I Market Power: Theory and Measurement 1

1 Introduction: What Empirical IO Studies 2
- 1.1 What industrial organization studies . . . 3
- 1.2 Market structure, market power, and markups . . . 4
  - 1.2.1 Markets and market definition . . . 5
  - 1.2.2 Concentration measures . . . 5
  - 1.2.3 Market power, markups, and the Lerner index . . . 8
  - 1.2.4 Markups are not profits: the role of fixed costs . . . 12
  - 1.2.5 The Cournot benchmark: concentration and margins . . . 14
- 1.3 The structure-conduct-performance paradigm . . . 19
  - 1.3.1 The SCP mechanism . . . 20
  - 1.3.2 Origins and practice . . . 22
- 1.4 What cross-industry regressions identify . . . 23
  - 1.4.1 Measurement: accounting versus economic margins . . . 23
  - 1.4.2 Market definition and measurement error in concentration . . . 25
  - 1.4.3 Endogeneity of structure: theory . . . 27
  - 1.4.4 A Monte Carlo experiment . . . 30
  - 1.4.5 Panel data and fixed effects . . . 33
- 1.5 Efficiency, prices, and the afterlife of SCP . . . 35
  - 1.5.1 Efficiency versus market power: the Demsetz critique . . . 35
  - 1.5.2 Price-concentration studies . . . 38
  - 1.5.3 SCP today . . . 40
  - 1.5.4 Rising markups and the production approach . . . 41
- 1.6 The New Empirical Industrial Organization . . . 46
  - 1.6.1 Industry studies before the NEIO . . . 46
  - 1.6.2 Principles of the NEIO . . . 50
  - 1.6.3 Bresnahan's stylized model . . . 51
  - 1.6.4 Conduct as a parameter . . . 53
- 1.7 How the data identify market power . . . 59
  - 1.7.1 The identification question . . . 59
  - 1.7.2 Five identification arguments . . . 60
  - 1.7.3 Market power with product differentiation . . . 66
  - 1.7.4 What the NEIO learned . . . 70
- 1.8 Empirical IO today . . . 72
  - 1.8.1 The structural workflow: demand, supply, counterfactuals . . . 72
  - 1.8.2 Demand estimation . . . 77
  - 1.8.3 Market power and pricing . . . 80

1.8.4 Auctions as pricing problems . . . 81
1.8.5 Market structure and dynamics . . . 84
1.8.6 Structural and design-based approaches . . . 92
1.9 Roadmap of the book . . . 95
1.9.1 The four parts . . . 95
1.9.2 Reading paths . . . 97
1.9.3 Prerequisites and conventions . . . 97
1.10 Bibliographic notes . . . 97
1.11 Exercises . . . 99

2 The Theory of Pricing and Market Power 103
2.1 Measuring market power: markups, margins and concentration . . . 104
2.1.1 Market power and margins . . . 104
2.1.2 Concentration . . . 105
2.2 Monopoly pricing . . . 106
2.2.1 The pricing problem . . . 106
2.2.2 Residual demand and the dominant firm . . . 109
2.2.3 Multiproduct monopoly . . . 110
2.2.4 Inferring marginal cost from prices . . . 112
2.2.5 Worked demand families . . . 113
2.3 Games and equilibrium . . . 116
2.3.1 Nash equilibrium . . . 116
2.3.2 Reaction functions . . . 117
2.3.3 Subgame perfection . . . 118
2.4 Cournot oligopoly with N firms . . . 119
2.4.1 The game . . . 119
2.4.2 Best responses and strategic substitutes . . . 120
2.4.3 Existence and uniqueness . . . 121
2.4.4 Markups and concentration . . . 124
2.4.5 The linear model in closed form . . . 127
2.4.6 Comparative statics . . . 128
2.5 Free entry and the number of firms . . . 134
2.5.1 The two-stage entry game . . . 134
2.5.2 The second-best planner and excess entry . . . 135
2.5.3 The integer constraint . . . 139
2.5.4 Product diversity . . . 140
2.5.5 Small set-up costs . . . 141
2.5.6 Margins and concentration under fixed and free entry . . . 142
2.6 Bertrand competition and capacity constraints . . . 144
2.6.1 Price competition with a homogeneous good . . . 144
2.6.2 Capacity constraints and rationing . . . 146
2.6.3 Bertrand or Cournot? . . . 151
2.7 Conduct: conjectural variations and the conduct parameter . . . 152
2.7.1 The supply relation . . . 152
2.7.2 Firm-level conduct and aggregation . . . 153
2.7.3 The menu of conduct . . . 154
2.7.4 Interpreting the conduct parameter . . . 157
2.7.5 Forward contracts . . . 159

2.7.6 Pricing rules for the Bulow-Pfleiderer family . . . 160
2.8 Pass-through . . . 160
2.8.1 Definition and uses . . . 161
2.8.2 Monopoly with constant marginal cost . . . 161
2.8.3 Conduct, curvature and rising marginal cost . . . 166
2.8.4 Firm-specific versus industry-wide cost shocks in Cournot . . . 170
2.8.5 Incidence . . . 172
2.8.6 Measured prices and composition . . . 174
2.9 Welfare and the deadweight loss of market power . . . 175
2.9.1 Surplus measures . . . 175
2.9.2 Linear demand with conduct . . . 177
2.9.3 The Harberger approximation . . . 178
2.9.4 Production inefficiency under asymmetric Cournot . . . 182
2.9.5 Entry, mergers and the second best . . . 183
2.10 Toward collusion: Stigler's theory and repeated interaction . . . 184
2.10.1 The static incentive to cheat . . . 184
2.10.2 Stigler's theory of oligopoly . . . 185
2.10.3 Repeated interaction: a preview . . . 197
2.11 From homogeneous to differentiated products . . . 200
2.12 Bibliographic notes . . . 201
2.13 Exercises . . . 203

3 Measuring Market Power in Homogeneous-Goods Industries 206
3.1 The measurement problem and the supply relation . . . 207
3.1.1 What we want to measure . . . 207
3.1.2 An unrestricted conduct parameter has no content . . . 209
3.1.3 Why structure does not pin down conduct: Stigler (1964) . . . 210
3.1.4 A taxonomy of approaches . . . 211
3.2 Testing with cost pass-through: Sumner (1981) . . . 212
3.2.1 Pass-through under conduct . . . 213
3.2.2 Sumner's design and results . . . 215
3.2.3 Curvature, cost, composition, and further critiques . . . 218
3.2.4 A replication and what it adds . . . 219
3.3 Comparative statics in cost without functional forms . . . 221
3.3.1 Sullivan's bound and why cost shifters give only inequalities . . . 222
3.3.2 Ashenfelter and Sullivan (1987): a revealed-preference test . . . 224
3.3.3 Panzar and Rosse (1987): the revenue test . . . 229
3.4 Residual demand: Baker and Bresnahan (1988) . . . 232
3.4.1 The question and the idea . . . 232
3.4.2 Deriving the residual demand curve . . . 233
3.4.3 When the residual demand slope measures the markup . . . 235
3.4.4 The brewing application . . . 236
3.4.5 Results . . . 238
3.4.6 Robustness, interpretation and critiques . . . 240
3.4.7 Residual demand, market definition and mergers . . . 240
3.5 The identification of conduct . . . 241
3.5.1 The linear model and observational equivalence . . . 241
3.5.2 Rotations of demand identify conduct . . . 243

3.5.3 Lau's theorem: identification without functional forms . . . 247
3.5.4 Other routes to identification . . . 249
3.6 Interpreting the conduct parameter . . . 250
3.6.1 Where the conduct parameter comes from . . . 250
3.6.2 The Corts critique . . . 251
3.6.3 Bounds instead of point estimates . . . 259
3.6.4 The record of conduct estimates . . . 261
3.7 Sugar refining, 1890–1914: Genesove and Mullin (1998) . . . 261
3.7.1 The question and why sugar . . . 261
3.7.2 The industry, 1887–1914 . . . 262
3.7.3 Technology and the direct measurement of marginal cost . . . 264
3.7.4 Data, instruments and the demand system . . . 265
3.7.5 The direct measure of conduct . . . 269
3.7.6 Estimating conduct with cost treated as unknown . . . 273
3.7.7 Conduct and structure: price wars . . . 279
3.7.8 Assessment . . . 281
3.8 The British electricity spot market: Wolfram (1999) . . . 282
3.8.1 The question and the institutions . . . 282
3.8.2 Data and the measurement of marginal cost . . . 285
3.8.3 The model and the direct measure of conduct . . . 287
3.8.4 Markups and conduct . . . 291
3.8.5 Why are markups so low? . . . 293
3.8.6 Estimates that ignore cost data . . . 295
3.8.7 Assessment . . . 298
3.8.8 Later evidence from restructured markets . . . 299
3.9 Synthesis: what conduct parameters can and cannot tell us . . . 302
3.9.1 The methods compared . . . 303
3.9.2 Seven lessons . . . 303
3.9.3 Where the field went . . . 305
3.10 Bibliographic notes . . . 305
3.11 Exercises . . . 306

4 Oligopoly with Differentiated Products 310
4.1 Why product differentiation matters . . . 311
4.1.1 Differentiation is the rule . . . 311
4.1.2 Questions that require a demand system . . . 312
4.1.3 Demand systems and market definition . . . 313
4.1.4 How theory and empirical work divide the problem . . . 314
4.2 Multi-product Bertrand-Nash pricing . . . 315
4.2.1 Environment and equilibrium . . . 315
4.2.2 The first-order conditions . . . 316
4.2.3 Matrix form and the markup equation . . . 317
4.2.4 Single-product firms and the inverse semi-elasticity rule . . . 320
4.2.5 Worked example: a linear differentiated duopoly . . . 321
4.2.6 Worked example: logit demand . . . 323
4.2.7 A numerical illustration: 25 logit products . . . 326
4.3 Diversion ratios . . . 328
4.3.1 Definitions and basic properties . . . 329

4.3.2 The first-order condition in diversion form . . . 331
4.3.3 Why diversion governs the unilateral effects of mergers . . . 332
4.3.4 Diversion in standard demand systems . . . 334
4.3.5 What diversion ratios do not tell us . . . 335
4.4 Existence, uniqueness and multiplicity of price equilibria . . . 336
4.4.1 The existence problem . . . 336
4.4.2 Sufficient conditions on demand . . . 337
4.4.3 The Caplin-Nalebuff existence theorem . . . 339
4.4.4 Uniqueness . . . 347
4.4.5 Multiple equilibria . . . 351
4.5 Using the supply side: costs, conduct and counterfactuals . . . 354
4.5.1 Why model supply when we estimate demand? . . . 354
4.5.2 Recovering marginal costs . . . 355
4.5.3 Conduct and the ownership matrix . . . 358
4.5.4 Counterfactual analysis . . . 361
4.5.5 Comparative statics and pass-through . . . 363
4.6 Product space versus characteristics space . . . 366
4.6.1 Two ways to write demand . . . 367
4.6.2 Advantages of characteristics space . . . 367
4.6.3 Drawbacks of characteristics space . . . 369
4.6.4 The dimension of characteristics space shapes competition . . . 370
4.6.5 Demand systems in product space . . . 374
4.7 Representative-consumer demand systems: linear, CES and logit . . . 375
4.7.1 Linear demand from quadratic utility . . . 376
4.7.2 CES demand . . . 378
4.7.3 The logit as the demand of a representative consumer . . . 381
4.7.4 CES as a discrete choice model . . . 382
4.7.5 The discrete-choice program of Anderson, de Palma and Thisse . . . 384
4.7.6 Monopolistic competition and optimal variety . . . 385
4.7.7 What symmetric systems are good for . . . 388
4.8 Location models: prices, products and entry in characteristics space . . . 389
4.8.1 Hotelling's line with linear transport costs . . . 391
4.8.2 Quadratic transport costs and the location-price game . . . 393
4.8.3 Salop's circle, free entry and excess variety . . . 395
4.8.4 Symmetric logit oligopoly and entry . . . 398
4.8.5 Vertical differentiation and quality choice . . . 401
4.8.6 From address models to discrete choice . . . 402
4.9 Bibliographic notes . . . 403
4.10 Exercises . . . 404

II Demand Estimation **408**

5 Demand in Product Space: The Almost Ideal Demand System **409**
5.1 Demand Systems in Product Space . . . 410
5.1.1 Questions a demand system answers . . . 410
5.1.2 Why microfoundations . . . 411
5.1.3 Product space and characteristic space . . . 412

5.1.4 Three product-space systems . . . 412
5.1.5 Conventions for this chapter . . . 416
5.2 Consumer Duality: The Toolkit . . . 416
5.2.1 Utility maximization and expenditure minimization . . . 416
5.2.2 Properties of the expenditure function . . . 417
5.2.3 Shephard's lemma . . . 417
5.2.4 Roy's identity . . . 418
5.2.5 The Slutsky equation . . . 418
5.2.6 Elasticity forms of the restrictions . . . 419
5.2.7 Welfare measures . . . 420
5.2.8 Flexible functional forms . . . 422
5.3 The Almost Ideal Demand System . . . 423
5.3.1 The PIGLOG class . . . 424
5.3.2 The AIDS cost function . . . 424
5.3.3 Deriving the share equations . . . 426
5.3.4 Restrictions from consumer theory . . . 428
5.3.5 Negativity . . . 429
5.3.6 Elasticities . . . 430
5.3.7 Flexibility . . . 431
5.3.8 Engel curves and rank . . . 433
5.3.9 Why only almost ideal . . . 435
5.4 Aggregation across consumers . . . 436
5.4.1 The aggregation problem . . . 436
5.4.2 The Gorman polar form and exact aggregation . . . 437
5.4.3 Muellbauer's generalization: PIGL and PIGLOG . . . 440
5.4.4 Almost exact aggregation of the AIDS . . . 444
5.5 Separability and multi-stage budgeting . . . 448
5.5.1 Weak separability and the second stage . . . 448
5.5.2 The first stage . . . 449
5.5.3 What separability implies for substitution . . . 452
5.5.4 Conditional and unconditional elasticities . . . 455
5.6 Estimation and identification . . . 458
5.6.1 Stochastic specification . . . 458
5.6.2 Adding up and the singular covariance matrix . . . 458
5.6.3 The nonlinear AIDS . . . 460
5.6.4 The linear approximate AIDS and the Stone index . . . 461
5.6.5 First differences and the Rotterdam model . . . 464
5.6.6 Testing the restrictions of demand theory . . . 465
5.6.7 Case study: the AIDS on British data, 1954–1974 . . . 466
5.6.8 Endogenous prices, endogenous expenditure and measured group prices . . . 471
5.7 Welfare, virtual prices and the supply side . . . 473
5.7.1 Compensating and equivalent variation in closed form . . . 474
5.7.2 Virtual prices . . . 476
5.7.3 Functional form and the value of variety . . . 479
5.7.4 The extrapolation problem . . . 481
5.7.5 Recovering marginal costs from first-order conditions . . . 481
5.7.6 Partial identification of marginal cost . . . 484

5.7.7 Counterfactual equilibrium after product withdrawal . . . 485
5.8 Case study: Hausman, Leonard and Zona (1994) . . . 487
5.8.1 The economic question . . . 487
5.8.2 Setting and data . . . 487
5.8.3 The three-level demand model . . . 488
5.8.4 Identification with prices in other cities . . . 490
5.8.5 Validity: Bresnahan's critique . . . 491
5.8.6 Results . . . 493
5.8.7 From elasticities to competitive analysis . . . 497
5.8.8 Limitations and contribution . . . 500
5.9 Case study: Chaudhuri, Goldberg and Jia (2006), patents and antibiotics in India 501
5.9.1 The question and the policy debate . . . 501
5.9.2 The setting . . . 502
5.9.3 Data . . . 503
5.9.4 The demand model . . . 504
5.9.5 Identification and estimation . . . 509
5.9.6 Demand estimates . . . 510
5.9.7 Supply: bounds on costs and markups . . . 515
5.9.8 Counterfactual design . . . 517
5.9.9 Counterfactual results . . . 518
5.9.10 Interpretation, limitations and contribution . . . 524
5.10 Retrospective evidence: what happened after patents arrived . . . 525
5.10.1 Setting and data . . . 525
5.10.2 Design . . . 526
5.10.3 Results . . . 526
5.10.4 Why the forecast and the evidence differ . . . 529
5.11 Assessment: what product-space demand can and cannot do . . . 529
5.12 Bibliographic notes . . . 530
5.13 Exercises . . . 531

6 Discrete Choice Foundations and the Vertical Model 535
6.1 Demand in characteristic space . . . 536
6.1.1 Products as bundles of characteristics . . . 536
6.1.2 Product space and characteristic space . . . 536
6.1.3 Two branches of theory . . . 537
6.1.4 Endogenous characteristics and instruments . . . 538
6.2 Random utility and aggregation to market shares . . . 539
6.2.1 The random utility model . . . 539
6.2.2 The outside good . . . 541
6.2.3 Normalizations and what is identified . . . 542
6.2.4 Additive random utility and the social surplus function . . . 543
6.2.5 A first example: two goods with additive shocks . . . 546
6.2.6 From individual choices to data . . . 546
6.2.7 The inversion strategy . . . 549
6.3 Type-I extreme value algebra and the logit model . . . 549
6.3.1 The Gumbel distribution . . . 550
6.3.2 Logit choice probabilities . . . 552
6.3.3 Expected maximum utility and the log-sum formula . . . 554

6.3.4 Luce's axiom, IIA and the generalized extreme value family 555
6.3.5 The multinomial probit 559
6.3.6 Choosing a functional form 560
6.4 Models of product differentiation as random utility models 560
6.4.1 Horizontal and vertical differentiation 560
6.4.2 Address models: Hotelling and Salop 561
6.4.3 The ideal-point model 563
6.4.4 Two families of empirical models 564
6.4.5 The vertical model as a random utility model 565
6.4.6 The logit as a model of differentiation 566
6.5 The vertical model 566
6.5.1 Setup and the ordering of products 566
6.5.2 Cutoffs and single crossing 569
6.5.3 Market shares 572
6.5.4 Inverting market shares 574
6.5.5 Substitution patterns 577
6.5.6 Pricing and recovering marginal costs 579
6.5.7 Extensions 582
6.6 Case study: the 1955 automobile price war 584
6.6.1 The question and why it matters 584
6.6.2 Setting and aggregate facts 585
6.6.3 Data and the quantity aggregation problem 586
6.6.4 The model 587
6.6.5 Econometric specification and estimation 598
6.6.6 Testing non-nested conduct hypotheses 600
6.6.7 Estimates 603
6.6.8 Counterfactual, fit and residuals 605
6.6.9 Robustness 606
6.6.10 Identification 607
6.6.11 Limitations and critiques 608
6.6.12 Contribution 609
6.7 The idiosyncratic shock: tastes for products versus tastes for characteristics . 609
6.7.1 Two specifications of the consumer-specific term 610
6.7.2 The logit benchmark 611
6.7.3 The pure characteristics benchmark 613
6.7.4 Why the distinction matters 615
6.7.5 What the idiosyncratic shock buys 616
6.7.6 Nesting the two models: the modified BLP model 616
6.8 Case study: estimating the pure characteristics model 617
6.8.1 The question 617
6.8.2 Model and normalizations 618
6.8.3 Computing market shares 618
6.8.4 Existence and uniqueness of the inverse 619
6.8.5 Computing the inverse 622
6.8.6 Simulation error and limit theory 623
6.8.7 Estimator, instruments and identification 624
6.8.8 The Monte Carlo designs 625
6.8.9 Results 626

6.8.10 Robustness and interpretation . . . 630
6.8.11 Limitations, critiques and contribution . . . 630
6.9 The hedonic approach . . . 631
6.9.1 Rosen's hedonic model . . . 631
6.9.2 Bajari and Benkard: the model and the price function . . . 633
6.9.3 The first stage: the unobserved characteristic as a price quantile . . . 635
6.9.4 The second stage: preferences . . . 636
6.9.5 Application: personal computers, December 1999 . . . 638
6.10 Bibliographic notes . . . 642
6.11 Exercises . . . 643

7 Logit, Nested Logit, and the Berry Inversion 647
7.1 The logit model of demand . . . 648
7.1.1 Setup and assumptions . . . 648
7.1.2 Choice probabilities and market shares . . . 649
7.1.3 Derivatives, elasticities and diversion . . . 650
7.1.4 Independence of irrelevant alternatives . . . 652
7.1.5 Logit with individual data: maximum likelihood . . . 655
7.2 The Berry inversion . . . 659
7.2.1 The estimation problem with aggregate data . . . 659
7.2.2 The logit inversion . . . 661
7.2.3 Invertibility in general . . . 661
7.2.4 Other analytic inversions . . . 664
7.2.5 Data requirements: market size, sampling error and zeros . . . 664
7.3 Price endogeneity and instruments . . . 666
7.3.1 Why prices are endogenous . . . 666
7.3.2 Instruments . . . 668
7.3.3 Product and market fixed effects . . . 672
7.3.4 Two-stage least squares, GMM and standard errors . . . 672
7.3.5 Evidence: what instrumenting does . . . 673
7.3.6 A Monte Carlo illustration: replicating Berry (1994) . . . 675
7.4 The supply side: Bertrand pricing with logit demand . . . 678
7.4.1 Single-product firms . . . 678
7.4.2 Multi-product firms . . . 680
7.4.3 Existence and uniqueness of equilibrium . . . 681
7.4.4 Pass-through . . . 682
7.4.5 Recovering marginal costs and joint estimation . . . 683
7.4.6 Testing conduct and ownership with logit demand . . . 684
7.5 GEV models and the nested logit . . . 686
7.5.1 Generalized extreme value models . . . 686
7.5.2 The nested logit model . . . 689
7.5.3 Substitution patterns . . . 692
7.5.4 Estimation . . . 695
7.5.5 Pricing with nested logit demand . . . 699
7.5.6 The two-level nested logit . . . 701
7.5.7 Other GEV models and the limits of nesting . . . 703
7.6 Welfare in logit models . . . 704
7.6.1 The log-sum formula . . . 704

7.6.2 Applications . . . 705
7.6.3 Caveats . . . 707
7.7 Case study: Berry (1994) and the mean-utility method . . . 708
7.7.1 The question . . . 708
7.7.2 The model . . . 709
7.7.3 The inversion and the estimator . . . 709
7.7.4 Instruments as Berry states them . . . 710
7.7.5 The worked examples . . . 710
7.7.6 The pricing equation and joint estimation . . . 712
7.7.7 Why the obvious alternatives fail . . . 713
7.7.8 Monte Carlo evidence . . . 713
7.7.9 Interpretation, limitations, and contribution . . . 713
7.8 Case study: Einav (2007), seasonality in motion pictures . . . 714
7.8.1 Question, setting, and data . . . 714
7.8.2 The model . . . 715
7.8.3 Identification and estimation . . . 716
7.8.4 Results . . . 717
7.8.5 Robustness . . . 718
7.8.6 Implications for release dates . . . 719
7.8.7 Interpretation and limitations . . . 720
7.9 Case study: Hendel (1999), multiple discrete choice . . . 720
7.9.1 Question and motivating facts . . . 720
7.9.2 The model . . . 720
7.9.3 Estimation . . . 722

7.12 Exercises . . . 730

8 Random Coefficients Logit: The BLP Model 732
8.1 The random coefficients logit model . . . 733
8.1.1 Primitives . . . 733
8.1.2 The linear random coefficients specification . . . 735
8.1.3 Income effects . . . 736
8.1.4 The outside good and normalizations . . . 737
8.1.5 Maintained assumptions and the two roles of characteristics . . . 738
8.1.6 Market shares . . . 739
8.1.7 Special cases and relatives . . . 740
8.1.8 Why the model needs an unobserved product characteristic . . . 741
8.1.9 Data requirements . . . 742
8.2 Substitution patterns and elasticities . . . 742

8.2.1 The logit benchmark and its restrictions . . . 743
8.2.2 Share derivatives in the random coefficients logit . . . 744
8.2.3 Diversion ratios . . . 745
8.2.4 Correlated utilities and the characteristics that matter . . . 746
8.2.5 Own-price elasticities and markups need not rise with price . . . 747
8.2.6 A numerical illustration . . . 748
8.2.7 Further contrasts . . . 750
8.3 Computing the share integral by simulation . . . 750
8.3.1 The smooth simulator . . . 751
8.3.2 Simulation error in log shares . . . 751
8.3.3 Draws in practice . . . 754
8.3.4 Importance sampling . . . 755
8.3.5 Quadrature and quasi-Monte Carlo . . . 756
8.3.6 Safe numerical evaluation . . . 757
8.4 Inverting the share equations: the BLP contraction . . . 758
8.4.1 The inversion problem . . . 758
8.4.2 Existence and uniqueness . . . 759
8.4.3 Speed of convergence and the practice of the inner loop . . . 762
8.5 The GMM estimator . . . 765
8.5.1 Why the error must be the structural error . . . 765
8.5.2 Moment conditions . . . 766
8.5.3 Concentrating out the linear parameters . . . 767
8.5.4 The nested fixed point algorithm . . . 768
8.5.5 The gradient . . . 768
8.5.6 Weighting, efficiency and clustering . . . 770
8.5.7 Asymptotic distribution and simulation error . . . 771
8.5.8 MPEC: estimation as constrained optimization . . . 773
8.6 Instruments and identification . . . 774
8.6.1 Price endogeneity . . . 774
8.6.2 How many instruments, and what they must do . . . 775
8.6.3 Optimal instruments . . . 777
8.6.4 Instrument families . . . 779
8.6.5 Brand fixed effects and minimum distance . . . 781
8.6.6 Nonparametric identification with market data . . . 782
8.6.7 Summary: what identifies what . . . 787
8.7 The supply side and joint estimation . . . 787
8.7.1 Multiproduct Bertrand-Nash pricing . . . 788
8.7.2 Joint estimation of demand and supply . . . 791
8.7.3 Marginal costs, markups and returns to scale . . . 793
8.7.4 Existence and uniqueness of equilibrium . . . 793
8.7.5 Computing counterfactual equilibria . . . 793
8.7.6 Conduct . . . 795
8.8 Micro data and micro moments . . . 795
8.8.1 What consumer-level data identify . . . 796
8.8.2 Two-step estimation with product-market effects . . . 797
8.8.3 Micro moments . . . 797
8.8.4 The micro BLP estimator . . . 798
8.8.5 Nonparametric identification with micro data: Berry and Haile (2024) 800

