln\tilde{f} \approx \ln f - \frac{1}{2}\,\frac{\mathbb{E}(\tilde{f}-f)^2}{f^2} = \ln f - \frac{1}{2}\,\frac{\mathrm{Var}(\tilde{f})}{f^2}.$$

The expected simulated log-likelihood is too low by about half the squared coefficient of variation of the simulator. If $\tilde{f} = \frac{1}{S}\sum_s P_{is}$ averages S independent draws, then $\mathrm{Var}(\tilde{f}) = \frac{1}{S}\mathrm{Var}(P_{is})$, which can be estimated by $\frac{1}{S^2}\sum_s (P_{is}-\tilde{f})^2$. The corrected objective adds this estimate back:

$$\hat{\theta} = \arg\max_{\theta} \sum_i \left\{ \ln\tilde{f}_i + \frac{1}{2}\,\frac{\frac{1}{S^2}\sum_s \big(P_{is}-\tilde{f}_i\big)^2}{\tilde{f}_i^2} \right\}. \tag{10.128}$$

The correction removes the bias of order $\frac{1}{S}$ (Gourieroux and Monfort, 1996, p. 45).[21] The robust standard errors follow McFadden and Train (2000). For welfare and other derived statistics, Gentzkow draws 100 parameter vectors from the estimated asymptotic distribution, recomputes the statistic at each, and reports the standard deviation (p. 733). This avoids the delta method, which linearizes highly nonlinear functions.

10.10.8 The price coefficient from the supply side

Demand data identify only $\bar{\delta}_j = \delta_j - \alpha p_j$. To express utility in dollars, Gentzkow backs out α from the condition that the *Post* sets its print price optimally (pp. 730–731 and 735–736). The idea is that the less price-sensitive consumers are, the higher the price a profit-maximizing firm would set (p. 715).

Profit. The *Post* sells copies at price p, and each copy is read by κ adults. The firm earns advertising revenue a_p per print reader and a_w per online reader, pays marginal cost c_p per printed copy, and bears a fixed cost. With N_p print readers and N_w online readers, the profit of the Washington Post Company is (p. 731, eq. 5)

$$\Pi = \left[a_p + \frac{p-c_p}{\kappa}\right]N_p + a_w N_w - F^{\text{fix}}. \tag{10.129}$$

[21] The version of (10.128) printed in Gentzkow's footnote 32 does not show the factor $\frac{1}{S^2}$ in the correction term. We state the expression that follows from the expansion.

The marginal cost of an extra online reader is taken to be zero, and advertising revenue per reader is constant. The second assumption treats both advertising markets as competitive at a fixed price per reader. It abstracts from the different values of different readers and from any market power of the *Post* (p. 735). Since κ readers share each copy, Gentzkow assumes that each reader pays $\frac{p}{\kappa}$ and that this reader price enters the utility (10.122) (p. 731).

Inputs. Every input comes from industry data (pp. 735–736).

- Print advertising revenue was \$574.3 million in 2001 and \$555.7 million in 2002. The daily edition's share gives \$1.5 and \$1.4 million per day, and with daily circulation of 771,614 and 768,600 the average is $a_p = \$1.91$.
- Online division revenue was \$30.4 million in 2001 and \$35.9 million in 2002. The post.com had 450,457 daily readers in the DMA, about 75 percent of its total. Dividing 75 percent of revenue by DMA readership gives $a_w = \$0.15$. A second estimate from the advertising revenue and readership of nytimes.com gives \$0.16, which Gentzkow uses.
- Newsprint consumption of 226,796 metric tons at \$541 per ton implies \$0.37 per copy. With ink and distribution, $c_p = \$0.40$.
- The cover price rose from \$0.25 to \$0.35 over the period, and the subscription price per daily copy was \$0.22 to \$0.25. Gentzkow uses $p = \$0.30$.
- Comparing survey readership with audited circulation gives $\kappa = 2.4$ readers per copy (2.3 for the *Times*). Whether κ reflects shared copies or overreporting does not change the welfare results (p. 731, n. 28).

The profit from one more print reader is \$0.75, and from one more online reader \$0.16 (p. 736).[22]

The first-order condition. Write the expected numbers of print and online readers as functions $N_p(\bar{\delta};\hat{\theta})$ and $N_w(\bar{\delta};\hat{\theta})$ of the vector of constants $\bar{\delta}$ and the other estimated parameters $\hat{\theta}$. These and their derivatives are computed by simulation. Let m_p denote the profit per print reader. Using $\frac{\partial \bar{\delta}_j}{\partial p_j} = -\alpha$ as Gentzkow does, the derivative of (10.129) with respect to the print price is (p. 736)

$$\frac{\partial \Pi}{\partial p} = -\alpha\left[m_p \frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}} + a_w \frac{\partial N_w}{\partial \bar{\delta}_{\text{post}}}\right] + \frac{1}{\kappa} N_p = 0. \tag{10.130}$$

Everything except α is known. Solving,

$$\hat{\alpha} = \frac{N_p}{\kappa\left[m_p \frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}} + a_w \frac{\partial N_w}{\partial \bar{\delta}_{\text{post}}}\right]}, \tag{10.131}$$

which is unique whenever the bracket is nonzero. Gentzkow obtains $\hat{\alpha} = 9.72$ (p. 736). As in Gentzkow's equation, α here is the coefficient on the copy price p. If utility depends instead on the reader price $\frac{p}{\kappa}$, the coefficient on that price is $\kappa\alpha$. Utils then convert into dollars at that rate (Gentzkow, 2007, n. 28). The elasticity (10.132) below is the same under either convention.

The condition has a transparent economic reading. A higher $\bar{\delta}_{\text{post}}$ raises print readership, $\frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}} > 0$, and lowers online readership when the goods are substitutes. Define the diversion

[22] With the reported inputs, $\frac{a_p + p - c_p}{\kappa} = \frac{1.91 + 0.30 - 0.40}{2.4} = 0.754$, which reproduces the \$0.75 in the paper. The bracket of (10.129) as printed, $a_p + \frac{p - c_p}{\kappa}$, would give about \$1.87. The reported figure is therefore consistent with a_p measured per copy, which is how it is computed from circulation.

ratio $D = -\frac{\partial N_w}{\partial \bar{\delta}_{\text{post}}}\left(\frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}}\right)^{-1}$ and the price elasticity of print readership $\varepsilon_p = -\frac{\partial N_p}{\partial p}\frac{p}{N_p}$. Rearranging (10.130) gives

$$\varepsilon_p = \frac{\frac{p}{\kappa}}{m_p - a_w D}. \tag{10.132}$$

The price paid per reader, $\frac{p}{\kappa}$ = \$0.125, is far below the profit per reader, \$0.75, because each reader brings advertising revenue. The *Post* therefore prices where its demand is inelastic. By the chain rule, $\varepsilon_p = \alpha\, p\, \frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}}\frac{1}{N_p}$, and the estimated demand parameters fix the readership response $\frac{\partial N_p}{\partial \bar{\delta}_{\text{post}}}$ and N_p. With these and p held fixed, the elasticity is proportional to α, so a low elasticity requires a small α. A price change then moves utility little relative to the spread of the taste shocks. The paper reports an implied own-price elasticity of 0.37 and finds that it tracks the *Post*'s readership response to its price increases over 1994–2003 (p. 738, n. 38).[23] The strategy rests on strong assumptions. The print price must be optimal given the zero online price, the advertising model must be right, and the cost data must be accurate. Gentzkow shows in Table 10.38 that the qualitative results survive reasonable changes in p, c_p and a_w.

10.10.9 Results: demand parameters and substitution

Observables. Table 10.33 reproduces Table 5, the coefficients on consumer characteristics in the mean utility of each good (p. 733). Most coefficients for the *Post* and the post.com are significant, as are about half of those for the *Times*. Gentzkow reads them through marginal effects on the probability of reading each paper, for a consumer at the mean of the data. The *Post* fits its reputation as a high-brow, liberal paper. Attending college, attending graduate school and doubling household income raise the probability of reading the *Post* by 31, 34 and 9 percentage points. Being a registered Democrat raises it by 3 points, and being a registered Republican lowers it by 2. Ten more years of age add 8 points, while full-time employment lowers the probability by 14 points. The post.com's coefficients mostly share the *Post*'s signs, with smaller marginal effects because its predicted probability is lower (16 percent against 53). Age and employment are exceptions. Ten more years of age lower the probability of reading the post.com by 1 point, and full-time work, white-collar work and computer work raise it by 2, 1 and 3 points. The online edition is often read at work and draws younger readers (p. 734). Registered Republicans are 3 points more likely to read the *Times*, whose mean predicted probability is 9 percent (p. 734).

Interactions and shocks. Table 10.34 reproduces Table 6. Both print-online interactions are significantly negative: −1.285 (0.2307) for the *Post* and the post.com and −1.231 (0.4832) for the post.com and the *Times*. The *Post-Times* interaction is small, positive and insignificant. Gentzkow reads these signs as making the post.com a substitute for both print papers (p. 734). In the two-good model this reading would follow from Proposition 10.48. In the three-good model the signs only suggest it, as Section 10.10.6 explains. The support comes from the full model's cross-price derivatives below. A \$0.10 rise in the price of the *Post* adds 8,358 post.com readers (p. 737), and the same rise for the *Times* adds 2,781 (p. 738). The first agrees with the 2SLS regressions. The day shock is large and rare. On 4.5 percent of days the utility of every paper rises by about seven units, which suggests major news stories that raise the demand for

[23] Inserting the reported inputs into (10.132) gives an elasticity between 0.17 (at $D = 0$) and 0.21 (at $D = 1$). The paper does not show how its elasticity of 0.37 is computed, so we cannot locate the source of the gap.

Table 10.33: Gentzkow's estimates of the effects of consumer characteristics on utility

	Post	post.com	*Times*
Age (ten years)	0.661** (0.0407)	−0.545** (0.0628)	0.688** (0.122)
Female	−0.473** (0.0921)	−0.423** (0.148)	−3.20** (0.344)
High school	1.95** (0.214)	2.87** (0.633)	1.29 (0.856)
College	2.54** (0.237)	4.03** (0.654)	1.49 (0.928)
Graduate school	2.76** (0.252)	4.16** (0.670)	1.19 (0.964)
Computer job	−0.567* (0.223)	1.22** (0.323)	0.322 (0.682)
White-collar job	−0.447** (0.118)	0.431* (0.195)	−0.591 (0.423)
Full-time	−1.13** (0.141)	0.935** (0.227)	−0.044 (0.450)
Log income	0.709** (0.0729)	0.217 (0.118)	0.934** (0.260)

Republican	−0.193 (0.119)	−0.0538 (0.193)	2.902** (0.408)
Constant	6.97** (0.852)	−1.54 (1.18)	−8.85** (1.91)
N	16,179	16,179	16,179

Source: Gentzkow (2007, Table 5), full model. Standard errors in parentheses. * significant at 5 percent, ** at 1 percent. The education categories are mutually exclusive, and so are the two occupation dummies. Democrat and Republican mark registered party members. The model also includes dummies for missing observations, the location of the respondent's residence, six-month time periods and having the print and online papers in the choice set, not reported.

news overall (p. 734). The four excluded variables all raise the utility of the post.com, and two of them significantly.

Table 10.34: Gentzkow's estimates of interactions, news-day shocks and excluded variables

Interaction terms Γ_r		*Excluded variables (post.com utility)*	
Post and post.com	−1.285** (0.2307)	Internet at work	1.357** (0.180)
Post and *Times*	0.0809 (0.2479)	Fast connection	0.146 (0.193)
post.com and *Times*	−1.231** (0.4832)	Use for education	0.361 (0.212)
News-day shock		Use for work	0.582** (0.222)
Size $\hat{\tau}$	6.846** (0.5027)		
Probability ω	0.0454** (0.0179)		

Source: Gentzkow (2007, Table 6), where the shock parameters are called τ and γ. Standard errors in parentheses. ** significant at 1 percent. The model also includes a third-order interaction for the bundle of all three papers, not reported. Fast connection means DSL, cable modem or T1 at home. N = 16,179.

Variance shares. Table 10.35 reproduces Table 7, which compares the variances of the utility components. Three facts stand out (p. 735). The random effects ν_i have large variances relative to the observables, so unobserved heterogeneity matters. The day shocks contribute a variance of 2.03, consistent with a two-point distribution, $\hat{\tau}^2\omega(1-\omega) = 6.846^2 \times 0.0454 \times 0.9546 \approx 2.03$. The logit errors have variance 1.64, the type-I extreme value variance $\frac{\pi^2}{6} \approx 1.645$ that fixes the scale of utility. Against random-effect variances of 11.0, 23.5 and 86.1, the logit errors play a small role. The concern of Section 10.7 and of Petrin's Table 8 is therefore limited here, as Gentzkow notes with reference to Petrin (2002) (p. 729, n. 22). The unobserved correlation between the *Post* and the *Times* is negative. Tastes for political coverage, on which Washington readers are divided, may explain it, or the lack of excluded variables separating the two print papers may bias it (p. 735).

Table 10.35: Variances and covariances of the components of utility

Observable utility $x_i\beta_j$				*Random effects* ν_i			
	Post	post.com	*Times*		*Post*	post.com	*Times*
Post	14.0			*Post*	11.0		
post.com	7.95	8.43		post.com	4.14	23.5	
Times	7.66	4.85	10.2	*Times*	−1.17	5.19	86.1
Variance of the day shock τ_{it}: 2.03.				Variance of the logit error ϵ_{irt}: 1.64.			

Source: Gentzkow (2007, Table 7). Covariances of the components of utility at the estimated parameters. The left block is the sample covariance of the fitted observable utilities.

The model fits well (p. 735). Simulated aggregate shares match the data with a mean squared error of 0.0016. On average, consumers who made a given choice have a predicted probability of that choice 2.1 times as high as consumers who did not.

Substitution patterns. Table 10.36 reproduces Table 8, the paper's key table. It reports three measures of the relation between the *Post* and the post.com. The first is the change in post.com readership when the *Post*'s price rises by $0.10. The second is the change in *Post* readership when the post.com is added to the choice set, and the third is the corresponding change in print profits.

Table 10.36: Impact of the online edition on demand for the print *Post*

	Full model (case 1)	Observables only (case 2)	No heterogeneity (case 3)
Cross-price derivative (readers)	8,358	−8,421	−16,143
	(1,436)	(752)	(702)
Change in print readership (readers)	−26,822	25,655	51,897
	(4,483)	(2,270)	(2,254)
Change in print profits ($ per year)	−5,466,846	5,229,009	10,577,720
	(913,699)	(462,771)	(459,464)

Source: Gentzkow (2007, Table 8). Standard errors in parentheses. The cross-price derivative is the change in post.com readership when the *Post*'s price rises by $0.10. The changes in print readership and print profits are the total changes for the *Post* when the post.com is added to the choice set. Case 2 has observable consumer characteristics but no unobservables other than the logit errors. Case 3 has no observable or unobservable heterogeneity except the logit errors.

Two conclusions follow (p. 737). First, the print and online papers are significant substitutes. A $0.10 rise in the *Post*'s price, about 33 percent, raises post.com readership by 8,358, about 2 percent. The post.com reduces *Post* readership by about 27,000 a day, about 1.5 percent, and print profits by about $5.5 million a year (p. 715). The effects are precise but moderate. They are far from one-for-one crowding out. Removing the post.com returns about 27,000 readers to the *Post*, roughly 7 percent of the 406,000 daily post.com readers. The linear probability model's magnitude, which refers to five-day readership, was far larger, a reminder of Gentzkow's caution about that model.

Second, accounting for heterogeneity reverses the answer. A model with observables but no correlated unobservables finds complements, with a cross-price derivative of the same size and opposite sign, and a $5.2 million gain in print profits. A model with no heterogeneity finds stronger complementarity, a $10.6 million gain. Correlated tastes for news masquerade as complementarity unless the model allows for them. The relationships with the *Times* are

weaker (p. 738). The post.com and the *Times* are significant substitutes, and a $0.10 rise in the *Times*'s price would add 2,781 post.com readers. The *Post*-*Times* cross derivative is negative, close to zero and insignificant, so the two print papers are essentially independent.

10.10.10 Results: welfare and online pricing

Consumer surplus. Let $\hat{u}_{ir}(\nu, \tau)$ be the utility of bundle r excluding ϵ_{irt}, $\mathcal{R}$ the set of all bundles and $\mathcal{R}^{-j}$ the bundles without good j. The expected gain of consumer i from adding good j is (p. 738, eq. 8)

$$\Delta_i^j = \mathbb{E}_{\nu,\tau,\epsilon}\left[\max_{r\in\mathcal{R}} \hat{u}_{ir}(\nu,\tau) + \epsilon_{irt}\right] - \mathbb{E}_{\nu,\tau,\epsilon}\left[\max_{r\in\mathcal{R}^{-j}} \hat{u}_{ir}(\nu,\tau) + \epsilon_{irt}\right]. \tag{10.133}$$

The expectation takes the econometrician's view given the data. The random effect ν is constant over time, so the observed choice is informative about it, and the expectation over ν conditions on that choice. The shocks τ and ϵ are i.i.d. over days, so their expectations are unconditional. The log-sum formula of Lemma 10.36 gives

$$\mathbb{E}_{\nu,\tau,\epsilon}\left[\max_{r\in\mathcal{R}} \hat{u}_{ir} + \epsilon_{irt}\right] = \mathbb{E}_{\nu,\tau}\left[\ln \sum_{r\in\mathcal{R}} e^{\hat{u}_{ir}(\nu,\tau)}\right] + \gamma_E, \tag{10.134}$$

where the constant cancels in (10.133). Gentzkow simulates the remaining expectation with unconditional draws ν_s reweighted by their posterior probability given the observed choice r_i (pp. 738–739, eqs. 10–11):

$$\begin{aligned} \mathbb{E}_{\nu,\tau}\left[\ln \sum_{r\in\mathcal{R}} e^{\hat{u}_{ir}}\right] &\approx \sum_{s=1}^{S}\left[\varpi \ln \sum_{r\in\mathcal{R}} e^{\hat{u}_{ir}(\nu_s,\hat{\tau})} + (1-\varpi)\ln \sum_{r\in\mathcal{R}} e^{\hat{u}_{ir}(\nu_s,0)}\right] R(\nu_s \mid r_i), \\ R(\nu_s \mid r_i) &= \frac{Q_{ir_i}(\nu_s)}{\sum_{s'=1}^{S} Q_{ir_i}(\nu_{s'})}. \end{aligned} \tag{10.135}$$

We normalize the weights to sum to one. Gentzkow writes the posterior as the ratio of $Q_{ir_i}(p, \nu_s) f(\nu_s)$ to a simulated unconditional probability. Dividing by the price coefficient converts utils into dollars, and summing over consumers gives the change in consumer surplus (eq. 12):

$$\Delta CS(j) = \sum_i \frac{1}{\alpha} \Delta_i^j. \tag{10.136}$$

This is the log-sum measure of Section 10.7, extended from products to bundles.

Gentzkow lists the caveats himself (p. 739). Prices do not vary over a wide range, so the dollar values rest on quasi-linearity, which converts utils into dollars at a constant rate. The scale of utility is fixed by the logit error, and other error distributions could give different answers. The analysis ignores post.com readers outside the DMA. The model also holds the prices and characteristics of other products fixed. If competing papers improved their quality in response to the post.com, consumer gains are understated.

Table 10.37 combines Tables 9 and 11. The average post.com reader values the paper at $0.30 a day, 70.4 percent of the average print reader's surplus from the *Post*. The total consumer gain is $123,413 per day, or $45.0 million per year (standard error $6.6 million), which is 16.0 percent of the total surplus from the print *Post*. The ratios to print surplus do not depend on α, which makes them more robust than the dollar values.

Table 10.37: Consumer and producer surplus from the post.com

A. Consumer surplus (Table 9)	
Per post.com reader, as % of per-reader print surplus	70.4%
Per post.com reader, $ per day	0.30
Total, as % of total print surplus	16.0%
Total, $ per day	123,413
Total, $ per year	45,045,862
Standard error	(6,606,939)
B. Producer surplus before post.com operating costs, $ per year (Table 11)	
Δ *Post* profit	−5,466,846
Δ *Times* profit	−2,687,348
Total post.com revenue	33,150,000
Δ Producer surplus	24,995,806
Standard error	(1,876,785)

Source: Gentzkow (2007, Tables 9 and 11). Panel A is the loss of consumer surplus if the post.com were removed. "Per reader" divides the total daily loss by the number of post.com readers. Panel B reports changes in firm profits from adding the post.com, and the advertising revenue of the post.com from readers inside and outside DC. In Panel B the producer surplus row equals the sum of the three rows above it.

Switching. Table 10 of the paper shows where post.com readers would go if it disappeared (p. 739). Of those who read both the post.com and the *Post*, 79.2 percent would read the *Post* alone, 17.2 percent would switch to the outside good, and 3.5 percent to other bundles. Of those who read only the post.com, 69.1 percent would switch to the outside good and 27.1 percent would start reading the *Post*. Some joint readers stop reading entirely because the logit errors make the interaction heterogeneous. For some consumers the goods are complements even though they are substitutes in aggregate (p. 739, n. 39).

Producer surplus. The post.com costs the *Post* about $5.5 million a year in lost print profits and the *Times* about $2.7 million, against $33.2 million of post.com revenue (p. 740). Producer surplus therefore rises by $25.0 million before the operating costs of the post.com. The Post does not report those costs. Costs of New York Times Digital were $63.5 million in 2001 and $67.7 million in 2002, which suggests an upper bound of $60 million. The Post's report of losses in its online division suggests a lower bound of $30 million. At the midpoint of $45 million, the post.com reduced producer surplus by about $20 million a year, which makes its introduction puzzling. Online revenues almost doubled between 2002 and 2004, however. With 2004 advertising revenue per reader, the gain to the Washington Post Company is about $56.5 million a year, or $11.5 million net of operating costs. Producer surplus then rises by about $9 million. The early losses may have been an investment in a growing advertising market.

Online pricing. The model can evaluate a price that was never charged (pp. 740–741). The estimate of α assumed only that the print price was optimal given the zero online price. Holding the print price and characteristics fixed, Gentzkow varies the online price and recomputes demand and profits. The profit-maximizing online price is $0.20 a day, about $6 a month. The loss from charging zero is about $9 million a year, more than a quarter of post.com advertising revenue. The computation accounts for the direct revenue, the lost advertising revenue and the readers who return to print. The $6 estimate is close to the online prices charged by the few papers that charged in 2003, $6.95 for the *Wall Street Journal* and $3.75 for the *Tulsa World*.

A second approach asks what transaction cost would make the zero price optimal. Suppose the post.com's constant is

$$\bar{\delta}_{\text{post.com}} = \delta_{\text{post.com}} - \alpha p_{\text{post.com}} - \alpha\chi\,\mathbf{1}\{p_{\text{post.com}} > 0\},$$

where χ is the dollar value of a real or perceived cost of paying online. Examples are the hassle of entering a card number and a sense that charging is unfair. With $\hat{\alpha}$ fixed, a zero price maximizes total profits whenever $\chi \geq \$0.13$ per day (p. 741).[24] With the 2004 advertising market the optimal price falls to \$0.09, the loss from a zero price to \$1.7 million, and the threshold to \$0.02. The zero price may have been part of a rational forward-looking strategy.

10.10.11 Robustness*

Table 10.38 reproduces Table 12 (pp. 741–742). The first two experiments recompute α from print prices of \$0.25 and \$0.35, the prices before and after the 2002 increase. The next two vary the marginal cost of a copy between \$0.30 and \$0.50, which moves the optimal online price by \$0.04 and consumer surplus by about \$5 million. A lower post.com revenue of \$25 million, which allows for the other ventures of the online division, cuts the Post Company surplus by about a third but leaves consumer surplus unchanged. Dropping the broadband exclusion changes little. Treating the *Times* as part of the outside good leaves the *Post*-post.com interaction unchanged, as the outside-option argument of Section 10.10.3 predicts.

Table 10.38: Robustness of Gentzkow's main estimates

	Post Company surplus (\$m)	Cross-price derivative	Optimal price of post.com (\$)	Consumer surplus per year (\$m)
Actual estimates	27.68	8,358	0.20	45.05
Price = \$0.25	27.83	8,598	0.19	43.79
Price = \$0.35	27.53	8,131	0.21	46.31
Marginal cost = \$0.30	27.38	7,916	0.22	47.56
Marginal cost = \$0.50	27.99	8,853	0.18	42.53
Online revenue = \$25m	19.53	8,342	0.24	45.13
Omit broadband variable	27.19	9,277	0.21	45.12
Only *Post* and post.com	31.52	8,683	0.22	47.15

Source: Gentzkow (2007, Table 12). "Post Company surplus" is post.com revenue less the lost *Post* print profits (\$33.15 million less \$5.47 million in the actual estimates). The last row includes the *Times* in the outside good.

10.10.12 Interpretation, limitations and contribution

The paper's contribution is a tractable bundle model in which the data choose between substitutes and complements. Its analysis of identification shows why the choice is hard. Joint

[24] Gentzkow's equation subtracts the cost from utility without the factor α, while his thresholds are in dollars. We include the factor so that χ is in dollars throughout. The dollar reading is the consistent one. A price of $\$0.20 - \chi$ leaves every reader's utility as at a price of \$0.20 without the cost. Its profit is therefore the profit at \$0.20 without the cost, less χ a day per post.com reader. The post.com has fewer readers at \$0.20 than at a zero price. So a zero price can be optimal only if χ is at least the daily loss from a zero price divided by the readership at a zero price. Gentzkow scales the 406,000 area readers up to total readership, using an estimate that about 25 percent of readers are outside the area (p. 731, n. 30). This gives about $\frac{406{,}000}{0.75} \approx 541{,}000$ readers and a bound of $\frac{9{,}000{,}000}{365\times 541{,}000} = \$0.046$ a day (our computation). A utility penalty of 0.13 is worth only $\frac{0.13}{9.72} = \$0.013$.

consumption is equally consistent with complementarity and with correlated tastes, and only excluded shifters or repeated choices separate them. The application shows the stakes. Raw correlations, OLS and models without unobserved heterogeneity all point to complementarity worth up to $10.6 million a year to the print *Post*. The full model finds substitution that costs it $5.5 million.

The limitations follow from the data. There is no usable price variation, so the price coefficient comes from a stylized supply side, and dollar values scale with $\frac{1}{\hat{\alpha}}$. The excluded variables shift only the online paper, so print-print substitution is weakly identified. The welfare measures are local. They hold the prices and characteristics of other news sources fixed and ignore advertisers and readers outside Washington. The model is static, although the zero online price may be part of a dynamic strategy, as Gentzkow's 2004 calculation suggests. The advertising market is reduced to a fixed price per reader.

The paper also completes an argument of this chapter. Characteristics models with single-unit choice can value goods that are new combinations of known characteristics, but they cannot represent complementarity (Section 10.7). Whether a single-unit model is acceptable depends on the market. It suits durables bought one at a time, such as cars. It fails for goods that households consume together, such as newspapers, music or groceries. In those markets a model like Gentzkow's is needed before any welfare number can be trusted.

Table 10.39: Identification and counterfactual map of Gentzkow (2007)

Observed data	A survey of 16,179 adults in the Washington area, 2000–2003, with 24-hour and five-day readership of the *Post*, the *Times* and the post.com, and their demographics.
Latent objects	Consumer random effects ν_i that are constant over the survey week, news-day shocks τ_{it}, and bundle-specific shocks.
Estimated parameters	Mean utilities, bundle interaction terms Γ_r, the covariance of the random effects, the news-day shock, coefficients on demographics and on four excluded variables, and the price coefficient α.
Identifying variation	Variables that shift only the online paper and repeated choices within the survey week separate complementarity from correlated tastes. The *Post*'s print pricing condition gives α.
Maintained assumptions	Quasi-linear utility, the exclusion of the four variables from print utilities, and an optimal print price with a fixed advertising price per reader.
Counterfactual and what it holds fixed	Removal of the post.com, and positive online prices. The prices and characteristics of other news sources, and the print price, are held fixed.
Conclusion	The post.com adds about $45.0 million a year to consumer surplus. It substitutes for the print *Post* and costs it about $5.5 million a year in print profits. Models without unobserved heterogeneity find complementarity instead.
One limitation	Prices do not vary, so every dollar value scales with $\frac{1}{\hat{\alpha}}$ from a stylized supply side.
Source and our additions	The tables are Gentzkow's. The exact statement and proof of Proposition 10.48 are ours.
Tools in the appendices	Sections A.6, A.7 and B.5.

10.11 Synthesis: what determines a measured value

The four studies of this chapter value very different goods with very different data. Their answers nevertheless depend on the same few modeling choices. A common formula makes the dependence explicit. In a random utility model with quasi-linear income, the gain from moving from choice set $\mathcal{R}^0$ at prices p^0 to choice set $\mathcal{R}^1$ at prices p^1 is

$$\Delta CS = \frac{1}{\alpha} \int \left\{ \mathbb{E}_\epsilon \left[\max_{r \in \mathcal{R}^1} u_{ir}(p^1) \right] - \mathbb{E}_\epsilon \left[\max_{r \in \mathcal{R}^0} u_{ir}(p^0) \right] \right\} \mathrm{d}P(i). \tag{10.137}$$

Here $\mathcal{R}$ is a set of products, or of bundles in Gentzkow's model. Adding and subtracting the expected maximum over $\mathcal{R}^0$ at the new prices p^1 splits (10.137) into two parts:

$$\begin{aligned} \Delta CS = & \underbrace{\frac{1}{\alpha} \int \left\{ \mathbb{E}\left[\max_{\mathcal{R}^1} u_{ir}(p^1) \right] - \mathbb{E}\left[\max_{\mathcal{R}^0} u_{ir}(p^1) \right] \right\} \mathrm{d}P(i)}_{\text{variety effect at new prices}} \\ & + \underbrace{\frac{1}{\alpha} \int \left\{ \mathbb{E}\left[\max_{\mathcal{R}^0} u_{ir}(p^1) \right] - \mathbb{E}\left[\max_{\mathcal{R}^0} u_{ir}(p^0) \right] \right\} \mathrm{d}P(i)}_{\text{price effect on existing goods}}. \end{aligned} \tag{10.138}$$

This is the decomposition (10.29) in random utility form. Hausman's product-space measure is the Hicksian area of Proposition 10.7, which plays the role of the first term. Each determinant of the measured value enters (10.138) at a definite place. The scale is $\frac{1}{\alpha}$. The expected maximum must be extrapolated beyond the observed prices, and it contains the logit errors. The price changes form the second term. The structure of the choice set $\mathcal{R}$ decides whether goods can complement one another.

10.11.1 Four studies side by side

Table 10.40 compares the four studies along these dimensions. The headline numbers are not comparable across rows of the table. They measure different goods, periods and objects, and we report each as its author states it.

10.11.2 Five determinants of the measured value

Value lives beyond the observed prices. The value of a new good is an area under the demand curve between the observed price and the virtual price, a range in which no data exist. Functional form therefore matters. A linear demand and a constant-elasticity demand through the same point give different surplus, and only convexity yields the robust lower bound of Proposition 10.21. Hausman's AIDS estimate and his CES estimate differ by a factor of about three (Section 10.5). The CES and logit forms make the gain depend only on the new good's share and one parameter (Propositions 10.17 and 10.37). In those forms the value of variety is built into the functional form. Gentzkow's dollar values rest on quasi-linearity, which converts utils into dollars at a constant rate well beyond the observed prices.

Idiosyncratic tastes create value mechanically. Models with an i.i.d. logit error give every product, even a clone, a positive value (Proposition 10.40). Proposition 10.45 sharpens the point. In a logit model the buyers of a small-share product gain about $\frac{1}{\alpha}$ each, and the gain is attributed to

Table 10.40: Four valuations of new goods compared

	Hausman (1997)	Trajtenberg (1989)	Petrin (2002)	Gentzkow (2007)
New good	Apple-Cinnamon Cheerios, U.S., 1990–92	CT scanners, U.S., 1973–82	Minivan, U.S., 1981–93 (welfare 1984–88)	Online *Washington Post*, DC, 2000–03
Data	City-week scanner prices and quantities (959 observations)	All scanner models, prices and characteristics, with over 2,000 installations	2,407 nameplate-years plus CEX averages for buyers	Survey of 16,179 adults, 24-hour and 5-day readership
Demand model	Three-level budgeting in product space: AIDS for brands within segments, log-log demand for segments and for total cereal	Multinomial and nested logit with hedonic residual price	Random coefficients logit with income effects and demographics	Logit over bundles with correlated normal random effects
Source of price sensitivity	Prices of the same brand in other cities (Hausman instruments)	Head-scanner price coefficients, to net out quality signalling	Characteristics-based instruments plus micro moments	The *Post*'s print pricing condition
What governs the extrapolation	AIDS curvature up to the virtual price	Logit form, including the entropy term	Random coefficients plus logit error	Interaction terms Γ_r and quasi-linearity
Competition	Multiproduct firm re-prices. Rivals' prices fixed	Not modeled (consumer surplus only)	Full Bertrand-Nash re-solution	Firm profits at fixed prices. Online-price counterfactual
Headline number	Consumer surplus about \$78.1 million a year, \$66.8 million net of price effects. Cereal CPI too high by about 25 percent	Social rate of return to CT research and development about 270 percent	Compensating variation \$2,804.55 million and welfare \$2,910.09 million over 1984–88	Consumer surplus \$45.0 million a year. Producer surplus \$25.0 million before operating costs
Main critique	Validity of the instruments. Rivals' responses ignored	No price instruments. Positive price coefficients. Representative buyer	Share of the logit error. Functional forms. Static, with fixed characteristics	No price variation. Supply-side α. Weak print-print identification

Sources: Sections 10.5, 10.6 and 10.8 to 10.10. Hausman's numbers are from pp. 228 and 234 of his chapter. Trajtenberg's rate of return is from the working-paper version (Trajtenberg, 1985, p. 73). Petrin's are from his Table 13 and Gentzkow's from his Tables 9 and 11.

large logit draws. Petrin's Table 8 shows the size of the effect. The logit component of a minivan buyer's compensation falls from $95,121 under the OLS logit to $396 once random coefficients and micro moments carry the heterogeneity. Trajtenberg's entropy term is the same object in a representative-consumer form (Proposition 10.41). Gentzkow's variance decomposition is the matching diagnostic. A small logit share of the variance of utility, as in his Table 7, signals that this mechanism is not driving the answer.

Price sensitivity scales everything. Every term of (10.138) is divided by α. An estimate of α that is too small, so that demand looks too steep, inflates the value one for one. Bresnahan's critique of Hausman's instruments is an argument of this kind (Proposition 10.32). In Petrin's data, instrumenting almost doubles the logit price coefficient and almost halves the mean compensation of minivan buyers. Trajtenberg's positive price coefficients for body scanners and Gentzkow's supply-side α show that each study had to bring in outside information to fix this scale.

Competition can deliver a large share of the gain. The second term of (10.138) is the gain to buyers of existing goods whose prices fall. Petrin finds that it delivered about 43 percent of consumer gains in 1984. The term combines the Competition cell of Table 10.2 with the price-discrimination cell. Proposition 10.27 signs the competition part in a symmetric logit market. With random coefficients, however, some prices rise on entry (Table 10.25), and the innovator raises the prices of its own substitutes through the diversion term of (10.110). Hausman's analysis lets the innovator re-price its own brands but holds rivals' prices fixed. Gentzkow's welfare calculation holds all other prices fixed. Both therefore omit most of this term.

New goods may complement old ones. Single-unit models force every new good to substitute for existing goods. Gentzkow's bundle model lets the data decide. With two goods the interaction term alone signs the cross-price effect (Proposition 10.48). With more goods the full model's cross-price derivatives must be computed. The model also shows that correlated tastes can masquerade as complementarity. The sign of the post.com's effect on print profits reverses once unobserved heterogeneity is allowed (Table 10.36). Any valuation of a good that is consumed alongside existing goods must decide this question before it can measure the variety effect.

10.11.3 Implications for price indexes and policy

These lessons bear on price measurement. A matched-model price index links a new good in only after its introduction, so it records none of the variety effect (Section 10.2). The report of the commission chaired by Michael Boskin argued that the slow incorporation of new goods was one source of upward bias in the U.S. consumer price index (Boskin et al., 1996). Corrections based on the CES index of Feenstra (1994) are attractive because they need only expenditure shares and one elasticity. The first two lessons show what that convenience costs. The correction inherits the CES functional form, in which the value of variety is fixed by the share of the new good. Estimated demand systems can relax these restrictions, but then the answer depends on the instruments and on the treatment of heterogeneity and competition.

The same machinery serves competition policy. Petrin's counterfactual solves the Bertrand-Nash equilibrium without a set of products. A merger simulation solves it with a different ownership matrix (Chapter 11). Both require a demand system whose substitution patterns are credible, and both usually hold product characteristics fixed. Firms reposition products after entry and after mergers, and the welfare effects of new goods depend on such responses

as much as on prices. The next generation of studies, in this chapter's tradition, endogenizes those choices.

10.12 Bibliographic notes

The welfare analysis of new goods starts with Hicks (1940), who valued a good not yet available at the price that would just choke off its demand. Rothbarth (1941) introduced the closely related virtual prices. Neary and Roberts (1980) develop the theory of rationing on which Section 10.2 builds. Deaton and Muellbauer (1980b) give the textbook treatment of the restricted cost function, the cost-of-living index, exact consumer surplus, two-stage budgeting and hedonic quality measurement that this chapter uses. The cost-of-living index is due to Konüs (1939), and Pollak (1989) collects its theory. Diewert (1976) relates exact and superlative index numbers to flexible functional forms. Willig (1976) bounds the gap between Marshallian surplus and the exact measures. Hausman (1981) and Hausman and Newey (1995) recover the exact measures from estimated demand, the first parametrically and the second nonparametrically. Feenstra (1994) derived the CES variety correction from the index of Sato (1976) and Vartia (1976), and Broda and Weinstein (2006) used it to measure the gains from imported varieties.

The volume edited by Bresnahan and Gordon (1997) collects studies of new goods and price measurement, among them Hausman (1997) and the comment of Bresnahan (1997). Hausman (1999) applies the same approach to cellular telephones and the consumer price index. Hausman and Leonard (2002) study the competitive effects of a new product introduction with data that span the launch, the kind of evidence Bresnahan asked for. The report of Boskin et al. (1996) placed the new-goods bias at the center of the debate on the consumer price index. Nevo (2003) shows how to compute price indexes, including the effects of new products and quality change, from an estimated demand system in characteristics space. Pakes (2003) reconsiders hedonic price indexes and their relation to compensating variation, with an application to personal computers.

Valuation in characteristics space rests on the models of Lancaster (1966, 1971) and McFadden (1981) and on the welfare measure of Small and Rosen (1981). Trajtenberg (1989) first applied it to product innovation. Pakes et al. (1993) discuss price indexes in the random coefficients framework, and Berry et al. (2004a) add micro and second-choice data. Petrin (2002) and Goolsbee and Petrin (2004) measure the gains from new products together with their effects on the prices of existing ones. Concern about the idiosyncratic logit taste led to the pure characteristics model of Berry and Pakes (2007), which Song (2007) applies to computer processors. It also led to the crowding correction of Ackerberg and Rysman (2005) and to the hedonic approach of Bajari and Benkard (2005).

Complementarity between new and old goods enters through the bundle model of Gentzkow (2007). Earlier models of multiple purchases include the bundle logit of Manski and Sherman (1980) and Train et al. (1987) and the multiple-discrete choice model of Hendel (1999). Whether markets supply too many or too few products is an old question of Spence (1976) and Mankiw and Whinston (1986). The survey of Eaton and Lipsey (1989) concludes that theory cannot sign the bias, which is why the measurement methods of this chapter matter.