8.9 Estimation in practice and the limits of the model . . . 804
8.9.1 A practical checklist . . . 804
8.9.2 The sign of the standard deviations . . . 805
8.9.3 The too-many-characteristics problem . . . 806
8.9.4 The pure characteristics model . . . 807
8.9.5 The hedonic approach . . . 808
8.10 A simulated market: estimation step by step . . . 809
8.10.1 Design . . . 810
8.10.2 Step 1: equilibrium prices . . . 810
8.10.3 Step 2: realized shares . . . 811
8.10.4 Step 3: logit demand . . . 811
8.10.5 Step 4: the contraction with Σ known . . . 811
8.10.6 Step 5: instrumental variables on the recovered mean utilities . . . 811
8.10.7 Step 6: estimating Σ by the nested fixed point . . . 812
8.10.8 Step 7: elasticities and diversion . . . 814
8.10.9 What the simulated market teaches . . . 817
8.11 Case study: Berry, Levinsohn and Pakes (1995), U.S. automobiles . . . 818
8.11.1 The question and why it matters . . . 818
8.11.2 Setting and earlier approaches . . . 819
8.11.3 Data . . . 819
8.11.4 The model . . . 821
8.11.5 Estimation and identification . . . 823
8.11.6 Results I: logit benchmarks . . . 826
8.11.7 Results II: parameters of the full model . . . 827
8.11.8 Results III: elasticities and substitution . . . 830
8.11.9 Results IV: markups and profits . . . 836
8.11.10 Robustness . . . 838
8.11.11 Interpretation . . . 839
8.11.12 Limitations and critiques . . . 839
8.11.13 Contribution . . . 840
8.12 Case study: Nevo (2000a), the practitioner's guide and its application . . . 840
8.12.1 Purpose and framing . . . 841
8.12.2 Specification choices and their implications . . . 841
8.12.3 Practical recommendations . . . 842
8.12.4 The application . . . 843
8.12.5 Lessons, extensions and assessment . . . 847
8.13 Case study: Nevo (2001), market power in ready-to-eat cereal . . . 848
8.13.1 The question . . . 849
8.13.2 The industry . . . 849
8.13.3 Supply: three models of conduct . . . 850
8.13.4 Demand . . . 853
8.13.5 Data . . . 854
8.13.6 Estimation . . . 855
8.13.7 Instruments and identification . . . 856
8.13.8 Brand fixed effects and the minimum-distance step . . . 857
8.13.9 Results from the logit model . . . 858
8.13.10 Results from the random coefficients model . . . 859
8.13.11 Price-cost margins and the test of conduct . . . 863

8.13.12 Robustness . . . 865
8.13.13 Interpretation, limitations and contribution . . . 866
8.14 Case study: Berry, Levinsohn and Pakes (2004), micro and macro data . . . 867
8.14.1 The question . . . 867
8.14.2 Data . . . 868
8.14.3 The model . . . 870
8.14.4 The estimator . . . 871
8.14.5 Estimates of the interaction parameters . . . 873
8.14.6 The level of price elasticities . . . 875
8.14.7 Substitution patterns . . . 877
8.14.8 Prediction exercises . . . 878
8.14.9 Lessons and critiques . . . 879
8.15 Case study: Goldberg (1995), micro data, nested choice and trade policy . . . 879
8.15.1 Question and setting . . . 880
8.15.2 Data . . . 880
8.15.3 Demand: a five-level nested logit . . . 881
8.15.4 Aggregation and supply . . . 884
8.15.5 Estimation and identification . . . 886
8.15.6 Results: demand, elasticities and markups . . . 887
8.15.7 Specification tests . . . 891
8.15.8 The voluntary export restraint . . . 893
8.15.9 Exchange-rate pass-through . . . 895
8.15.10 Assessment . . . 895

8.17 Exercises . . . 897

9 Airlines: Hubs, Entry, and Market Power 900
9.1 Introduction . . . 900
9.2 The U.S. airline industry after deregulation . . . 901
9.2.1 Regulation and the case for deregulation . . . 901
9.2.2 Deregulation, entry, and the rise of hubs . . . 902
9.2.3 Markets, products, and data . . . 904
9.2.4 Sources of airport dominance . . . 906
9.3 Contestability, entry, and incumbent profits . . . 909
9.3.1 Contestable markets . . . 909
9.3.2 Why airlines, and why the theory may fail . . . 914
9.3.3 Entry with sunk costs: what an incumbent's value loss reveals . . . 917
9.4 Market power in airline markets: pricing theory . . . 920
9.4.1 From conduct to a route-level pricing equation . . . 921
9.4.2 Dominance as product differentiation: markups without an umbrella 924
9.4.3 Consumer heterogeneity: a finite-mixture nested logit . . . 927
9.4.4 Network costs and economies of density . . . 932
9.5 Hubs and high fares: Borenstein (1989) . . . 936
9.5.1 The question . . . 937
9.5.2 Setting . . . 937
9.5.3 Data . . . 938
9.5.4 The estimating equations . . . 942
9.5.5 Estimation and identification . . . 946

9.5.6 Results . . . 951
9.5.7 From descriptive results to economic inferences . . . 956
9.5.8 Limitations and critiques . . . 958
9.5.9 Contribution . . . 959
9.6 Entry and incumbent value: Whinston and Collins (1992) . . . 960
9.6.1 Event-study methodology . . . 960
9.6.2 Question, logic, and setting . . . 965
9.6.3 Data . . . 966
9.6.4 Estimating equations and specifications . . . 968
9.6.5 Results on value . . . 970
9.6.6 Price, quantity, and capacity responses . . . 974
9.6.7 Conclusions, limitations, and contribution . . . 977
9.7 Hubs, costs, and markups: Berry, Carnall and Spiller (2006) . . . 979
9.7.1 The question . . . 979
9.7.2 Data . . . 980
9.7.3 Demand . . . 982
9.7.4 Costs and pricing . . . 984
9.7.5 Estimation and identification . . . 986
9.7.6 Results . . . 989
9.7.7 Conclusions, limitations, and contribution . . . 999
9.8 Synthesis: what three methods teach about hub premia . . . 1000
9.8.1 Three designs side by side . . . 1001
9.8.2 What each method identifies . . . 1002
9.8.3 The contribution of each paper given the other two . . . 1002
9.8.4 Sources of hub premia . . . 1003
9.8.5 Merger policy: two hypothetical mergers . . . 1004
9.8.6 Later evidence . . . 1005
9.9 Bibliographic notes . . . 1006
9.10 Exercises . . . 1007

10 Valuing New Goods **1010**
10.1 Introduction . . . 1010
10.2 The welfare value of a new good: virtual prices and exact measures . . . 1011
10.2.1 Setting and notation . . . 1011
10.2.2 A new good as a rationed good . . . 1012
10.2.3 The compensating variation of a new good . . . 1014
10.2.4 The cost-of-living index and the new-goods bias . . . 1017
10.2.5 Index-number bounds . . . 1017
10.2.6 Separability: which demand curves are needed . . . 1019
10.2.7 The CES variety-adjusted price index . . . 1021
10.3 Functional form, extrapolation and bounds . . . 1024
10.3.1 The extrapolation problem . . . 1024
10.3.2 Three canonical shapes . . . 1025
10.3.3 Exact surplus from Marshallian demand . . . 1027
10.3.4 A lower bound from convexity . . . 1028
10.4 New goods under imperfect competition . . . 1029
10.4.1 Welfare accounting with equilibrium prices . . . 1029
10.4.2 Private and social returns . . . 1031

10.4.3 Multiproduct pricing in elasticity form . . . 1032
10.4.4 The introducer's other prices . . . 1033
10.4.5 Rivals' prices . . . 1035
10.5 Case study: Apple-Cinnamon Cheerios (Hausman 1997) . . . 1038
10.5.1 The question . . . 1038
10.5.2 The setting: brand proliferation in ready-to-eat cereal . . . 1038
10.5.3 Data . . . 1039
10.5.4 A three-level demand system . . . 1040
10.5.5 Identification and estimation . . . 1042
10.5.6 Estimates . . . 1044
10.5.7 The virtual price and consumer surplus . . . 1046
10.5.8 Implications for the cereal price index . . . 1048
10.5.9 Alternative specifications: attributes, logit and CES . . . 1049
10.5.10 Imperfect competition . . . 1051
10.5.11 Robustness . . . 1052
10.5.12 Interpretation, critiques and contribution . . . 1053
10.6 Bresnahan's Comment: instruments and competition . . . 1053
10.6.1 Why a steep single-product demand curve means large value . . . 1053
10.6.2 Is the large surplus an artifact of the specification? . . . 1054
10.6.3 Instruments and national demand shocks . . . 1055
10.6.4 Imperfect competition is "off point" . . . 1059
10.6.5 Assessment . . . 1060
10.7 Valuing new goods in characteristics space . . . 1061
10.7.1 Predicting demand for products that have never been sold . . . 1061
10.7.2 Consumer surplus in random utility models . . . 1062
10.7.3 The idiosyncratic-taste problem . . . 1067
10.7.4 Pure characteristics and vertical models . . . 1070
10.7.5 Hedonic methods, quality change and changing tastes . . . 1073
10.8 Case study: CT scanners (Trajtenberg 1989) . . . 1075
10.8.1 The question . . . 1075
10.8.2 Setting . . . 1076
10.8.3 Data . . . 1077
10.8.4 The model . . . 1079
10.8.5 Estimation and specification tests . . . 1081
10.8.6 Positive price coefficients and signaling . . . 1085
10.8.7 Welfare computations . . . 1087
10.8.8 Who is the consumer? . . . 1088
10.8.9 Diffusion, total gains and social returns . . . 1089
10.8.10 Robustness . . . 1093
10.8.11 Interpretation, critiques and contribution . . . 1094
10.9 Case study: the minivan (Petrin 2002) . . . 1094
10.9.1 The question . . . 1095
10.9.2 The minivan innovation . . . 1095
10.9.3 Data . . . 1096
10.9.4 The demand model . . . 1097
10.9.5 Supply and the counterfactual equilibrium . . . 1098
10.9.6 Compensating variation with income effects . . . 1099
10.9.7 Estimation: market moments plus micro moments . . . 1101

10.9.8 Results . . . 1103
10.9.9 Robustness . . . 1109
10.9.10 Interpretation, limitations and critiques . . . 1110
10.9.11 Contribution . . . 1110
10.10 Case study: complementarity and online news (Gentzkow 2007) . . . 1111
10.10.1 The question . . . 1111
10.10.2 A two-good model of bundles . . . 1111
10.10.3 What the data can and cannot identify . . . 1114
10.10.4 Setting and data . . . 1115
10.10.5 Reduced-form evidence . . . 1116
10.10.6 The empirical model . . . 1117
10.10.7 Simulated maximum likelihood . . . 1119
10.10.8 The price coefficient from the supply side . . . 1120
10.10.9 Results: demand parameters and substitution . . . 1121
10.10.10 Results: welfare and online pricing . . . 1124
10.10.11 Robustness . . . 1126
10.10.12 Interpretation, limitations and contribution . . . 1126
10.11 Synthesis: what determines a measured value . . . 1127
10.11.1 Four studies side by side . . . 1128
10.11.2 Five determinants of the measured value . . . 1128
10.11.3 Implications for price indexes and policy . . . 1130
10.12 Bibliographic notes . . . 1130
10.13 Exercises . . . 1131

III Competition Policy 1135

11 Horizontal Mergers 1136
11.1 Why firms merge and how mergers are reviewed . . . 1137
11.1.1 Merger activity and merger waves . . . 1137
11.1.2 The legal framework and the US review process . . . 1141
11.1.3 What the agencies analyze . . . 1145
11.2 Market definition and concentration screens . . . 1146
11.2.1 The hypothetical monopolist test . . . 1146
11.2.2 Critical loss analysis . . . 1146
11.2.3 Concentration measures and the Guidelines . . . 1149
11.2.4 Why market definition struggles with differentiated products . . . 1152
11.3 Unilateral effects with homogeneous goods . . . 1152
11.3.1 The Williamson trade-off . . . 1153
11.3.2 The merger paradox . . . 1154
11.3.3 Farrell and Shapiro (1990): mergers as transfers of capital . . . 1156
11.3.4 Mergers under free entry . . . 1171
11.4 Unilateral effects with differentiated products: diversion, pricing pressure and pass-through . . . 1173
11.4.1 Mergers of Bertrand competitors . . . 1174
11.4.2 Diversion ratios . . . 1176
11.4.3 Upward pricing pressure: Farrell and Shapiro (2010) . . . 1178
11.4.4 From pricing pressure to price changes: pass-through . . . 1185

11.5 Merger simulation . . . 1189
11.5.1 The framework . . . 1189
11.5.2 A worked example with logit demand . . . 1192
11.5.3 Nevo (2000): mergers in ready-to-eat cereal . . . 1194
11.6 Retrospective merger evaluation . . . 1204
11.6.1 Potential outcomes and the difference-in-differences regression . . . 1204
11.6.2 The choice of control group . . . 1206
11.6.3 Event windows and transitory selection . . . 1208
11.6.4 Measuring prices and drawing inferences . . . 1209
11.6.5 Which mergers can we study? Selection by the agencies . . . 1210
11.6.6 Stock-market event studies . . . 1211
11.6.7 Five consumer-product mergers: Ashenfelter and Hosken (2010) . . . 1212
11.6.8 A nearly blocked merger of appliance makers: Ashenfelter, Hosken and Weinberg (2013) . . . 1215
11.6.9 Hospital mergers and rival analysis with an instrument: Dafny (2009) 1219
11.6.10 What the retrospective literature finds . . . 1227
11.7 Does merger simulation work? The Swedish analgesics merger . . . 1228
11.7.1 Question and setting . . . 1228
11.7.2 The retrospective evidence . . . 1230
11.7.3 The prospective models . . . 1232
11.7.4 Predictions and outcomes . . . 1236
11.8 Coordinated effects: the MillerCoors joint venture . . . 1242
11.8.1 The theory of coordinated effects . . . 1243
11.8.2 The question . . . 1244
11.8.3 The industry and the event . . . 1245
11.8.4 Facts and hypotheses . . . 1246
11.8.5 Theory: partial internalization of pricing externalities . . . 1248
11.8.6 Data . . . 1252
11.8.7 Demand: the random coefficients nested logit . . . 1252
11.8.8 Supply and the estimation of the internalization weight . . . 1258
11.8.9 Counterfactuals and welfare . . . 1262
11.8.10 Robustness . . . 1265
11.8.11 Assessment . . . 1266
11.9 Beyond short-run prices: spatial markets, repositioning and investment . . . 1268
11.9.1 Spatial competition and the Ultramar-Sunoco transaction: Houde (2012) 1268
11.9.2 Mergers and product repositioning in music radio: Sweeting (2010) . 1279
11.9.3 Mergers and capacity investment in the paper industry: Pesendorfer (2003) . . . 1284
11.10Merger policy with merger choice . . . 1291
11.10.1 The model . . . 1291
11.10.2 Three lemmas on the shape of merger outcomes . . . 1292
11.10.3 The optimal approval policy . . . 1294
11.10.4 Cutoff policies, a numerical example and comparative statics . . . 1296
11.10.5 Extensions . . . 1297
11.10.6 Lessons and limits . . . 1298
11.10.7 Merger review over time, investment and innovation . . . 1299
11.11Assessment and open issues . . . 1301
11.11.1 What the approaches deliver . . . 1301

11.11.2 Limitations of current practice . . . 1302
11.11.3 Remedies . . . 1302
11.11.4 Recent controversial mergers . . . 1304
11.11.5 Open issues . . . 1304
11.12 Bibliographic notes . . . 1306
11.13 Exercises . . . 1307

12 Collusion: Theory **1310**
12.1 Collusion: Forms, Law, and Facts . . . 1311
12.1.1 Forms of collusion . . . 1311
12.1.2 How economists model collusion . . . 1312
12.1.3 When tacit collusion fails . . . 1313
12.1.4 Legal treatment . . . 1315
12.1.5 Facts from enforcement . . . 1316
12.2 Repeated Games . . . 1318
12.2.1 The stage game and the repeated game . . . 1318
12.2.2 Subgame perfection . . . 1319
12.2.3 The one-shot deviation principle . . . 1319
12.2.4 Nash reversion, minmax payoffs and individual rationality . . . 1320
12.2.5 Folk theorems . . . 1321
12.2.6 Finite horizons, reputation and bootstrap strategies . . . 1323
12.2.7 Recursive structure and self-generation . . . 1325
12.3 Collusion under Perfect Monitoring . . . 1325
12.3.1 The Bertrand supergame . . . 1325
12.3.2 Comparative statics: firms, detection, growth and capacity . . . 1328
12.3.3 The Cournot supergame . . . 1330
12.3.4 Optimal punishments . . . 1334
12.3.5 Asymmetric firms . . . 1337
12.3.6 Differentiated products . . . 1339
12.3.7 Coordinated effects of mergers . . . 1341
12.4 Collusion When Demand Fluctuates . . . 1342
12.4.1 A two-state model . . . 1343
12.4.2 Rotemberg and Saloner (1986): price wars during booms . . . 1347
12.4.3 Predictable cycles: Haltiwanger and Harrington (1991) . . . 1363
12.4.4 Bagwell and Staiger (1997): collusion over the business cycle . . . 1364
12.4.5 Comparing the models . . . 1373
12.5 Imperfect Public Monitoring: Green and Porter . . . 1374
12.5.1 Secret price cuts: Stigler's policing problem . . . 1374
12.5.2 A Bertrand version with zero-demand shocks . . . 1375
12.5.3 The original model: Green and Porter (1984) . . . 1381
12.5.4 The price process and its estimation . . . 1386
12.5.5 Testable implications, extensions and critiques . . . 1389
12.6 Private Information about Costs: Collusion and Price Rigidity . . . 1390
12.6.1 Question and motivation . . . 1390
12.6.2 The static game . . . 1391
12.6.3 The repeated game and its recursive formulation . . . 1393
12.6.4 Incentive compatibility and efficiency rents . . . 1395
12.6.5 Inelastic demand: full sorting, no wars, and rigid prices . . . 1397

12.6.6 Downward-sloping demand . . . 1400
12.6.7 Impatient firms . . . 1402
12.6.8 Asymmetric schemes . . . 1404
12.6.9 Testable implications, limitations and contribution . . . 1405
12.7 How Cartels Organize: Communication, Facilitating Practices, and Transfers 1407
12.7.1 The anatomy of explicit cartels . . . 1407
12.7.2 Facilitating practices and market structure . . . 1412
12.7.3 Harrington and Skrzypacz (2011): private monitoring, sales reports and transfers . . . 1418
12.7.4 Tolerated cheating: a preview . . . 1431
12.8 Antitrust Enforcement and Leniency . . . 1431
12.8.1 The legal framework . . . 1431
12.8.2 Fines in the repeated game . . . 1433
12.8.3 Chen and Rey (2013): the design of leniency programs . . . 1435
12.8.4 The agreement requirement: Kaplow (2013) . . . 1446
12.9 What Determines Cartel Success? . . . 1448
12.9.1 Theory and measurement . . . 1448
12.9.2 How long cartels last . . . 1449
12.9.3 Determinants of cartel duration . . . 1450
12.9.4 Why cartels break down . . . 1454
12.9.5 Effects on prices . . . 1455
12.9.6 What the evidence says about the theory . . . 1455
12.10 Synthesis: What the Theory Predicts and How to Test It . . . 1456
12.11 Bibliographic notes . . . 1459
12.12 Exercises . . . 1460

13 Collusion: Evidence and Detection 1463
13.1 Collusion in Practice and the Nature of the Evidence . . . 1463
13.2 From Theory to Testable Implications: The Econometrics of Regime Switching 1465
13.2.1 What the theories predict . . . 1466
13.2.2 A supply relation with switching conduct . . . 1466
13.2.3 Identification and an observational-equivalence result . . . 1471
13.2.4 Estimation with unobserved regimes: the EM algorithm . . . 1473
13.2.5 Markov switching and time-varying transition probabilities . . . 1475
13.2.6 Testing for regime switching and for the order of the regime process 1476
13.3 The Joint Executive Committee Railroad Cartel . . . 1480
13.3.1 Question and setting . . . 1480
13.3.2 Data . . . 1481
13.3.3 Model and estimating equations . . . 1482
13.3.4 Results . . . 1483
13.3.5 Ellison's re-examination . . . 1487
13.3.6 Assessment of the JEC evidence . . . 1494
13.4 Rules, Communication and Price Wars in Other Legal Cartels . . . 1495
13.4.1 The Sugar Institute, 1927–1936 . . . 1495
13.4.2 Price wars in pre-1914 sugar refining . . . 1503
13.4.3 The bromine cartel, 1885–1914 . . . 1503
13.5 Information, Transparency and Coordination . . . 1512
13.5.1 Transparency and the incentive constraint . . . 1512

13.5.2 Government-assisted coordination: Danish ready-mixed concrete . . 1515
13.5.3 Signaling through a fare-publishing system: the Airline Tariff Publishing case . . . 1519
13.5.4 Rules among nonprofits: the Overlap group and financial aid 1522
13.5.5 What the information cases show . . . 1527
13.6 Retail Gasoline: Dynamic Pricing, Price Cycles and a Prosecuted Cartel 1527
13.6.1 Theory: collusive margins and expected future conditions 1528
13.6.2 Margins and expected demand in U.S. cities: Borenstein and Shepard (1996) . . . 1532
13.6.3 Edgeworth cycles in Toronto: Noel (2007) . . . 1538
13.6.4 A prosecuted cartel with asymmetric retailers: Clark and Houde (2013) 1543
13.6.5 The end of the cartel as a natural experiment: Erutku and Hildebrand (2010) . . . 1549
13.6.6 Learning to coordinate in Perth: Byrne and de Roos (2019) 1552
13.6.7 What the gasoline evidence shows . . . 1553
13.7 Imperfect Cartels: Tolerated Cheating and Business Stealing 1553
13.7.1 Evidence from prosecuted industrial cartels 1555
13.7.2 A model of imperfect collusion with business stealing 1556
13.8 Inside a Bidding Ring: Asker's Stamp Cartel 1565
13.8.1 Question and institutions 1565
13.8.2 The theory of the knockout 1568
13.8.3 Data and descriptive evidence 1571
13.8.4 Structural estimation 1574
13.8.5 Results 1578
13.8.6 Interpretation, critiques and contribution 1582
13.9 Detecting Collusion: Market Evidence and Tests for Bid Rigging 1584
13.9.1 Market evidence, plus factors and screens 1585
13.9.2 The theory of detection tests 1593
13.9.3 Long Island highway paving: Porter and Zona (1993) 1599
13.9.4 Ohio school milk: Porter and Zona (1999) 1605
13.10 Enforcement, Damages and What the Evidence Shows 1616
13.10.1 Enforcement institutions and the selection of observed cartels 1616
13.10.2 Measuring the effects of collusion 1619
13.10.3 What the evidence shows 1625
13.11 Bibliographic notes 1628
13.12 Exercises 1629

IV Auctions **1633**

14 Auction Theory for Single-Object Auctions **1634**
14.1 Why Study Auctions 1635
14.1.1 Why auctions are attractive to empirical economists 1635
14.1.2 A first look at auction data: offshore oil leases 1636
14.1.3 Plan of the chapter and notation 1638
14.2 Auction Formats and Strategic Equivalence 1638
14.2.1 A classification 1638
14.2.2 Varieties of the English auction 1642

14.2.3 Strategic equivalence . . . 1643
14.3 Values, Signals, and Information Structures . . . 1644
14.3.1 The general model . . . 1644
14.3.2 A taxonomy of information structures . . . 1646
14.3.3 Affiliation . . . 1649
14.3.4 The winner's curse . . . 1654
14.3.5 Order statistics . . . 1656
14.4 Second-Price and Ascending Auctions with Private Values . . . 1659
14.4.1 Truthful bidding in the second-price auction . . . 1659
14.4.2 The English auction with private values . . . 1661
14.4.3 Revenue and surplus with symmetric independent private values . . . 1662
14.4.4 What second-price and English auctions reveal . . . 1664
14.5 First-Price Auctions with Symmetric Independent Private Values . . . 1664
14.5.1 The first-price auction as a Bayesian game . . . 1664
14.5.2 Equilibrium by the first-order condition . . . 1666
14.5.3 Equilibrium by the envelope theorem . . . 1669
14.5.4 Examples . . . 1670
14.5.5 The first-order condition in terms of the bid distribution . . . 1673
14.5.6 Reserve prices, the Dutch auction, and multiplicity . . . 1675
14.5.7 Risk-averse bidders . . . 1676
14.6 Revenue Equivalence . . . 1679
14.6.1 The self-selection view . . . 1679
14.6.2 Mechanisms and incentive compatibility . . . 1680
14.6.3 The revenue equivalence theorem . . . 1682
14.6.4 Using revenue equivalence to solve for equilibria . . . 1683
14.6.5 Interdependent values with independent signals . . . 1684
14.6.6 When revenue equivalence fails . . . 1685
14.7 Reserve Prices and Optimal Auctions . . . 1686
14.7.1 Expected revenue in terms of virtual values . . . 1686
14.7.2 The optimal auction . . . 1687
14.7.3 Symmetric bidders: the optimal reserve price . . . 1688
14.7.4 The cost of a reserve price: a worked example . . . 1689
14.7.5 Competition versus mechanism design . . . 1690
14.7.6 Asymmetric bidders: favoring the weak . . . 1691
14.7.7 Entry fees . . . 1692
14.8 Affiliated Values I: Equilibrium Bidding . . . 1693
14.8.1 The question and the setting . . . 1693
14.8.2 The model . . . 1695
14.8.3 Properties of affiliation . . . 1695
14.8.4 The second-price auction . . . 1697
14.8.5 Bidders with inferior information . . . 1699
14.8.6 The English auction . . . 1703
14.8.7 The first-price auction . . . 1705
14.9 Affiliated Values II: The Linkage Principle, Revenue Ranking, and Information Disclosure . . . 1709
14.9.1 The linkage principle . . . 1710
14.9.2 Revenue ranking . . . 1711
14.9.3 Information disclosure by the seller . . . 1713

14.9.4 Reserve prices and entry fees . . . 1716
14.9.5 Risk aversion . . . 1718
14.9.6 Assessment of Milgrom and Weber (1982) . . . 1720
14.10 Asymmetric Bidders . . . 1721
14.10.1 The asymmetric private values model . . . 1721
14.10.2 Second-price and ascending auctions with asymmetric bidders . . . 1722
14.10.3 The first-price auction: first-order conditions . . . 1723
14.10.4 Common support of the bid distributions . . . 1725
14.10.5 Strong bidders shade more: the Maskin-Riley properties . . . 1726
14.10.6 A closed-form example: uniform values with different supports . . . 1728
14.10.7 Revenue comparisons with asymmetric bidders . . . 1731
14.11 Participation and Entry . . . 1731
14.11.1 Entry with values known in advance . . . 1732
14.11.2 Entry with values learned after entry: the Levin-Smith model . . . 1733
14.11.3 Asymmetric bidders and type-symmetric entry equilibria . . . 1735
14.12 Collusion and the Choice of Format . . . 1739
14.12.1 Rings in second-price and ascending auctions . . . 1739
14.12.2 Rings in first-price auctions . . . 1740
14.12.3 Ring size, leakage and secret deviations . . . 1740
14.12.4 Knockouts and side payments . . . 1742
14.12.5 Collusion and entry: Athey, Levin and Seira's Proposition 3 . . . 1744
14.13 Procurement Auctions . . . 1746
14.13.1 The model and the equilibrium bid . . . 1746
14.13.2 The first-order condition in terms of the bid distribution . . . 1747
14.13.3 The oligopoly analogy . . . 1747
14.13.4 Other formats, reserve prices and preferences . . . 1748
14.14 From Theory to Data . . . 1749
14.15 Bibliographic notes . . . 1750
14.16 Exercises . . . 1751

15 Identification and Estimation of Single-Object Auctions 1755
15.1 The Structural Approach to Auction Data . . . 1756
15.1.1 Primitives and observables . . . 1757
15.1.2 Identification and testability . . . 1758
15.1.3 Two routes from bids to primitives . . . 1758
15.2 Second-Price and Ascending Auctions . . . 1761
15.2.1 All bids observed in a second-price auction . . . 1761
15.2.2 Only the transaction price: order-statistic inversion . . . 1761
15.2.3 Asymmetric independent private values: competing risks . . . 1764
15.2.4 Covariates . . . 1767
15.2.5 Correlated values: what incomplete bids cannot reveal . . . 1770
15.2.6 An incomplete model of ascending auctions . . . 1771
15.2.7 Binding reserve prices . . . 1774
15.3 First-Price Auctions I: The Inversion Problem and Direct Methods . . . 1776
15.3.1 Why first-price auctions are harder . . . 1776
15.3.2 Maximum likelihood and its non-regularity . . . 1777
15.3.3 Laffont, Ossard and Vuong (1995): simulated nonlinear least squares 1778
15.3.4 From direct to indirect methods . . . 1783

15.4 First-Price Auctions II: The Guerre-Perrigne-Vuong Approach 1783
15.4.1 Setting and the inversion 1785
15.4.2 Identification and testable restrictions 1787
15.4.3 The bid density is smoother than the value density 1791
15.4.4 The two-step estimator 1792
15.4.5 Rates of convergence and inference 1795
15.4.6 A Monte Carlo illustration 1798
15.4.7 Binding reserve prices and unknown numbers of potential bidders . 1801
15.4.8 Incomplete bid data and Dutch auctions 1804
15.4.9 Specification testing in first-price auctions 1807
15.5 Affiliated and Asymmetric Private Values 1809
15.5.1 Symmetric affiliated private values: Li, Perrigne and Vuong (2002) . 1809
15.5.2 What the two highest bids reveal 1815
15.5.3 Asymmetric affiliated private values: Campo, Perrigne and Vuong (2003) 1816
15.5.4 Asymmetric independent private values with all bids 1821
15.6 Common Values: Limits of Identification and Tests 1823
15.6.1 What bids can and cannot reveal 1823
15.6.2 Testing private against common values 1826
15.6.3 Interdependent costs: Somaini (2020) 1831
15.6.4 An auction with an informed bidder: Hendricks and Porter (1988) . 1837
15.7 Unobserved Auction Heterogeneity 1841
15.7.1 The problem 1841
15.7.2 Separability and homogenization 1843
15.7.3 Identification by deconvolution: Krasnokutskaya (2011) 1845
15.7.4 Parametric approaches 1860
15.7.5 Reserve prices as a control for quality: Roberts (2013) 1860
15.7.6 Comparing the approaches 1865
15.8 Entry, Participation, Dynamics and Risk Aversion 1865
15.8.1 Potential and actual bidders 1866
15.8.2 Selection by a reserve price or a bid cost 1866
15.8.3 Costly signal acquisition and the entry cost 1866
15.8.4 Bidders uncertain about the competition 1869
15.8.5 Dynamics and capacity: Jofre-Bonet and Pesendorfer (2003) 1870
15.8.6 Risk aversion 1874
15.9 Open versus Sealed Bidding in Timber Auctions: Athey, Levin and Seira (2011) 1876
15.9.1 The question 1876
15.9.2 Institutions 1877
15.9.3 Data 1877
15.9.4 The model and its predictions 1879
15.9.5 Reduced-form evidence 1881
15.9.6 Structural estimation 1883
15.9.7 Out-of-sample predictions and the competitiveness of open auctions 1892
15.9.8 Counterfactual comparison of formats 1895
15.9.9 Assessment 1896
15.10 Testing for Collusion with Auction Data 1897
15.11 Divisible-Good Auctions: Bidding with Demand Schedules 1903
15.11.1 The share auction with step bids 1904

15.11.2 Uniform pricing: Kastl (2011) . . . 1904
15.11.3 Discriminatory pricing: Cassola, Hortaçsu and Kastl (2013) . . . 1909
15.12 What Auction Data Can and Cannot Tell Us . . . 1913
15.13 Bibliographic notes . . . 1913
15.14 Exercises . . . 1916

Appendices **1919**

A Econometric Toolkit **1919**
A.1 Identification and the logic of empirical models . . . 1921
A.1.1 Models, structures and identification . . . 1921
A.1.2 Simultaneous equations . . . 1923
A.1.3 Potential outcomes and selection . . . 1926
A.1.4 Monte Carlo experiments . . . 1927
A.2 Least squares, panel data and systems . . . 1928
A.2.1 OLS as a projection . . . 1928
A.2.2 Large-sample theory . . . 1929
A.2.3 Three sources of bias . . . 1930
A.2.4 Panel data . . . 1932
A.2.5 Systems of equations . . . 1934
A.2.6 Testing linear restrictions . . . 1935
A.3 Instrumental variables . . . 1937
A.3.1 The IV model . . . 1937
A.3.2 Two-stage least squares . . . 1940
A.3.3 Endogeneity in nonlinear models . . . 1942
A.3.4 Where instruments come from in IO . . . 1943
A.3.5 Weak instruments . . . 1945
A.3.6 Specification tests . . . 1949
A.3.7 What IV estimates when effects differ . . . 1950
A.3.8 System IV: three-stage least squares . . . 1951
A.4 Extremum estimators . . . 1952
A.4.1 Consistency . . . 1953
A.4.2 Asymptotic normality . . . 1955
A.4.3 Profile objectives . . . 1956
A.4.4 Numerical practice . . . 1957
A.5 Generalized method of moments . . . 1958
A.5.1 Moment conditions . . . 1958
A.5.2 The estimator and its asymptotic distribution . . . 1959
A.5.3 Efficient weighting . . . 1961
A.5.4 Testing . . . 1962
A.5.5 Optimal instruments . . . 1963
A.5.6 Two-step estimators and generated regressors . . . 1965
A.5.7 Computation . . . 1967
A.6 Maximum likelihood . . . 1968
A.6.1 Likelihood and identification . . . 1968
A.6.2 Score, information and asymptotic normality . . . 1969
A.6.3 Quasi-maximum likelihood . . . 1970

A.6.4 The trinity of tests . . . 1970
A.6.5 Likelihoods for discrete outcomes . . . 1972
A.6.6 Latent variables . . . 1975
A.6.7 Non-regular problems . . . 1981
A.6.8 Non-nested tests . . . 1982
A.6.9 Testing a parametric distribution . . . 1983
A.7 Simulation-based estimation . . . 1983
A.7.1 Monte Carlo integration . . . 1984
A.7.2 The method of simulated moments . . . 1986
A.7.3 Simulated maximum likelihood . . . 1988
A.7.4 Simulated nonlinear least squares . . . 1991
A.7.5 Indirect inference . . . 1992
A.7.6 Inference on functions of estimated parameters . . . 1993
A.8 Standard errors under dependence . . . 1993
A.8.1 One formula for all robust variances . . . 1994
A.8.2 Clustered data . . . 1994
A.8.3 Serial correlation and HAC estimators . . . 1997
A.8.4 Dependence structures in IO data . . . 1998
A.8.5 Worked application: Sumner's regression revisited . . . 1998
A.9 The delta method and the bootstrap . . . 2001
A.9.1 The delta method . . . 2001
A.9.2 The bootstrap: principle and theory . . . 2003
A.9.3 Bootstraps for dependent data . . . 2005
A.9.4 Multi-step estimators and counterfactuals . . . 2007
A.9.5 When the bootstrap fails . . . 2007
A.10 Nonparametric estimation of distributions and densities . . . 2008
A.10.1 The empirical distribution function . . . 2009
A.10.2 The kernel density estimator . . . 2010
A.10.3 Smoothness, higher-order kernels and derivatives . . . 2013
A.10.4 Boundary bias and trimming . . . 2015
A.10.5 Bandwidth choice and inference . . . 2017
A.10.6 Multivariate and conditional densities . . . 2017
A.10.7 Worked application: the GPV estimator in a Monte Carlo . . . 2019
A.11 Nonparametric regression, deconvolution and bounds . . . 2021
A.11.1 The Nadaraya-Watson estimator . . . 2021
A.11.2 Local polynomial regression . . . 2022
A.11.3 Series and sieve estimators . . . 2024
A.11.4 The partially linear model . . . 2024
A.11.5 Deconvolution . . . 2025
A.11.6 Estimation and inference under partial identification . . . 2028
A.12 Difference in differences and panel event studies . . . 2030
A.12.1 The two-by-two design . . . 2030
A.12.2 Two-way fixed effects and continuous treatment . . . 2032
A.12.3 Control groups in IO retrospectives . . . 2034
A.12.4 Inference . . . 2039

Part I

Market Power: Theory and Measurement

Chapter 1

Introduction: What Empirical IO Studies

Consider a coffee shop on a university campus. It is the only seller of coffee inside one building, and a few other cafes operate a short walk away. Does it have market power, and how much? To answer we would like to know three things. The first is its demand curve, that is, how many cups it would sell at each price. The second is its marginal cost of a cup. The third is how its rivals would respond if it raised its price. None of the three is written down anywhere. What we can observe is its price and perhaps the number of cups it sells. Now and then an event moves one of the unknowns, such as a tax on coffee, a rise in the price of beans or a new cafe next door. Empirical industrial organization is the craft of learning about demand, cost and the conduct of firms from data of this kind. This chapter introduces that craft, its history and the questions it serves.

The chapter has four movements. Sections 1.1 and 1.2 state the questions of the field and define its basic objects: markets, concentration, the Lerner index and markups. They end with the Cournot model, which links concentration to margins and so motivates the first empirical program of the field. Sections 1.3 to 1.5 study that program, the structure-conduct-performance paradigm. Its cross-industry regressions of margins on concentration dominated the field for three decades. We show formally why they cannot separate demand, cost and conduct, and we follow the debates they left behind, including the recent one over rising markups. Sections 1.6 and 1.7 present the response, the New Empirical Industrial Organization of Bresnahan (1989). It studies one industry at a time, treats conduct as a parameter, and asks which features of the data identify market power. Section 1.8 describes empirical IO today, following Einav and Levin (2010). Most work now estimates demand, recovers marginal costs from first-order conditions and simulates counterfactual equilibria. Section 1.9 lays out the rest of the book.

The coffee shop returns twice. Example 1.12 uses an estimated elasticity to infer its marginal cost and shows how the answer depends on conduct. Example 1.40 predicts the effect of a tax on its price and shows how the answer depends on the shape of demand. These two dependencies, on conduct and on functional form, recur in every chapter. The theory behind this chapter is developed in Chapter 2, the measurement of conduct in Chapter 3, and the demand models of the structural workflow in Chapters 5 to 8. The Cournot, collusion and cross-industry regression models of Sections 1.2.5 and 1.4.3 are worked through in full in Appendix C.

1.1 What industrial organization studies

Industrial organization (IO) is the field of economics that studies how industries are organized and how firms and consumers behave within them. In the words of Einav and Levin (2010, p. 146), the field "is concerned with the structure of industries in the economy and the behavior of firms and individuals in these industries." Its distinctive focus is on markets that depart from *perfect competition*, the benchmark in which many small firms take the price as given and price equals marginal cost. Such departures arise from scale economies, transaction costs, strategic behavior and other frictions (Einav and Levin, 2010, p. 146).

The traditional questions of IO concern competition policy, regulation, and the determinants and consequences of market power. Competition policy asks, for example, whether a merger will raise prices or whether a group of sellers is fixing prices. Regulation asks how to set prices and entry rules in industries with large scale economies, such as electricity transmission or local telephone service. The study of *market power*, the ability of a firm to keep its price above the competitive level, asks where such power comes from and what it costs consumers. Each of these questions requires a model of how firms interact. A firm's best price depends on the prices of its rivals, and a merger changes the incentives of the merging firms and of every firm that competes with them.

The field therefore looks mostly at what happens between firms. What happens inside a firm, such as how it organizes production or designs incentives for its employees, belongs largely to other fields. Productivity is the main exception. Many IO economists measure productivity and study how competition and the selection of efficient firms shape it. This book does not cover productivity.

Empirical IO relies on economic theory more than most other fields of applied microeconomics. We see two reasons. The first is that theory has a great deal to say about firms and markets. Firms that set prices every day plausibly come close to maximizing profit, and profit maximization in equilibrium imposes sharp restrictions on data. Einav and Levin (2010, pp. 158–159) draw the contrast with research on education. Standard theory says little about how third graders learn. For firms and markets, they argue, theory "has a lot to say and, when appropriately used, generally serves to clarify rather than to complicate one's understanding of a market." The second reason is historical. IO had a head start on the econometric modeling of strategic behavior. By the late 1980s a body of work already estimated demand, cost and the form of competition jointly within single industries, and Bresnahan (1989) could survey it. A further consideration reinforces both reasons. Many IO questions concern events that have not yet happened, such as a proposed merger, and only a model of the industry can predict their effects.

These tools now travel beyond the traditional boundaries of the field. IO-trained economists study insurers and hospitals in health care, schools and colleges in education, and banks and lenders in finance. Questions about competition have become central in each of these sectors. The same methods serve markets with *adverse selection*, such as insurance, where the customers most eager to buy are the most costly to serve. They also serve platforms that bring two groups of users together. Einav and Levin (2010, p. 149) report that the demand models developed in Chapters 5 to 8 have spread into trade, education, housing, health and environmental economics. Economists sometimes call this expansion "IO+." The editors of the latest Handbook of Industrial Organization describe the same trend (Ho et al., 2021a, Preface, p. xv). In their account, the "econometric revolution" that began with the New Empirical Industrial Organization of Section 1.6 has kept maturing. Its toolbox now reaches credit and insurance markets, financial markets, health care, the energy sector and the environment.

Empirical IO also has a large footprint in policy and business. Its methods are used in merger reviews and antitrust litigation, in regulatory decisions, in price setting by retailers, and in the design of auctions and marketplaces (Einav and Levin, 2010, p. 145). Antitrust agencies and courts use demand estimates to define markets, to simulate the price effects of mergers, and to compute damages from excessive prices (Einav and Levin, 2010, p. 149). Around 1980, antitrust arguments often rested on simple concentration measures. Today the agencies routinely commission econometric studies of the industry under review (Einav and Levin, 2010, p. 152). Welfare measures derived from estimated demand have shaped the debate over how the Consumer Price Index should account for new goods (Einav and Levin, 2010, p. 149). Empirical studies of bidding have informed the regulation of wholesale electricity markets (Einav and Levin, 2010, p. 154). We treat merger analysis in Chapter 11, new goods in Chapter 10, and auctions in Chapters 14 and 15.

Almost every question in this book comes back to three objects, which we call the *primitives* of a market. The first is *demand*, which describes how many units consumers buy at each price and how they substitute between products. The second is *cost*, in particular the *marginal cost* of producing one more unit. The third is *conduct*, the way firms compete. Firms may set prices or quantities, act independently or coordinate, and look ahead to rivals' reactions or ignore them. Price equals marginal cost plus a markup, and the markup depends on demand and on conduct:

$$\text{price} = \text{marginal cost} + \text{markup}(\text{demand}, \text{conduct}). \tag{1.1}$$

Sections 1.2.3 and 1.2.5 make this decomposition precise.

In most data sets none of the three primitives is observed directly. We observe prices and quantities, which are equilibrium outcomes. Each observed pair lies on the demand curve and on the firms' pricing rule at the same time, so a scatter of prices and quantities traces out neither of them. Chapters 5 and 7 treat this simultaneity problem. Accounting data record average and historical costs, with overhead allocated by convention. Einav and Levin (2010, p. 151), following Bresnahan (1989), stress that accounting practices are not designed to report the economic notion of marginal cost. Conduct is recorded nowhere, and firms that coordinate have every reason to hide it. The history of empirical IO, told in the rest of this chapter, is a sequence of answers to one problem. How can we learn about demand, cost and conduct from data on prices and quantities?

Remark 1.1 (Scope of this book). The book covers static imperfect competition and its measurement (Chapters 2 to 4) and demand estimation and its applications (Chapters 5 to 10). It also covers competition policy toward mergers and collusion (Chapters 11 to 13) and auctions of a single object (Chapters 14 and 15). It does not treat in depth the models of entry and market structure, dynamic competition and investment, productivity, vertical relations, consumer search, or price discrimination. Section 1.8 sketches some of these topics, and Section 1.9 gives a detailed roadmap.

1.2 Market structure, market power, and markups

A question in the background of much of empirical IO is how market structure affects market power. Do markets with fewer or larger firms have higher prices relative to cost? Answering it requires four ingredients, which this section develops in turn. We need a definition of the market (Section 1.2.1) and a measure of its structure (Section 1.2.2). We also need a measure of market power (Sections 1.2.3 and 1.2.4) and a theory that links structure to market power (Section 1.2.5).

1.2.1 Markets and market definition

Definition 1.2 (Market)**.** A *market* is a set of products and a geographic area within which buyers substitute strongly, and from which they substitute only weakly toward outside products or sellers. The set of products is the *product market*, and the area is the *geographic market*.

Market shares, concentration and even the label "monopoly" are defined only relative to a market. A firm that sells the only brand of a particular breakfast cereal has a monopoly over that brand. The same firm has a modest share of ready-to-eat cereal and a negligible share of all breakfast foods. Every statistic computed from shares therefore inherits the choice of market.

Sometimes the market is obvious. Cement is heavy and cheap relative to its weight, so a cement plant in an isolated town competes only with plants within a short trucking distance. The product market is cement, and the geographic market is the area around the town. Sometimes the market is far from obvious. Online retailers sell to the whole country and compete with physical stores. Breakfast cereals form a chain of substitutes, from children's cereals to adult cereals to other breakfast foods, with no natural break. In such cases any boundary is a judgment call.

Antitrust practice disciplines this judgment with the *hypothetical monopolist test*. We start from a candidate set of products and an area. We then ask whether a hypothetical profit-maximizing firm that owned all of them would impose a *small but significant and non-transitory increase in price* (SSNIP), commonly 5 percent. If substitution to products outside the set would make such an increase unprofitable, the set is too narrow, and we add the next closest substitute. The *relevant market* is the smallest set that passes the test. The test is a statement about demand elasticities, so it needs the demand models of Chapters 5 to 8. Chapter 11 develops it, together with the loss of sales that would make a price increase unprofitable and the concentration thresholds used in merger review.

Some economists doubt that market definition is the right first step at all. Bresnahan (1989, p. 1049) notes that antitrust often needs to know whether a group of firms acting together, or a single firm, has market power. He adds in a footnote that "these questions are well-posed, even where the usual method of answering them ... is senseless" (Bresnahan, 1989, p. 1049, n. 44). The usual method defines a 'relevant market' and calculates market shares in it. Market power is a property of the demand curve that a firm or group faces, and we can try to estimate that curve directly. Market definition is a device for approximating the same object with shares. Chapter 3 shows how to estimate the demand curve that a single firm faces after its rivals respond. This direct approach is one motivation for the New Empirical Industrial Organization of Section 1.6.

1.2.2 Concentration measures

In empirical work, *market structure* usually means a measure of concentration computed from market shares. Consider a market with N firms $i = 1, \dots, N$ that sell a homogeneous good. Firm i produces q_i, total output is $Q = \sum_{i=1}^{N} q_i$, and firm i's *market share* is $s_i = \frac{q_i}{Q}$. Shares are fractions that sum to one. With differentiated products, shares are computed from units or revenues within the defined market. We write $s_{(1)} \geq s_{(2)} \geq \cdots \geq s_{(N)}$ for the shares sorted from largest to smallest.

Definition 1.3 (Concentration measures)**.**

(i) The *m-firm concentration ratio* is the combined share of the m largest firms,

$$CR_m = \sum_{i=1}^{m} s_{(i)}.$$

(ii) The *Herfindahl-Hirschman index*, often shortened to the Herfindahl index, is the sum of squared shares,

$$HHI = \sum_{i=1}^{N} s_i^2. \tag{1.2}$$

Antitrust agencies report it in *HHI points*, equal to $10{,}000 \times HHI$, which is the sum of squared shares measured in percent.

(iii) The *numbers equivalent* is $N^{\text{eq}} = \frac{1}{HHI}$, the number of equal-sized firms that would produce the same index.

The concentration ratios in common use are CR_1 (the share of the largest firm), CR_3, CR_4 and CR_8. They satisfy $\frac{m}{N} \le CR_m \le 1$ for $m \le N$, because the average of the m largest shares is at least the average share $\frac{1}{N}$. The Herfindahl-Hirschman index is named after Orris Herfindahl and Albert Hirschman. It uses every share, and it weights large firms more heavily because each share is weighted by itself. The next result makes precise what the index measures.

Lemma 1.4 (Bounds and variance decomposition)**.** *Let $\sigma_s^2 = \frac{1}{N}\sum_{i=1}^{N}\left(s_i - \frac{1}{N}\right)^2$ be the cross-firm variance of market shares. Then*

$$HHI = \frac{1}{N} + N\sigma_s^2, \tag{1.3}$$

and $\frac{1}{N} \le HHI \le 1$. The lower bound holds with equality if and only if all shares are equal. The upper bound holds with equality if and only if one firm has the whole market.