10.13 Exercises

1. Let the Marshallian demand for a new good be $q = a + bp + cy$, with $b < 0$ and $c > 0$, and let the other prices be fixed.

(a) Derive the expenditure function as in Example 10.20. Show that the Hicksian virtual price at the period-1 utility satisfies $p^V - p^1 = -\frac{1}{c}\ln\left(1 + \frac{cq^1}{b}\right)$.

(b) Take $p^1 = 2$, $y = 50$, $q^1 = 3$, $b = -1.5$ and $c = 0.03$. Compute a, the Slutsky term, the Marshallian choke price, the Hicksian virtual price, the Marshallian surplus and the compensating variation.

(c) Compare the proportional gap between the compensating variation and the Marshallian surplus with the approximation of Willig (1976) in Remark 10.9, evaluated at the observed income elasticity. Explain the difference.

(d) Invert the compensated demand curve at the period-1 utility to obtain the shadow price $\tilde{p}_n(p_{-n}, u^1, z)$ of Lemma 10.5. Compute the compensating variation from Corollary 10.8 and confirm that it equals your answer in (b).

2. Apple-Cinnamon Cheerios had about 1.6 percent of cereal spending, a price of \$3.48 per pound and an estimated virtual price of \$7.14 (Section 10.5). Treat cereal as the whole budget and hold the other prices fixed.

(a) Compute the Laspeyres and Paasche indexes of Proposition 10.11. Compute the exact index implied by a linear compensated demand curve between the observed point and the virtual price.

(b) Hausman's exact surplus is about 43 percent of the Paasche rectangle (Section 10.5.7). What does Corollary 10.12 then imply about the shape of the compensated demand curve over the extrapolated range?

(c) Apply the tangent bound of Proposition 10.21 with the conditional own elasticity of -2.117 in Table 10.7. Compare the result with Hausman's bounds of \$5.55 to \$5.94 and give two reasons for the gap.

(d) Hausman concludes that the cereal price index is about 25 percent too high, extrapolating from this brand to all brands introduced over ten years. Which of your measures in (a) does his rule of thumb correspond to? How would the conclusion change under the other measures?

3. This exercise connects the CES and logit valuations.

(a) Prove Corollary 10.18 directly from the CES unit expenditure function (10.17), without using Proposition 10.17.

(b) Compute $\frac{CV}{y}$ and $\frac{EV}{y}$ for a new variety with a 6.19 percent share of group spending, for $\eta = 2.13$ and $\eta = 2.38$. Which feature of the formula makes the answer independent of how close the new variety is to particular old ones?

(c) In the representative-consumer model of Remark 10.19, each consumer spends all income on one variety. Use the expected maximum utility to derive the equivalent variation of adding variety n. Show that it equals the CES formula of Corollary 10.18 with w_n equal to the choice probability s_n.

(d) A logit market without an outside good has two products with $V_1 = 1$ and $V_2 = 0$. A clone of product 1 enters. Compute the gain in the log-sum, and split it into the change in $\sum_j s_j V_j$ and the change in entropy using Proposition 10.41. Explain why the first term changes even though the clone offers nothing new.

4. Consider the nested logit of Proposition 10.38.

(a) Derive (10.64) from the inclusive values, step by step.

(b) Let the post-introduction shares be $s_g = 0.4$ and $s_{n|g} = 0.2$. Compute the gain in units of $\frac{1}{\alpha}$ for $\sigma \in \{0, 0.5, 0.9\}$, and compare each value with the logit formula $-\frac{1}{\alpha}\ln(1 - s_n)$ at the same s_n.

(c) Find the value of σ at which the nested-logit gain is half the logit gain.

(d) Relate your answers to the slope of the single-product demand curve dd in Figure 10.5.

5. Return to the model of Proposition 10.32.

(a) Reproduce the probability limits (10.53).

(b) Linear demand through the observed point (p, q) with estimated slope $-\hat{b}$ implies the virtual price $p + \frac{q}{\hat{b}}$. Derive its probability limit when the Hausman instrument is used. For which values of λ is it below the observed price, and what does that mean?

(c) Suppose the instrument is the average price in $L \geq 1$ other cities. Show that the probability limit does not depend on L. Explain why adding cities does not help.

(d) Show that week fixed effects remove all identifying variation when the system has one product. Explain why week effects common to all brands do not remove brand-specific national demand shocks in a system with many brands.

(e) State Hausman's "predetermined prices" defense as an assumption on the information set of the price setter. Propose one test of it with weekly scanner data.

6. This exercise compares the repricing of an introducer's existing product under linear and logit demand.

(a) Let $q = a - Bp$ with $B = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, $a = (10, 8)^\top$ and $mc = (1, 1)^\top$. Compute the monopoly price of product 1 when product 2 is absent, using its virtual price, and when the firm sells both. Confirm Proposition 10.25 and check that product 2 sells a positive quantity.

(b) A logit monopolist faces only the outside good, with $\alpha = 0.5$ and $e^{x_1\beta + \xi_1 - \alpha mc_1} = e$. Use Remark 10.26 to compute its markup. Then add a second product with $e^{x_2\beta + \xi_2 - \alpha mc_2} = e^{0.5}$ and compute the new common markup.

(c) Explain which property of logit demand makes the existing price rise, and why the linear model rules it out.

7. Consider the two-good bundle model (10.119) without price variation.

(a) Show that the marginal probabilities Q_A and Q_B determine δ_A and δ_B for given (Γ_{AB}, ρ). Argue that P_{AB} rises with both Γ_{AB} and ρ when the marginals are held fixed. Conclude that one moment cannot pin down two parameters.

(b) Add a variable x that shifts u_A only and takes two values. Count the moments and the parameters. Using Proposition 10.48, explain how the response of Q_B to x reveals the sign of Γ_{AB}.

(c) A researcher estimates a logit over the four bundles with independent errors. Explain why a positive correlation of tastes would appear as a positive interaction term. Relate this to the reversal in Table 10.36.

8. Answer in words, citing the results of this chapter.

(a) What identifies the slope of the demand curve for Apple-Cinnamon Cheerios? Is the independence of city-level demand shocks credible for a heavily advertised national brand, and in which direction would a violation bias the surplus?

(b) How much does the virtual price of \$7.14 rely on extrapolation, and what does the tangent bound add?

(c) Why do the CES and logit models give larger valuations than the almost ideal demand system?

(d) Is holding Kellogg's and Post's prices fixed a lower bound on the price effects of the introduction? What would a full Bertrand-Nash re-solution do, and what does Petrin's study suggest about its size?

(e) Several overall cross elasticities in Hausman's Table 5.6 are negative. Explain how Proposition 10.28 produces them and whether they indicate complementarity.

Part III

Competition Policy

Chapter 11

Horizontal Mergers

In June 2008 the second and third largest brewers in the United States combined their American operations in a joint venture. The Department of Justice let the deal go ahead, in part because it expected the new firm to produce and distribute beer at lower cost. Soon afterward the prices of Miller Lite and Coors Light rose. So did the price of Bud Light, the flagship of their largest rival, while the prices of the leading imports kept falling. Was this the predictable effect of having one competitor fewer? Did the remaining brewers start to compete less hard? Or were the cost savings simply smaller than hoped? Answering such questions is the business of merger analysis, and Section 11.8 returns to this case.

This chapter asks three questions. What motivates firms in an industry to merge? How can we evaluate the effects of a merger, before it takes place or after? And what stance should regulators take toward mergers? A *horizontal merger* combines firms that sell substitutes in the same market. A *vertical merger* combines firms at different stages of a supply chain, such as a manufacturer and a retailer. A *conglomerate merger* combines firms in unrelated markets. We study horizontal mergers, which raise the most direct competitive concerns. Vertical relations enter only where they shape a horizontal case, as in the gasoline market of Section 11.9.1.

A horizontal merger moves prices through three channels. *Unilateral effects* arise because the merged firm internalizes the competition between the products it now owns. It then has a reason to raise their prices even if every other firm keeps competing as before. *Coordinated effects* arise when the merger also changes conduct, so that the remaining firms find it easier to compete less aggressively with one another (Chapter 12). *Efficiencies* are the cost reductions and product improvements that the merger makes possible, such as economies of scale, the rationalization of production across plants and the transfer of know-how. The first two channels push prices up, and efficiencies push them down.

Merger analysis comes in two forms. A *prospective* (ex ante) evaluation predicts the effects of a proposed merger from pre-merger data, as a competition agency must do before the merger closes. A *retrospective* (ex post) evaluation measures what a consummated merger did, by comparing outcomes before and after it with those of a control group. The chapter develops both and shows how each disciplines the other. Retrospective estimates grade prospective models. Models in turn explain what a retrospective design can and cannot identify.

The chapter draws on most of the book. Concentration measures and the Cowling-Waterson formula come from Chapter 1, and Cournot competition and pass-through from Chapter 2. The multi-product pricing model and the diversion ratios of Chapter 4 are the core of unilateral effects with differentiated products. Merger simulation uses the demand systems of Chapters 5, 7 and 8. The internalization parameter of Section 11.8 is a conduct parameter in the sense

of Chapter 3. The econometrics of event studies, differences in differences and instrumental variables is reviewed in Sections A.3, A.12 and A.13. The airline industry of Chapter 9 and the collusion chapters that follow (Chapters 12 and 13) are natural companions.[1]

The chapter proceeds as follows. Section 11.1 documents merger activity, the motives for merging and the US review process, with the evidence on how notification rules select mergers and on efficiencies. Section 11.2 develops the screens that agencies apply first: the hypothetical monopolist test, critical loss and concentration thresholds. Section 11.3 studies mergers with homogeneous goods. It moves from the Williamson trade-off and the merger paradox to the equilibrium analysis of Farrell and Shapiro (1990), and it ends with mergers under free entry. Section 11.4 turns to differentiated products and derives diversion ratios, the upward pricing pressure test of Farrell and Shapiro (2010) and the role of pass-through. Section 11.5 develops merger simulation, works a logit example and studies Nevo (2000b) in depth. Section 11.6 develops the econometrics of retrospective evaluation. It applies it to five consumer-product mergers, an appliance merger and hospital mergers, and then surveys what the wider retrospective literature finds. Section 11.7 uses a retrospective to test a merger simulation in the Swedish market for painkillers. Section 11.8 sets out the theory of coordinated effects and measures them in the MillerCoors joint venture. Section 11.9 looks beyond short-run prices, at spatial competition, product repositioning and capacity investment. Section 11.10 asks how policy should respond when firms choose which merger to propose and when mergers arrive over time. Section 11.11 weighs the approaches, studies remedies and lists open issues.

11.1 Why firms merge and how mergers are reviewed

A horizontal merger removes the competition between the merging firms and may let them produce more cheaply. Whether consumers gain or lose depends on which force dominates, and on how rivals respond. This section describes how often firms merge, why they do so, and how a proposed merger is reviewed in the United States. Section 11.2 turns to the screens that the agencies apply first, and Section 11.3 develops the theory of mergers in homogeneous-goods markets.

11.1.1 Merger activity and merger waves

Mergers are frequent, and their total value is large. Figure 11.1 shows the number and value of mergers and acquisitions worldwide since 1985. The number of deals trends upward fairly smoothly. Their value moves in *waves*, periods in which deal values rise quickly and then collapse. Values peak around 1999 and 2000, in 2007, in 2015 and in 2021, and they reach troughs around 2002, 2009 and 2023. The highlighted year, 1997, saw 26,227 transactions worth $1,824 billion. The last two entries are not full-year data. One covers January to March 2026, and the other is a projection for the whole of 2026.

Within an industry, mergers often come in sequences that reshape the market over two or three decades. Table 11.1 summarizes three such histories. US telecommunications went

[1] Several readings are cited from the working-paper versions available to us. Page, table, equation and proposition numbers then follow those versions, and the text says so at first use. For Farrell and Shapiro (1990) we use Farrell and Shapiro (1988). For Farrell and Shapiro (2010) we use the version of 25 November 2008, and for Nevo (2000b) the version of November 1997. Pinpoint references to Ashenfelter and Hosken (2010), Ashenfelter et al. (2013) and Dafny (2009) go to Ashenfelter and Hosken (2008), Ashenfelter et al. (2011) and Dafny (2005). The same caveat applies to Pesendorfer (2003), Sweeting (2010) and Nocke and Whinston (2013).

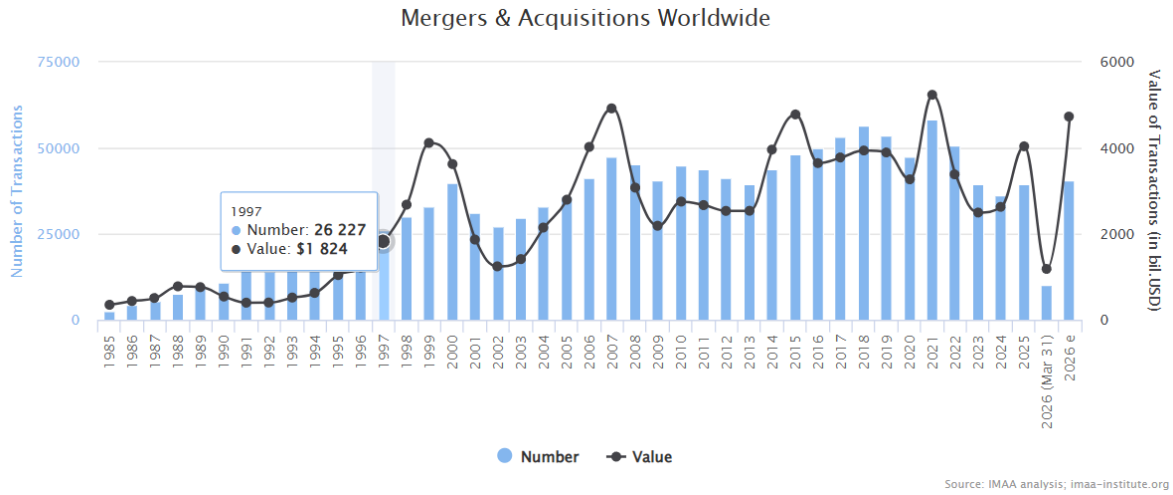

Figure 11.1: Number of transactions (bars, left axis) and value of transactions in billions of US dollars (line, right axis) of mergers and acquisitions worldwide, 1985–2026. The 2026 entries are the first quarter and a full-year estimate. Source: Institute for Mergers, Acquisitions and Alliances (IMAA), imaa-institute.org.

from the 1984 breakup of AT&T into seven regional "Baby Bells" to a handful of national carriers. The major US airlines consolidated through mergers and failures after deregulation (Chapter 9). World brewing was transformed by a chain of very large deals between 2000 and 2012, and Section 11.8 studies one of them, the MillerCoors joint venture, in detail. Figure 11.2 reproduces the brewing timeline.

Two views of why firms merge. Industrial organization economists stress three motives. The first is market power. A merger internalizes the competition between the merging firms, which gives them a reason to raise prices even if all other firms keep competing as before. These are the unilateral effects defined in the introduction to this chapter. A merger may also make it easier for the remaining firms to coordinate, tacitly or explicitly, which gives rise to coordinated effects (Chapter 12). The second motive is efficiencies. They include economies of scale and scope, the rationalization of production and distribution across plants, and the transfer of know-how from the better-run firm to the other. The third motive is strategic. A merger can deter entry or allow the firms to reposition their products.

Corporate finance asks different questions. One is why mergers come in waves and why they cluster within industries. Mitchell and Mulherin (1996) and Andrade et al. (2001) attribute the clustering to industry shocks, such as deregulation, new technologies and changes in input prices. A shock triggers restructuring and can make a different organization of the industry attractive to its firms. This evidence explains when and where mergers occur. It does not by itself establish that the resulting consolidation raises efficiency. Andrade et al. (2001) regard the efficiency benefits in the deregulated industries that drove the mergers of the 1990s as unresolved. They also find that operating performance improves after mergers, relative to industry peers. A second question is why the stock returns of acquirers are weak around acquisitions while targets gain. Several theories blame agency problems or mispricing. Jensen (1986) argues that managers of firms with free cash flow overinvest in acquisitions to build empires. Roll (1986) argues that overconfident managers overpay. Shleifer and Vishny (2003) argue that overvalued acquirers use their stock to buy targets that are less overvalued, so that the target's shares are cheap relative to the acquirer's. Waves then follow stock-market

Table 11.1: Three consolidation histories

Industry	Main combinations and outcome
US telecom	In 1984 AT&T's local operations were split into seven regional companies: Ameritech, Bell Atlantic, BellSouth, NYNEX, Pacific Telesis, Southwestern Bell and U S West. Southwestern Bell, renamed SBC, absorbed Pacific Telesis (1997) and Ameritech (1999), then acquired AT&T Corp. (2005) and took the name AT&T Inc., and then acquired BellSouth (2006). Bell Atlantic, NYNEX and GTE formed Verizon (2000), which later absorbed MCI, while Verizon Wireless absorbed Alltel. Qwest absorbed U S West and was in turn absorbed by CenturyLink (April 2011). Subscribers at the end of 2010 were: AT&T 24 million landline and 96 million wireless, Verizon 26 million landline and Verizon Wireless 94 million. Sprint had 50 million and T-Mobile USA 34 million. CenturyLink and Qwest together had 15 million landline subscribers, a combined count for two firms that merged only in April 2011. AT&T's proposed $39 billion purchase of T-Mobile USA (2011) was abandoned the same year (Table 11.42).
US airlines	After deregulation in 1978, Trans World Airlines (which had absorbed Ozark) was acquired by American (2001). Republic Airlines, itself formed from North Central, Southern and Hughes Airwest, merged into Northwest, and Northwest merged into Delta (2008), which had absorbed Western (1987). Continental, which had absorbed People Express among others, merged with United (2010). US Airways merged with America West (2005) and later with American (2013). Southwest absorbed AirTran (2011). Braniff (1982), Eastern (1991) and Pan Am (1991) failed.
World beer	Interbrew and AmBev ($11.5 billion) formed InBev (2004), which bought Anheuser-Busch for $52 billion (2008) to form AB InBev and later bought the rest of Grupo Modelo for $20.1 billion. SAB bought Miller ($5.6 billion, 2002) and later Bavaria, Grolsch and Foster's. Coors and Molson merged (2005). Heineken and Carlsberg divided the assets of Scottish & Newcastle ($15.3 billion, 2008). In the United States, SABMiller and Molson Coors combined their operations in the MillerCoors joint venture (2008).

Notes: Subscriber counts and the T-Mobile deal value are from a 2011 *Wall Street Journal* graphic ("A Tangled Family Tree"), which counts CenturyLink including Qwest. CenturyLink alone reported 6.5 million access lines at the end of 2010 in its annual report for that year, and it acquired Qwest on April 1, 2011. Airline combinations follow the Aviation Week Intelligence Network's Fleet Database as reproduced in the source chart, and beer deal values follow the timeline of Figure 11.2. Years are completion years, except the year of the proposed T-Mobile purchase. The telecom and beer years, Western (1987) and the three airline failures are read off the time axes of these charts. The airline mergers of 2001 to 2011 are dated by U.S. Government Accountability Office (2013, p. 11), and the 2013 merger of American and US Airways by Asker and Nocke (2021, p. 263). MillerCoors is dated by its consummation in June 2008 (Miller and Weinberg, 2017, p. 1768).