Proof. The mean share is $\frac{1}{N}\sum_i s_i = \frac{1}{N}$, so σ_s^2 is the variance of shares around their mean. Expand the sum of squared deviations:

$$\begin{aligned}\sum_{i=1}^{N}\left(s_i - \frac{1}{N}\right)^2 &= \sum_{i=1}^{N} s_i^2 - \frac{2}{N}\sum_{i=1}^{N} s_i + N \cdot \frac{1}{N^2} \\ &= HHI - \frac{2}{N} + \frac{1}{N} \\ &= HHI - \frac{1}{N}.\end{aligned}$$

The second line uses $\sum_i s_i = 1$. The left side equals $N\sigma_s^2$, which gives (1.3). Because $\sigma_s^2 \ge 0$, we have $HHI \ge \frac{1}{N}$, with equality if and only if every share equals $\frac{1}{N}$. For the upper bound, $0 \le s_i \le 1$ implies $s_i^2 \le s_i$, so $HHI \le \sum_i s_i = 1$. Equality requires $s_i^2 = s_i$ for every i, so every share is zero or one. Since the shares sum to one, exactly one firm has share one. □

Lemma 1.4 shows that the index combines two features of a market. The term $\frac{1}{N}$ reflects the number of firms, and the term $N\sigma_s^2$ reflects the inequality of their sizes. A market with many firms is highly concentrated if one of them is much larger than the rest. Correspondingly, the numbers equivalent N^{eq} lies between 1 and N, and it falls below N whenever shares are unequal. Section 1.5.1 uses the decomposition to show that cost differences between firms raise concentration in a Cournot market.

Example 1.5 (Two rankings of concentration)**.** Consider two hypothetical industries. Industry A has one dominant firm with half of the market and 25 small firms with 2 percent each. Industry B has four firms with 20 percent each and four firms with 5 percent each. The four-firm concentration ratios are

$$CR_4^A = 0.50 + 3 \times 0.02 = 0.56,$$
$$CR_4^B = 4 \times 0.20 = 0.80,$$

so this ratio ranks B as more concentrated. The Herfindahl-Hirschman indices are

$$HHI^A = 0.50^2 + 25 \times 0.02^2 = 0.25 + 0.01 = 0.26,$$
$$HHI^B = 4 \times 0.20^2 + 4 \times 0.05^2 = 0.16 + 0.01 = 0.17,$$

or 2,600 and 1,700 HHI points. The index ranks A as more concentrated. The numbers equivalents are $N_A^{\text{eq}} = \frac{1}{0.26} \approx 3.8$ and $N_B^{\text{eq}} = \frac{1}{0.17} \approx 5.9$. Industry A has 26 firms but is as concentrated as a market with about four equal firms. In industry B, $N = 8$ and every share deviates from the mean $\frac{1}{8}$ by 0.075, so (1.3) confirms the arithmetic:

$$HHI^B = \frac{1}{8} + 8 \times 0.075^2 = 0.125 + 0.045 = 0.17.$$

The ratio CR_4 ignores how shares are distributed within the top four and among the remaining firms. The index HHI responds mostly to the single large firm in A.

Remark 1.6 (Which indices are admissible?). Encaoua and Jacquemin (1980) ask which functions $R(s_1, \ldots, s_N)$ of the shares deserve the name of a concentration index (Tirole, 1988, Section 5.5). They impose three axioms. The index is symmetric, so that permuting the shares leaves it unchanged. It satisfies the *Lorenz condition*, which says that a mean-preserving spread of the shares, moving share toward the tails of their distribution, raises the index. With symmetric firms it falls as their number grows, so that $R\left(\frac{1}{N}, \ldots, \frac{1}{N}\right) \geq R\left(\frac{1}{N+1}, \ldots, \frac{1}{N+1}\right)$. They show that a family of indices satisfying the axioms takes the form

$$R(s_1, \ldots, s_N) = \sum_{i=1}^{N} s_i \, h(s_i), \tag{1.4}$$

where h is nondecreasing and $s\,h(s)$ is convex. The Herfindahl-Hirschman index has $h(s) = s$. The *entropy index* $\sum_i s_i \ln s_i$ has $h(s) = \ln s$, and it equals $-\ln N$ when N firms are equal. The ratio CR_m satisfies the axioms, yet it does not belong to the family.

Two steps show why every member of the family satisfies the axioms. Let $g(s) = s\,h(s)$. With equal shares, $R = N g\left(\frac{1}{N}\right) = h\left(\frac{1}{N}\right)$, which cannot rise with N because h is nondecreasing. For the Lorenz condition, move the share $\Delta > 0$ from firm j to a firm i with $s_i \geq s_j$. This transfer is the elementary step of a mean-preserving spread. The index changes by

$$\big[g(s_i + \Delta) - g(s_i)\big] - \big[g(s_j) - g(s_j - \Delta)\big] \geq 0.$$

The inequality holds because the slope of a convex function over an interval of length Δ rises as the interval moves to the right. For the Herfindahl index the change is $2\Delta(s_i - s_j) + 2\Delta^2 > 0$. The ratio CR_m meets the Lorenz condition only weakly, since a transfer between two firms outside the top m can leave it unchanged.

Remark 1.7 (What concentration measures leave out). A concentration index summarizes shares and nothing else. It ignores how close the products of different firms are as substitutes, whether firms have spare capacity, how easily new firms can enter, and whether buyers are large enough to bargain. Market structure in the broad sense includes the number of sellers and buyers, vertical integration, and product differentiation. Differentiation is *vertical* when all buyers rank the products the same way, as with quality grades. It is *horizontal* when buyers rank them differently, as with flavors or locations. No single index captures all of these features. Baker and Bresnahan (1988, p. 283) give an example from US brewing over 1962–1982. Pabst and Coors had similar national market shares, yet their estimates show that Pabst was virtually a price taker while Coors had substantial market power.

Shares are also used mechanically in merger review. If firms i and j merge and the merged firm keeps the combined share $s_i + s_j$, the index rises by

$$(s_i + s_j)^2 - s_i^2 - s_j^2 = 2s_i s_j.$$

Oligopoly theory does not guarantee that the merged firm keeps the combined share, so this calculation is only a first screen (Chapters 2 and 11).

1.2.3 Market power, markups, and the Lerner index

The competitive benchmark is price equal to marginal cost. A firm that takes the market price as given expands output until its marginal cost reaches the price. Market power is the ability to do better than this, and we measure it by the gap between price and marginal cost.

Definition 1.8 (Market power and markups)**.** A firm has *market power* if it can profitably set its price above the competitive level, which is its marginal cost mc. For a firm that charges the price p, we use four measures of the gap between price and marginal cost.

(i) The *Lerner index* is $L = \frac{p-mc}{p}$, the margin as a fraction of price (Lerner, 1934).

(ii) The *markup ratio* is $\mu = \frac{p}{mc}$.

(iii) The *markup rate* is $\mu - 1 = \frac{p-mc}{mc}$, the margin as a fraction of marginal cost.

(iv) The *dollar markup* is $p - mc$.

In this chapter μ always denotes the markup ratio. Later chapters use μ_{ijt} for the consumer-specific part of utility, and the context keeps the two apart. The recent literature on markups, including De Loecker et al. (2020), reports the ratio μ. The Lerner index and the markup ratio carry the same information:

$$\begin{aligned} L = \frac{p - mc}{p} &= 1 - \frac{mc}{p} \\ &= 1 - \frac{1}{\mu} \\ &= \frac{\mu - 1}{\mu}. \end{aligned} \tag{1.5}$$

Inverting gives $\mu = \frac{1}{1-L}$. When $0 < mc \le p$, the Lerner index lies in $[0, 1]$ and $\mu \ge 1$. Price taking gives $L = 0$ and $\mu = 1$. A markup rate of 50 percent, or $\mu = 1.5$, corresponds to $L = \frac{0.5}{1.5} = \frac{1}{3}$.

The basic theory of how a firm with market power sets its price fits in one proposition. We state it for a firm that faces a *residual demand* curve $Q(p)$, the quantity it sells at each of its own

prices once we account for what its rivals do. For a monopolist, residual demand is market demand.

Proposition 1.9 (The pricing rule)**.** *A firm faces a twice differentiable residual demand $Q(p)$ with $Q(p) > 0$ and $Q'(p) < 0$, and it produces at constant marginal cost $c > 0$. Let p be an interior maximizer of profit $\pi(p) = (p - c)Q(p)$. Then the following hold at p.*

(i) The dollar markup equals the reciprocal of the semi-elasticity *of demand $-\frac{\mathrm{d}\ln Q(p)}{\mathrm{d}p}$:*

$$p - c = m \equiv -\frac{Q(p)}{Q'(p)}, \qquad -\frac{\mathrm{d}\ln Q(p)}{\mathrm{d}p} = -\frac{Q'(p)}{Q(p)} = \frac{1}{m}. \tag{1.6}$$

(ii) The Lerner index equals the reciprocal of the residual demand elasticity $\varepsilon^R = -Q'(p)\frac{p}{Q(p)}$:

$$\frac{p - c}{p} = \frac{1}{\varepsilon^R}. \tag{1.7}$$

(iii) Price is a multiple of marginal cost,

$$p = \frac{\varepsilon^R}{\varepsilon^R - 1}\, c, \tag{1.8}$$

and the residual elasticity exceeds one, $\varepsilon^R > 1$.

The second-order condition is $\pi''(p) = 2Q'(p) + (p - c)Q''(p) \leq 0$.

Proof. Differentiate profit with respect to price:

$$\pi'(p) = Q(p) + (p - c)Q'(p).$$

At an interior maximum the first-order condition holds:

$$Q'(p)(p - c) + Q(p) = 0. \tag{1.9}$$

For (i), divide (1.9) by $-Q'(p) > 0$ and rearrange:

$$-(p - c) - \frac{Q(p)}{Q'(p)} = 0,$$
$$p - c = -\frac{Q(p)}{Q'(p)} = m.$$

The semi-elasticity is $-\frac{\mathrm{d}\ln Q}{\mathrm{d}p} = -\frac{Q'(p)}{Q(p)}$, which is $\frac{1}{m}$ by definition of m. For (ii), divide both sides of (i) by p:

$$\frac{p - c}{p} = -\frac{Q(p)}{p\,Q'(p)} = \frac{1}{-Q'(p)\frac{p}{Q(p)}} = \frac{1}{\varepsilon^R}.$$

For (iii), multiply (ii) by p and collect the terms in p:

$$p - c = \frac{p}{\varepsilon^R},$$
$$p\left(1 - \frac{1}{\varepsilon^R}\right) = c,$$
$$p = \frac{\varepsilon^R}{\varepsilon^R - 1}\, c.$$

The first line shows that $p > c > 0$, because $Q > 0$ and $Q' < 0$ make $\varepsilon^R > 0$. The ratio $\frac{p}{c} = \frac{\varepsilon^R}{\varepsilon^R - 1}$ must then exceed one. If $\varepsilon^R < 1$ the ratio would be negative, and $\varepsilon^R = 1$ would make the second line read $0 = c$. Hence $\varepsilon^R > 1$. The second-order condition is the requirement that $\pi''(p) \leq 0$ at a maximum. □

The two arrangements (i) and (ii) are the formulas used most often in this book. Arrangement (i) says that the markup in dollars equals the inverse of the semi-elasticity, the proportional fall in quantity per dollar of price increase. Arrangement (ii), often called the *Lerner equation* or the *inverse elasticity rule*, says that the markup as a fraction of price equals the inverse of the elasticity. A firm prices further above cost when its customers respond less to price. Both formulas involve only the residual demand curve of the firm itself, evaluated at the chosen price. The same logic carries over to the models of price competition with differentiated products that dominate modern work. There, each firm's price equals its marginal cost plus a markup that depends on the semi-elasticity of its own demand (Einav and Levin, 2010, p. 151). Statement (iii) adds that a firm with market power never prices where its residual demand is inelastic. At such a price, a small price increase would raise revenue and lower cost.

Two demand curves show the difference between the arrangements. With constant-elasticity demand $Q(p) = Ap^{-\varepsilon^R}$, the Lerner index is the constant $\frac{1}{\varepsilon^R}$, so price is a fixed multiple of cost. With exponential demand $Q(p) = Ae^{-\frac{p}{b}}$, the semi-elasticity is the constant $\frac{1}{b}$, so the dollar markup is the constant b whatever the cost. Chapter 2 develops these cases and their implications for how cost changes pass through to prices.

Remark 1.10 (Residual versus market demand). In an oligopoly the residual elasticity ε^R differs from the *market elasticity* $\varepsilon = -\frac{\mathrm{d}Q}{\mathrm{d}p}\frac{p}{Q}$ of total industry demand. Customers who leave one firm may buy from a rival instead of leaving the market, so a firm typically faces more elastic demand than the industry as a whole. A simple case makes this precise. Suppose N firms sell a homogeneous good with inverse market demand $P(Q)$, and firm i takes its rivals' total output $Q_{-i} = Q - q_i$ as fixed. The firm's inverse residual demand is then $P(q_i + Q_{-i})$, whose slope in q_i is $P'(Q)$. Since the slope of demand is the reciprocal of the slope of inverse demand, the market elasticity is $\varepsilon = -\frac{P(Q)}{QP'(Q)}$. The residual elasticity of firm i is therefore

$$\varepsilon_i^R = -\frac{P(Q)}{q_i P'(Q)} = \frac{Q}{q_i}\left(-\frac{P(Q)}{QP'(Q)}\right) = \frac{\varepsilon}{s_i}. \tag{1.10}$$

A firm with a 25 percent share faces a residual elasticity four times the market elasticity. Section 1.2.5 returns to this case. Chapter 3 shows how Baker and Bresnahan (1988) estimate residual demand curves directly, and Chapter 4 treats firms that sell several differentiated products.

Proposition 1.9 can be run in reverse. If we know the elasticity of the demand that a firm faces and we observe its price, the pricing rule tells us its marginal cost.

Corollary 1.11 (Inferring marginal cost from prices)**.** *Suppose we observe the price p of a firm that maximizes profit as in Proposition 1.9, and we have an estimate $\hat{\varepsilon}^R$ of its residual demand elasticity at that price. Then the Lerner index and marginal cost are estimated by*

$$\hat{L} = \frac{1}{\hat{\varepsilon}^R}, \qquad \hat{c} = p + \frac{Q(p)}{\hat{Q}'(p)} = p\left(1 - \frac{1}{\hat{\varepsilon}^R}\right). \tag{1.11}$$

If $\hat{\varepsilon}^R$ has standard error $\mathrm{se}(\hat{\varepsilon}^R)$ and p is measured without error, the delta method gives the approximate standard errors

$$\mathrm{se}(\hat{c}) \approx \frac{p}{(\hat{\varepsilon}^R)^2}\,\mathrm{se}(\hat{\varepsilon}^R), \qquad \mathrm{se}(\hat{L}) \approx \frac{1}{(\hat{\varepsilon}^R)^2}\,\mathrm{se}(\hat{\varepsilon}^R). \tag{1.12}$$

Proof. Solving (i) of Proposition 1.9 for c gives $c = p + \frac{Q(p)}{Q'(p)}$. Solving (ii) gives $c = p\left(1 - \frac{1}{\varepsilon^R}\right)$. Replacing the unknown slope or elasticity with its estimate gives (1.11). For the standard errors, write $\hat{c} = g(\hat{\varepsilon}^R)$ with $g(\varepsilon) = p - \frac{p}{\varepsilon}$. Its derivative is

$$g'(\varepsilon) = \frac{p}{\varepsilon^2}.$$

Let ε_0^R be the true elasticity. A first-order Taylor expansion gives $\hat{c} - c \approx g'(\varepsilon_0^R)\left(\hat{\varepsilon}^R - \varepsilon_0^R\right)$, so

$$\mathrm{Var}(\hat{c}) \approx \left(\frac{p}{(\varepsilon_0^R)^2}\right)^2 \mathrm{Var}(\hat{\varepsilon}^R).$$

Taking square roots and evaluating the derivative at the estimate gives the first formula in (1.12). The same steps with $h(\varepsilon) = \frac{1}{\varepsilon}$, whose derivative is $h'(\varepsilon) = -\frac{1}{\varepsilon^2}$, give the second. Appendix A states the delta method in general. □

This inversion runs through the rest of the book. Rosse (1970) used it to estimate the cost functions of newspapers "without using cost data," as his title puts it. Einav and Levin (2010, p. 151) describe it as the standard way to recover costs in modern work when cost data are unavailable or unreliable. The inversion rests on a maintained assumption, namely that the firm maximizes profit under a known form of conduct. If firms compete differently, the same price and elasticity imply a different cost. With the industry *conduct parameter* θ, which we introduce in Section 1.2.5 and develop in Section 1.6.4, the inversion becomes

$$\hat{c} = p + \theta\,\frac{Q(p)}{\hat{Q}'(p)} = p\left(1 - \frac{\theta}{\hat{\varepsilon}}\right), \tag{1.13}$$

where Q and $\hat{\varepsilon}$ now refer to market demand. Monopoly corresponds to $\theta = 1$. Price taking corresponds to $\theta = 0$, which gives $\hat{c} = p$.

Example 1.12 (A campus coffee shop)**.** The numbers in this example are hypothetical. A coffee shop on a university campus charges $p = 4$ dollars for a cup. Suppose an econometrician has estimated the elasticity of the shop's residual demand at $\hat{\varepsilon}^R = 2.5$, with standard error 0.5. Under profit maximization, Proposition 1.9 and Corollary 1.11 give

$$\begin{aligned}
\hat{L} &= \frac{1}{2.5} = 0.40,\\
\hat{m} &= \frac{p}{\hat{\varepsilon}^R} = \frac{4}{2.5} = 1.60,\\
\hat{c} &= 4\left(1 - \frac{1}{2.5}\right) = 4 \times 0.6 = 2.40,\\
\hat{\mu} &= \frac{4}{2.40} \approx 1.67.
\end{aligned}$$

The margin over marginal cost is 40 percent of the price, or about 67 percent of marginal cost. The delta-method standard errors are

$$\operatorname{se}(\hat{c}) \approx \frac{4}{2.5^2} \times 0.5 = \frac{4}{6.25} \times 0.5 = 0.32,$$
$$\operatorname{se}(\hat{L}) \approx \frac{0.5}{6.25} = 0.08.$$

An approximate 95 percent confidence interval for marginal cost is $2.40 \pm 1.96 \times 0.32$, or $[1.77, 3.03]$. The mapping from elasticity to cost is nonlinear, and the linear approximation hides this. An elasticity one standard error below the estimate, 2.0, implies $\hat{c} = 2.00$. An elasticity one standard error above it, 3.0, implies $\hat{c} \approx 2.67$. The implied band is asymmetric around 2.40.

Now change the interpretation of the estimate. Suppose 2.5 is the elasticity of total campus demand for coffee, and the shop is one of three identical sellers that compete in quantities as in the Cournot model. By (1.10), the shop's residual elasticity is $\frac{2.5}{\frac{1}{3}} = 7.5$, and the inversion gives

$$\hat{L} = \frac{1}{7.5} \approx 0.13,$$
$$\hat{c} = 4\left(1 - \frac{1}{7.5}\right) \approx 3.47.$$

Treating the market elasticity as if it were the shop's own elasticity would overstate the Lerner index threefold and understate marginal cost by more than a dollar. If instead the three shops coordinate and price as one monopolist, the market elasticity is the relevant one and $\hat{c} = 2.40$ again. In terms of (1.13), Cournot behavior is $\theta = \frac{1}{3}$ and joint monopoly is $\theta = 1$. The same price and the same demand estimate imply a marginal cost anywhere from 2.40 to 3.47. The data on price and demand do not pin down cost by themselves. A maintained assumption about conduct does.

1.2.4 Markups are not profits: the role of fixed costs

Markups are often used as a synonym for market power, and market power is often read as a sign of excess profit. The second step is unwarranted. A positive markup over marginal cost is what a firm needs to cover its fixed costs, so a firm can charge well above marginal cost and still earn no economic profit.

Proposition 1.13 (The zero-profit markup)**.** *A firm produces $q > 0$ units at constant marginal cost $c > 0$, sells them at price p, and incurs a fixed cost $F > 0$. Its economic profit $\pi = (p - c)q - F$ can be written as*

$$\pi = L\,pq - F. \tag{1.14}$$

If the firm earns zero economic profit, then

$$p = c + \frac{F}{q}, \qquad \mu - 1 = \frac{F}{cq} > 0, \qquad L = \frac{F}{pq} > 0. \tag{1.15}$$

Proof. Since $L = \frac{p-c}{p}$, we have $(p-c)q = L\,pq$, which gives (1.14). Setting $\pi = 0$ gives $(p-c)q = F$, so $p - c = \frac{F}{q}$ and $p = c + \frac{F}{q}$. Dividing $p - c = \frac{F}{q}$ by c gives the markup rate $\frac{F}{cq}$. Dividing it by p gives $L = \frac{F}{pq}$, the ratio of fixed cost to revenue. □

The identity (1.14) shows what the Lerner index measures. It is the gross margin per dollar of revenue, before fixed costs are paid. Profit is positive only if the gross margin $L\,pq$ exceeds F. A software firm with almost no marginal cost has a Lerner index close to one, yet it may barely recover the cost of writing its software. Market power in the sense of Definition 1.8 is therefore compatible with zero economic profit.

The classic setting where this happens is *monopolistic competition* (Chamberlin, 1933). Each firm sells a differentiated product and faces a downward-sloping inverse residual demand curve $P^R(q)$, so it has market power. Entry is free. New products enter while profits are positive, and each entrant takes customers from existing products, which shifts their residual demand curves inward. Entry stops when each firm just covers its costs. At that point the residual demand curve touches the average cost curve without crossing it. This configuration is the *Chamberlin tangency*, shown in Figure 1.1.

With constant marginal cost c and fixed cost F, average cost is $AC(q) = c + \frac{F}{q}$. It falls with output, with slope $AC'(q) = -\frac{F}{q^2}$. A tangency at output q^* means that two conditions hold:

$$P^R(q^*) = AC(q^*) = c + \frac{F}{q^*}, \tag{1.16}$$

$$P^{R\prime}(q^*) = AC'(q^*) = -\frac{F}{(q^*)^2}. \tag{1.17}$$

The first condition is zero profit. The second says that the two curves have the same slope at q^*. For the curves of Figure 1.1, with $c = 2$, $F = 4$ and $P^R(q) = 6 - q$, the gap between them is $AC(q) - P^R(q) = \frac{(q-2)^2}{q} \geq 0$. Demand therefore lies below average cost at every other output, and no output earns positive profit. The tangency is consistent with profit maximization. Marginal revenue at q^* is

$$\begin{aligned} MR(q^*) &= P^R(q^*) + q^* P^{R\prime}(q^*) \\ &= c + \frac{F}{q^*} - q^* \frac{F}{(q^*)^2} \\ &= c, \end{aligned}$$

where the second line uses (1.16) and (1.17). Marginal revenue therefore equals marginal cost. Price exceeds marginal cost by $p^* - c = \frac{F}{q^*}$, and the Lerner index is

$$L = \frac{F}{p^* q^*} = -\frac{q^* P^{R\prime}(q^*)}{p^*} = \frac{1}{\varepsilon^R(q^*)},$$

where the second equality uses (1.17). The firm follows the inverse elasticity rule of Proposition 1.9, and its markup exactly covers its fixed cost.

Bresnahan (1989, p. 1050) draws the welfare lesson. "In the Chamberlinian tangency of monopolistic competition, every firm has market power in the sense of this section. Yet that does not establish that there is any inefficiency, once the need to cover the fixed costs of product design are taken into account." Forcing every price down to marginal cost would leave each firm with a loss equal to its fixed cost, and some products would disappear. Whether the market supplies too many or too few products depends on how much a product adds to consumer surplus relative to the business it takes from rivals. Free entry can give too little variety under monopolistic competition and too much entry in homogeneous-product markets (see Mankiw and Whinston, 1986, and the work they cite). Bresnahan concludes that the welfare meaning of

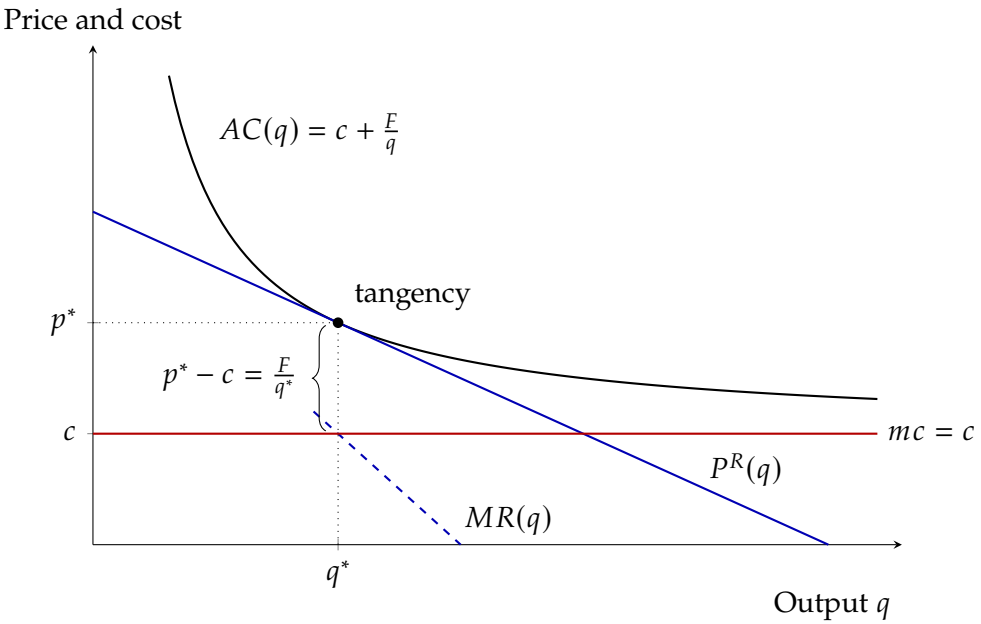

Figure 1.1: The Chamberlin tangency under monopolistic competition. Free entry shifts the firm's inverse residual demand $P^R(q)$ inward until it is tangent to average cost $AC(q) = c + \frac{F}{q}$ at q^*. There, marginal revenue $MR(q)$ equals marginal cost c, and price equals average cost, so profit is zero. The markup $p^* - c = \frac{F}{q^*}$ exactly covers the fixed cost. The curves are drawn for $c = 2$, $F = 4$ and $P^R(q) = 6 - q$, which give $q^* = 2$ and $p^* = 4$.

short-run market power with differentiated products depends on the supply of new firms and new products. That supply is an empirical question.

The same logic sits at the center of the recent debate over rising markups. De Loecker et al. (2020) estimate that the average ratio of price to marginal cost among US public firms has risen since 1980. By Proposition 1.13, a higher markup need not mean higher profit if fixed and overhead costs have risen as well. Section 1.5.4 returns to this debate.

1.2.5 The Cournot benchmark: concentration and margins

We now have a measure of structure and a measure of market power. The simplest model that links them is the Cournot model of quantity competition with a homogeneous good. Its central result motivates the cross-industry regressions of Section 1.3. A small extension of the same result shows why those regressions are hard to interpret.

Assumption 1.14 (Homogeneous-good Cournot oligopoly)**.**

(i) There are N firms selling a homogeneous good. Inverse market demand $P(Q)$ is twice differentiable, with $P'(Q) < 0$, where $Q = \sum_{i=1}^{N} q_i$.

(ii) Firm i has constant marginal cost c_i. It may also have a fixed cost, which does not affect its choice of output once it is active.

(iii) Firms choose quantities simultaneously. Firm i maximizes $\pi_i = (P(Q) - c_i)\, q_i$, taking its rivals' quantities as given.

(iv) The equilibrium is interior. Every firm produces $q_i > 0$, and every firm's second-order condition $2P'(Q) + q_i P''(Q) < 0$ holds.

Chapter 2 gives conditions for the existence and uniqueness of this equilibrium, and Tirole (1988, Section 5.7.1) surveys them. Under mild boundary conditions, a pure-strategy equilibrium exists when each firm's profit is concave in its own output, for which convex costs and concave demand suffice. With two firms it is unique when the reaction functions have slopes below one in absolute value. Linear demand with constant marginal cost gives the slope $-\frac{1}{2}$. Here we take an interior equilibrium as given. As in Remark 1.10, the market elasticity at the equilibrium is $\varepsilon = -\frac{P(Q)}{QP'(Q)}$. Firm i's Lerner index is $L_i = \frac{P - c_i}{P}$, and the share-weighted average $\sum_i s_i L_i$ is the industry Lerner index.

Proposition 1.15 (Cowling and Waterson)**.** *Under Assumption 1.14, every firm's Lerner index equals its market share divided by the market elasticity, and the share-weighted Lerner index equals the Herfindahl-Hirschman index divided by the market elasticity:*

$$L_i = \frac{P - c_i}{P} = \frac{s_i}{\varepsilon}, \qquad \sum_{i=1}^{N} s_i L_i = \frac{HHI}{\varepsilon}. \tag{1.18}$$

Proof. Firm i's first-order condition is

$$\frac{\partial \pi_i}{\partial q_i} = P(Q) + q_i P'(Q) - c_i = 0.$$

Rearrange it as $P - c_i = -q_i P'(Q)$ and divide by P:

$$\frac{P - c_i}{P} = -\frac{q_i P'(Q)}{P}.$$

Multiply and divide the right side by Q:

$$\frac{P - c_i}{P} = \frac{q_i}{Q}\left(-\frac{QP'(Q)}{P}\right).$$

The first factor is s_i and the second is $\frac{1}{\varepsilon}$, which gives $L_i = \frac{s_i}{\varepsilon}$. Multiply by s_i and sum over firms:

$$\sum_{i=1}^{N} s_i L_i = \sum_{i=1}^{N} \frac{s_i^2}{\varepsilon} = \frac{HHI}{\varepsilon}. \qquad \square$$

The result is due to Cowling and Waterson (1976). It fits together with the firm-level pricing rule. By (1.10), firm i's residual elasticity with rivals' output held fixed is $\varepsilon_i^R = \frac{\varepsilon}{s_i}$, so

$$L_i = \frac{s_i}{\varepsilon} = \frac{1}{\varepsilon_i^R}.$$

Each Cournot firm follows the inverse elasticity rule of Proposition 1.9 for its own residual demand. Large firms face less elastic residual demand and set higher margins. Since a firm's output and its margin are chosen together, low-cost firms are both large and high-margin. Section 1.5.1 develops this observation into the efficiency critique of regressions of profitability on concentration.

The same result links concentration to industry profit (Tirole, 1988, Section 5.5, eq. 5.14 and Exercise 5.6). Industry variable profit is

$$\Pi = \sum_{i=1}^{N} (P - c_i)\, q_i = \sum_{i=1}^{N} P L_i\, s_i Q = PQ \sum_{i=1}^{N} s_i L_i = \frac{PQ}{\varepsilon}\, HHI.$$

The second equality uses $P - c_i = PL_i$ and $q_i = s_i Q$, and the last uses (1.18). The ratio of industry variable profit to industry revenue is therefore $\frac{HHI}{\varepsilon}$. Suppose further that demand has unit elasticity, $Q = \frac{k}{P}$ for a constant $k > 0$, so that consumers spend the fixed amount k on the good. Then $PQ = k$ and $\Pi = k\, HHI$, which is Tirole's equation (5.15). In this case the index measures industry profitability exactly, up to the constant k.

Corollary 1.16 (Special cases)**.** *Under Assumption 1.14, the following hold.*

(i) With symmetric costs $c_i = c$, every firm has share $\frac{1}{N}$, $HHI = \frac{1}{N}$, and $L = \frac{P-c}{P} = \frac{1}{N\varepsilon}$.

(ii) With $N = 1$, $L = \frac{1}{\varepsilon}$, the monopoly inverse elasticity rule.

(iii) With symmetric costs and an equilibrium elasticity bounded away from zero, $L \to 0$ and $P \to c$ as $N \to \infty$.

Proof. With equal costs, the first-order conditions $P - c = -q_i P'(Q)$ have the same left side for every firm, so all firms produce the same output and $s_i = \frac{1}{N}$. Then $HHI = N \cdot \frac{1}{N^2} = \frac{1}{N}$, and all the L_i are equal to L, so (1.18) gives (i). Setting $N = 1$ in (i) gives (ii). For (iii), $L = \frac{1}{N\varepsilon}$ goes to zero when ε stays above a positive constant, and $L = 1 - \frac{c}{P} \to 0$ means $P \to c$. □

Statement (iii) is the sense in which Cournot competition approaches perfect competition as the number of firms grows. The Cournot model therefore generates the hypothesis behind a generation of empirical work, namely that margins rise with concentration. Read literally, (1.18) suggests regressing the average margin of each industry on its *HHI* across industries, with slope $\frac{1}{\varepsilon}$.

The Cournot result fixes the form of competition. To see what happens when conduct varies, we use a device from the older literature. Suppose firm i chooses its output as if its rivals' total output $Q_{-i} = Q - q_i$ responded to its own output at the rate

$$r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}.$$

The number r_i is firm i's *conjectural variation*. The firm then perceives $\frac{\mathrm{d}Q}{\mathrm{d}q_i} = 1 + r_i$. Cournot behavior is $r_i = 0$.

Proposition 1.17 (Margins and concentration under general conduct)**.** *Keep Assumption 1.14, except that firm i maximizes profit under the conjectural variation r_i, with $1 + r_i \geq 0$. Then*

$$L_i = \frac{s_i(1 + r_i)}{\varepsilon}, \qquad \sum_{i=1}^{N} s_i L_i = \frac{\theta}{\varepsilon}, \qquad \theta = \sum_{i=1}^{N} s_i^2 (1 + r_i). \tag{1.19}$$

Suppose conjectures are proportional, as in Clarke and Davies (1982). Firm i expects every rival $j \neq i$ to change its output by κ times firm i's own percentage change, for some $\kappa \in [0, 1]$. Then

$$r_i = \kappa\, \frac{1 - s_i}{s_i}, \qquad L_i = \frac{\kappa + (1 - \kappa)s_i}{\varepsilon}, \qquad \sum_{i=1}^{N} s_i L_i = \frac{\kappa + (1 - \kappa)HHI}{\varepsilon}. \tag{1.20}$$

Proof. Under the conjecture, firm i perceives $\frac{\mathrm{d}Q}{\mathrm{d}q_i} = 1 + r_i$, so its perceived marginal profit is

$$\frac{\mathrm{d}\pi_i}{\mathrm{d}q_i} = P(Q) + q_i P'(Q)\frac{\mathrm{d}Q}{\mathrm{d}q_i} - c_i = P(Q) + q_i P'(Q)(1 + r_i) - c_i.$$

Setting it to zero and following the steps in the proof of Proposition 1.15,

$$\begin{aligned} P + P'(Q)\, q_i(1 + r_i) &= c_i, \\ \frac{P - c_i}{P} &= \frac{q_i}{Q}\left(-\frac{QP'(Q)}{P}\right)(1 + r_i), \\ L_i &= \frac{s_i(1 + r_i)}{\varepsilon}. \end{aligned} \tag{1.21}$$

Multiplying by s_i and summing gives $\sum_i s_i L_i = \frac{1}{\varepsilon}\sum_i s_i^2(1 + r_i) = \frac{\theta}{\varepsilon}$.

In the proportional case, the conjecture is $\frac{\mathrm{d}q_j}{q_j} = \kappa\,\frac{\mathrm{d}q_i}{q_i}$ for every $j \neq i$, that is, $\frac{\mathrm{d}q_j}{\mathrm{d}q_i} = \kappa\,\frac{q_j}{q_i}$. Summing over rivals,

$$r_i = \sum_{j \neq i} \frac{\mathrm{d}q_j}{\mathrm{d}q_i} = \kappa\,\frac{Q_{-i}}{q_i} = \kappa\,\frac{Q - q_i}{q_i} = \kappa\,\frac{1 - s_i}{s_i}.$$

Then

$$s_i(1 + r_i) = s_i + \kappa(1 - s_i) = \kappa + (1 - \kappa)s_i,$$

which gives the firm-level formula. Multiplying by s_i and summing over firms,

$$\begin{aligned} \theta = \sum_{i=1}^{N} s_i^2(1 + r_i) &= \sum_{i=1}^{N}\left(\kappa s_i + (1 - \kappa)s_i^2\right) \\ &= \kappa\sum_{i=1}^{N} s_i + (1 - \kappa)\sum_{i=1}^{N} s_i^2 \\ &= \kappa + (1 - \kappa)HHI, \end{aligned}$$

where the last line uses $\sum_i s_i = 1$. □

The parameter θ is the index of industry conduct that we use throughout the book. Price-taking behavior, $r_i = -1$ for every firm, gives $\theta = 0$ and $L_i = 0$. Cournot behavior, $r_i = 0$, gives $\theta = HHI$, which equals $\frac{1}{N}$ when firms are symmetric. In the Clarke-Davies family, $\kappa = 0$ is Cournot behavior and $\kappa = 1$ is joint profit maximization. With $\kappa = 1$ the firm expects all rivals to move in proportion, so $1 + r_i = \frac{1}{s_i}$ and $q_i(1 + r_i) = Q$. Condition (1.21) then becomes $P + QP'(Q) = c_i$, the first-order condition of a monopolist. With constant marginal costs, these conditions can hold for all active firms only if their costs are equal, and the split of output among them is then indeterminate. Every firm has $L_i = \frac{1}{\varepsilon}$ and $\theta = 1$. With rising marginal costs, as in Proposition 1.33, the same conditions equalize marginal costs across firms, as joint profit maximization requires. Summing (1.21) with weights s_i gives the industry relation

$$P = \bar{c} - \theta\, QP'(Q), \qquad \bar{c} = \sum_{i=1}^{N} s_i c_i, \tag{1.22}$$

because $\sum_i s_i q_i(1+r_i) = Q\sum_i s_i^2(1+r_i) = Q\theta$. Section 1.6.4 calls (1.22) the supply relation and shows how the New Empirical Industrial Organization is built around it.

Conjectural variations must be read with care. In a static game a firm moves once and never observes a response, so a "conjecture" about its rivals' reactions has no behavioral content within the game. The parameter θ is best read as an index of how close the outcome is to the collusive one. Bresnahan (1989) stresses this reading, and Section 1.6.4 explains it. Chapter 2 discusses the theory of conjectural variations and the conduct parameter.

Proposition 1.17 contains the main message of this section. In the Clarke-Davies family the average margin is a linear function of the index,

$$\sum_{i=1}^{N} s_i L_i = \frac{\kappa}{\varepsilon} + \frac{1-\kappa}{\varepsilon} HHI, \tag{1.23}$$

with intercept $\frac{\kappa}{\varepsilon}$ and slope $\frac{1-\kappa}{\varepsilon}$. Both depend on conduct and on the demand elasticity. The slope is largest under Cournot behavior. It is zero under collusion, where margins are at the monopoly level whatever the concentration. Panel (a) of Figure 1.2 plots (1.23) for $\varepsilon = 2$. The slope of margins on concentration is therefore no constant of nature shared by all industries. This is at once the theoretical case for regressing margins on concentration and the first reason such regressions fail. Industries differ in their elasticities and their conduct, and these differences are correlated with concentration in ways that Section 1.4 explores.

Even within one industry with fixed conduct, the relation need not be linear, because the elasticity changes with concentration. Take linear inverse demand $P(Q) = a - bQ$ with $a > c > 0$ and $b > 0$, and N symmetric Cournot firms with marginal cost c. The first-order condition $a - bQ - bq_i - c = 0$ holds for every firm, so outputs are equal and $q_i = \frac{Q}{N}$. Summing the conditions over firms and solving,

$$\begin{aligned} N(a-c) - NbQ - bQ &= 0, \\ Q &= \frac{N(a-c)}{b(N+1)}, \\ P = a - bQ &= \frac{a+Nc}{N+1}. \end{aligned}$$

The Lerner index and the market elasticity at the equilibrium are

$$\begin{aligned} L &= \frac{P-c}{P} = \frac{\frac{a-c}{N+1}}{\frac{a+Nc}{N+1}} = \frac{a-c}{a+Nc}, \\ \varepsilon &= \frac{P}{bQ} = \frac{a+Nc}{N(a-c)}. \end{aligned}$$

Substitute $N = \frac{1}{HHI}$ and multiply each numerator and denominator by HHI:

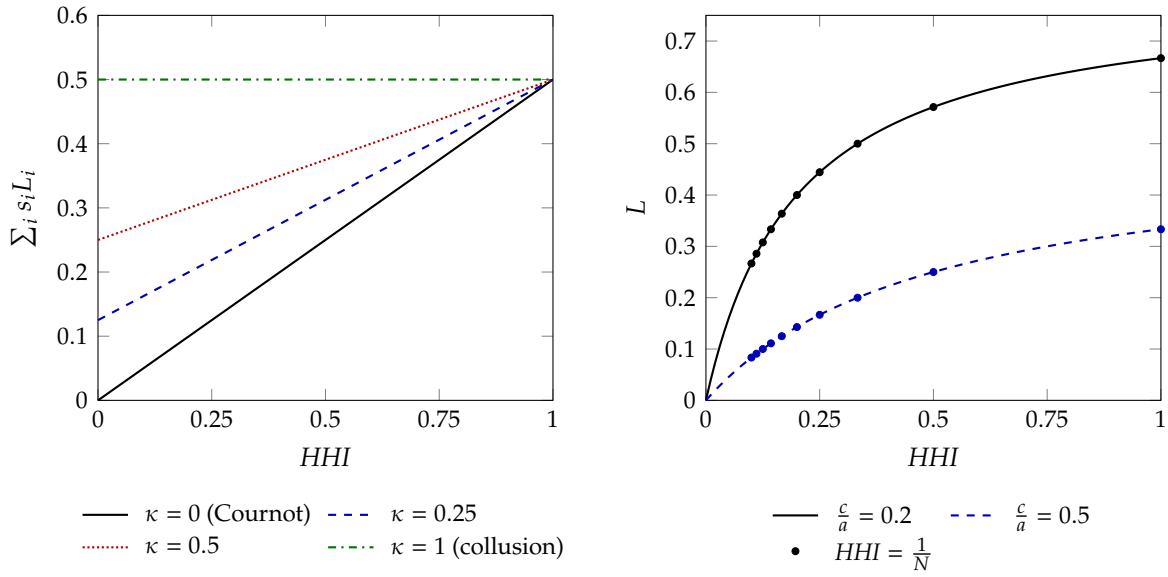
$$L = \frac{(a-c)HHI}{aHHI + c}, \qquad \varepsilon = \frac{aHHI + c}{a-c}. \tag{1.24}$$

As a check, $\frac{HHI}{\varepsilon} = \frac{(a-c)HHI}{aHHI+c} = L$, as Proposition 1.15 requires. The elasticity rises with concentration, because fewer firms means a higher price and a lower quantity along a linear

demand curve. Differentiating L with respect to HHI,

$$\frac{\mathrm{d}L}{\mathrm{d}HHI} = \frac{(a-c)(aHHI+c) - (a-c)HHI \cdot a}{(aHHI+c)^2} = \frac{c(a-c)}{(aHHI+c)^2} > 0,$$
$$\frac{\mathrm{d}^2L}{\mathrm{d}HHI^2} = -\frac{2ac(a-c)}{(aHHI+c)^3} < 0.$$

The margin rises with concentration at a decreasing rate. Panel (b) of Figure 1.2 plots the curve for two values of the ratio $\frac{c}{a}$. A higher ratio of marginal cost to the demand intercept lowers the whole curve. Industries with different cost-demand ratios lie on different curves, so even the causal effect of concentration on margins differs across industries. Throughout this calculation N is fixed. When entry determines N, concentration becomes an equilibrium outcome itself, a problem that Section 1.4.3 takes up.



(a) Clarke-Davies conduct, $\varepsilon = 2$

(b) Symmetric Cournot, linear demand

Figure 1.2: Margins and concentration. Panel (a) plots the share-weighted Lerner index against the Herfindahl-Hirschman index in the Clarke-Davies family, $\sum_i s_i L_i = \frac{\kappa+(1-\kappa)HHI}{\varepsilon}$, for $\varepsilon = 2$. The lines run from $\left(0, \frac{\kappa}{\varepsilon}\right)$ to $\left(1, \frac{1}{\varepsilon}\right)$. Panel (b) plots the symmetric Cournot relation with linear demand, $L = \frac{(a-c)HHI}{aHHI+c}$, for $\frac{c}{a} = 0.2$ and $\frac{c}{a} = 0.5$. Dots mark $HHI = \frac{1}{N}$ for $N = 1, \ldots, 10$.

1.3 The structure-conduct-performance paradigm

For about three decades the main empirical program in industrial organization put one question to cross-industry data. Do more concentrated industries earn higher margins? The program is known as the *structure-conduct-performance* (SCP) paradigm. This section states its logic, formalizes the experiment it had in mind, and describes how it was carried out. Section 1.4 then asks what its regressions identify, and Section 1.5 follows the debates it left behind.

1.3.1 The SCP mechanism

The paradigm describes a causal chain with four links, summarized in Figure 1.3. *Basic conditions* are the primitives of an industry. On the supply side they include technology, unionization, the transportability of the product and the legal environment. On the demand side they include preferences, the growth of demand and its seasonality. Basic conditions determine *market structure*, which comprises the number of sellers and buyers, the extent of vertical integration, and the degree of vertical and horizontal product differentiation. Structure determines conduct, the pricing, advertising and investment decisions of firms. Conduct in turn determines *performance*, measured by profits and by welfare.

Tirole (1988, Introduction) calls this program the "Harvard tradition" and associates it with Joe Bain and Edward Mason. In his history it was the first of two waves of interest in industrial organization, and it was empirical in nature. His statement of the chain is close to ours. Structure comprises the number of sellers, their degree of product differentiation, the cost structure and the degree of vertical integration with suppliers. Conduct comprises price, research and development, investment and advertising. Performance comprises efficiency, the ratio of price to marginal cost, product variety, the rate of innovation, profits and distribution. Tirole adds that the paradigm, although plausible, often rested on loose theories.

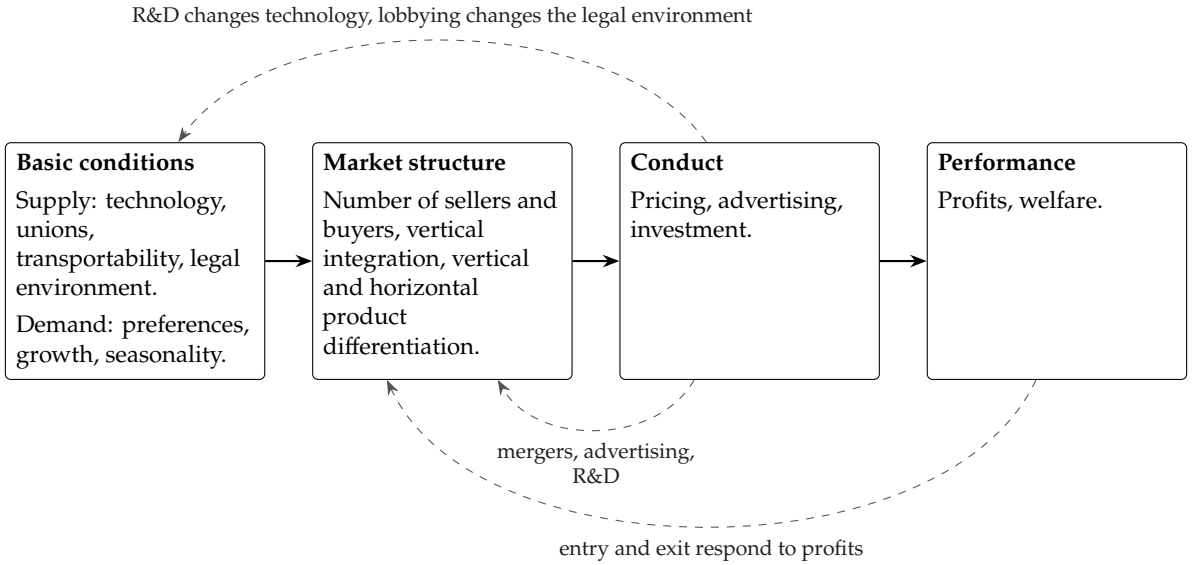


Figure 1.3: The structure-conduct-performance paradigm. Solid arrows show the causal chain that the paradigm assumes. Dashed arrows show feedback that it ignores. Conduct and performance shape market structure, and conduct reshapes basic conditions. Once the dashed arrows are admitted, market structure is an equilibrium outcome.

The chain has a strong implication for policy. If structure causes performance, a regulator can improve performance by acting on structure, for example by blocking mergers or breaking up dominant firms. The empirical task then reduces to measuring how performance varies with structure. Conduct rarely needs to be observed, because structure is assumed to pin it down.

The dashed arrows in Figure 1.3 show why the chain is incomplete. Profits attract entry and losses induce exit, so performance feeds back into the number of sellers. Mergers, advertising and research and development (R&D) are forms of conduct, yet they shape concentration and

differentiation. Research changes technology and lobbying changes the legal environment, so conduct also feeds back into basic conditions. In modern terms, market structure is an equilibrium outcome, determined jointly with conduct and performance by the basic conditions. Section 1.4 works out the consequences of this observation for the regressions that the paradigm relied on.

The ideal experiment behind the paradigm is easy to state. We would take many otherwise identical industries, randomly assign each one a market structure, and compare their performance. In practice, researchers compared markups or profitability across existing industries with different levels of concentration. The gap between the two designs can be stated precisely in the language of potential outcomes, which Appendix A reviews.

Definition 1.18 (Potential margins)**.** Index industries by $k = 1, \dots, n$. For each concentration level $h \in (0, 1]$, let $L_k(h)$ be the industry-wide Lerner index that industry k would have if an outside intervention set its Herfindahl index to h. The intervention holds the demand, costs and conduct of the industry fixed. The function $h \mapsto L_k(h)$ is the *causal curve* of industry k. We observe only the realized margin $L_k = L_k(HHI_k)$.