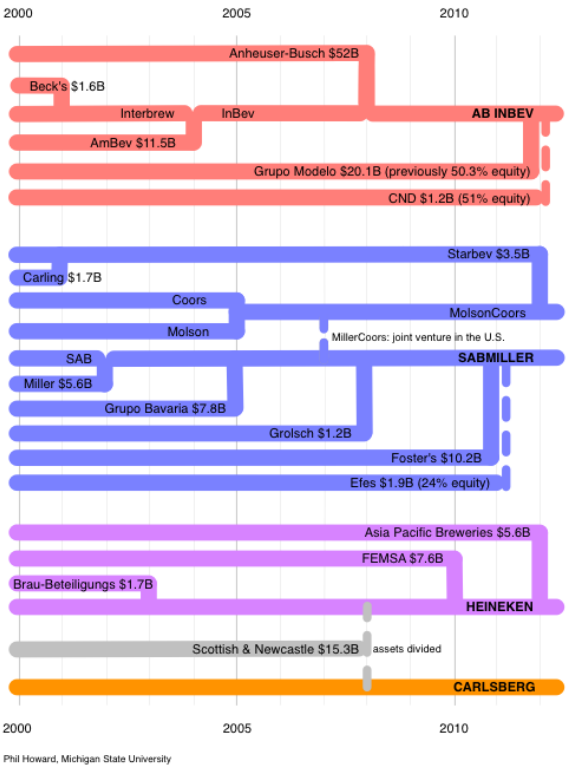

Figure 11.2: Consolidation of the world beer industry, 2000–2012. Each band is a brewer, and a band that ends in a vertical connector is acquired by the band it joins. Labels give deal values in billions of US dollars. Source: Phil Howard, Michigan State University, as printed on the figure.

valuations. In their model, cash acquisitions instead require a target undervalued relative to fundamentals. These explanations are complements to the industrial organization view and say little about prices. We therefore leave them aside.

The theory developed in this chapter delivers three results that will guide the empirical work. In a Cournot market, a merger without cost savings raises the price, and it is often unprofitable for the merging firms (Section 11.3). In a symmetric market with differentiated products and price competition, every merger is profitable (Section 11.4). When firms must invest in costly capacity, a merger can be profitable even without cost savings (Section 11.9).

11.1.2 The legal framework and the US review process

Section 7 of the Clayton Act of 1914, as amended in 1950, prohibits acquisitions whose effect "may be substantially to lessen competition, or to tend to create a monopoly" (Farrell and Shapiro, 2010, p. 2). The word "may" matters. The government does not have to prove that a merger will harm competition, only that it is likely to. Section 7 applies to every acquisition, including those that are too small to be reported and those already consummated.

Notification and the waiting period. The Hart-Scott-Rodino Antitrust Improvements Act of 1976 (HSR) added Section 7A to the Clayton Act. It requires the parties to a sufficiently large transaction to notify the Federal Trade Commission (FTC) and the Antitrust Division of the Department of Justice (DOJ) before they close. Its motivation was the cost of undoing completed mergers. The leading example, *United States v. El Paso Natural Gas*, took seven years to litigate and ten more years to carry out the divestiture the Supreme Court had ordered (Ashenfelter and Hosken, 2008, p. 5). A deal must be reported when it passes two tests. The *size-of-person* test concerns the parties, and before 2001 it typically required a target with at least $10 million in assets or sales and a buyer with at least $100 million. The *size-of-transaction* test concerns the deal. Until 2001 it was met by acquiring 15 percent or more of the target's voting securities or assets, or more than $15 million of them (Wollmann, 2019). In February 2001 the $15 million threshold rose to $50 million and the 15 percent alternative was dropped. From fiscal year 2005 the dollar thresholds have been indexed to the growth of national income. These changes explain much of the fall in reported mergers after 2001 (Ashenfelter and Hosken, 2008, p. 6, n. 7). The indexed threshold was $63 million in 2008 (Farrell and Shapiro, 2010, p. 2, n. 3) and $133.9 million in 2026 (Federal Trade Commission, 2026, p. 2134). The 2001 change also altered which mergers took place, as the end of this subsection shows.

After both parties file, a waiting period of 30 days begins (15 days for cash tender offers and bankruptcy sales). During this period the two agencies decide which one will review the deal, a step called *clearance*. That agency then conducts a preliminary review of market shares, concentration, company documents and complaints from customers or rivals. The agency may end the wait early through *early termination*. If the deal looks problematic, the agency issues a *Second Request*, a detailed subpoena for documents and data on competition, entry, substitution and claimed efficiencies. The waiting period then extends until 30 days after the parties have substantially complied (Ashenfelter and Hosken, 2008, p. 6). Compliance typically takes two or three months and sometimes six months or more. The whole investigation, with depositions and interviews of customers and competitors, often lasts about a year.

Outcomes. An investigation ends in one of four ways. The agency may close it and let the merger proceed. It may negotiate a *consent decree*, usually requiring the parties to divest overlapping assets. For DOJ decrees, the Tunney Act requires a federal court to find that the decree is in the public interest. The agency may sue to block the merger, which in practice

means seeking a preliminary injunction in federal court. Finally, the parties may abandon the deal. The last three outcomes are counted as *enforcement actions*. Much of the bargaining takes place in the shadow of litigation. In fiscal year 2006, for example, 1,768 transactions were reported, the agencies issued 45 Second Requests and challenged 32 transactions. The challenges led to 17 settlements, 6 restructured transactions and 9 abandoned deals (Farrell and Shapiro, 2010, p. 2, n. 5). Some industries follow their own rules. Rail mergers, for instance, fall under the exclusive jurisdiction of the Surface Transportation Board. Figure 11.3 summarizes the process.

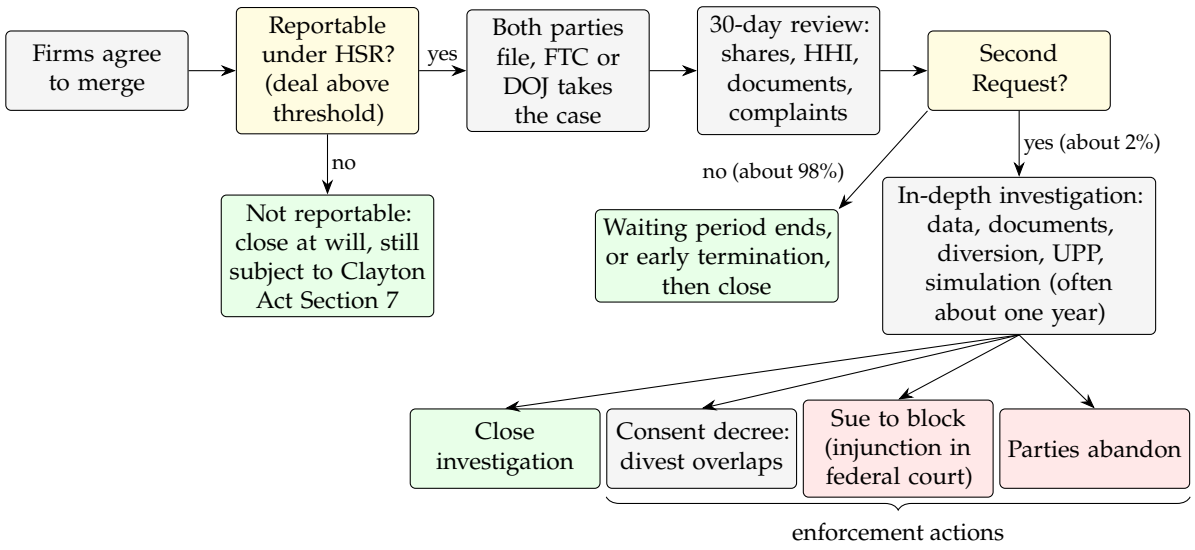

Figure 11.3: From the decision to merge to closing in the United States. In fiscal year 2025, 2,006 transactions were reported under HSR, with 3,851 filings because both parties usually file. There were 41 Second Requests and 18 enforcement actions, equal to 2.0 and 0.9 percent of reported transactions. Two of the 18 actions concerned transactions not reported under HSR.

Table 11.2 reports the number of reported transactions, Second Requests and enforcement actions in each fiscal year from 2003 to 2025, and Figure 11.4 extends the series back to 1991. The unit is the transaction. A transaction usually generates two filings, one from each party. Three patterns stand out. Reported transactions fell from 4,926 in fiscal year 2000 to 1,187 in 2002 after the threshold increase, and to 716 in fiscal year 2009 during the financial crisis. They spiked in 2021 and 2022. Over 2003–2025 the agencies issued 2.6 Second Requests and brought 2.0 enforcement actions for every 100 reported transactions. These are annual activity ratios. An action can concern a transaction reported in an earlier year, or one that was never reportable. The ratio is therefore not the share of a year's transactions that led to enforcement. Actions relative to reported transactions have drifted down, from about 3 percent in 2010–2013 to about 2 percent in 2014–2020 and between 0.9 and 1.6 percent since 2021. Most mergers are never examined closely.

Enforcement and selection. Enforcement shapes which mergers we observe. Ashenfelter and Hosken (2008, p. 5) report that 37,201 mergers were filed from 1991 through 2004. About 97 percent were allowed to proceed without a full investigation. Of the 3 percent investigated in depth, roughly 65 percent were modified, abandoned or blocked. Ashenfelter et al. (2011, p. 4, n. 5) summarize the first figure as 97 percent of proposed mergers going through without modification. Because the agencies try to stop the mergers most likely to raise prices, the

Table 11.2: Hart-Scott-Rodino reported transactions, Second Requests and enforcement actions, fiscal years 2003–2025

	Reported			Ratio to transactions (percent)	
Fiscal year	transactions	Second Requests	Enforcement actions	Second Requests	Enforcement actions
2003	1,014	33	36	3.3	3.6
2004	1,454	35	24	2.4	1.7
2005	1,675	50	18	3.0	1.1
2006	1,768	45	32	2.5	1.8
2007	2,201	63	34	2.9	1.5
2008	1,726	41	37	2.4	2.1
2009	716	31	31	4.3	4.3

Notes: Compiled from the annual HSR reports of the FTC and DOJ. The unit is the transaction reported under HSR. Both parties usually file, so the reports count more filings than transactions, for example 3,851 filings for the 2,006 transactions of 2025. Enforcement actions combine the merger challenges of both agencies as printed in each year's joint report, using the corrected report for 2022. The FTC later raised its 2017 count from 21 to 23, which would give 41 for that year. A report counts an action in the year of the agency's first public action. The action can concern a transaction reported in an earlier year or one not reportable under HSR, as did two of the 18 actions in 2025. The ratios are counts divided by reported transactions in the same year, so they measure annual activity. The reports' own Second Request percentages divide by the smaller number of adjusted transactions in which a Second Request could have been issued (1,944 in 2025). They therefore run about 0.1 point higher, for example 2.6, 2.2, 3.0 and 3.0 for 2017–2020. The 2025 report repeats the transaction and Second Request counts for 2016–2025, except that it revises the 2021 Second Requests from 65 to 66. The 2003 and 2004 rows coincide with Ashenfelter and Hosken (2008, Table 1), and the 2006 row with Farrell and Shapiro (2010, n. 5).

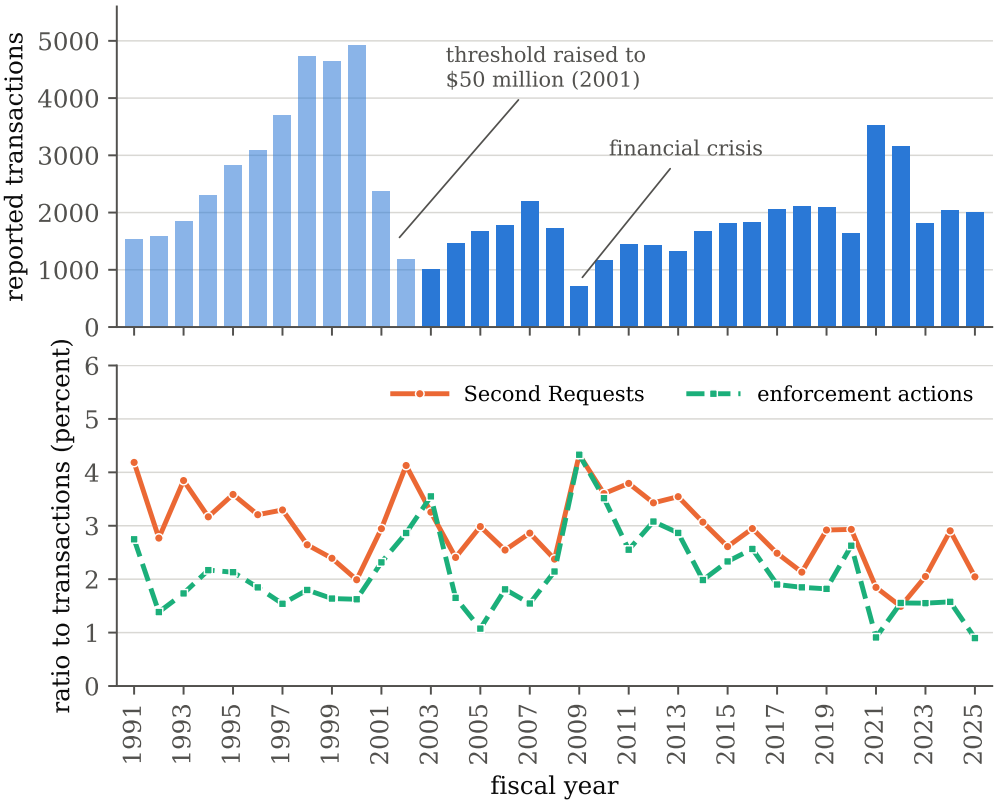

Figure 11.4: Transactions reported under HSR (top) and the ratios of Second Requests and enforcement actions to reported transactions in the same year, in percent (bottom), fiscal years 1991–2025. The lighter bars for 1991–2002 come from Ashenfelter and Hosken (2008, Table 1), who call the series mergers filed, and the rest from Table 11.2. Both ratios use all reported transactions as the denominator.

consummated mergers that a researcher can study are a selected sample. The average price effect of approved mergers is a lower bound on the average effect that mergers would have in a world without enforcement (Carlton, 2009). The informative object for policy is the effect of the *marginal* merger, one that was nearly blocked. Section 11.6 returns to this problem.

Notification thresholds as a screen. Reporting thresholds do more than save the agencies work. They also shape which mergers firms propose. Besanko and Spulber (1993) model a review in which the merging parties know their merger-specific efficiencies and the authority does not. Proposing a merger costs a fixed amount that cannot be recovered. Holding fixed the probability of approval, only mergers whose efficiencies exceed a threshold are then worth proposing. A positive proposal cost can therefore benefit consumers, because it improves the pool of proposed mergers (Asker and Nocke, 2021, p. 223). The same model suggests one reason why authorities apply a consumer surplus standard rather than a total surplus standard. An authority that puts less weight on profit than society does is tougher. It approves fewer mergers, and the proposals it receives are better as a result (Asker and Nocke, 2021, p. 223, n. 120).

Wollmann (2019) tests this selection effect with the 2001 amendment, which raised the size-of-transaction threshold. *Newly exempt* mergers are those that the old rules required to be reported and the new rules did not. The agencies almost never investigated them afterward, in line with the long-standing observation that they rarely examine mergers that need not be reported. Wollmann compares newly exempt horizontal mergers with newly exempt non-horizontal ones, which seldom raise concerns. This is a *difference-in-differences* design, which compares the change in a treated group with the change in a control group (Section 11.6.1 develops it). A *triple difference* also subtracts the same comparison among *never-exempt* mergers, those above the new threshold of $50 million, which had to be reported both before and after the amendment. Because the old size-of-transaction test was also met by acquiring 15 percent of the target, the old rules caught almost every acquisition of control whose parties passed the size-of-person tests. The newly exempt group is therefore wider than deals valued between $15 million and $50 million. Wollmann classifies deals by their adjusted transaction value and the target's assets and sales, and he drops deals whose target has assets below $10 million (online appendix, Section 4.3). After 2001, never-exempt horizontal and non-horizontal mergers moved together. Newly exempt horizontal mergers rose relative to newly exempt non-horizontal ones. The triple-difference estimate is a 50 percent increase: 324 additional newly exempt horizontal mergers per year on a pre-amendment base of 634 (Asker and Nocke, 2021, pp. 224–226). Through the lens of the Besanko-Spulber model, the amendment removed both the proposal cost and the risk of a challenge for these deals. Mergers without large synergies became worth doing, so the pool of mergers grew and worsened at the same time.

Firms also size their deals around the threshold. Cunningham et al. (2021) study pharmaceutical acquisitions. Acquisitions of targets whose drug projects overlap with the acquirer's bunch just below the HSR threshold, while acquisitions without such overlap do not (Asker and Nocke, 2021, pp. 226–227 and Figure 9). Section 11.11.5 returns to these acquisitions.

11.1.3 What the agencies analyze

The agencies' Horizontal Merger Guidelines describe five tasks (U.S. Department of Justice and Federal Trade Commission, 1992, 2010), which Ashenfelter and Hosken (2008, p. 7) summarize. The first two define the market. The *relevant product market* is a set of close substitutes for the merging firms' products, found with the hypothetical monopolist test of Section 11.2.1. The

relevant geographic market is the narrowest area in which anticompetitive effects could occur. For nationally distributed branded goods it is typically the whole country (Ashenfelter and Hosken, 2008, p. 7). The third task is to assess competitive effects, both unilateral and coordinated. The fourth is to evaluate efficiency claims. Efficiencies count only if they are *merger-specific*, meaning that no other arrangement that harms competition less could achieve them, and *verifiable* by the authority at the time of review (Asker and Nocke, 2021, p. 221). They must also be large enough to reverse the merger's potential to harm customers, for instance by preventing price increases (U.S. Department of Justice and Federal Trade Commission, 2010, Section 10). The fifth is to ask whether entry would be timely, likely and sufficient to deter or counteract the competitive effects of concern (Section 9). Section 11.3.4 shows what free entry implies for the effects of a merger and how slowly entry can come in practice. Economists at the agencies work mostly on market definition and competitive effects. The rest of this chapter follows the same order. Section 11.2 covers market definition and concentration, and the remaining sections cover competitive effects and efficiencies.

Evidence on efficiencies. The efficiency defense rests on a thin empirical base. Asker and Nocke (2021, pp. 219–221) single out two studies that document merger-specific efficiencies. The first, Ashenfelter et al. (2015), measures the shipping savings of the MillerCoors joint venture, which Section 11.8.11 discusses. The second, Braguinsky et al. (2015), studies 73 acquisitions in the Japanese cotton-spinning industry between 1896 and 1920. More profitable firms bought less profitable ones, although the two groups had similar physical productivity. The acquired mills then improved their inventory management, accounts receivable and capacity utilization, and market power explains little of their higher profitability. The two cases illustrate the two conditions above. The beer savings came from shorter shipping distances, which are easy to verify. The brewers might, however, have obtained them by brewing each other's beer under contract while pricing independently, which questions their merger specificity. The managerial gains in cotton spinning are specific to the merger but hard to verify before they occur.

Evidence on how often mergers create efficiencies, and how large they are, is scarcer still. Geurts and Van Biesebroeck (2019) find that about 80 percent of the mergers in Belgium between 2005 and 2012 raised employment, which may reflect higher output. Grieco et al. (2018) estimate returns to scale in the Molson-Coors merger and translate them into marginal-cost reductions (Asker and Nocke, 2021, pp. 221–222). In the words of Asker and Nocke (2021, p. 261), not much is known about the typical magnitudes of merger efficiencies or about how they relate to market structure.

11.2 Market definition and concentration screens

Market shares and concentration indices are defined only relative to a market (Section 1.2.1). The agencies therefore begin by defining the relevant market, and they then compute shares and the Herfindahl-Hirschman index within it. This section derives the logic of the hypothetical monopolist test, the algebra of critical loss, the theory behind concentration thresholds, and the reasons the whole approach struggles with differentiated products.

11.2.1 The hypothetical monopolist test

Definition 11.1 (Hypothetical monopolist test)**.** Consider a hypothetical profit-maximizing firm that owns all products in a candidate set and faces no regulation of its prices. Hold the terms of sale of all other products fixed. The set is a *relevant product market* if this firm would

impose at least a *small but significant and non-transitory increase in price* (SSNIP) on some product of the merging firms.

The SSNIP is usually 5 percent of the price and sometimes 10 percent. The test is applied iteratively. We start from the products of the merging firms. If a hypothetical monopolist of this set would not raise price by the SSNIP, because too many buyers would switch to products outside the set, the set is too narrow. We then add the next-closest substitute and repeat. The relevant market is the smallest set that passes. The relevant geographic market is defined the same way, with locations in place of products. The test turns market definition into a statement about demand, so it can draw on the demand models of Chapters 5, 7 and 8.