The industry-wide Lerner index is the share-weighted index $\sum_i s_i L_i$ of Proposition 1.15. An intervention that sets h could be a regulator that fixes the number of licenses in an industry of symmetric firms. Now compare the average margins of industries observed at two concentration levels h and h'. We add and subtract $\mathbb{E}[L_k(h') \mid HHI_k = h]$:

$$\begin{aligned}\mathbb{E}[L_k \mid HHI_k = h] - \mathbb{E}[L_k \mid HHI_k = h'] &= \mathbb{E}[L_k(h) \mid HHI_k = h] - \mathbb{E}[L_k(h') \mid HHI_k = h'] \\ &= \underbrace{\mathbb{E}[L_k(h) - L_k(h') \mid HHI_k = h]}_{\text{causal effect at } h} \\ &\quad + \underbrace{\mathbb{E}[L_k(h') \mid HHI_k = h] - \mathbb{E}[L_k(h') \mid HHI_k = h']}_{\text{selection}}.\end{aligned} \tag{1.25}$$

The first equality uses $L_k = L_k(HHI_k)$. The first term after the second equality is the average causal effect of moving from h' to h among the industries observed at h. The second term compares the margins that two different groups of industries would earn at the same concentration h'. It differs from zero whenever the industries that end up concentrated differ in demand, cost or conduct from those that do not. Random assignment makes HHI_k independent of the whole curve $L_k(\cdot)$. The selection term then vanishes, and the first term becomes the population average effect $\mathbb{E}[L_k(h) - L_k(h')]$.

Example 1.19 (Selection on the demand elasticity)**.** Suppose industry k has constant-elasticity demand with elasticity ε_k and symmetric Cournot firms. By Proposition 1.15, its causal curve is $L_k(h) = \frac{h}{\varepsilon_k}$. Substituting into (1.25), the selection term equals

$$h' \left(\mathbb{E}\left[\frac{1}{\varepsilon_k} \,\middle|\, HHI_k = h \right] - \mathbb{E}\left[\frac{1}{\varepsilon_k} \,\middle|\, HHI_k = h' \right] \right).$$

Its sign depends on how industries sort. Margins are higher where demand is less elastic, so free entry tends to draw more firms into those industries and to make them less concentrated. The conditional mean of $\frac{1}{\varepsilon_k}$ then falls with concentration, and the selection term is negative for $h > h'$. If inelastic demand instead goes with high fixed costs, the term can be positive.

1.3.2 Origins and practice

The SCP approach grew out of the Harvard tradition associated with Mason (1939). As its title indicates, Mason's article studied the price and production policies of large-scale enterprise. Joe Bain turned the SCP view into a statistical program. Bain (1951) related the profit rates of American manufacturing industries over 1936–1940 to their concentration. Bain (1951, 1956) hypothesized that concentration facilitates collusion between firms and so raises industry-wide profits (Tirole, 1988, Section 5.5). Levenstein and Suslow (2006, p. 46) attribute the same hypothesis to Bain. Bain (1956) added the theory of *barriers to entry*, the advantages of established sellers over potential entrants. In Tirole's paraphrase, a barrier to entry is anything that lets incumbent firms earn supranormal profits without the threat of entry (Tirole, 1988, Chapter 8, introduction). Tirole lists the four elements of market structure that Bain identified informally. They are economies of scale, absolute cost advantages, product-differentiation advantages and capital requirements, the last of which Tirole calls controversial. Bain also distinguished three cases. Entry is blockaded when incumbents ignore the threat and entry is still unattractive. It is deterred when incumbents change their behavior to prevent it, and accommodated when they find it more profitable to let entrants in. For the quarter century that followed Bain (1951), the cross-section study of many industries was the main empirical method of the field (Bresnahan, 1989, p. 1012). Schmalensee (1989) wrote its definitive review.

A typical study used one cross-section of industries. The dependent variable was an accounting measure of profitability, such as the profit rate on equity or assets or the price-cost margin computed from the Census of Manufactures. The key regressor was a concentration measure, often the four-firm ratio CR_4 or the Herfindahl index of Definition 1.3. The canonical specification is

$$\pi_k = \beta_0 + \beta_1 HHI_k + \varphi^\top X_k + e_k, \qquad k = 1, \dots, n, \tag{1.26}$$

where π_k is the profitability measure of industry k and e_k is an error term. The Herfindahl index may be replaced by $CR_{4,k}$. The vector X_k collects controls, typically the ratios of R&D spending, capital and advertising spending to sales, together with the import share. Its coefficients are φ, and the whole equation is estimated by ordinary least squares (OLS). The typical finding was $\hat{\beta}_1 > 0$. It was read as evidence that concentration raises margins, and hence that concentration is harmful.

Tirole (1988, Introduction) writes the typical regression as $\pi_k = f(CR_k, BE_k, \dots)$, run on a cross-section of many industries. Here CR_k is a concentration ratio and BE_k collects measures of barriers to entry. Two common measures were the ratio of advertising to sales and the *minimum efficient scale* of entry, the smallest output at which average cost reaches its minimum. Regression (1.26) is the linear version. Tirole stresses that its coefficients are correlations, or "descriptive statistics," and not causal relationships. Industry profit, the concentration ratio and the ratio of advertising to sales "are jointly endogenous." The basic conditions of the market and the behavior of its firms determine all three at once.

The tradition also tried to measure basic conditions directly, scale economies in particular (Tirole, 1988, Introduction, note 4). The most common method estimates a cost function of output and input prices. Bain built "engineering production functions" from engineering data on plants, and he asked managers what the optimal plant size was. George Stigler's *survivorship technique* infers efficient scale instead from the sizes of the firms that survive. Tirole notes that such measures are hard to make accurate and comparable across industries.

The design reflected the econometric practice of its time. Samples were small, the data were industry aggregates, and matrices were sometimes inverted by hand. Identification in the

modern sense received little attention. Concentration was treated as an exogenous regressor, and its coefficient was read as a structural constant.

Einav and Levin (2010, p. 146) describe two challenges that held the field back into the 1970s. The first was the lack of compelling theoretical models of imperfect competition, which the game theory revolution of the 1980s later supplied. The second was the lack of good data and of convincing strategies for testing hypotheses about competition. Researchers knew that concentration might depend on the same factors as profitability. More sophisticated studies tried to fix this by treating concentration as driven by "exogenous" barriers to entry, such as scale economies, advertising or R&D (Einav and Levin, 2010, p. 146). Yet advertising intensity and capital intensity are chosen by firms, so they are hard to defend as instruments (Einav and Levin, 2010, p. 147). Schmalensee (1989, p. 954) opened his review by acknowledging that "essentially all variables that have been employed in such studies are logically endogenous" (quoted in Einav and Levin, 2010, p. 147).

Tirole (1988, Introduction, note 2) recommends the review of Schmalensee (1989), which he dates 1986, as an excellent survey and assessment of this approach. His own summary of the evidence records two facts that frame the rest of this chapter (note 3). First, the cross-industry relation between rates of return and concentration "is weak." Second, "introducing a market-share variable on the right-hand side of the regression tends to wipe out concentration-ratio effects." Tirole explains the second fact by cost heterogeneity. In industries where a few low-cost firms produce most of the output, concentration and profits are both high. The concentration ratio may then pick up the effect of the omitted market share. The first fact motivates Section 1.4, and the second lies at the center of the Demsetz debate in Section 1.5.1. Section 1.6.2 returns to the maintained hypotheses of the paradigm that the next generation of research rejected.

1.4 What cross-industry regressions identify

Regression (1.26) always estimates something. Its probability limit is a linear projection coefficient, and the question is whether that coefficient measures an economic object. This section takes the problems in turn. Margins are mismeasured (Section 1.4.1), concentration is mismeasured (Section 1.4.2), and concentration is endogenous (Section 1.4.3). A Monte Carlo experiment shows the size of the problems (Section 1.4.4), and Section 1.4.5 asks whether panel data solve them.

1.4.1 Measurement: accounting versus economic margins

The theory of Section 1.2.5 concerns the Lerner index $L = \frac{p-mc}{p}$. SCP studies used accounting data instead. The most common margin was the *Census price-cost margin*,

$$PCM = \frac{\text{value of shipments} - \text{payroll} - \text{cost of materials}}{\text{value of shipments}}, \tag{1.27}$$

computed for each manufacturing industry from the Census of Manufactures. It nets out the main variable inputs and ignores the cost of capital. The next proposition shows what it measures. In this subsection only, ρ denotes the rental price of capital (elsewhere in the book ρ is the pass-through rate).

Proposition 1.20 (What the Census margin measures)**.** *Consider an industry that sells output $q > 0$ at price p, so that sales are $S = pq$. Payroll and materials form the variable cost $VC(q)$, with*

$VC(0) = 0$ and marginal cost $mc(q) = VC'(q)$. The industry uses a capital stock K with rental price ρ, the interest and depreciation cost per dollar of capital. Economic profit is $\pi = pq - VC(q) - \rho K$.

(i) If $VC(q) = cq$, then $PCM = \frac{p-c}{p} = L$.

(ii) In general, $PCM = \frac{\pi}{S} + \rho\frac{K}{S}$. An industry that earns zero economic profit has $PCM = \rho\frac{K}{S} > 0$.

(iii) If VC is convex, then $PCM \geq L$. The inequality is strict if VC is strictly convex.

Proof. By definition, $PCM = \frac{S-VC(q)}{S}$. For (i), substitute $VC(q) = cq$:

$$PCM = \frac{pq - cq}{pq} = \frac{p - c}{p} = L.$$

For (ii), the definition of economic profit gives $pq - VC(q) = \pi + \rho K$. Divide both sides by S:

$$PCM = \frac{pq - VC(q)}{S} = \frac{\pi + \rho K}{S} = \frac{\pi}{S} + \rho\frac{K}{S}.$$

Setting $\pi = 0$ gives $PCM = \rho\frac{K}{S}$, which is positive whenever $K > 0$. For (iii), write $PCM = \frac{p-AVC(q)}{p}$ with average variable cost $AVC(q) = \frac{VC(q)}{q}$. A convex function lies above its tangent lines, so

$$VC(0) \geq VC(q) + VC'(q)(0 - q).$$

With $VC(0) = 0$, this reads $q\,mc(q) \geq VC(q)$, so $AVC(q) \leq mc(q)$. Therefore

$$PCM = \frac{p - AVC(q)}{p} \geq \frac{p - mc(q)}{p} = L.$$

Strict convexity makes the tangent inequality strict for $q > 0$. □

The Census margin therefore mixes three things: the Lerner index, the return to capital, and the curvature of variable cost. Capital-intensive industries show high margins even when they earn no rents. Capital intensity also tends to raise minimum efficient scale and hence concentration. A regression of PCM on concentration that omits capital intensity then attributes the return to capital to concentration.

Corollary 1.21 (Omitted capital intensity)**.** *Suppose economic profitability satisfies $\frac{\pi_k}{S_k} = \beta_0 + \beta_1 HHI_k + e_k$, where e_k is uncorrelated with HHI_k and with $\frac{K_k}{S_k}$, and the rental price ρ is common to all industries. Then OLS of PCM_k on a constant and HHI_k converges to*

$$\beta_1 + \rho\,\frac{\operatorname{Cov}\left(\frac{K_k}{S_k}, HHI_k\right)}{\operatorname{Var}(HHI_k)}.$$

Proof. By Proposition 1.20(ii), $PCM_k = \beta_0 + \beta_1 HHI_k + \rho\frac{K_k}{S_k} + e_k$. The OLS slope converges to $\frac{\operatorname{Cov}(PCM_k, HHI_k)}{\operatorname{Var}(HHI_k)}$. Substituting,

$$\frac{\operatorname{Cov}(PCM_k, HHI_k)}{\operatorname{Var}(HHI_k)} = \beta_1 + \rho\frac{\operatorname{Cov}\left(\frac{K_k}{S_k}, HHI_k\right)}{\operatorname{Var}(HHI_k)} + \frac{\operatorname{Cov}(e_k, HHI_k)}{\operatorname{Var}(HHI_k)},$$

and the last term is zero by assumption. □

This is why Collins and Preston (1969) and most later studies included the capital-sales ratio $\frac{K}{S}$ as a regressor next to concentration. The control removes the bias in Corollary 1.21 only if ρ is common across industries and capital is measured correctly.

Accounting rates of return on equity or assets have their own problems. Fisher and McGowan (1983) showed that the accounting rate of return can differ widely from the economic rate of return, which is the internal rate of return on an investment. The gap depends on the time profile of cash flows and on depreciation rules, so it varies across industries even when no industry earns rents. Inflation and the valuation of assets at historical cost add further distortions. A simple case shows the direction of one common bias.

Remark 1.22 (Expensed intangible capital). Consider a firm in a steady state with tangible capital K. It also builds an intangible stock A, such as brand capital or knowledge, by spending I per period on advertising or R&D. The stock depreciates at rate d_A, so in the steady state $A = \frac{I}{d_A}$. Let R be revenue net of variable costs and of the depreciation of tangible capital. Economic depreciation of the intangible stock is $d_A A = I$, so the economic rate of return on all capital is

$$r^e = \frac{R - d_A A}{K + A} = \frac{R - I}{K + A}.$$

Accounting rules expense I and leave A off the balance sheet, so the accounting rate of return is $r^{acc} = \frac{R-I}{K}$. Dividing the two expressions gives

$$\frac{r^{acc}}{r^e} = \frac{K + A}{K} = 1 + \frac{A}{K} > 1.$$

When $R > I$, accounting returns overstate economic returns, and they do so most in industries that are intensive in advertising or R&D. If those industries are also more concentrated, the measured profit-concentration relation is biased upward.

The controls that theory calls for are the demand elasticity, the height of entry barriers and the degree of product differentiation. They are hard to measure, so SCP studies rarely included them. The regression thus omits the very variables that theory says determine margins. Section 1.2.5 showed that the slope of margins on concentration is $\frac{1-\kappa}{\varepsilon}$, which depends on conduct and on the demand elasticity. Table 1.1 compares what theory needs with what the studies measured.

1.4.2 Market definition and measurement error in concentration

Concentration is defined relative to a market (Section 1.2.1). SCP studies used industries as defined by the Standard Industrial Classification (SIC), usually at the four-digit level. The SIC was replaced by the North American Industry Classification System (NAICS) in 1997. These classifications group plants by production process more than by substitution in demand. A four-digit industry can be too broad, pooling products that do not compete with each other. It can also be too narrow, leaving out close substitutes classified elsewhere and leaving out imports. Census concentration ratios are national, while many products are sold in local markets because transport is costly. Cement, ready-mixed concrete and newspapers are standard examples. The next lemma shows how large the resulting error can be.

Lemma 1.23 (Pooling local markets)**.** *Suppose a national industry consists of G local markets of equal size. Each local market ℓ is served by its own firms and has Herfindahl index HHI_ℓ. Then the*

Table 1.1: What the theory of margins needs and what SCP studies measured

Object	What theory needs	What SCP studies used	Consequence for the regression
Margin	Lerner index $\frac{p-mc}{p}$	Accounting profit rate, return on assets, Census *PCM*	Mixes rents with the return to capital and cost curvature (Proposition 1.20, Remark 1.22)
Concentration	Shares in the economic market (Section 1.2.1)	National shares in a four-digit SIC industry	Measurement error and attenuation (Section 1.4.2)
Demand elasticity	ε, which scales the slope	Rarely measured	Omitted variable that enters the slope itself
Entry barriers	Sunk and fixed costs, regulation	Capital, advertising and R&D intensities	The proxies are chosen by firms, hence endogenous
Differentiation	Substitution patterns among products	Advertising intensity, at best	Crude and endogenous proxy
Conduct	κ or θ (Proposition 1.17)	Not measured, implicitly common	The slope averages over conduct regimes (Proposition 1.24)
Foreign competition	Imports in the relevant market	Import share	Partial correction of national shares

national Herfindahl index is

$$HHI^{nat} = \frac{1}{G}\left(\frac{1}{G}\sum_{\ell=1}^{G} HHI_\ell\right).$$

Proof. Let $s_{i\ell}$ be the share of firm i in local market ℓ. Because the markets have equal size, the national share of that firm is $\frac{s_{i\ell}}{G}$. Summing squared national shares over all firms,

$$HHI^{nat} = \sum_{\ell=1}^{G}\sum_{i}\left(\frac{s_{i\ell}}{G}\right)^2 = \frac{1}{G^2}\sum_{\ell=1}^{G}\sum_{i} s_{i\ell}^2 = \frac{1}{G^2}\sum_{\ell=1}^{G} HHI_\ell.$$

Rearranging the last expression gives the result. □

National concentration thus understates local concentration by the factor G. Two industries with the same local Herfindahl index of 0.5, one sold nationally and one sold in 50 separate local markets, have national indices of 0.5 and 0.01. The number of local markets differs across industries with transport costs, so this error is large, systematic and correlated with industry characteristics. It cannot be treated as noise.

Even classical noise has a known cost. Suppose the true relation is $L_k = \beta_0 + \beta_1 HHI_k^* + e_k$, and we observe $HHI_k = HHI_k^* + u_k$. Assume u_k has mean zero and variance σ_u^2 and is uncorrelated with HHI_k^* and e_k. The OLS slope of L_k on HHI_k converges to

$$\frac{\operatorname{Cov}(\beta_0 + \beta_1 HHI_k^* + e_k,\ HHI_k^* + u_k)}{\operatorname{Var}(HHI_k^* + u_k)} = \frac{\beta_1 \operatorname{Var}(HHI_k^*)}{\operatorname{Var}(HHI_k^*) + \sigma_u^2} \equiv \beta_1 \chi. \tag{1.28}$$

The numerator keeps only $\beta_1 \operatorname{Var}(HHI_k^*)$ because the other covariances are zero. The *reliability ratio* $\chi \in (0, 1]$ is the share of the variance of measured concentration that is signal. Measurement error biases the slope toward zero, and Section 1.4.5 shows that panel methods can make this bias much worse.

1.4.3 Endogeneity of structure: theory

Suppose margins and concentration were measured without error. OLS still converges to a projection coefficient, and the next proposition characterizes it. The industry-level model is the conduct-adjusted Cowling-Waterson relation of Proposition 1.17 (Cowling and Waterson, 1976; Clarke and Davies, 1982).

Proposition 1.24 (What the SCP slope converges to)**.** *Let (L_k, HHI_k) be independent and identically distributed across industries with finite second moments and $\mathrm{Var}(HHI_k) > 0$.*

(i) The OLS slope of L_k on a constant and HHI_k converges in probability to $\frac{\mathrm{Cov}(L_k, HHI_k)}{\mathrm{Var}(HHI_k)}$.

(ii) Suppose every industry satisfies $L_k = A_k + B_k HHI_k$ with $A_k = \frac{\kappa_k}{\varepsilon_k}$ and $B_k = \frac{1-\kappa_k}{\varepsilon_k}$, where κ_k is the Clarke-Davies conduct parameter and ε_k the market elasticity of industry k. Then the slope converges to

$$\mathbb{E}[B_k] + \frac{\mathrm{Cov}(A_k, HHI_k) + \mathrm{Cov}(B_k, HHI_k^2) - \mathbb{E}[HHI_k]\,\mathrm{Cov}(B_k, HHI_k)}{\mathrm{Var}(HHI_k)}. \tag{1.29}$$

(iii) If $(\kappa_k, \varepsilon_k)$ is independent of HHI_k, the slope converges to $\mathbb{E}\left[\frac{1-\kappa_k}{\varepsilon_k}\right]$ and the intercept to $\mathbb{E}\left[\frac{\kappa_k}{\varepsilon_k}\right]$.

Proof. (i) The OLS slope is the ratio of the sample covariance of (L_k, HHI_k) to the sample variance of HHI_k. By the law of large numbers each converges to its population counterpart, and the continuous mapping theorem gives the limit of the ratio. (ii) Write $H = HHI_k$ and drop the index k. Then $\mathrm{Cov}(L, H) = \mathrm{Cov}(A, H) + \mathrm{Cov}(BH, H)$. Expand the second term:

$$\mathrm{Cov}(BH, H) = \mathbb{E}[BH^2] - \mathbb{E}[BH]\,\mathbb{E}[H].$$

Use $\mathbb{E}[BH^2] = \mathbb{E}[B]\,\mathbb{E}[H^2] + \mathrm{Cov}(B, H^2)$ and $\mathbb{E}[BH] = \mathbb{E}[B]\,\mathbb{E}[H] + \mathrm{Cov}(B, H)$:

$$\begin{aligned}\mathrm{Cov}(BH, H) &= \mathbb{E}[B]\,\mathbb{E}[H^2] + \mathrm{Cov}(B, H^2) - \mathbb{E}[B]\,\mathbb{E}[H]^2 - \mathbb{E}[H]\,\mathrm{Cov}(B, H) \\ &= \mathbb{E}[B]\,\mathrm{Var}(H) + \mathrm{Cov}(B, H^2) - \mathbb{E}[H]\,\mathrm{Cov}(B, H).\end{aligned}$$

Add $\mathrm{Cov}(A, H)$ and divide by $\mathrm{Var}(H)$ to obtain (1.29). (iii) Independence sets $\mathrm{Cov}(A, H)$, $\mathrm{Cov}(B, H)$ and $\mathrm{Cov}(B, H^2)$ to zero, so the slope converges to $\mathbb{E}[B]$. The intercept converges to

$$\mathbb{E}[L] - \mathbb{E}[B]\,\mathbb{E}[H] = \mathbb{E}[A] + \mathbb{E}[BH] - \mathbb{E}[B]\,\mathbb{E}[H] = \mathbb{E}[A] + \mathrm{Cov}(B, H) = \mathbb{E}[A]. \qquad \square$$

Part (iii) is the best case, the analogue of random assignment in (1.25). Even then the slope is an average of $\frac{1-\kappa_k}{\varepsilon_k}$ that mixes conduct with the demand elasticity. It predicts the effect of a policy that changes concentration only if the policy leaves conduct and elasticities unchanged. Part (ii) shows how sorting moves the slope. Sorting on conduct moves both terms, because a higher κ_k raises A_k and lowers B_k. With a common elasticity ε, $B_k = \frac{1}{\varepsilon} - A_k$, and the bias term in (1.29) becomes

$$\frac{\mathrm{Cov}\left(A_k, g(HHI_k)\right)}{\mathrm{Var}(HHI_k)}, \qquad g(h) = (1 + \mathbb{E}[HHI_k])\,h - h^2.$$

The function g increases for $h < \frac{1+\mathbb{E}[HHI_k]}{2}$, a range that contains most observed values of the index. Suppose collusive industries are less concentrated, in the sense that $\mathbb{E}[A_k \mid HHI_k]$ falls

with HHI_k, and every HHI_k lies where g increases. Then the covariance is negative, because a decreasing and an increasing function of the same variable covary negatively. The slope is then biased down, and Exercise 3 in Section 1.11 gives a case in which it falls to zero. The weaker condition $\mathrm{Cov}(A_k, HHI_k) < 0$ does not fix the sign. When $(\kappa_k, \varepsilon_k)$ and HHI_k are jointly determined, as they are under free entry, the slope has no structural meaning. The following model makes this concrete.

Free entry with Cournot competition. Each industry has inverse demand $P = a - bQ$ with $a > c > 0$ and $b > 0$. Firms have constant marginal cost c and pay a fixed cost $F > 0$ to enter. In stage one, potential entrants decide whether to enter. In stage two, the N entrants play the symmetric Cournot game, whose equilibrium has $P - c = \frac{a-c}{N+1}$ and $q = \frac{a-c}{b(N+1)}$ (Section 1.2.5). We treat N as continuous, as in the full worked problem of Appendix C. The free-entry equilibrium follows in four steps. Profit per firm is

$$\pi(N) = (P - c)q - F = \frac{(a-c)^2}{b(N+1)^2} - F. \tag{1.30}$$

Zero profit, $\pi(N^*) = 0$, gives

$$N^* + 1 = \frac{a-c}{\sqrt{bF}}, \qquad N^* = \frac{a-c}{\sqrt{bF}} - 1. \tag{1.31}$$

The free-entry dollar markup is therefore

$$m^* \equiv P^* - c = \frac{a-c}{N^*+1} = \sqrt{bF}. \tag{1.32}$$

Concentration and the Lerner index follow:

$$HHI^* = \frac{1}{N^*} = \frac{1}{\frac{a-c}{m^*} - 1} = \frac{m^*}{a - c - m^*}, \qquad L^* = \frac{P^* - c}{P^*} = \frac{m^*}{c + m^*}. \tag{1.33}$$

The equilibrium has at least one firm when $N^* \geq 1$, that is, when $m^* \leq \frac{a-c}{2}$, or $F \leq \frac{(a-c)^2}{4b}$. Every free-entry industry lies on its own Cournot causal curve. With $bQ^* = N^* m^*$, the elasticity is $\varepsilon^* = \frac{P^*}{bQ^*} = \frac{c+m^*}{N^* m^*}$ and

$$\frac{HHI^*}{\varepsilon^*} = \frac{1}{N^*} \cdot \frac{N^* m^*}{c + m^*} = \frac{m^*}{c + m^*} = L^*.$$

Free entry selects the point on the curve, and the same primitives also shift the curve.

The comparative statics follow from (1.33). Both outcomes rise with m^*:

$$\frac{\partial HHI^*}{\partial m^*} = \frac{a - c}{(a - c - m^*)^2} > 0, \qquad \frac{\partial L^*}{\partial m^*} = \frac{c}{(c + m^*)^2} > 0.$$

Because $m^* = \sqrt{bF}$, a higher fixed cost or a higher slope b raises both. The slope b measures market size inversely, since doubling the number of consumers at every price halves b. The demand intercept enters only HHI^*:

$$\frac{\partial HHI^*}{\partial a} = -\frac{m^*}{(a - c - m^*)^2} < 0, \qquad \frac{\partial L^*}{\partial a} = 0.$$

Marginal cost moves the two outcomes in opposite directions:

$$\frac{\partial HHI^*}{\partial c} = \frac{m^*}{(a - c - m^*)^2} > 0, \qquad \frac{\partial L^*}{\partial c} = -\frac{m^*}{(c + m^*)^2} < 0.$$

Across industries, margins and concentration are therefore positively correlated if fixed costs or market size vary. They are uncorrelated if only the level of demand varies, and negatively correlated if only marginal cost varies.

Collusion with free entry. Suppose instead that the firms in an industry collude perfectly, charge the monopoly price and split output equally. Chapter 12 studies when such collusion can be sustained. The joint monopoly solution has $Q^m = \frac{a-c}{2b}$ and $P^m = \frac{a+c}{2}$, so each of N firms earns

$$\frac{(P^m - c)Q^m}{N} - F = \frac{(a-c)^2}{4bN} - F.$$

Zero profit gives the number of collusive firms and the two outcomes:

$$N^m = \frac{(a-c)^2}{4bF}, \qquad L^m = \frac{a-c}{a+c}, \qquad HHI^m = \frac{1}{N^m} = \frac{4bF}{(a-c)^2}. \tag{1.34}$$

Total fixed costs $N^m F = \frac{(a-c)^2}{4b}$ equal the monopoly profit, so entry dissipates the whole rent while consumers still pay the monopoly price. Now let $x = \frac{a-c}{\sqrt{bF}} \geq 2$, so $N^* = x - 1$ and $N^m = \frac{x^2}{4}$. Then

$$N^m - N^* = \frac{x^2}{4} - x + 1 = \left(\frac{x}{2} - 1\right)^2 \geq 0.$$

The collusive industry also has the higher margin, because $P^* = c + \sqrt{bF} \leq c + \frac{a-c}{2} = P^m$ whenever $x \geq 2$. Collusion raises margins, attracts entry and lowers concentration.

Under collusion, F and b move only HHI^m. The demand intercept and marginal cost move the margin according to

$$\frac{\partial L^m}{\partial a} = \frac{2c}{(a+c)^2} > 0, \qquad \frac{\partial L^m}{\partial c} = -\frac{2a}{(a+c)^2} < 0,$$

while HHI^m falls with a and rises with c. Both primitives therefore move L^m and HHI^m in opposite directions. Table 1.2 collects the signs.

Table 1.2: Comparative statics of concentration and margins under free entry

	Cournot			Collusion		
Primitive that rises	HHI^*	L^*	Co-movement	HHI^m	L^m	Co-movement
Demand intercept a	−	0	None	−	+	Negative
Marginal cost c	+	−	Negative	+	−	Negative
Demand slope b (smaller market)	+	+	Positive	+	0	None
Fixed cost F	+	+	Positive	+	0	None

Notes: Linear inverse demand $P = a - bQ$, constant marginal cost c, fixed cost F, continuous number of firms. Cournot values from (1.33), collusion values from (1.34). "Co-movement" is the sign of the relation between L and HHI traced out when only that primitive varies across industries.

Mixing conduct. Compare two industries with identical primitives, one Cournot and one collusive. The collusive industry has the higher margin and, under free entry, the lower concentration. A cross-section that mixes the two pairs high margins with low concentration. In terms of Proposition 1.24, conduct is negatively correlated with concentration. When this sorting satisfies the condition stated after Proposition 1.24, the slope falls below the Cournot slope. It can turn negative.

Omitted industry features. The model is stylized, and real industries differ in many features that move margins and concentration together. Each item below is a candidate omitted variable in (1.26).

- Scale economies and fixed costs reduce the number of firms that fit in a market. They also raise measured margins, because price must cover fixed costs (Proposition 1.13).
- A low demand elasticity raises margins at any market structure and changes the incentive to enter.
- Product differentiation raises margins, and it can raise or lower concentration depending on how many varieties the market supports.
- Advertising and R&D are *endogenous sunk costs*, outlays that firms choose in order to raise demand. Sutton (1991) shows that they can keep concentration high as markets grow, and gross margins must be high enough to pay for them.
- Entry regulation, such as licensing caps, raises concentration and margins at the same time.
- Cost heterogeneity across firms makes efficient firms large, which raises both the Herfindahl index and the average margin (Section 1.5.1).

1.4.4 A Monte Carlo experiment

We now generate industries from known models and run the SCP regression on them. Because we know the truth, we can compare the OLS slope with the slope that random assignment of concentration would deliver. The script `figures/ch01/src/scp_montecarlo.py` reproduces every number below with a fixed seed.

Each of $n = 1{,}000$ industries has inverse demand $P = a - bQ$, marginal cost c and fixed cost F. The primitives are drawn independently, with $a \sim U[8, 12]$, $c \sim U[1, 4]$, $b \sim U[0.5, 2]$ and $\ln F \sim U[\ln 0.1, \ln 10]$. We keep a draw only if the free-entry Cournot equilibrium has at least one firm, which holds for 96.6 percent of draws. For each industry we compute the equilibrium Herfindahl index and Lerner index under six designs.

(1) Cournot with a fixed number of firms $N \sim U\{1, \ldots, 20\}$, drawn independently of the primitives. Fixed costs are sunk, and in 64.4 percent of these industries the firms do not cover them.

(2) Cournot with free entry, using (1.33).

(3) Collusion with free entry, using (1.34).

(4) Mixed conduct with free entry, in which each industry colludes with probability $\frac{1}{2}$, independently of its primitives.

(5) Cost heterogeneity with a fixed structure. Each industry has $N = 3$ Cournot firms with marginal costs $c_i = \bar{c} + \lambda(P - \bar{c})z_i$, where $z = (-1, 0, 1)$ and the spread parameter $\lambda \sim U[0, 0.95]$ is drawn independently of $(a, b, \bar{c})$. The mean cost is $\bar{c} \sim U[2.5, 4]$, which keeps every marginal cost positive.

(6) One primitive at a time in Cournot with free entry, holding the others at the base point $(a, c, b, F) = (10, 2.5, 1.25, 1)$.

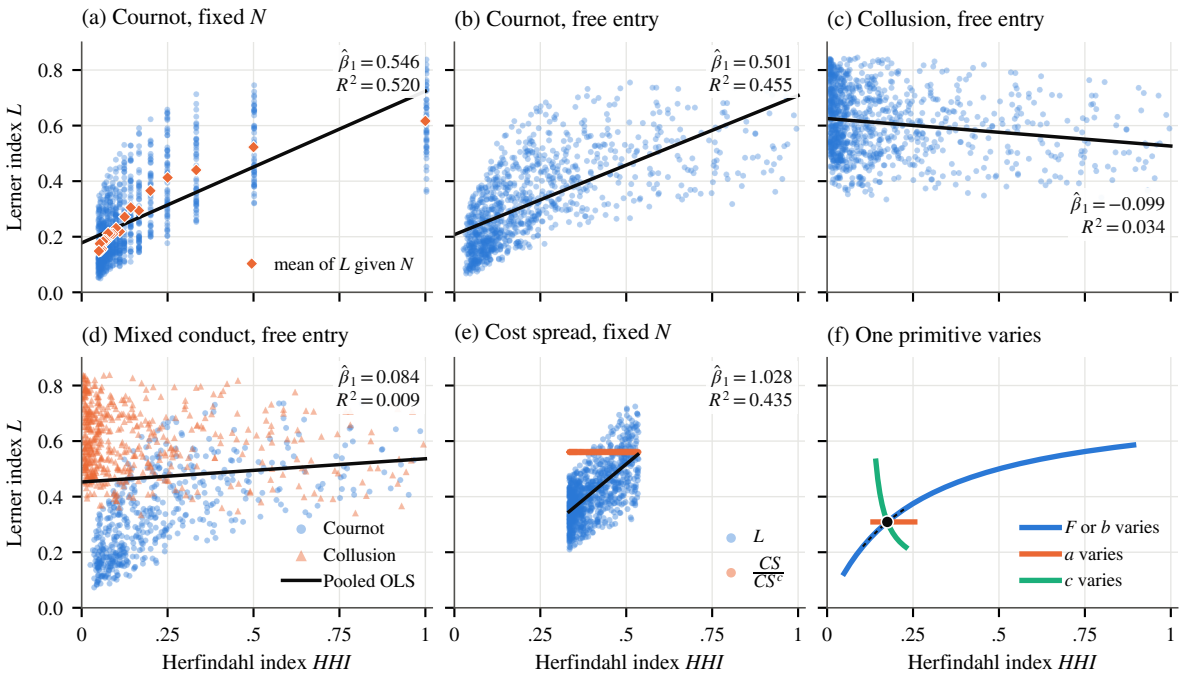

Figure 1.4: Cross-industry SCP regressions on simulated industries. Each dot is an industry and each black line is the OLS fit of the Lerner index on the Herfindahl index. Panel (a) also marks the mean margin at each number of firms. Panel (d) separates Cournot and collusive industries. Panel (e) adds the consumer surplus ratio $\frac{CS}{CS^c}$, which is the same in every industry. Panel (f) traces the free-entry Cournot equilibrium as one primitive varies through the base point (black dot).

For designs (1) to (5) we estimate $L_k = \beta_0 + \beta_1 HHI_k + e_k$ by OLS with heteroskedasticity-robust standard errors in the HC1 form, which scales the White estimator by $\frac{n}{n-2}$. As a benchmark we compute the *slope under random assignment*. It is the OLS slope of the average causal curve $\frac{1}{n}\sum_k L_k(h)$ on h, with h drawn from each design's own distribution of the Herfindahl index. In designs (1), (2) and the Cournot half of (4), the causal curve of industry k is $L_k(h) = \frac{(a_k - c_k)h}{a_k h + c_k}$ (Section 1.2.5). Under collusion it is flat. In design (5), where concentration moves through the cost spread at fixed N, it is $L_k(h) = \frac{h}{\varepsilon_k}$. We also regress the consumer surplus ratio $\frac{CS}{CS^c}$, consumer surplus relative to its level at price equal to (average) marginal cost, on the Herfindahl index. Figure 1.4 plots the simulated industries and Table 1.3 reports the regressions.

In design (1) the number of firms is independent of the primitives. Then $\mathbb{E}[L_k \mid HHI_k = h] = \mathbb{E}[L_k(h)]$, and OLS estimates the best linear approximation to the average causal curve. The estimate $\hat{\beta}_1 = 0.546$ is close to the benchmark of 0.535, and the difference is sampling error. Even here the linear model is misspecified. Every causal curve passes through the origin and is concave (Figure 1.2), and the mean margins in panel (a) trace this concavity. The fitted intercept of 0.178 is an artifact of fitting a line to a curve. The average derivative of the causal curves at the observed concentrations is 1.452, more than two and a half times the OLS slope. Most industries sit at low concentration, where the curves are steep, while OLS gives much weight to the flat region at high concentration.

In design (2) every industry lies on its causal curve, yet the OLS slope of 0.501 falls about 16 percent short of the random-assignment slope of 0.594. The gap is the selection term of (1.25). Industries become concentrated when $a - c$ is small relative to $\sqrt{bF}$, and a small $a - c$

Table 1.3: Cross-industry OLS of the Lerner index on the Herfindahl index in 1,000 simulated industries

	Cournot		Collusion	Mixed	Cost spread
	Fixed N (1)	Free entry (2)	Free entry (3)	Free entry (4)	Fixed $N = 3$ (5)
$\hat{\beta}_0$	0.178	0.208	0.625	0.453	0.003
	(0.004)	(0.005)	(0.005)	(0.009)	(0.016)
$\hat{\beta}_1$	0.546	0.501	−0.099	0.084	1.028
	(0.022)	(0.020)	(0.016)	(0.022)	(0.042)
R^2	0.520	0.455	0.034	0.009	0.435
Mean *HHI*	0.179	0.238	0.174	0.206	0.398
Mean L	0.275	0.327	0.608	0.470	0.412
Slope under random assignment	0.535	0.594	0	0.340	1.036
Slope of $\frac{CS}{CS^c}$ on *HHI*	−0.752	−0.827	0	−0.217	0
	(0.014)	(0.012)		(0.024)	

Notes: 1,000 industries with $P = a - bQ$, marginal cost c and fixed cost F. The primitives $a \sim U[8, 12]$, $c \sim U[1, 4]$, $b \sim U[0.5, 2]$ and $\ln F \sim U[\ln 0.1, \ln 10]$ are drawn independently and kept if the free-entry Cournot number of firms is at least one (96.6 percent of draws). Column (1) draws $N \sim U\{1, \ldots, 20\}$ independently of the primitives. Columns (2) to (4) use the continuous free-entry number of firms. In column (4) each industry colludes with probability $\frac{1}{2}$. Column (5) has 3 Cournot firms with costs $\bar{c} + \lambda(P - \bar{c})z_i$, $z = (-1, 0, 1)$, $\lambda \sim U[0, 0.95]$ and $\bar{c} \sim U[2.5, 4]$. HC1 standard errors in parentheses. The slope under random assignment regresses the average causal curve $\frac{1}{n}\sum_k L_k(h)$ on h, with h drawn from the column's own distribution of *HHI*. $\frac{CS}{CS^c}$ is consumer surplus relative to its level at price equal to (average) marginal cost. In columns (3) and (5) this ratio is the same in every industry, so its slope is exactly zero.

also lowers the causal curve $\frac{(a-c)h}{ah+c}$. The industries observed at high concentration therefore have systematically lower curves, as in Example 1.19.

In design (3) every causal curve is flat, so concentration has no effect on margins at all. Yet OLS reports a slope of −0.099 with a standard error of 0.016. The negative sign comes from variation in a and c, which moves the two outcomes in opposite directions (Table 1.2). Consumer surplus is one quarter of its competitive level in every collusive industry, so concentration carries no information about consumers either.

Design (4) mixes the two populations. The random-assignment slope is 0.340, below the Cournot benchmark because half of the causal curves are flat. The OLS slope is 0.084, a quarter of the benchmark, with an R^2 below one percent. Panel (d) of Figure 1.4 shows why. Collusive industries combine high margins with low concentration and pull the pooled line toward zero.

Design (5) produces the strongest relation in the table, with $\hat{\beta}_1 = 1.028$ and $R^2 = 0.435$. The benchmark slope is 1.036, the mean of $\frac{1}{\varepsilon_k}$, because a wider cost spread raises L_k and HHI_k in the ratio $\frac{1}{\varepsilon_k}$ while leaving price unchanged. In this design the benchmark curve comes from an intervention on the cost spread. It departs from Definition 1.18, since costs cannot stay fixed while concentration moves. In this narrower sense the relation is causal. Yet price, output and consumer surplus are identical to those of the same industry with symmetric costs, and $\frac{CS}{CS^c} = \frac{9}{16}$ in every industry. A researcher would see a strong positive concentration-margin relation with no harm to consumers. Section 1.5.1 develops this case.

Panel (f) isolates the comparative statics of Table 1.2. Variation in F or b moves the industry along an increasing concave curve, variation in a moves it horizontally, and variation in c moves it down and to the right. The sign of the SCP slope depends on which primitive varies across the sample. The slope is a property of the sample and says nothing about the technology

of competition. The fully worked version of these models is in Appendix C.

1.4.5 Panel data and fixed effects

A natural response to omitted industry characteristics is to observe each industry several times and remove what does not change. Salinger (1990) reconsidered the concentration-margins relation with such data. He used a Census of Manufactures panel of industries and restricted most of his analysis to 1972–84 (Salinger, 1990, p. 301). Besides annual cross sections, he estimated the relation in long differences, which remove time-invariant industry effects. The general fixed-effects version of the regression is

$$PCM_{kt} = \alpha_k + \beta_1 CR_{kt} + \varphi^\top X_{kt} + e_{kt}, \qquad k = 1, \dots, n, \quad t = 1, \dots, T, \tag{1.35}$$

where α_k is a fixed effect for industry k and CR_{kt} is a concentration ratio. The symbol α_k is local to this subsection and differs from the price coefficient α of demand models. The *within estimator* subtracts each industry's time average from every variable:

$$PCM_{kt} - \overline{PCM}_k = \beta_1 (CR_{kt} - \overline{CR}_k) + \varphi^\top (X_{kt} - \bar{X}_k) + (e_{kt} - \bar{e}_k),$$

with $\overline{PCM}_k = \frac{1}{T}\sum_t PCM_{kt}$ and similarly for the other variables. The transformation removes α_k, and with it every time-invariant feature of the industry, such as its demand elasticity, its technology or its accounting conventions.

With $T = 2$ the within estimator equals OLS on first differences, $\Delta PCM_k = \beta_1 \Delta CR_k + \varphi^\top \Delta X_k + \Delta e_k$. Salinger's long-difference regression has this form without controls, plus a constant for the common change over the decade. Across 363 industries, he regressed the change in margins from 1972 to 1982 on the change in CR_4, adjusted for market definition. The slope is 0.178, with a t-statistic of 3.49 (Salinger, 1990, Table 4, row 1). He notes that it is roughly the size of his cross-sectional estimates (Salinger, 1990, p. 310). He reads the similarity as a sign that the cross-sectional relation could have evolved from changes in concentration over time (Salinger, 1990, pp. 310–311).

The cost is that identification now comes only from changes in concentration within an industry over time. Consistency requires *strict exogeneity*, $\mathbb{E}[e_{kt} \mid CR_{k1}, \dots, CR_{kT}, X_{k1}, \dots, X_{kT}, \alpha_k] = 0$. Changes in concentration are responses to the same demand and cost shocks that move margins. A demand boom raises margins and attracts entry, and a cost shock can trigger exit or mergers. Such feedback violates strict exogeneity, as a simple model shows.

Example 1.25 (Entry feedback)**.** Let margin shocks e_{kt} be independent over time with variance σ_e^2, and suppose the true effect of concentration is β_1. Entry responds to last period's margin shock:

$$CR_{kt} = CR_{k,t-1} - \zeta e_{k,t-1} + v_{kt}, \qquad \zeta > 0,$$

with v_{kt} independent noise of variance σ_v^2. In first differences, $\Delta PCM_{kt} = \beta_1 \Delta CR_{kt} + \Delta e_{kt}$, where $\Delta CR_{kt} = -\zeta e_{k,t-1} + v_{kt}$ and $\Delta e_{kt} = e_{kt} - e_{k,t-1}$. The two terms share $e_{k,t-1}$:

$$\operatorname{Cov}(\Delta CR_{kt}, \Delta e_{kt}) = (-\zeta)(-\sigma_e^2) = \zeta \sigma_e^2.$$

With $\operatorname{Var}(\Delta CR_{kt}) = \zeta^2 \sigma_e^2 + \sigma_v^2$, the first-difference estimator converges to

$$\beta_1 + \frac{\zeta \sigma_e^2}{\zeta^2 \sigma_e^2 + \sigma_v^2} > \beta_1.$$

A favorable shock raises the margin today and attracts entry tomorrow, when the margin reverts. Concentration and margins then fall together, and the estimator finds a positive relation even when $\beta_1 = 0$.

Fixed effects also magnify measurement error. Most of the variation in concentration is between industries and persists over time, while the within-industry changes are small. Noise in measured concentration does not shrink in the same way. Griliches and Hausman (1986) make this point for panel data in general, and the next proposition states it for the SCP regression.

Proposition 1.26 (Attenuation of the within estimator)**.** *Suppose $L_{kt} = \alpha_k + \beta_1 HHI^*_{kt} + e_{kt}$ and we observe $HHI_{kt} = HHI^*_{kt} + u_{kt}$. Industries are independent across k, and T is fixed. The errors u_{kt} are independent across k and t with mean zero and variance σ_u^2, and independent of $\{HHI^*_{ks}\}$, $\{e_{ks}\}$ and α_k. The shocks satisfy $\mathbb{E}[e_{kt} \mid HHI^*_{k1}, \dots, HHI^*_{kT}, \alpha_k] = 0$. Let $\sigma^2_{\ddot{H}} = \mathbb{E}\left[\frac{1}{T}\sum_t (HHI^*_{kt} - \overline{HHI^*_k})^2\right] > 0$ be the within-industry variance of true concentration. As $n \to \infty$, the within estimator converges to*

$$\beta_1 \frac{\sigma^2_{\ddot{H}}}{\sigma^2_{\ddot{H}} + \sigma^2_{\ddot{u}}}, \qquad \sigma^2_{\ddot{u}} = \frac{T-1}{T}\sigma_u^2.$$

Proof. Write $H_{kt} = HHI_{kt}$ and $H^*_{kt} = HHI^*_{kt}$, and write $\ddot{y}_{kt} = y_{kt} - \bar{y}_k$ for the within transformation of any variable y. The fixed effect drops out, so $\ddot{L}_{kt} = \beta_1 \ddot{H}^*_{kt} + \ddot{e}_{kt}$. The measured regressor is $\ddot{H}_{kt} = \ddot{H}^*_{kt} + \ddot{u}_{kt}$. The within estimator is

$$\hat{\beta}_1^W = \frac{\sum_k \sum_t \ddot{H}_{kt}\, \ddot{L}_{kt}}{\sum_k \sum_t \ddot{H}^2_{kt}}.$$

Divide numerator and denominator by nT and apply the law of large numbers across industries. The numerator converges to

$$\beta_1 \mathbb{E}\left[\frac{1}{T}\sum_t \ddot{H}^*_{kt}(\ddot{H}^*_{kt} + \ddot{u}_{kt})\right] + \mathbb{E}\left[\frac{1}{T}\sum_t \ddot{H}_{kt}\, \ddot{e}_{kt}\right] = \beta_1 \sigma^2_{\ddot{H}}.$$

The cross term in $\ddot{u}_{kt}$ vanishes because u is independent of HHI^*. The second expectation vanishes by strict exogeneity and the independence of u and e. The denominator converges to $\sigma^2_{\ddot{H}} + \mathbb{E}\left[\frac{1}{T}\sum_t \ddot{u}^2_{kt}\right]$. For each t,

$$\mathbb{E}[\ddot{u}^2_{kt}] = \mathrm{Var}(u_{kt}) - 2\,\mathrm{Cov}(u_{kt}, \bar{u}_k) + \mathrm{Var}(\bar{u}_k) = \sigma_u^2 - \frac{2\sigma_u^2}{T} + \frac{\sigma_u^2}{T} = \frac{T-1}{T}\sigma_u^2.$$

Taking the ratio of the two limits gives the result. □

Compare the within estimator with a pooled regression that ignores the fixed effects and is valid only if α_k is unrelated to concentration. Its reliability ratio is $\frac{\mathrm{Var}(HHI^*)}{\mathrm{Var}(HHI^*)+\sigma_u^2}$, which uses the total variance of true concentration. The within estimator uses only the within part. Normalize $\mathrm{Var}(HHI^*) = 1$, and suppose 95 percent of it is between industries and $\sigma_u^2 = 0.05$. The pooled reliability ratio is $\frac{1}{1.05} = 0.95$. With many periods, the within ratio is $\frac{0.05}{0.05+0.05} = 0.5$, so the within estimator recovers only half of β_1. Fixed effects remove one bias and enlarge another.

The lesson of this subsection holds for any such design. Industry fixed effects do not solve the endogeneity of concentration, and where they remove one problem they create others: dynamic feedback between margins and entry, and attenuation from measurement error.

1.5 Efficiency, prices, and the afterlife of SCP

Suppose we found the econometric evidence credible: more concentrated markets have higher margins and higher profits. Would that show that concentration is bad for consumers? This section takes up the efficiency critique, the shift from profits to prices as the dependent variable, and the recent return of cross-industry work in the debate over rising markups.

1.5.1 Efficiency versus market power: the Demsetz critique

Demsetz (1973) argued that concentration can be the result of superior efficiency or quality. Firms with lower costs or better products grow, the industry becomes concentrated, and industry profits rise because the efficient firms earn rents on their advantage. Consumers need not lose. On this view, which became part of the Chicago critique of antitrust, the measurement may be correct while its normative reading is wrong. Bresnahan (1989, p. 1013, fn. 2) summarizes the argument. "Demsetz' alternative interpretation was that high profits measure good performance, i.e. low costs, an argument he buttressed by the observation that much of the profit in concentrated industries goes to large firms." Bresnahan cites Demsetz (1974) and notes that Bain (1951) had already given a "poor performance" reading of the same observation. He describes the SCP literature as caught in "a kind of gridlock" over whether high accounting profits signal good or bad performance (Bresnahan, 1989, p. 1013).