The test must be applied at the right prices. In *United States v. E. I. du Pont de Nemours & Co.* (1956) the Supreme Court held that cellophane competed with other flexible wrapping materials, partly because many buyers switched between them. Du Pont, however, already set the price of cellophane as a near monopolist. A monopolist prices where its demand is elastic, since its Lerner condition $\frac{p-c}{p} = \frac{1}{\varepsilon}$ requires $\varepsilon > 1$. At monopoly prices, almost any product looks like it has close substitutes. Applying the test at prices that already reflect market power therefore yields markets that are too broad. This error is called the *cellophane fallacy*. In merger review the problem is milder, because the question is whether the merger would raise prices above their current level.

11.2.2 Critical loss analysis

Critical loss analysis turns the hypothetical monopolist test into a comparison of two numbers. Consider a hypothetical monopolist of the candidate set that sells quantity q at price p, with constant marginal cost c and percentage margin $L = \frac{p-c}{p}$. Suppose it raises the price by a fraction X to $p(1+X)$, and let AL be the resulting *actual loss*, the fraction of unit sales lost. Profit before the increase is

$$(p - c)\, q = L\, pq.$$

Profit after the increase is

$$\begin{aligned}\big(p(1+X) - c\big)\, q\, (1 - AL) &= \big(pX + (p-c)\big)\, q\, (1 - AL) \\ &= (X + L)(1 - AL)\, pq.\end{aligned}$$

Profit per dollar of pre-merger revenue therefore moves from L to $(X+L)(1-AL)$. The increase is profitable if and only if

$$\begin{aligned}&(X + L)(1 - AL) \geq L \\ \iff\ & X + L - (X + L)\, AL \geq L \\ \iff\ & AL \leq \frac{X}{X + L} \equiv CL. \end{aligned} \tag{11.1}$$

The number CL is the *critical loss*, the largest loss of sales that leaves the price increase profitable. With $X = 0.05$ and $L = 0.4$, the critical loss is $\frac{0.05}{0.45} = 11.1$ percent.

From critical loss to a threshold elasticity. The actual loss depends on the shape of demand. With linear demand $q(p) = d_0 - d_1 p$, the quantity falls by $d_1 pX$, so

$$AL = \frac{d_1 pX}{q} = \varepsilon X,$$

where $\varepsilon = \frac{d_1 p}{q}$ is the elasticity of the candidate market's demand at the initial price. Substituting into (11.1), the SSNIP breaks even if and only if

$$\varepsilon \leq \frac{1}{X + L}. \tag{11.2}$$

We call the right side the breakeven *threshold elasticity*. The test in (11.1) asks whether a price increase of X is *profitable*. The Guidelines ask whether the monopolist *would impose* it, which is the stronger requirement that the profit-maximizing increase be at least X. With linear demand, profit after an increase x is

$$\pi(x) = (x + L)(1 - \varepsilon x)\, pq,$$

which is concave in x. Its derivative is

$$\pi'(x) = \big[(1 - \varepsilon x) - \varepsilon(x + L)\big]\, pq = (1 - 2\varepsilon x - \varepsilon L)\, pq.$$

By concavity, the optimal increase is at least X if and only if $\pi'(X) \geq 0$, that is,

$$\varepsilon \leq \frac{1}{2X + L}. \tag{11.3}$$

This bound is tighter than (11.2). With constant-elasticity demand $q(p) = Ap^{-\varepsilon}$ the loss is $AL = 1 - (1 + X)^{-\varepsilon}$. The breakeven condition becomes $(X + L)(1 + X)^{-\varepsilon} \geq L$, or

$$\varepsilon \leq \frac{\ln\left(\frac{X+L}{L}\right)}{\ln(1 + X)}.$$

For the profit-maximizing version, the monopoly price with constant elasticity $\varepsilon > 1$ is $\frac{\varepsilon}{\varepsilon - 1} c$, and $c = (1 - L)p$. The optimal increase is at least X if and only if $\frac{\varepsilon}{\varepsilon - 1}(1 - L) \geq 1 + X$, which rearranges to $\varepsilon \leq \frac{1+X}{X+L}$.

Table 11.3 reports these thresholds. Two lessons emerge. First, the critical loss falls steeply as the margin rises. Second, the threshold elasticity depends on the curvature of demand. With $X = 0.05$ and $L = 0.4$, a market elasticity of 2.2 passes the breakeven test under both demand curves. It fails the profit-maximizing test under linear demand and passes it under constant elasticity. Market definition thus depends on curvature, and hence on pass-through (Section 2.8), a point we return to in Section 11.2.4.

The critical loss paradox and aggregate diversion. High margins make the critical loss small. Merging parties have used this to argue for broad markets. With a 40 percent margin, they say, losing just 11 percent of sales makes a 5 percent increase unprofitable, and surely more buyers than that would switch. Katz and Shapiro (2003) and O'Brien and Wickelgren (2003) point out the flaw. High margins are not exogenous. Before the merger, each firm in the candidate market sets its own price, so its own demand elasticity equals the inverse of its margin. A high margin therefore signals that each firm faces less elastic demand and loses fewer sales when it raises its price alone. What matters for the hypothetical monopolist is where those sales go. Sales diverted to other products in the candidate market are recaptured by the monopolist.

To make this precise, we use the diversion ratio D_{jk} of Definition 4.10, the fraction of the sales that j loses when its price rises that go to k. The aggregate diversion ratio of j to a set of products sums its diversion ratios to the members of the set (Definition 11.25).

Table 11.3: Critical loss and the threshold elasticity of market demand

			Linear demand		Constant elasticity	
SSNIP X	Margin L	Critical loss CL (%)	Breakeven	Profit-maximizing	Breakeven	Profit-maximizing
0.05	0.2	20.0	4.00	3.33	4.57	4.20
0.05	0.4	11.1	2.22	2.00	2.41	2.33
0.05	0.6	7.7	1.54	1.43	1.64	1.62
0.10	0.2	33.3	3.33	2.50	4.25	3.67
0.10	0.4	20.0	2.00	1.67	2.34	2.20
0.10	0.6	14.3	1.43	1.25	1.62	1.57

Notes: The SSNIP passes if the elasticity of the candidate market's demand is at most the entry shown. Linear demand: $\frac{1}{X+L}$ (breakeven) and $\frac{1}{2X+L}$ (profit-maximizing). Constant elasticity: $\frac{\ln(\frac{X+L}{L})}{\ln(1+X)}$ (breakeven) and $\frac{1+X}{X+L}$ (profit-maximizing).

Proposition 11.2 (Critical loss and aggregate diversion, Katz and Shapiro, 2003)**.** *Consider a candidate market of n symmetric products, each sold by a single-product firm at price p with marginal cost c and margin $L = \frac{p-c}{p}$. Assume pre-merger prices satisfy each firm's first-order condition, and demand is linear over the relevant range. Let $\bar{D}$ be each product's aggregate diversion ratio to the other $n-1$ products. A uniform price increase X on all n products causes the actual loss*

$$AL = \frac{X(1-\bar{D})}{L}, \tag{11.4}$$

and the increase is profitable for a hypothetical monopolist if and only if

$$\bar{D} \geq \frac{X}{X+L} = CL. \tag{11.5}$$

Proof. Write $\varepsilon_{jj} = -\frac{\partial q_j}{\partial p_j}\frac{p}{q_j}$ for the own elasticity of product j. Its firm's first-order condition gives the Lerner condition $L = \frac{1}{\varepsilon_{jj}}$. When all prices rise by pX, linearity gives the change in q_j as

$$\Delta q_j = \frac{\partial q_j}{\partial p_j}\, pX + \sum_{k \neq j} \frac{\partial q_j}{\partial p_k}\, pX.$$

By symmetry of the products, $\frac{\partial q_j}{\partial p_k} = \frac{\partial q_k}{\partial p_j}$, and the definition of diversion gives

$$\sum_{k \neq j} \frac{\partial q_j}{\partial p_k} = \sum_{k \neq j} \frac{\partial q_k}{\partial p_j} = -\bar{D}\, \frac{\partial q_j}{\partial p_j}.$$

Substituting,

$$\Delta q_j = \frac{\partial q_j}{\partial p_j}\, pX\,(1-\bar{D}), \qquad AL = -\frac{\Delta q_j}{q_j} = \varepsilon_{jj} X(1-\bar{D}) = \frac{X(1-\bar{D})}{L}.$$

This is (11.4). By (11.1) the increase is profitable if and only if $\frac{X(1-\bar{D})}{L} \leq \frac{X}{X+L}$. Multiplying by $\frac{L(X+L)}{X} > 0$ gives $(1-\bar{D})(X+L) \leq L$, which rearranges to $X \leq \bar{D}(X+L)$, that is, $\bar{D} \geq \frac{X}{X+L}$. □

Proposition 11.2 reverses the paradox. A single firm that raised its price alone would lose $\frac{X}{L}$ of its sales, which always exceeds $CL = \frac{X}{X+L}$. The hypothetical monopolist loses only the part that leaves the candidate market. With $L = 0.4$ and $X = 0.05$, it suffices that 11.1 percent of the sales lost by each product are recaptured by the others. High margins thus make narrow markets more likely, because the hurdle CL falls while diversion is unchanged. Analyses that estimate the hypothetical monopolist's actual loss from single-firm elasticities ignore recapture. Some such analyses have concluded that a hypothetical monopolist would want to cut price below pre-merger levels, which contradicts the premise that pre-merger prices maximize each firm's profit (Farrell and Shapiro, 2010, p. 25, n. 74). The uniform price increase in Proposition 11.2 is a simplification, since the test only requires an increase on one product of the merging firms.

Farrell and Shapiro (2010, Appendix) use the same logic to link market definition to diversion between the merging products. In a candidate market that exactly meets the breakeven test, the aggregate diversion ratio of each product equals $\frac{X}{L+X}$. If diversion within the market is proportional to market shares s_k, the diversion from product 1 to product 2 is

$$D_{12} = \frac{s_2}{1 - s_1} \cdot \frac{X}{L + X}. \tag{11.6}$$

Section 11.4 uses diversion ratios of this kind directly, without defining a market.

11.2.3 Concentration measures and the Guidelines

Once a market is defined, the agencies compute the Herfindahl-Hirschman index $HHI = \sum_i s_i^2$ of Definition 1.3, reported in HHI points ($10{,}000 \times HHI$, or shares in percent squared). If firms A and B merge and the merged firm keeps their combined share, the index changes by

$$\begin{aligned} \Delta HHI &= (s_A + s_B)^2 - s_A^2 - s_B^2 \\ &= s_A^2 + 2 s_A s_B + s_B^2 - s_A^2 - s_B^2 \\ &= 2 s_A s_B. \end{aligned} \tag{11.7}$$

The Guidelines classify mergers by the post-merger index and by this change. Table 11.4 compares the thresholds of the 1992 and 2010 Horizontal Merger Guidelines and the 2023 Merger Guidelines.

Why concentration. The theoretical case for concentration screens comes from Cournot competition. With homogeneous goods and constant marginal costs, firm i's first-order condition $P + q_i P'(Q) = c_i$ implies $\frac{P - c_i}{P} = \frac{s_i}{\varepsilon}$. Weighting by shares and summing gives the share-weighted Lerner index $\frac{HHI}{\varepsilon}$ (Cowling and Waterson, 1976), as Proposition 1.15 shows. A higher share lowers a firm's marginal revenue, and concentration summarizes this force for the industry (Farrell and Shapiro, 2010, p. 3). The formula $\Delta HHI = 2 s_A s_B$, however, assumes that the merged firm keeps the combined share. Farrell and Shapiro (1988, p. 2) note that this assumption is self-defeating. If all firms kept their outputs, the merger would affect neither consumers nor rivals. Once outputs respond, the formula is wrong.

Example 11.3 (Naive and equilibrium changes in concentration)**.** Consider N symmetric Cournot firms with constant marginal cost, and suppose two of them merge without cost savings. The merged firm is then just another symmetric firm, so the post-merger equilibrium has $N - 1$ symmetric firms. The equilibrium change and the naive change in the index are

$$\Delta HHI = \frac{1}{N-1} - \frac{1}{N} = \frac{1}{N(N-1)}, \qquad 2 s_A s_B = \frac{2}{N^2}.$$

Table 11.4: Concentration thresholds in the US merger guidelines

	1992 Horizontal Merger Guidelines	2010 Horizontal Merger Guidelines	2023 Merger Guidelines
Market categories (post-merger HHI)	Unconcentrated below 1,000, moderately concentrated from 1,000 to 1,800, highly concentrated above 1,800	Unconcentrated below 1,500, moderately concentrated from 1,500 to 2,500, highly concentrated above 2,500	Highly concentrated above 1,800
Safe harbors	Unconcentrated markets, and $\Delta HHI < 100$ (moderately concentrated) or $\Delta HHI < 50$ (highly concentrated)	Unconcentrated markets, and $\Delta HHI < 100$ in any market	No explicit safe harbor
Potential concern	$\Delta HHI > 100$ in moderately concentrated markets, and ΔHHI from 50 to 100 in highly concentrated markets	$\Delta HHI > 100$ in moderately concentrated markets, and ΔHHI from 100 to 200 in highly concentrated markets	
Presumption of harm	Post-merger HHI above 1,800 and $\Delta HHI > 100$	Post-merger HHI above 2,500 and $\Delta HHI > 200$	Post-merger HHI above 1,800 and $\Delta HHI > 100$, or a merged firm with a share above 30 percent and $\Delta HHI > 100$

Notes: HHI points (shares in percent). The 1992 presumption is quoted from Section 1.51 in Ashenfelter and Hosken (2008, p. 11, n. 25) and Farrell and Shapiro (2010, p. 26). The other 1992 entries are the boundaries of 1,000 and 1,800 and the thresholds of 100 and 50 points. They coincide with the screen of the 1982 and 1984 Guidelines as Nevo (2000b, pp. 5–6) describes it. Sources: U.S. Department of Justice and Federal Trade Commission (1992, Section 1.51), U.S. Department of Justice and Federal Trade Commission (2010, Section 5.3) and U.S. Department of Justice and Federal Trade Commission (2023, Section 2.1). The 2023 Guidelines contain no safe harbor.

The ratio of the naive change to the equilibrium change is $\frac{2(N-1)}{N}$, which exceeds one whenever $N > 2$. The naive formula overstates the change in concentration because the merged firm contracts and the outsiders expand. For a symmetric seven-to-six merger, the naive calculation raises the index from 1,429 to 1,837, an increase of 408 points (Farrell and Shapiro, 2010, p. 26). Six symmetric firms, however, have an index of 1,667, so the equilibrium increase is 238 points. The naive numbers trigger the presumption of the 1992 and 2023 Guidelines. The equilibrium numbers trigger neither. Moreover, Section 11.3.2 shows that this merger would be unprofitable in Cournot without cost savings, so it would not be proposed in the first place. Appendix C works through the same calculations in a Cournot exercise.

Newer foundations for the screens. Recent theory gives the naive change $2s_A s_B$ a firmer foundation than the Cowling-Waterson formula does. Nocke and Schutz (2019) study multiproduct firms that compete in prices under logit, nested logit or CES demand. Without merger-specific efficiencies, the losses of consumer surplus and of aggregate surplus caused by a merger are both approximately proportional to the naive ΔHHI. The approximation is taken around small market shares (Asker and Nocke, 2021, p. 226). Nocke and Whinston (2020) ask how large the efficiencies must be for a merger not to harm consumers. They also ask how the answer depends on the change and on the level of the index. They answer in theory for Cournot competition with homogeneous goods and for price competition with logit and CES demand. They also answer empirically for hypothetical mergers in the US beer industry, using the demand and cost estimates of Miller and Weinberg (2017). The required efficiencies rise with the naive ΔHHI and, holding it fixed, do not depend on the level of the index (Asker and Nocke, 2021, p. 227). The results favor screens based on the change in concentration over screens based on its level. Nocke and Whinston also argue that the presumptions of the 2010

Guidelines are likely too lax unless the typical merger is credited with large synergies (n. 124). The level regains a role if the agency tolerates a small loss of consumer surplus. The efficiency needed to keep the loss below a given small fraction rises with the level of the index, holding its change fixed (n. 125). Section 11.3.3 derives the Cournot version of the required efficiency, and Section 11.10 gives a further reason to screen on naive concentration.

A worked example. Ashenfelter and Hosken (2008, Table 2) report the pre-merger shares, the post-merger index and its change for five consumer-product mergers. Table 11.5 recomputes the change from the rounded shares. The recomputed values are within 20 points of the reported ones. The gaps come from rounding. For General Mills and Ralcorp, for instance, shares in $[27.5, 28.5)$ and $[3.5, 4.5)$ give $2s_A s_B$ anywhere in $[192.5, 256.5)$, an interval that contains the reported 238. The same check works for the other four mergers. The authors treat the combined private-label share as one participant (Ashenfelter and Hosken, 2008, p. 11, n. 24).

Table 11.5: Recomputing the change in concentration for five consumer-product mergers

Industry	Firm A	Firm B	s_A (%)	s_B (%)	$2s_A s_B$	Reported ΔHHI
Cereal	General Mills	Ralcorp (Chex)	28	4	224	238
Liquor	Guinness	Grand Metropolitan	21	22	924	935
Motor oil	Pennzoil	Quaker State	29	9	522	517
Feminine protection	Procter & Gamble	Tambrands	25	19	950	959
Pancake syrup	Aurora Foods	Log Cabin	15	19	570	589

Notes: Shares are pre-merger revenue shares from scanner data of Information Resources Inc. (IRI). Post-merger HHIs reported in the source are 2,357, 2,026, 2,189, 2,815 and 1,990. Aurora Foods (Mrs. Butterworth's) bought the Log Cabin business from Philip Morris (Kraft). Guinness and Grand Metropolitan combined their spirits businesses. In the other three mergers firm A bought firm B's brands. Source: Ashenfelter and Hosken (2008, Table 2).

11.2.4 Why market definition struggles with differentiated products

The structural presumption has deep roots in US law. In *United States v. Philadelphia National Bank* (1963), the Supreme Court considered a merger that creates a firm with "an undue percentage share of the relevant market" and raises concentration significantly. It held that such a merger is "so inherently likely to lessen competition substantially that it must be enjoined" unless the parties show otherwise (Farrell and Shapiro, 2010, p. 4). The presumption fits a homogeneous-goods market with clear boundaries. It fits poorly when products are differentiated.

With differentiated products, any boundary is a line drawn through a chain of substitutes, and products are either in or out. Farrell and Shapiro (2010, p. 5) ask whether the relevant market for the Miller and Coors combination was domestic beer, all beer, all alcoholic beverages, or all beverages. Courts tend to define markets broadly, including all products "reasonably interchangeable by consumers for the same purposes". The hypothetical monopolist test with high margins often implies narrow markets instead. The binary choice also fits badly with what matters for unilateral effects, which is how close the merging products are to each other.

The proposed merger of Whole Foods and Wild Oats in 2007 illustrates the problem. The two chains specialized in natural and organic groceries. Whole Foods planned to close Wild Oats stores near its own. Its internal projections suggested that most customers of a closed Wild Oats store would switch to Whole Foods rather than to conventional supermarkets. Its

chief executive told his board that buying Wild Oats would "avoid nasty price wars", and he stated that "one of the motivations is to eliminate a competitor" (Farrell and Shapiro, 2010, pp. 5–6). To invoke the structural presumption, the FTC had to define a market. It proposed "premium natural and organic supermarkets". The District Court rejected this market because shoppers also bought organic food at conventional supermarkets. The FTC appealed and won a remand. The litigation forced a choice between two answers, a near monopoly or two small players among all supermarkets, when the economics pointed to substantial but incomplete differentiation. In the Oracle and PeopleSoft case, the DOJ showed that the two firms competed head to head in high-function human resources and financial management software. There the merger would have reduced the number of major suppliers from three to two. The court found that the DOJ had not established its market, and the merger went ahead (Farrell and Shapiro, 2010, p. 6, n. 19).

Market definition also has a hidden dependence on demand curvature. The hypothetical monopolist test is close to simulating a merger of all products in the candidate market. Its outcome therefore depends on pass-through in the same way as a merger simulation (Farrell and Shapiro, 2010, p. 25). Table 11.3 showed the same dependence in the simplest case. These problems motivate the approach of Section 11.4, which measures the pricing pressure created by a merger directly from margins and diversion ratios.

11.3 Unilateral effects with homogeneous goods

This section studies mergers in markets for a homogeneous good. We begin with the trade-off between market power and cost savings. We then show that mergers without cost savings are often unprofitable in Cournot markets. Next comes the equilibrium analysis of Farrell and Shapiro (1990), which links private profitability, prices and welfare. We end by asking what free entry changes.

11.3.1 The Williamson trade-off

Williamson (1968) framed the basic question of merger policy as a trade-off. Suppose an industry is competitive before the merger, so that the price equals unit cost, $p_0 = c_0$, and output is $q_0 = Q(p_0)$. The merger creates market power, so the price rises to $p_1 > p_0$ and output falls to $q_1 = Q(p_1)$. It also lowers unit cost to $c_1 < c_0$. Figure 11.5 shows the two effects.

Total surplus is consumer surplus plus profit. Approximate demand by a straight line between the two points. The change in consumer surplus is

$$\Delta CS = -\int_{p_0}^{p_1} Q(p)\,\mathrm{d}p = -(p_1 - p_0)\,q_1 - \frac{1}{2}(p_1 - p_0)(q_0 - q_1).$$

Profit is zero before the merger. After it, profit is

$$\begin{aligned}\Delta\pi = (p_1 - c_1)\,q_1 &= \big[(p_1 - p_0) + (p_0 - c_1)\big]\,q_1 \\ &= (p_1 - p_0)\,q_1 + (c_0 - c_1)\,q_1,\end{aligned}$$

where the second line uses $p_0 = c_0$. The rectangle $(p_1 - p_0)q_1$ appears in both changes with opposite signs. Adding them,

$$\Delta W = \underbrace{(c_0 - c_1)\,q_1}_{A_2} - \underbrace{\frac{1}{2}(p_1 - p_0)(q_0 - q_1)}_{A_1}. \tag{11.8}$$

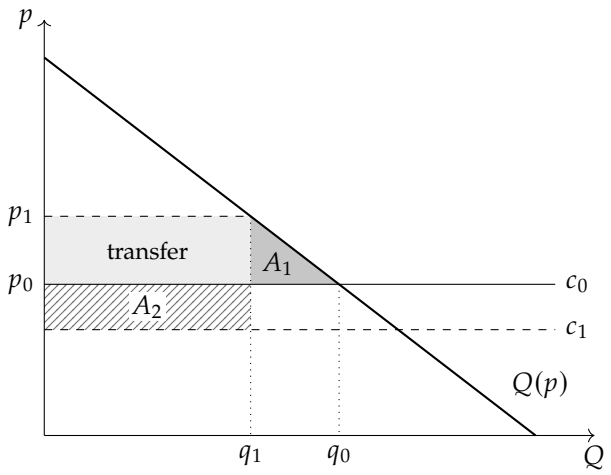

Figure 11.5: The Williamson trade-off. The merger raises the price from $p_0 = c_0$ to p_1 and lowers unit cost from c_0 to c_1. The dark triangle A_1 is the deadweight loss. The hatched rectangle A_2 is the cost saving on the remaining output q_1. The light rectangle is a transfer from consumers to the merged firm.

How large must the cost saving be. Set $\Delta W = 0$ and divide (11.8) by $c_0 q_1 = p_0 q_1$:

$$\frac{c_0 - c_1}{c_0} = \frac{1}{2} \cdot \frac{p_1 - p_0}{p_0} \cdot \frac{q_0 - q_1}{q_1}.$$

With a linear demand curve of elasticity ε at p_0, the output loss is $q_0 - q_1 = \varepsilon \frac{\Delta p}{p_0} q_0$, where $\Delta p = p_1 - p_0$. Substituting, and using $q_1 = q_0\big(1 - \varepsilon \frac{\Delta p}{p_0}\big)$,

$$\frac{c_0 - c_1}{c_0} = \frac{\varepsilon \big(\frac{\Delta p}{p_0}\big)^2}{2\big(1 - \varepsilon \frac{\Delta p}{p_0}\big)} \approx \frac{1}{2} \varepsilon \Big(\frac{\Delta p}{p_0}\Big)^2. \tag{11.9}$$

The approximation drops a term of third order in $\frac{\Delta p}{p_0}$. The breakeven cost saving is second order in the price increase, because the deadweight loss is a triangle while the cost saving is a rectangle. With unit elasticity, a 10 percent price increase is offset by a cost saving of about 0.5 percent (0.56 percent with the exact formula). A 5 percent increase needs about 0.13 percent. With an elasticity of 2 and a 10 percent price increase, the saving must be about 1 percent (1.25 percent exactly). Williamson concluded that modest cost savings can offset sizable price increases under a total surplus standard.

Welfare standards. The conclusion depends on counting the transfer $(p_1 - p_0)q_1$ as neutral. Under a *total surplus standard*, the agency approves a merger that raises the sum of consumer and producer surplus. Under a *consumer surplus standard*, it approves only mergers that do not harm consumers, which in this setting means the price must not rise. Antitrust authorities by and large apply the second standard (Asker and Nocke, 2021, p. 223, n. 120). Under the 2010 Guidelines, efficiencies save a merger only if they would reverse its potential to harm customers, for instance by preventing price increases (U.S. Department of Justice and Federal Trade Commission, 2010, Section 10). A consumer surplus standard can serve a total surplus objective, because a tougher authority induces a better pool of proposed mergers (Section 11.1.2). Under a consumer surplus standard the trade-off disappears, and the required cost saving is much

larger. Suppose demand is $P(Q) = a - bQ$ and the merged firm becomes a monopolist with cost c_1. It charges $\frac{a+c_1}{2}$, which does not exceed $p_0 = c_0$ if and only if $c_1 \le 2c_0 - a = c_0 - (a - c_0)$. Marginal cost must therefore fall by at least $a - c_0 > 0$, the gap between the demand intercept and the initial price.

Pre-existing market power. If the industry already had market power, so that $p_0 > c_0$, the lost output was worth more than its cost. The same steps, now with $\Delta\pi = (p_1 - c_1)q_1 - (p_0 - c_0)q_0$, give

$$\Delta W = (c_0 - c_1)\, q_1 - \frac{1}{2}(p_1 - p_0)(q_0 - q_1) - (p_0 - c_0)(q_0 - q_1). \tag{11.10}$$

The extra rectangle $(p_0 - c_0)(q_0 - q_1)$ is first order in the price increase, so in an industry that is already concentrated, a given price increase requires a much larger cost saving.

The Williamson calculation treats the cost saving and the price increase as separate primitives. It does not ask how the nature of the merger links the two (Farrell and Shapiro, 1988, p. 1, n. 1). In an oligopoly, the price effect itself depends on the cost saving and on how rivals respond. The rest of this section builds that link.

11.3.2 The merger paradox

Salant et al. (1983) studied mergers in the simplest Cournot model and found that most of them reduce the merging firms' profits. Let inverse demand be $P(Q) = a - Q$ and let N firms have the same constant marginal cost $c < a$. With n active symmetric firms, the Cournot equilibrium (Chapter 2) has

$$q = \frac{a - c}{n + 1}, \qquad P = \frac{a + nc}{n + 1}, \qquad \pi = \frac{(a - c)^2}{(n + 1)^2}.$$

A merger of M firms, $2 \le M \le N$, without cost savings leaves $N - M + 1$ symmetric firms, because the merged firm has the same cost as every other firm. Here M counts the merging firms. Market size plays no role in this section.

Proposition 11.4 (The merger paradox, Salant et al., 1983)**.** *In the linear Cournot model with N symmetric firms and constant marginal cost, a merger of M firms without cost savings raises the price and the profit of every outsider. It is profitable for the merging firms if and only if*

$$\frac{1}{(N - M + 2)^2} \ge \frac{M}{(N + 1)^2}. \tag{11.11}$$

A merger of two firms is profitable only if $N = 2$. A merger to monopoly ($M = N$) is always profitable.

Proof. After the merger there are $n = N - M + 1$ firms, so $n + 1 = N - M + 2$. The price rises from $\frac{a+Nc}{N+1}$ to $\frac{a+(N-M+1)c}{N-M+2}$, since $P = c + \frac{a-c}{n+1}$ decreases in n. Each outsider's profit rises from $\frac{(a-c)^2}{(N+1)^2}$ to $\frac{(a-c)^2}{(N-M+2)^2}$. The merged firm earns $\frac{(a-c)^2}{(N-M+2)^2}$, and the M insiders earned $\frac{M(a-c)^2}{(N+1)^2}$ together before the merger. Comparing the two gives (11.11). For $M = 2$ the condition reads $(N + 1)^2 \ge 2N^2$, or $N + 1 \ge \sqrt{2}\, N$, that is,

$$N \le \frac{1}{\sqrt{2} - 1} = 1 + \sqrt{2} \approx 2.41.$$

Only $N = 2$ satisfies it. For $M = N$ the condition reads $(N + 1)^2 \ge 4N$, or $(N - 1)^2 \ge 0$, which always holds. □

How large must a merger be to pay? For $N = 5$ the smallest profitable merger has $M = 4$, which exactly breaks even. For $N = 10$ it has $M = 9$, and for $N = 20$ it has $M = 17$. Among all N up to 1,000, the smallest profitable merger never includes fewer than 80 percent of the firms. The fraction is not monotone in N. It is 0.8 at $N = 5$, 0.9 at $N = 10$ and 0.82 at $N = 11$. It approaches one as N grows, because for large N condition (11.11) is approximately $\frac{M}{N}\left(1 - \frac{M}{N}\right)^2 \leq \frac{1}{N}$. Figure 11.6 plots the percentage change in the insiders' joint profit against the fraction of firms that merge.

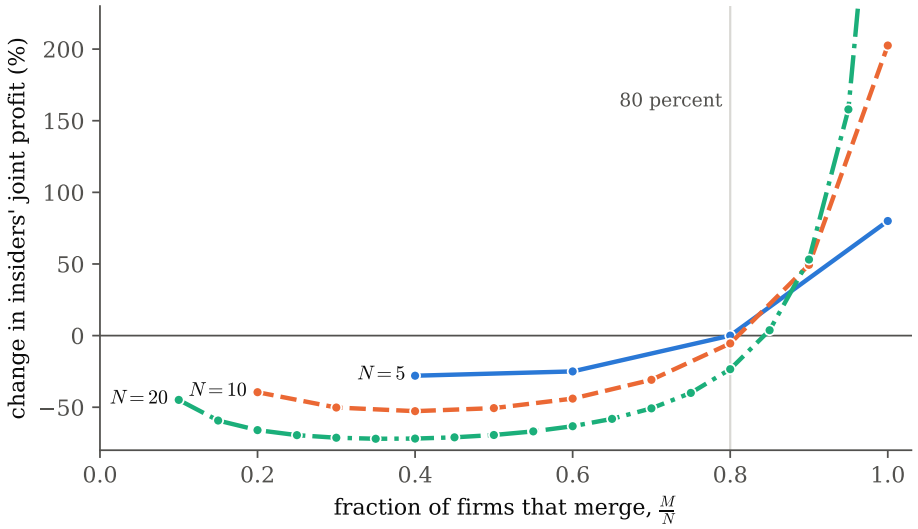

Figure 11.6: The merger paradox. Percentage change in the joint profit of M merging firms in a linear Cournot market with N symmetric firms and no cost savings, $100\left[\frac{(N+1)^2}{M(N-M+2)^2} - 1\right]$, against $\frac{M}{N}$. Points above zero are profitable mergers. Curves are clipped at 230 percent.

The reason is the response of the outsiders. In Cournot competition, quantities are strategic substitutes. When the merged firm cuts its output, the outsiders expand theirs and capture much of the benefit of the higher price. Moreover, a merger in this model is equivalent to $M - 1$ firms shutting down. The merged firm is no larger and no more efficient than any other firm, so it ends up with a share of only $\frac{1}{N-M+1}$ (Farrell and Shapiro, 1988, p. 4). The paradox is that we observe many horizontal mergers.

Three features of the model drive the result, and relaxing any of them can overturn it. First, the merging firms bring no assets. Perry and Porter (1985) let each firm own capital that lowers its marginal cost, so the merged firm has the combined capital and is larger than its rivals. Mergers can then be profitable, and Section 11.3.3 develops this idea in general. Second, the model has no investment. Pesendorfer (2003, Remark 3) considers firms that hold capacity, with linear demand $P = a - bQ$, constant marginal cost c, a linear cost r per unit of new capacity, and initial capacities at Cournot levels. He also normalizes the discount and depreciation factors. He shows that a merger without cost savings is profitable whenever $n + 1 > \frac{a-c}{r}$. Building capacity is costly while scrapping it is not, and this asymmetry favors the merged firm. The Salant-Switzer-Reynolds result is the limit as $r \to 0$ (Pesendorfer, 2003, p. 7, n. 6). Section 11.9 returns to this model. Third, quantities are strategic substitutes. With price competition and differentiated products, rivals raise their prices after a merger, and the merger is profitable (Section 11.4).

11.3.3 Farrell and Shapiro (1990): mergers as transfers of capital

The question. Farrell and Shapiro (1990) ask when a horizontal merger raises the price, when it raises welfare, and what a regulator can infer from the fact that the merging firms want to merge. Their answer rests on three ideas. A merger is a transfer of industry-specific capital from one firm to another. The welfare effect of a merger can be split into the change in the merging firms' profits, which they internalize, and an *external effect* on consumers and rivals. The external effect depends only on observable market data, while the private effect may include synergies that only the firms know. A regulator should therefore approve any merger that is proposed and has a positive external effect, because private profitability then guarantees a welfare gain. We follow the 1988 working-paper version (Farrell and Shapiro, 1988), whose numbering of equations and propositions differs from the published article. The result on the cost savings needed to lower the price belongs to the published article (Farrell and Shapiro, 1990) and is not in the working paper. We state it as Asker and Nocke (2021, pp. 216–217 and 229) report it, and we prove it in full.

The model

There are N firms producing a homogeneous good, and their number is fixed by barriers to entry. A competitive fringe can be absorbed into the demand curve, which is then a residual demand. We write q_i for firm i's output, $Q = \sum_i q_i$ for industry output, $P(Q)$ for inverse demand and $s_i = \frac{q_i}{Q}$ for market shares (Farrell and Shapiro write x_i, X and $p(X)$).

Assumption 11.5 (Cournot oligopoly with capital)**.**

(i) Inverse demand $P(Q)$ is twice differentiable with $P'(Q) < 0$.

(ii) Firm i owns capital k_i and has a twice differentiable cost function $C^i(q_i, k_i)$. More capital lowers marginal cost, $C^i_{qk} < 0$, where subscripts denote partial derivatives.

(iii) Given the capital vector $k = (k_1, \dots, k_N)$, firms choose outputs simultaneously (Cournot). The equilibrium is unique and interior.

(iv) Reaction functions slope down and the equilibrium is stable. Formally, at the equilibrium, $P' + q_i P'' < 0$ and $C^i_{qq} - P' > 0$ for every firm.

Firms may have different technologies, and C^i may then embody firm-specific assets that cannot be transferred. Capital is industry specific and fixed in the short run, while outputs adjust quickly. Firm i maximizes $\pi_i = P(Q)\, q_i - C^i(q_i, k_i)$, with first-order condition

$$P(Q) + q_i P'(Q) - C^i_q(q_i, k_i) = 0, \qquad i = 1, \dots, N. \tag{11.12}$$

The condition implies $P - C^i_q = -q_i P'$, so each firm's margin over marginal cost is proportional to its output. Comparing two firms, $q_i > q_j$ if and only if $C^i_q < C^j_q$. In a Cournot equilibrium, *larger firms have lower marginal costs*. Whenever firms produce different quantities, marginal costs differ, so total cost is not minimized for the industry's output. Shifting output toward large firms would lower it.

Welfare is consumers' gross benefit minus production costs,

$$W = \int_0^Q P(z)\, \mathrm{d}z - \sum_{i=1}^{N} C^i(q_i, k_i).$$

Profit and welfare effects of a change in capital

Consider a small change $\mathrm{d}k = (\mathrm{d}k_1, \ldots, \mathrm{d}k_N)$ in the allocation of capital, and the induced changes $\mathrm{d}q_i$ in outputs. Differentiating π_i,

$$\mathrm{d}\pi_i = (P - C_q^i)\,\mathrm{d}q_i + q_i P'\,\mathrm{d}Q - C_k^i\,\mathrm{d}k_i. \tag{11.13}$$

A firm gains from extra output in proportion to its margin, gains from a price increase in proportion to its output, and saves costs through its own capital. Differentiating W and using $\frac{\mathrm{d}}{\mathrm{d}Q}\int_0^Q P = P$,

$$\mathrm{d}W = \sum_{i=1}^{N}(P - C_q^i)\,\mathrm{d}q_i - \sum_{i=1}^{N} C_k^i\,\mathrm{d}k_i. \tag{11.14}$$

The first sum values each change in output at the gap between price and marginal cost. The second is the direct effect of capital on costs at given outputs. Equations (11.13) and (11.14) hold for any theory of oligopoly. Under Cournot competition, $P - C_q^i = -q_i P'$, and (11.14) becomes

$$\mathrm{d}W = -P' \sum_{i=1}^{N} q_i\,\mathrm{d}q_i - \sum_{i=1}^{N} C_k^i\,\mathrm{d}k_i. \tag{11.15}$$

Lemma 11.6 (Welfare and the Herfindahl index)**.** *Under Assumption 11.5,*

$$\mathrm{d}W = -P'\Big(HHI\,Q\,\mathrm{d}Q + \frac{1}{2}Q^2\,\mathrm{d}HHI\Big) - \sum_{i=1}^{N} C_k^i\,\mathrm{d}k_i. \tag{11.16}$$

Proof. Since $HHI = \sum_i \left(\frac{q_i}{Q}\right)^2$, we have $Q^2 HHI = \sum_i q_i^2$. Differentiating both sides,

$$2\sum_i q_i\,\mathrm{d}q_i = \mathrm{d}\big(Q^2 HHI\big) = 2HHI\,Q\,\mathrm{d}Q + Q^2\,\mathrm{d}HHI.$$

Dividing by two and substituting into (11.15) gives (11.16). □

Lemma 11.6 splits a welfare change into three parts: a change in industry output, a change in its distribution, and the direct effect on costs. More output raises welfare because price exceeds marginal cost. More surprisingly, for a given change in output, a larger increase in the Herfindahl index raises welfare more, since $-P' > 0$. Large firms have the lowest marginal costs, so shifting output toward them saves resources. Any analysis that treats increases in concentration as bad per se is therefore misleading under Cournot competition (Farrell and Shapiro, 1988, p. 8).

Comparative statics

Lemma 11.7 (Output responses)**.** *Under Assumption 11.5, define for each firm*

$$\lambda_i = \frac{-P' - q_i P''}{C_{qq}^i - P'} > 0, \qquad \chi_i = \frac{-C_{qk}^i}{C_{qq}^i - P'} > 0, \qquad \Lambda = \sum_{i=1}^{N}\lambda_i. \tag{11.17}$$

A small change $\mathrm{d}k$ *changes outputs by*

$$\mathrm{d}q_i = -\lambda_i\,\mathrm{d}Q + \chi_i\,\mathrm{d}k_i, \qquad \mathrm{d}Q = \frac{1}{1+\Lambda}\sum_{i=1}^{N}\chi_i\,\mathrm{d}k_i. \tag{11.18}$$

Proof. Totally differentiate the first-order condition (11.12), holding the equilibrium:

$$\big(P' + q_i P''\big)\,\mathrm{d}Q + P'\,\mathrm{d}q_i - C^i_{qq}\,\mathrm{d}q_i - C^i_{qk}\,\mathrm{d}k_i = 0.$$

Collect the terms in $\mathrm{d}q_i$:

$$\big(C^i_{qq} - P'\big)\,\mathrm{d}q_i = \big(P' + q_i P''\big)\,\mathrm{d}Q - C^i_{qk}\,\mathrm{d}k_i.$$

Dividing by $C^i_{qq} - P' > 0$ gives the first part of (11.18). Signs follow from part (iv) of Assumption 11.5 and from $C^i_{qk} < 0$. Summing over i,

$$\mathrm{d}Q = -\Lambda\,\mathrm{d}Q + \sum_i \chi_i\,\mathrm{d}k_i,$$

and solving for $\mathrm{d}Q$ gives the second part. □

The coefficient χ_i is the *direct effect* of firm i's capital on its output at a given industry output (Farrell and Shapiro call it δ_i). The coefficient λ_i measures how firm i responds to a change in industry output, and hence to the price. A firm whose capital does not change adjusts its output by $\mathrm{d}q_i = -\lambda_i\,\mathrm{d}Q$. Its response to the combined output of the others, Q_{-i}, follows from $\mathrm{d}Q = \mathrm{d}q_i + \mathrm{d}Q_{-i}$ and is $\frac{\mathrm{d}q_i}{\mathrm{d}Q_{-i}} = -\frac{\lambda_i}{1+\lambda_i}$. Two special cases recur. With constant marginal cost, $C^i_{qq} = 0$ and

$$\lambda_i = \frac{-P' - q_i P''}{-P'} = 1 + \frac{q_i P''}{P'} = 1 - s_i\,\mathcal{E}, \qquad \mathcal{E} = -\frac{Q P''(Q)}{P'(Q)}, \tag{11.19}$$

where $\mathcal{E}$ is the elasticity of the slope of inverse demand (Farrell and Shapiro write E). With linear demand $P = a - Q$ and the cost function $C(q,k) = \frac{q^2}{2k}$, we have $C_{qq} = \frac{1}{k}$ and $P' = -1$, so $\lambda_i = \frac{1}{1+\frac{1}{k_i}} = \frac{k_i}{1+k_i}$.

Example 11.8 (Two technologies)**.** *Physical capital.* Let $P(Q) = a - Q$ and $C(q,k) = \frac{q^2}{2k}$ for all firms. This technology has constant returns to scale and corresponds to the production function $q = \sqrt{kv}$ with a variable input v. Firm i's first-order condition is $a - Q - q_i - \frac{q_i}{k_i} = 0$. Define the *adjusted capital* $\tilde{k}_i = \frac{k_i}{1+k_i}$. The condition becomes

$$q_i\Big(1 + \frac{1}{k_i}\Big) = a - Q \quad\Longrightarrow\quad q_i = (a - Q)\,\tilde{k}_i = P\,\tilde{k}_i.$$

Summing over firms, $Q = (a - Q)\tilde{K}$ with $\tilde{K} = \sum_i \tilde{k}_i$, so

$$Q = \frac{a\tilde{K}}{1 + \tilde{K}}, \qquad P = \frac{a}{1 + \tilde{K}}, \qquad C^i_q = \frac{q_i}{k_i} = \frac{P}{1 + k_i}.$$

Firms with more capital produce more and have lower marginal costs. Here $\lambda_i = \tilde{k}_i = \frac{q_i}{P}$, and the direct effect is

$$\chi_i = \frac{\frac{q_i}{k_i^2}}{\frac{1}{k_i} + 1} = \frac{q_i}{k_i(1 + k_i)} = \frac{P}{(1 + k_i)^2}.$$

Know-how. Let unit cost depend on capital but not on output, $C(q,k) = q\,\phi(k)$ with $\phi' < 0$. This fits patents, know-how and managerial talent, which can be applied to any scale of output. The first-order conditions are $P + q_i P' = \phi(k_i)$, and summing them gives

$$NP(Q) + QP'(Q) = \sum_{i=1}^{N} \phi(k_i), \tag{11.20}$$

so industry output depends on capital only through the sum of marginal costs.

Investment by one firm

Before turning to mergers, consider investment, $\mathrm{d}k = (\mathrm{d}k_1, 0, \ldots, 0)$. By Lemma 11.7,

$$\frac{\mathrm{d}Q}{\mathrm{d}k_1} = \frac{\chi_1}{1+\Lambda}, \qquad \frac{\mathrm{d}q_i}{\mathrm{d}k_1} = -\frac{\lambda_i \chi_1}{1+\Lambda}\ (i \neq 1), \qquad \frac{\mathrm{d}q_1}{\mathrm{d}k_1} = \chi_1\Big(1 - \frac{\lambda_1}{1+\Lambda}\Big).$$

The investing firm expands, its rivals contract, and industry output rises. Subtracting (11.14) from (11.13) for $i = 1$, the private and social returns differ by

$$\mathrm{d}\pi_1 - \mathrm{d}W = q_1 P'\,\mathrm{d}Q - \sum_{i \neq 1} (P - C_q^i)\,\mathrm{d}q_i. \tag{11.21}$$

The first term is a private loss that is a transfer to consumers: the investor's price falls on its own sales. The second is a social cost the investor ignores: rivals, whose price exceeds marginal cost, cut their output. Using $P - C_q^i = -q_i P'$ and $\mathrm{d}q_i = -\lambda_i\,\mathrm{d}Q$ for $i \neq 1$,

$$\frac{\mathrm{d}\pi_1}{\mathrm{d}k_1} - \frac{\mathrm{d}W}{\mathrm{d}k_1} = -P' \frac{\mathrm{d}Q}{\mathrm{d}k_1}\Big(\sum_{i \neq 1} \lambda_i q_i - q_1\Big). \tag{11.22}$$

Proposition 11.9 (Investment incentives)**.** *Under Assumption 11.5, firm 1 has an excessive incentive to invest, $\frac{\mathrm{d}\pi_1}{\mathrm{d}k_1} > \frac{\mathrm{d}W}{\mathrm{d}k_1}$, if and only if*

$$s_1 < \sum_{i \neq 1} \lambda_i s_i. \tag{11.23}$$

With linear demand and the costs $\frac{q^2}{2k}$, the condition is $s_1 < \frac{1}{\varepsilon}\sum_{i\neq 1} s_i^2$, where $\varepsilon = -\frac{P}{QP'}$. With constant marginal costs, it is $s_1 < \frac{1}{2} - \frac{\mathcal{E}}{2}\sum_{i\neq 1} s_i^2$.

Proof. In (11.22), $-P' > 0$ and $\frac{\mathrm{d}Q}{\mathrm{d}k_1} > 0$, so the wedge is positive if and only if $\sum_{i\neq 1}\lambda_i q_i > q_1$. Dividing by Q gives (11.23). In the quadratic case, $\lambda_i = \frac{q_i}{P}$, so $\sum_{i\neq 1}\lambda_i s_i = \frac{Q}{P}\sum_{i\neq 1} s_i^2$, and $\frac{Q}{P} = \frac{1}{\varepsilon}$ because $P' = -1$. With constant marginal costs, $\sum_{i\neq 1}(1 - s_i\mathcal{E})s_i = 1 - s_1 - \mathcal{E}\sum_{i\neq 1} s_i^2$, and the inequality $s_1 < 1 - s_1 - \mathcal{E}\sum_{i\neq 1} s_i^2$ rearranges to the stated form. □

Small firms invest too much. Their investment lowers the price and helps consumers, but it steals valuable business from larger rivals with high margins, and the second effect dominates (Farrell and Shapiro, 1988, pp. 10–11). If λ_i rises with firm size, as in the quadratic case, large efficient firms invest too little.

Small capital transfers and the price

A merger moves capital from one firm to another. Consider a small transfer from firm 2 to firm 1, $\mathrm{d}k_1 = \mathrm{d}k = -\mathrm{d}k_2 > 0$, with $k_1 > k_2$, so that the transfer increases the concentration of capital. A complete merger of the two firms is the accumulation of such transfers, from (k_1, k_2) to $(k_1 + k_2, 0)$. Divestitures are the reverse.

Proposition 11.10 (Price effect of a transfer)**.** *Under Assumption 11.5, a small transfer of capital from firm 2 to firm 1 changes industry output by*

$$\frac{\mathrm{d}Q}{\mathrm{d}k} = \frac{\chi_1 - \chi_2}{1 + \Lambda}. \tag{11.24}$$

It reduces output and raises the price if and only if $\chi_1 < \chi_2$, that is, if and only if the direct output effect of capital is smaller at the acquiring firm.

Proof. Substitute $\mathrm{d}k_1 = \mathrm{d}k$, $\mathrm{d}k_2 = -\mathrm{d}k$ and $\mathrm{d}k_i = 0$ for $i \geq 3$ into (11.18). Since $1 + \Lambda > 0$, the sign of $\mathrm{d}Q$ is the sign of $\chi_1 - \chi_2$. □

In the physical-capital example, $\chi_i = \frac{P}{(1+k_i)^2}$ falls with k_i, so every concentration-increasing transfer raises the price. The same follows from the closed form $P = \frac{a}{1+\tilde{K}}$. Adjusted capital $\tilde{k}(k) = \frac{k}{1+k}$ is strictly concave with $\tilde{k}(0) = 0$, so moving capital from the smaller to the larger firm lowers $\tilde{k}_1 + \tilde{k}_2$, and a complete merger gives $\tilde{k}(k_1 + k_2) < \tilde{k}(k_1) + \tilde{k}(k_2)$. In the know-how example, (11.20) shows that output falls if and only if the transfer raises $\sum_i \phi(k_i)$, and the transfer changes this sum by $\big(\phi'(k_1) - \phi'(k_2)\big)\mathrm{d}k$. With $k_1 > k_2$, the price rises if and only if $\phi'' > 0$. A merger of know-how raises the price when units of know-how are substitutes, which lower unit cost at a diminishing rate. It lowers the price when they are complements.

Proposition 11.10 needs the χ_i, which are hard to measure. A condition on the technology alone is more useful.

Proposition 11.11 (A sufficient condition, Farrell and Shapiro, 1988)**.** *Suppose that, in addition to Assumption 11.5, all firms share the cost function $C(q, k)$ and the marginal cost C_q is jointly convex in (q, k). Then every concentration-increasing transfer, small or large, weakly reduces output and weakly raises the price, as long as the selling firm remains active. The effects are strict when the Hessian of C_q is positive definite.*

Proof. Fix industry output Q, and let $\tilde{q}(Q, k)$ be the output of a firm with capital k that satisfies the first-order condition, $P(Q) + \tilde{q}P'(Q) = C_q(\tilde{q}, k)$. Because the technology is common, firm i's output in equilibrium is $\tilde{q}(Q, k_i)$ and its direct effect is $\chi_i = \tilde{q}_k(Q, k_i)$. To see this, differentiate the condition in k at fixed Q:

$$P'\,\tilde{q}_k = C_{qq}\,\tilde{q}_k + C_{qk} \quad \Longrightarrow \quad \tilde{q}_k = \frac{-C_{qk}}{C_{qq} - P'} = \chi.$$

Differentiating once more in k,

$$P'\,\tilde{q}_{kk} = C_{qqq}\,\tilde{q}_k^2 + 2C_{qqk}\,\tilde{q}_k + C_{qkk} + C_{qq}\,\tilde{q}_{kk},$$

so

$$\tilde{q}_{kk} = -\frac{C_{qqq}\,\tilde{q}_k^2 + 2C_{qqk}\,\tilde{q}_k + C_{qkk}}{C_{qq} - P'}.$$

The numerator is $\gamma^\top H\gamma$ with $\gamma = (\tilde{q}_k, 1)^\top$ and H the Hessian of C_q. Joint convexity makes it nonnegative, so $\tilde{q}_{kk} \le 0$ and $\chi = \tilde{q}_k$ is nonincreasing in k across firms. Hence $k_1 > k_2$ implies $\chi_1 \le \chi_2$, and Proposition 11.10 applies. A positive definite Hessian makes the numerator positive, because $\gamma \neq 0$, and then $\chi_1 < \chi_2$. A large transfer is a sequence of small transfers, each from the smaller to the larger firm, so output falls along the whole path. □

Farrell and Shapiro add that the condition is sufficient but not necessary. The physical-capital technology violates it, since its marginal cost $\frac{q}{k}$ is not jointly convex, yet every merger raises the price there. The know-how technology satisfies it exactly when $\phi'' \ge 0$, since $C_q = \phi(k)$. Its Hessian is singular, yet the numerator in the proof equals $\phi''(k)$, so the price rises strictly when $\phi'' > 0$. Under the conditions of Propositions 11.10 and 11.11, a merger harms consumers. Because rivals' profits rise exactly when the price rises, the same conditions tell us when rivals gain (Farrell and Shapiro, 1988, p. 15).

Discrete mergers and the synergies needed to lower the price

A merger can also reorganize production or create synergies that a reallocation of existing capital cannot capture. To study such mergers, we replace capital by constant marginal costs. Firm i has marginal cost c_i. Firms 1 and 2 merge, and the merged firm has marginal cost c_M, which summarizes its post-merger technology. A merger with no synergies can at best produce everything at the lower of the two costs, $c_M = \min\{c_1, c_2\}$. We write $P^0 = P(Q^0)$ for the pre-merger price.

Proposition 11.12 (Synergies needed to lower the price, Farrell and Shapiro, 1990)**.** *Suppose firms have constant marginal costs, $P'(Q) + qP''(Q) < 0$ for all $0 \le q \le Q$, and all firms are active before and after the merger. The merger of firms 1 and 2 lowers the equilibrium price if and only if*

$$c_M < \hat{c} \equiv c_1 + c_2 - P^0, \quad \textit{equivalently} \quad P^0 - c_M > (P^0 - c_1) + (P^0 - c_2). \tag{11.25}$$

It leaves the price unchanged if $c_M = \hat{c}$ and raises it if $c_M > \hat{c}$.

Proof. Summing the first-order conditions $P + q_i P' = c_i$ over the n active firms gives the aggregate condition

$$\Gamma_n(Q) \equiv nP(Q) + QP'(Q) = \sum_{i \text{ active}} c_i.$$

Its slope is $\Gamma_n'(Q) = P' + \sum_i \left(P' + q_i P''\right) < 0$, so Γ_n is strictly decreasing and the equilibrium output is the unique solution. Only the number of firms and the sum of their marginal costs matter for Q. Before the merger,

$$NP^0 + Q^0 P'(Q^0) = c_1 + c_2 + \sum_{i \ge 3} c_i.$$

After the merger there are $N - 1$ firms, and the post-merger output Q^1 solves $\Gamma_{N-1}(Q^1) = c_M + \sum_{i \ge 3} c_i$. Evaluate Γ_{N-1} at the pre-merger output and use the pre-merger condition:

$$\Gamma_{N-1}(Q^0) = NP^0 + Q^0 P'(Q^0) - P^0 = c_1 + c_2 - P^0 + \sum_{i \ge 3} c_i.$$

Since Γ_{N-1} is decreasing, $Q^1 > Q^0$ if and only if $\Gamma_{N-1}(Q^1) < \Gamma_{N-1}(Q^0)$, that is, if and only if

$$c_M + \sum_{i \ge 3} c_i < c_1 + c_2 - P^0 + \sum_{i \ge 3} c_i \quad \Longleftrightarrow \quad c_M < c_1 + c_2 - P^0.$$

A higher output means a lower price. The cases of equality and of the reverse inequality follow the same way. □

Corollary 11.13 (No synergies, higher price)**.** *Under the conditions of Proposition 11.12, the price-neutral cost satisfies $\hat{c} < \min\{c_1, c_2\}$. Any merger with $c_M \geq \min\{c_1, c_2\}$, including every merger that only rationalizes production, raises the price.*

Proof. Firm 2 is active before the merger, so $P^0 - c_2 = -q_2 P'(Q^0) > 0$. Hence $\hat{c} = c_1 - (P^0 - c_2) < c_1$. By the same argument with the roles reversed, $\hat{c} < c_2$. If $c_M \geq \min\{c_1, c_2\}$, then $c_M > \hat{c}$, and Proposition 11.12 applies. □

The required synergy is large. Let firm 1 be the more efficient partner. The merged firm's cost must fall below c_1 by firm 2's entire margin, $c_1 - \hat{c} = P^0 - c_2$. As a fraction of the price, the reduction equals firm 2's Lerner index, $\frac{c_1 - \hat{c}}{P^0} = \frac{s_2}{\varepsilon}$. As a fraction of firm 1's cost it is $\frac{L_2}{1 - L_1}$, where $L_i = \frac{P^0 - c_i}{P^0}$. Two firms with 20 percent shares each, facing a market elasticity of one, have $L_1 = L_2 = 0.2$. For their merger not to raise the price, marginal cost must fall by $\frac{0.2}{0.8} = 25$ percent.

The required reduction can also be written with the naive change in concentration. Let $s_I = s_1 + s_2$ and let $\bar{c} = \frac{s_1 c_1 + s_2 c_2}{s_I}$ be the partners' share-weighted marginal cost. The first-order conditions give $P^0 - c_i = \frac{s_i P^0}{\varepsilon}$, so

$$P^0 - \bar{c} = \frac{s_1(P^0 - c_1) + s_2(P^0 - c_2)}{s_I} = \frac{s_1^2 + s_2^2}{s_I} \cdot \frac{P^0}{\varepsilon},$$
$$P^0 - \hat{c} = (P^0 - c_1) + (P^0 - c_2) = s_I \frac{P^0}{\varepsilon}.$$

Subtracting the first line from the second,

$$\frac{\bar{c} - \hat{c}}{P^0} = \frac{1}{\varepsilon}\left(s_I - \frac{s_1^2 + s_2^2}{s_I}\right) = \frac{(s_1 + s_2)^2 - s_1^2 - s_2^2}{\varepsilon\, s_I} = \frac{2 s_1 s_2}{\varepsilon\, s_I}. \tag{11.26}$$

The numerator is the naive ΔHHI of (11.7). The outsiders' shares do not enter, so for given shares of the merging firms the required efficiency does not depend on the level of the index. This parallels the finding of Nocke and Whinston (2020), reported in Section 11.2.3, that required efficiencies track the change in concentration and not its level. In the example above, $\frac{2 \times 0.2 \times 0.2}{0.4} = 0.2$ of the price, which is 25 percent of $\bar{c} = 0.8 P^0$.

Proposition 11.12 is the condition that Nocke and Whinston (2013, Lemma 1 and eq. (5)) use to define a *CS-neutral merger*, one that leaves consumer surplus unchanged. In their notation, with acquirer 0 and target k, the condition is $\bar{c}_k = c_k - \left[P(Q^0) - c_0\right]$, the same as (11.25). They also note that such a merger is profitable. The argument is short.

Corollary 11.14 (A price-neutral merger is profitable)**.** *Under the conditions of Proposition 11.12, let $c_M = \hat{c}$. The merger leaves the price and every outsider's output unchanged and gives the merged firm the output $q_1 + q_2$. It raises the joint profit of the merging firms by $(P^0 - c_1)q_2 + (P^0 - c_2)q_1 > 0$.*

Proof. With $c_M = \hat{c}$, Proposition 11.12 gives $Q^1 = Q^0$, so the price and its slope are unchanged. Each outsider's first-order condition $P + q_i P' = c_i$ then gives the same q_i. The merged firm

produces the rest, $Q^0 - \sum_{i\geq 3} q_i = q_1 + q_2$. Its profit is

$$\begin{aligned}(P^0 - \hat{c})(q_1 + q_2) &= \big[(P^0 - c_1) + (P^0 - c_2)\big](q_1 + q_2) \\ &= \underbrace{(P^0 - c_1)q_1 + (P^0 - c_2)q_2}_{\pi_1+\pi_2} + (P^0 - c_1)q_2 + (P^0 - c_2)q_1.\end{aligned}$$

Both extra terms are positive because both firms were active. □

Figure 11.7 illustrates these results. Demand is $P = 10 - Q$ and three firms have costs $(c_1, c_2, c_3) = (2, 3, 3)$, so $P^0 = 4.5$ and outputs are $(2.5, 1.5, 1.5)$. If firms 1 and 2 merge, the post-merger price is $\frac{13+c_M}{3}$. The price-neutral cost is $\hat{c} = 2 + 3 - 4.5 = 0.5$, well below $c_1 = 2$. Rationalization alone, $c_M = 2$, raises the price to 5. This merger is still profitable, because the merged firm earns 9 against the 8.5 the two firms earned before. It lowers total surplus by 0.375, as consumers lose 2.625 while the outsider gains 1.75. Every cost between 0.5 and about 2.13 makes the merger both profitable and price-increasing. Total surplus rises only for costs below about 1.91.

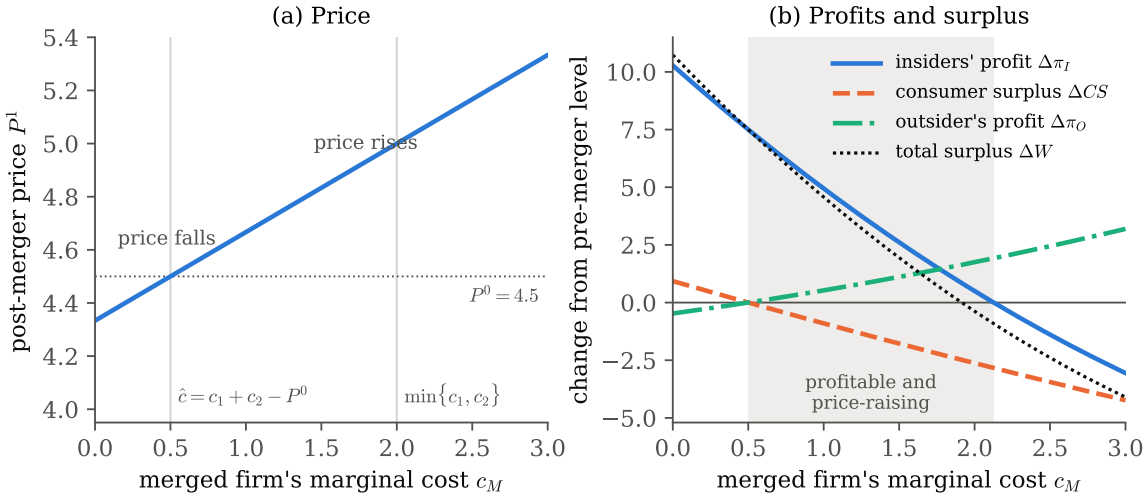

Figure 11.7: A Cournot merger with constant marginal costs. Demand $P = 10 - Q$, costs $(c_1, c_2, c_3) = (2, 3, 3)$, and firms 1 and 2 merge with marginal cost c_M. Panel (a) shows the post-merger price, with the price-neutral cost $\hat{c} = 0.5$ and the rationalization cost $\min\{c_1, c_2\} = 2$. Panel (b) shows the changes in the insiders' joint profit, consumer surplus, the outsider's profit and total surplus. The shaded band, $0.5 < c_M < 2.13$, contains the mergers that are profitable and raise the price. Total surplus falls for $c_M > 1.91$.

General costs, many partners and aggregate surplus

Proposition 11.12 assumes constant marginal costs and two partners. Asker and Nocke (2021, p. 229, eq. (6)) state the condition of Farrell and Shapiro (1990) for any cost functions and any number of partners. We hold capital fixed and write $C_i(q_i)$ for firm i's cost function. A set $\mathcal{M}$ of at least two firms merges into a firm with cost function $C_{\mathcal{M}}(q)$, and $q^0_{\mathcal{M}} = \sum_{i\in\mathcal{M}} q^0_i$ is the partners' combined pre-merger output.

Proposition 11.15 (The synergy condition with general costs, Farrell and Shapiro, 1990)**.** *Let Assumption 11.5 hold with capital fixed, let $C''_{\mathcal{M}} - P' > 0$, and let all firms be active before and after the merger. The merger weakly raises industry output, and so does not lower consumer surplus, if and only if*

$$P(Q^0) - C'_{\mathcal{M}}(q^0_{\mathcal{M}}) \;\geq\; \sum_{i\in\mathcal{M}} \left[P(Q^0) - C'_i(q^0_i)\right]. \tag{11.27}$$

It weakly lowers industry output if and only if the reverse weak inequality holds.

Proof. For a firm with cost function C, define its *fitting-in output* $r(Q)$ as the solution in q of $P(Q) + qP'(Q) = C'(q)$. It is the output at which the firm's first-order condition holds when industry output is Q. The left side minus the right side falls in q at rate $P' - C'' < 0$, so $r(Q)$ is unique. Differentiating the condition in Q,

$$P' + r'P' + rP'' = C''r' \quad\Longrightarrow\quad r'(Q) = \frac{P' + rP''}{C'' - P'} = -\lambda,$$

with $\lambda > 0$ the response coefficient of Lemma 11.7. An equilibrium is an industry output at which the fitting-in outputs add up to Q. After the merger, let

$$\Phi(Q) = \sum_{i\notin\mathcal{M}} r_i(Q) + r_{\mathcal{M}}(Q) - Q.$$

It is strictly decreasing, with slope $-\sum_{i\notin\mathcal{M}}\lambda_i - \lambda_{\mathcal{M}} - 1 < 0$, so the post-merger output Q^1 is its unique zero, and $Q^1 \geq Q^0$ if and only if $\Phi(Q^0) \geq 0$. At Q^0 each outsider's fitting-in output is its pre-merger output, $r_i(Q^0) = q^0_i$. Hence

$$\Phi(Q^0) = \sum_{i\notin\mathcal{M}} q^0_i + r_{\mathcal{M}}(Q^0) - Q^0 = r_{\mathcal{M}}(Q^0) - q^0_{\mathcal{M}}.$$

The merged firm's marginal profit at fixed Q^0, $P(Q^0) + qP'(Q^0) - C'_{\mathcal{M}}(q)$, falls in q and is zero at $r_{\mathcal{M}}(Q^0)$. So $r_{\mathcal{M}}(Q^0) \geq q^0_{\mathcal{M}}$ if and only if the marginal profit is nonnegative at $q^0_{\mathcal{M}}$:

$$P(Q^0) + q^0_{\mathcal{M}}P'(Q^0) - C'_{\mathcal{M}}\left(q^0_{\mathcal{M}}\right) \geq 0.$$

The partners' pre-merger first-order conditions give $q^0_i P'(Q^0) = -\left[P(Q^0) - C'_i(q^0_i)\right]$. Summing over $i \in \mathcal{M}$,

$$q^0_{\mathcal{M}}P'(Q^0) = -\sum_{i\in\mathcal{M}} \left[P(Q^0) - C'_i(q^0_i)\right].$$

Substituting into the marginal profit gives (11.27). The reverse case follows from the same steps with the inequalities reversed. □

With constant marginal costs and two partners, (11.27) is (11.25). Every term on the right of (11.27) is positive, because each partner was active. The right side therefore exceeds each single term $P(Q^0) - C'_j(q^0_j)$. The condition thus requires the merged firm's marginal cost at the combined output to lie below the pre-merger marginal cost of every partner, $C'_{\mathcal{M}}(q^0_{\mathcal{M}}) < \min_{i\in\mathcal{M}} C'_i(q^0_i)$ (Asker and Nocke, 2021, p. 229).

A merger can raise productive efficiency even without synergies, in the sense of Farrell and Shapiro (1990). Say the merger creates *no synergies* when the merged firm can do no better than allocate output among the partners' existing technologies,

$$C_{\mathcal{M}}(q) = \min\left\{ \sum_{i\in\mathcal{M}} C_i(q_i) : \sum_{i\in\mathcal{M}} q_i = q,\; q_i \geq 0 \right\}. \tag{11.28}$$

By the pre-merger first-order conditions, $P - C_i'(q_i^0) = -q_i^0 P'$, so the smaller partner has the higher marginal cost. Shifting output from it to the larger partner lowers the cost of producing $q_{\mathcal{M}}^0$. The next result shows that such output shifting is not enough.

Corollary 11.16 (Rationalization is not enough)**.** *Under the conditions of Proposition 11.15, suppose every C_i is convex and the merger creates no synergies, as in (11.28). Then the merger strictly lowers industry output and consumer surplus.*

Proof. Let $(q_i^*)_{i\in\mathcal{M}}$ solve the problem in (11.28) at $q = q_{\mathcal{M}}^0$. By the envelope theorem, $C_{\mathcal{M}}'(q_{\mathcal{M}}^0)$ equals the multiplier on the output constraint, which equals $C_i'(q_i^*)$ for every partner with $q_i^* > 0$. The q_i^* add up to $\sum_{i\in\mathcal{M}} q_i^0$, so some partner j has $q_j^* \geq q_j^0 > 0$. Convexity of C_j gives

$$C_{\mathcal{M}}'(q_{\mathcal{M}}^0) = C_j'(q_j^*) \geq C_j'(q_j^0) \geq \min_{i\in\mathcal{M}} C_i'(q_i^0).$$

This violates the necessary condition stated after Proposition 11.15, so (11.27) fails, the reverse strict inequality holds, and $Q^1 < Q^0$. □

The result extends to multiproduct firms that compete in prices under logit, nested logit or CES demand. Nocke and Schutz (2018, 2019) show that each firm can then be summarized by a single number, its *type*, which measures its contribution to consumer surplus if it priced at cost. Without synergies the merged firm's type is the sum of the partners' types. A merger does not lower consumer surplus if and only if the merged firm's type exceeds a cutoff above that sum, so it again requires synergies (Asker and Nocke, 2021, p. 229).

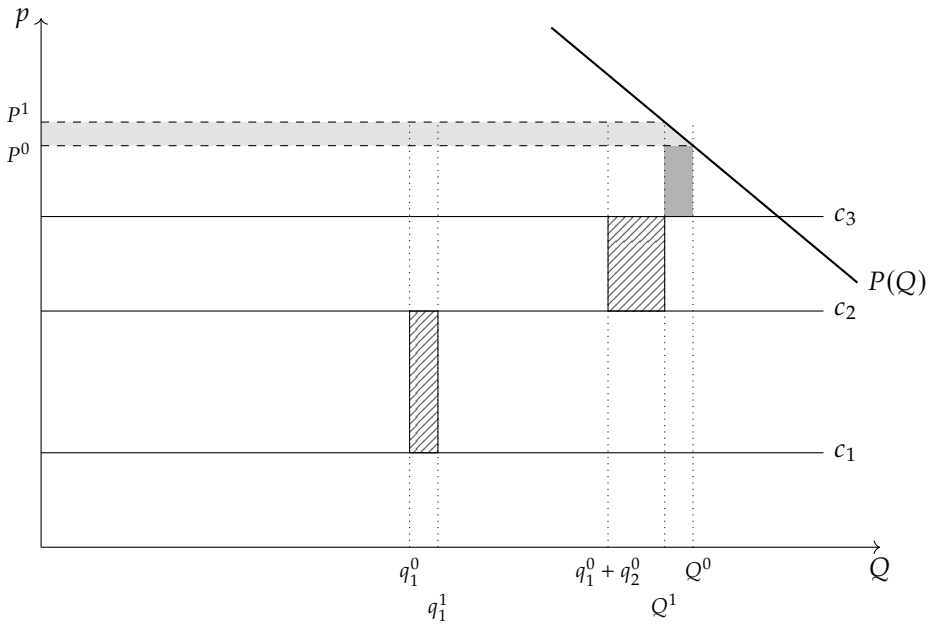

Figure 11.8: A Cournot merger without synergies, redrawn after Asker and Nocke (2021, Figure 6). Demand is $P = 10 - Q$ and marginal costs are $c_1 = 1$, $c_2 = 2.5$ and $c_3 = 3.5$. Firms 2 and 3 merge and produce at c_2. The price rises from $P^0 = 4.25$ to $P^1 = 4.5$, and output falls from $Q^0 = 5.75$ to $Q^1 = 5.5$. The light trapezoid is the loss of consumer surplus (1.41). The dark rectangle is the margin lost on units that are no longer produced (0.19). The hatched rectangles are cost savings, from output that moves to firm 1 (0.375) and from former firm-3 output now produced at c_2 (0.5). Our computation.

Figure 11.8 redraws the diagram that Asker and Nocke (2021, pp. 216–217) use to introduce merger analysis. Firms 2 and 3 merge without synergies, so the merged firm produces at c_2. By Corollary 11.13 the price rises. Firm 1 expands from $q_1^0 = 3.25$ to $q_1^1 = 3.5$, and the merged firm produces 2, less than the 2.5 that firms 2 and 3 produced before. The welfare accounting has four pieces. Consumers lose the light trapezoid, $(P^1 - P^0)Q^1 + \frac{1}{2}(P^1 - P^0)(Q^0 - Q^1) = 1.375 + 0.031$. The rectangle $(P^1 - P^0)Q^1$ is a transfer to the firms, so only the triangle is a deadweight loss. The units between Q^1 and Q^0 were produced by firm 3 at cost c_3, and their lost margin $(P^0 - c_3)(Q^0 - Q^1) = 0.1875$ is the dark rectangle. Production costs fall on the remaining output, by $(c_2 - c_1)(q_1^1 - q_1^0) = 0.375$ and $(c_3 - c_2)\big(Q^1 - q_1^0 - q_2^0\big) = 0.5$. Aggregate surplus therefore changes by

$$\Delta W = -0.031 - 0.1875 + 0.375 + 0.5 = 0.656 > 0.$$

Asker and Nocke leave the sign open for the case they draw, and they suggest that the reallocation gain may fall short of the losses there (p. 216). With our numbers the reallocation gain dominates. The merger harms consumers, by 1.41, but raises aggregate surplus, because it moves production away from the least efficient firm. It is also profitable, since the insiders gain 0.375. The price-neutral cost is $\hat{c} = c_2 + c_3 - P^0 = 1.75$, so a merged firm with firm 1's cost of 1 would lower the price.

Two further results link consumer surplus, profit and aggregate surplus (Asker and Nocke, 2021, p. 230). With constant marginal costs, a merger that does not lower consumer surplus is profitable (Nocke and Whinston, 2010). Corollary 11.14 shows this for the price-neutral merger, and a lower merged cost only raises the merged firm's profit (Lemma 11.65). A price-neutral merger leaves every outsider's output and profit unchanged, so it raises aggregate surplus. The converse direction is less tidy. Aggregate surplus is not monotone in a firm's marginal cost, so a given merger need not have a cutoff cost below which it raises aggregate surplus and above which it lowers it. In the example of Figure 11.7, a cutoff does exist, near $c_M = 1.91$. Total surplus is still not monotone. With the outsider's cost at 3, the derivative of total surplus in c_M is

$$\frac{\mathrm{d}W}{\mathrm{d}c_M} = (P - c_M)\frac{\mathrm{d}q_M}{\mathrm{d}c_M} + (P - 3)\frac{\mathrm{d}q_3}{\mathrm{d}c_M} - q_M = -\frac{2}{3}q_M + \frac{1}{3}q_3 - q_M = \frac{q_3 - 5q_M}{3}.$$

It turns positive once the merged firm produces less than a fifth of the outsider's output, which happens for $c_M > \frac{61}{11} \approx 5.55$. Total surplus then rises as the inefficient merged firm shrinks, although the merger still lowers it. With logit or CES demand and price competition, by contrast, a unique cutoff type exists (Asker and Nocke, 2021, n. 129).

The external effect of a merger

We return to capital transfers and ask when a merger that the firms want also raises welfare. Write $I = \{1, 2\}$ for the insiders and $O = \{3, \ldots, N\}$ for the outsiders, with combined insider share $s_I = s_1 + s_2$, and $\pi_I = \pi_1 + \pi_2$. The *external effect* of a transfer is its effect on everyone other than the insiders, consumers and outsiders together. It equals $\mathrm{d}W - \mathrm{d}\pi_I$.

Proposition 11.17 (The external effect)**.** *Under Assumption 11.5, a small transfer of capital from firm 2 to firm 1 has the external effect*

$$\frac{\mathrm{d}W}{\mathrm{d}k} - \frac{\mathrm{d}\pi_I}{\mathrm{d}k} = \frac{\mathrm{d}P}{\mathrm{d}k}\,\omega, \qquad \omega \equiv \sum_{i \in O} \lambda_i q_i - \sum_{i \in I} q_i. \tag{11.29}$$

If the transfer raises the price, the external effect is positive if and only if

$$s_I < \sum_{i \in O} \lambda_i s_i. \tag{11.30}$$

Proof. Add up the gains of consumers and outsiders. Consumers lose $Q\,\mathrm{d}P$. An outsider's capital does not change, so by (11.13) its profit changes by $(P - C_q^i)\,\mathrm{d}q_i + q_i\,\mathrm{d}P$. Under Cournot, $P - C_q^i = -q_i P'$, and by Lemma 11.7, $\mathrm{d}q_i = -\lambda_i\,\mathrm{d}Q$. Hence

$$(P - C_q^i)\,\mathrm{d}q_i = (-q_i P')(-\lambda_i\,\mathrm{d}Q) = \lambda_i q_i\,P'\,\mathrm{d}Q = \lambda_i q_i\,\mathrm{d}P.$$

The external effect is therefore

$$\begin{aligned} -Q\,\mathrm{d}P + \sum_{i \in O} \left(\lambda_i q_i + q_i\right)\mathrm{d}P &= \Big(-\sum_{i \in I} q_i - \sum_{i \in O} q_i + \sum_{i \in O} q_i + \sum_{i \in O} \lambda_i q_i \Big)\mathrm{d}P \\ &= \Big(\sum_{i \in O} \lambda_i q_i - \sum_{i \in I} q_i \Big)\mathrm{d}P = \varpi\,\mathrm{d}P. \end{aligned}$$

Dividing by $\mathrm{d}k$ gives (11.29). If $\frac{\mathrm{d}P}{\mathrm{d}k} > 0$, the sign is that of ϖ, and dividing $\varpi > 0$ by Q gives (11.30). □

The proof shows where the external effect comes from. The price increase on outsiders' units is a transfer from consumers to outsiders and cancels. Two terms remain. Consumers lose the price increase on the insiders' units, $q_I\,\mathrm{d}P$. The outsiders expand by $\lambda_i\,\mathrm{d}Q$ and earn their margin $-q_i P'$ on the extra units, a gain of $\lambda_i q_i\,\mathrm{d}P$. The anticompetitive effect grows with the insiders' size, while the offsetting benefit grows with the outsiders' responsiveness and margins. This *induced output effect* is the welfare gain from moving output toward large, low-cost outsiders. Farrell and Shapiro write (11.29) as $-\frac{\mathrm{d}p}{\mathrm{d}k}\left(x_1 + x_2 - \sum_{i \geq 3} \lambda_i x_i\right)$ (their eq. (16)), and they state the result as excessive incentives to merge when $s_1 + s_2 > \sum_{i \geq 3} \lambda_i s_i$ (their Proposition 4).

The direct effects of capital on the insiders' costs appear in both $\mathrm{d}W$ and $\mathrm{d}\pi_I$, so they cancel from the external effect. Synergies, fixed-cost savings and other benefits that only the merging firms observe do not enter (11.29). The external effect depends on shares and on the responses λ_i, which an agency can hope to estimate. This is the basis of a policy rule (Farrell and Shapiro, 1988, p. 18). Since a proposed merger must be privately profitable, $\mathrm{d}\pi_I > 0$, a merger with a positive external effect raises welfare and should be approved, whatever its unobserved synergies. A merger with a negative external effect should be allowed only if it is sufficiently profitable, which shifts the burden of proof to the parties.

Corollary 11.18 (Special cases)**.** *Suppose the transfer raises the price.*

(i) With constant marginal costs, $\lambda_i = 1 - s_i\mathcal{E}$, and the external effect has the sign of $1 - 2s_I - \mathcal{E}\sum_{i \in O} s_i^2$. With linear demand, $\mathcal{E} = 0$, the external effect is positive if and only if $s_I < \frac{1}{2}$.