The next proposition shows that the efficiency story holds exactly in the linear Cournot model with heterogeneous costs.

Proposition 1.27 (Concentration from cost differences)**.** *Let inverse demand be $P = a - bQ$, and let N Cournot firms have constant marginal costs $c_1, \dots, c_N$. Suppose all firms are active, $P > \max_i c_i$. Let $\bar{c} = \frac{1}{N}\sum_i c_i$ and $\sigma_c^2 = \frac{1}{N}\sum_i (c_i - \bar{c})^2$.*

(i) Output and price are $Q = \frac{Na - \sum_i c_i}{b(N+1)}$ and $P = \frac{a + \sum_i c_i}{N+1}$. They depend on costs only through $\sum_i c_i$.

(ii) Shares are $s_i = \frac{P - c_i}{bQ}$, and $HHI = \frac{1}{N} + \frac{N\sigma_c^2}{b^2Q^2}$.

(iii) Industry variable profit is $\sum_i (P - c_i)q_i = bQ^2 HHI$, and the share-weighted Lerner index is $\sum_i s_i L_i = \frac{HHI}{\varepsilon}$ with $\varepsilon = \frac{P}{bQ}$.

Proof. (i) Firm i maximizes $(a - bQ - c_i)q_i$. Its first-order condition is $a - bQ - bq_i - c_i = 0$, or

$$bq_i = P - c_i.$$

Sum over the N firms: $bQ = NP - \sum_i c_i$. Substitute $P = a - bQ$:

$$bQ = N(a - bQ) - \sum_i c_i \quad \Longrightarrow \quad bQ(N+1) = Na - \sum_i c_i.$$

Solve for Q and substitute back into the demand curve:

$$P = a - bQ = \frac{(N+1)a - Na + \sum_i c_i}{N+1} = \frac{a + \sum_i c_i}{N+1}.$$

(ii) The first-order condition gives $s_i = \frac{q_i}{Q} = \frac{P - c_i}{bQ}$. Because $\sum_i (P - c_i) = bQ$, the mean of $P - c_i$ across firms is $\frac{bQ}{N} = P - \bar{c}$. Hence

$$s_i - \frac{1}{N} = \frac{(P - c_i) - (P - \bar{c})}{bQ} = \frac{\bar{c} - c_i}{bQ}.$$

The variance of shares is $\sigma_s^2 = \frac{1}{N}\sum_i (s_i - \frac{1}{N})^2 = \frac{\sigma_c^2}{b^2Q^2}$. By Lemma 1.4, $HHI = \frac{1}{N} + N\sigma_s^2 = \frac{1}{N} + \frac{N\sigma_c^2}{b^2Q^2}$.

(iii) Using $P - c_i = bq_i$,

$$\sum_i (P - c_i)q_i = b\sum_i q_i^2 = bQ^2 \sum_i s_i^2 = bQ^2 HHI.$$

Similarly, the Lerner index of firm i is

$$L_i = \frac{P - c_i}{P} = \frac{bq_i}{P} = \frac{bQ}{P}s_i = \frac{s_i}{\varepsilon}.$$

Multiplying by s_i and summing gives $\sum_i s_i L_i = \frac{HHI}{\varepsilon}$. □

Corollary 1.28 (A mean-preserving spread of costs)**.** *Change the costs c_i so that $\sum_i c_i$ is unchanged, σ_c^2 rises and all firms remain active. Then price, output and consumer surplus $\frac{bQ^2}{2}$ are unchanged. The Herfindahl index, industry variable profit and the share-weighted Lerner index all rise, and so does total surplus.*

Proof. By Proposition 1.27(i), P and Q depend only on $\sum_i c_i$, so they and consumer surplus are unchanged. With Q fixed, part (ii) shows that HHI rises with σ_c^2. Part (iii) then shows that industry profit bQ^2HHI and $\sum_i s_i L_i = \frac{bQ}{P}HHI$ rise. Total surplus is consumer surplus plus industry profit (gross of fixed costs), so it rises by the increase in profit. □

The corollary is the efficiency critique in one line. Across industries that differ only in the dispersion of firm costs, concentration, margins and profits move together, and consumers are equally well off in all of them. Design (5) of the Monte Carlo experiment is exactly this case.

Tirole (1988, Section 5.5) presents Demsetz's argument with two further examples. In Bertrand competition with constant marginal costs, the lowest-cost firm charges the second-lowest cost and takes the whole market. Concentration is then as high as any index that satisfies the axioms of Remark 1.6 allows, and the firm earns a positive profit. With symmetric costs, concentration is lower and profit is zero. Proposition 1.29 below studies this equilibrium when costs are random. Tirole's Exercise 5.7 is a special case of Corollary 1.28. Let demand be $Q = 1 - P$, so that $a = b = 1$, and let two Cournot firms have costs $c_1 = c - d$ and $c_2 = c + d$ with $0 \le d$ and $c < 1$. The sum $c_1 + c_2 = 2c$ stays fixed as d varies, and $\sigma_c^2 = d^2$. By Proposition 1.27,

$$Q = \frac{2(1-c)}{3}, \qquad P = \frac{1+2c}{3}, \qquad HHI = \frac{1}{2} + \frac{2d^2}{Q^2} = \frac{1}{2} + \frac{9d^2}{2(1-c)^2}.$$

Industry variable profit is

$$bQ^2HHI = \frac{Q^2}{2} + 2d^2 = \frac{2(1-c)^2}{9} + 2d^2.$$

Both firms stay active as long as $P > c + d$, that is, $d < \frac{1-c}{3}$. Over this range a wider cost spread raises concentration and industry profit and leaves price unchanged.

Tirole draws a general lesson from such examples. Concentration indices give an easily computed indication of how competitive an industry is. "However, they have no systematic relationship with economic variables of interest for assessing changes in cost, demand, or policy." With asymmetric firms, a given index need not be related in a systematic way to welfare either. The indices are also endogenous, so their correlations with other variables cannot be read as causal effects (Tirole, 1988, Section 5.5).

The decomposition in part (ii) also shows that the source of concentration matters. Its first term, $\frac{1}{N}$, reflects the number of firms. An extra active firm with cost $c_{N+1} < P$ lowers price, because

$$\frac{a + \sum_i c_i + c_{N+1}}{N+2} < \frac{a + \sum_i c_i}{N+1} = P \quad \Longleftrightarrow \quad (N+1)\, c_{N+1} < a + \sum_i c_i \quad \Longleftrightarrow \quad c_{N+1} < P.$$

Fewer firms therefore mean higher prices and lower consumer surplus. The second term reflects cost dispersion, which leaves consumers unaffected. A single concentration index cannot tell the two apart.

The critique generated a large literature of firm-level *horse-race regressions*. They include both industry concentration and the firm's own market share:

$$\pi_{ik} = \beta_0 + \beta_1 CR_k + \beta_2 s_{ik} + \varphi^\top X_{ik} + e_{ik}, \tag{1.36}$$

where π_{ik} is the profitability of firm i in industry k and s_{ik} its market share. The efficiency view predicts $\beta_2 > 0$ with β_1 near zero, since large firms are profitable because they are efficient. The market-power view predicts $\beta_1 > 0$, since concentration facilitates high prices for all firms in the industry.

Demsetz stated the testable implication of his view himself (Demsetz, 1973, p. 5, quoted in Levenstein and Suslow, 2006, p. 46, n. 5). Suppose that efficiency is associated with concentration. Then "there should be a positive correlation between concentration and the difference between the rate of return earned by large firms and that earned by small firms." Let $\bar{\pi}_k^L$ and $\bar{\pi}_k^S$ be the average rates of return of the large and the small firms in industry k. The implication concerns the cross-industry regression

$$\bar{\pi}_k^L - \bar{\pi}_k^S = \gamma_0 + \gamma_1 CR_k + e_k, \tag{1.37}$$

and the efficiency view predicts $\gamma_1 > 0$. If concentration instead facilitates high prices for every firm in the industry, the returns of small firms rise with concentration as well, and the gap need not widen. In (1.36) the same contrast appears as $\beta_2 > 0$ against $\beta_1 > 0$.

Demsetz's own evidence fit the efficiency view. It was the observation, quoted above from Bresnahan (1989, p. 1013, n. 2), that much of the profit in concentrated industries goes to large firms. Hopenhayn (1992, p. 1142) puts it more precisely: "as reported by Demsetz (1973), more concentrated industries could show higher profits for large firms and not for small ones." Hopenhayn also shows that the pattern does not single out efficiency. In his competitive model of industry dynamics, a higher cost of entry protects incumbents. It raises the profits of large firms but not necessarily those of small ones, and it raises the market share of the largest firms. Industries with high entry costs then show the Demsetz pattern, although every firm takes the price as given.

Later evidence was mixed. Studies that add the firm's own market share to the regression find that concentration loses its effect (Tirole, 1988, Introduction, note 3). Ravenscraft (1983) reports evidence of this kind from the line-of-business data of the Federal Trade Commission, for 3,186 business units in 258 manufacturing industries in 1975 (Ravenscraft, 1983, p. 24). In the business-unit regressions of his Table 1, the share coefficient is positive and significant. The concentration coefficient is small and negative, and significant in the generalized least squares estimate (Ravenscraft, 1983, Table 1). In the industry-level regression, which omits share, concentration has a positive coefficient (Ravenscraft, 1983, p. 26). Schmalensee (1985a) decomposed the variance of business-unit returns on assets in the 1975 line-of-business data

into industry, firm and share components. Firm effects were never statistically significant. Share effects were significant but explained less than 1 percent of the variance. Industry effects explained about a fifth of it, and at least 75 percent of the variance of industry average returns. About 80 percent of the variance was unrelated to industry or share effects (Schmalensee, 1985a, pp. 346–350). Ravenscraft's paper focuses on the firm's share and Schmalensee's on the industry. Schmalensee finds the two consistent, since share also explains less than 1 percent of the variance of profitability in Ravenscraft's estimates (Schmalensee, 1985a, p. 347). Tirole (1988, Section 5.5) and Levenstein and Suslow (2006, p. 46, n. 5) point to Schmalensee (1987) for a test of collusion against differential efficiency.

The horse race cannot settle the question, because firm share is itself an equilibrium outcome. The model of Proposition 1.27 makes the point sharply. There, $L_{ik} = \frac{s_{ik}}{\varepsilon_k}$ for every firm. In a sample of industries with a common elasticity ε, a regression of firm margins on share and concentration returns $\beta_2 = \frac{1}{\varepsilon}$ and $\beta_1 = 0$ exactly. Yet every firm prices above marginal cost because it internalizes the effect of its output on price, which is market power by definition. The pattern "$\beta_1 = 0$ and $\beta_2 > 0$" is thus fully consistent with a model in which firms exercise market power. It shows that margins line up with shares, which the Cournot model of Proposition 1.15 predicts as well.

The argument has a modern echo. Dominant digital platforms attribute their large shares to the quality of their products. Defendants have advanced this argument in recent monopolization cases. The logic is Demsetz's: concentration may be high because some firms deliver more value per dollar, so the measured concentration is fine and its normative reading is contested. Separating the two readings requires a model of demand that values quality, which is the subject of Chapters 6 and 8.

Efficiency and structure can also be jointly determined by competition itself. Syverson (2004) studies plants in the US ready-mixed concrete industry, where high transport costs make markets local. Markets with denser demand have more plants, so buyers can switch between suppliers more easily. Less efficient plants then find it harder to operate profitably, and the productivity distribution is truncated from below. Denser markets have higher minimum and average productivity and less dispersion. The causal arrow runs from demand density to both structure and efficiency, which no cross-industry regression of performance on structure can capture.

1.5.2 Price-concentration studies

A later wave of studies replaced accounting profit with price as the dependent variable. They used cross-sections of similar, geographically local markets within one industry (Bresnahan, 1989, Section 3.5). Examples include banking, for which Rhoades (1982) lists dozens of studies, and retail food (Cotterill, 1986; Lamm, 1981). Others cover gasoline (Marvel, 1978), airline city pairs (Graham et al., 1983) and cement (Koller and Weiss, 1986). Weiss (1989) collected many such studies. The estimating equation is typically a reduced form for price,

$$p_k = \beta_0 + \beta_1 HHI_k + \varphi^\top X_k + e_k, \tag{1.38}$$

where k now indexes local markets of one industry and X_k contains demand and cost shifters. The studies typically treat concentration as exogenous (Bresnahan, 1989, p. 1043). They confirm a positive relation between price and concentration, which is at least suggestive of market power increasing with concentration. A variant uses changes in structure over time, as in the study of a merger in the microfiche industry by Barton and Sherman (1984).

Price avoids the accounting problems of Section 1.4.1, and similar local markets share many omitted features. Yet the interpretation that concentration raises margins by changing conduct still needs a defense. Bresnahan (1989, p. 1043) writes, "I have seen no careful defense of this interpretation, and I am troubled by it." He then lists difficulties which, in his words, "have not yet been rebutted." We state each one as an argument.

(i) Free entry links price and concentration through scale, because larger markets fit more firms. Take the free-entry Cournot model of Section 1.4.3 with M consumers, so that $b = \frac{1}{M}$. Then $P^* = c + \sqrt{\frac{F}{M}}$ and $HHI^* = \frac{m^*}{a-c-m^*}$ with $m^* = \sqrt{\frac{F}{M}}$, so both fall as M grows. Firm output is $q^* = \frac{m^*}{b} = \sqrt{FM}$ and average cost is $c + \frac{F}{q^*} = c + \sqrt{\frac{F}{M}} = P^*$. Firms in larger markets are larger, have lower average costs and break even everywhere. Price and concentration are related "in a way that has no obvious bad effects, and does not imply entry barriers" (Bresnahan, 1989, p. 1044).

(ii) Cost heterogeneity varies across markets with the same number of firms. Among such markets, the more concentrated ones likely have more heterogeneous costs. By Proposition 1.27(ii), concentration rises with σ_c^2 at fixed N. Cost heterogeneity may or may not interact with conduct to raise prices.

(iii) Markets with more firms offer more draws on the lowest-cost firm, even if concentration is exogenous. If that firm matters for price, price falls with the number of firms for purely statistical reasons. Proposition 1.29 below formalizes the point.

(iv) Market-level data identify only an average of costs and conduct. Summing the first-order conditions of Proposition 1.17 with share weights gave the industry relation (1.22). With marginal costs mc_i that may vary across firms, the same steps give Bresnahan's equation (17′) in our notation,

$$P = \overline{mc} - P'(Q)\,Q\,\theta, \qquad \overline{mc} = \sum_i s_i\, mc_i, \qquad \theta = \sum_i s_i^2(1 + r_i), \tag{1.39}$$

which Proposition 1.33 derives in general. A lower price in less concentrated markets can reflect a lower $\overline{mc}$, a lower θ, or both. Most authors have the second in mind. The two can also be linked, because a firm with a large cost advantage may behave less competitively than it would against equal rivals.

(v) The identity of the competitors matters as well as their number. Graham et al. (1983) found that airline city-pair markets served by carriers new to the industry have lower prices, all else equal. These entrants very likely had lower marginal costs, and their presence may also have changed the conditions of competition. "Which is it? The analysis of the paper cannot say" (Bresnahan, 1989, p. 1044). The same question applies to the structure dummies in Porter's (1983a) railroad cartel study.

(vi) Tests of the exogeneity of concentration have little power. Graham et al. (1983) tested the exogeneity of their concentration measures and did not reject it. Their concentration coefficients nevertheless changed substantially when concentration was treated as endogenous. Bresnahan concludes that the test had little power, so the assumption should not be taken as innocuous (Bresnahan, 1989, p. 1043, fn. 35).

Bresnahan stresses that these questions "are not unanswerable" and that the methods of Section 1.7 can tell marginal cost from conduct. "The questions are, however, unanswered"

(Bresnahan, 1989, p. 1044). One clean exception he notes is Spiller and Favaro (1984). They study Uruguayan banking over a period that includes a change in entry regulation, and find that freer entry shifts the supply relation down (Bresnahan, 1989, p. 1044, fn. 36).

The more-draws argument can be made precise with order statistics, which Appendix B reviews. Let $c_{(k:N)}$ denote the k-th lowest of N costs.

Proposition 1.29 (More firms, more draws)**.** *Let the marginal costs of $N \geq 2$ firms be independent draws from a distribution F_c on $[\underline{c}, \bar{c}]$, and let firms compete in prices with a homogeneous good. In the equilibrium in which the lowest-cost firm serves the market at the second-lowest cost, the price is $c_{(2:N)}$, and*

$$\mathbb{E}[c_{(2:N)}] = \underline{c} + \int_{\underline{c}}^{\bar{c}} G_N(x)\,\mathrm{d}x, \qquad G_N(x) \equiv \mathbb{P}(c_{(2:N)} > x) = (1 - F_c(x))^N + NF_c(x)(1 - F_c(x))^{N-1}.$$

The expected price is strictly decreasing in N whenever F_c is nondegenerate:

$$\mathbb{E}[c_{(2:N)}] - \mathbb{E}[c_{(2:N+1)}] = \int_{\underline{c}}^{\bar{c}} NF_c(x)^2(1 - F_c(x))^{N-1}\,\mathrm{d}x > 0.$$

Proof. For a random variable Y on $[\underline{c}, \bar{c}]$, $\mathbb{E}[Y] = \underline{c} + \int_{\underline{c}}^{\bar{c}} \mathbb{P}(Y > x)\,\mathrm{d}x$. The second-lowest cost exceeds x exactly when at most one of the N costs is below x. No cost is below x with probability $(1 - F_c(x))^N$. Exactly one is below x with probability $NF_c(x)(1 - F_c(x))^{N-1}$. Adding the two gives $G_N(x)$. For the difference, write $F = F_c(x)$ and compute

$$\begin{aligned} G_N(x) - G_{N+1}(x) &= (1 - F)^N\,[1 - (1 - F)] + F(1 - F)^{N-1}\,[N - (N + 1)(1 - F)] \\ &= F(1 - F)^N + F(1 - F)^{N-1}\,[(N + 1)F - 1] \\ &= F(1 - F)^{N-1}\,[(1 - F) + (N + 1)F - 1] = NF^2(1 - F)^{N-1}. \end{aligned}$$

Integrating over x gives the expression for the difference in expected prices. The integrand is positive wherever $0 < F_c(x) < 1$, a set of positive length when F_c is nondegenerate. □

The difference has a coupling interpretation. Adding a firm can only add a draw below x, so the event "at most one cost below x" becomes less likely. It fails exactly when one, and only one, of the first N costs is below x and the new cost is also below x, which has probability $NF_c(x)^2(1 - F_c(x))^{N-1}$. With costs uniform on $[0, 1]$, $G_N(x) = (1 - x)^N + Nx(1 - x)^{N-1}$ and

$$\mathbb{E}[c_{(2:N)}] = \int_0^1 (1 - x)^N \mathrm{d}x + N \int_0^1 x(1 - x)^{N-1} \mathrm{d}x = \frac{1}{N + 1} + \frac{N}{N(N + 1)} = \frac{2}{N + 1}.$$

The expected price is $\frac{2}{3}$ with two firms, $\frac{1}{2}$ with three and $\frac{1}{3}$ with five, with identical Bertrand conduct in every market. In this stark model the lowest-cost firm serves the whole market, so its share is one and the structural variable that varies is the number of firms present. The same logic applies in any model in which the most efficient firms carry extra weight in price determination.

1.5.3 SCP today

SCP regressions survive as descriptive exercises. They are useful for laying out facts and empirical regularities, such as which industries are concentrated and how margins and

concentration move over time. For the reasons in Sections 1.4, 1.5.1 and 1.5.2, they are of little use for testing theories of market power. Schmalensee's own post-mortem concluded that the cross-industry literature had not taught us much about how markets work (Einav and Levin, 2010, p. 160).

A recent survey of health care markets restates the verdict (Handel and Ho, 2021, p. 527). Handel and Ho note that the SCP approach persisted longer in health economics than elsewhere. They summarize the reasons that Berry et al. (2019) give for the move away from it in the late 1980s. The first is measurement. Markets are not observed directly in the data, and economic profits are hard to measure. The second is the endogeneity of concentration. As a function of market shares, it is likely to be correlated with the unobserved demand shifters that also move price. The third, and in their words the most fundamental, is that different changes in primitives can produce the same correlation between concentration and prices. Mergers raise concentration, markups and prices together and lower consumer surplus. Large firms with low marginal costs and high fixed costs produce the same correlation, as in Demsetz (1973). So does a fall in search costs that shifts share toward firms with high-quality products, which raises both concentration and consumer welfare (Autor et al., 2020). The results of such regressions are therefore "at best suggestive." Handel and Ho conclude with the point of Bresnahan (1989). The effect of concentration can be studied only through three objects: a demand system, the marginal costs of firms and the nature of oligopolistic competition.

Industry studies, the response described in Section 1.6, taught much about particular industries, at the price of leaving cross-industry questions to other fields (Section 1.8.6). The debate over rising markups and their role in rising inequality has brought cross-industry, SCP-style work back, and the reactions within IO have been mixed.

1.5.4 Rising markups and the production approach

The recent cross-industry literature measures markups from production data instead of demand. The approach goes back to Hall (1988), and De Loecker and Warzynski (2012) developed its firm-level version. In this subsection Q and P denote the output and price of a single firm, and $\mu = \frac{P}{mc}$ is the markup ratio of Section 1.2.3.

Proposition 1.30 (Markups from a flexible input)**.** *A firm produces $Q = f(V, K, \omega)$, where V is a variable input bought at price P^V, K collects the other inputs and ω is productivity. Suppose the firm minimizes cost, takes P^V as given, and adjusts V freely. Let λ be the multiplier on the output constraint. Then $\lambda = mc$ and*

$$\mu = \frac{P}{\lambda} = \phi^V \frac{PQ}{P^V V}, \qquad \phi^V = \frac{\partial f}{\partial V}\frac{V}{Q},$$

where ϕ^V is the output elasticity of the variable input.

Proof. The firm chooses V to minimize $P^V V$ plus the cost of the other inputs subject to $f(V, K, \omega) \geq Q$. The Lagrangian is

$$\mathcal{L} = P^V V + C^K(K) - \lambda \left[f(V, K, \omega) - Q \right],$$

where $C^K(K)$ is the cost of the other inputs. The first-order condition for V is

$$P^V = \lambda \frac{\partial f}{\partial V}.$$

By the envelope theorem (Appendix B), the derivative of minimized cost with respect to Q equals $\frac{\partial \mathcal{L}}{\partial Q} = \lambda$, so $\lambda = mc$. Multiply the first-order condition by $\frac{V}{\lambda Q}$:

$$\frac{P^V V}{\lambda Q} = \frac{\partial f}{\partial V}\frac{V}{Q} = \phi^V.$$

Solve for $\lambda = \frac{P^V V}{\phi^V Q}$ and divide price by it:

$$\mu = \frac{P}{\lambda} = \frac{P\phi^V Q}{P^V V} = \phi^V \frac{PQ}{P^V V}. \qquad \square$$

The formula needs no demand model and no assumption about conduct. The markup is the output elasticity of a flexible input divided by that input's share of revenue. Its appeal for cross-industry work is obvious, because revenue shares are available in accounting data for many firms.

De Loecker et al. (2020) applied the formula to US publicly listed firms in the Compustat data from 1955 to 2016, treating cost of goods sold as the variable input. Each firm's markup is the ratio of its revenue to its cost of goods sold, multiplied by an estimated output elasticity of the variable inputs. The method follows De Loecker and Warzynski (2012), and the firm markups are then averaged with revenue weights (Asker and Nocke, 2021, p. 258 and n. 203). As read from the figure in Asker and Nocke (2021, Figure 11, p. 259), the revenue-weighted average markup rose from about 1.21 in 1980 to about 1.61 in 2016. The rise was confined to the upper tail. The median markup is flat over the period, and in the authors' own words, "Most firms see no increase in markups. For the higher percentiles, markups increase. For the 90th percentile in particular, the increase is sharpest. Between 1980 and 2016, it increases from 1.5 to 2.5" (quoted in Asker and Nocke, 2021, p. 258). The rise in the average is thus "largely driven by a few firms that currently have much higher markups than decades ago." The finding drew wide attention because it suggested a rise in market power across the economy. De Loecker and Syverson (2021) survey the production approach behind it, and their chapter closes with its use to measure market power in product and labor markets (Ho et al., 2021a, Preface, p. xvi).

The critiques mirror the problems of the SCP literature.

- The output elasticity ϕ^V must be estimated, usually from a production function by industry. Most data record revenue instead of physical output. With revenue $R = PQ$ and profit maximization, which sets marginal revenue MR equal to $mc = \lambda$, the elasticity of revenue with respect to V is

  $$\frac{\partial \ln R}{\partial \ln V} = \frac{\partial \ln R}{\partial \ln Q}\phi^V = \frac{MR}{P}\phi^V = \frac{\phi^V}{\mu}.$$

  Plugging this revenue elasticity into Proposition 1.30 in place of ϕ^V gives

  $$\frac{\phi^V}{\mu} \cdot \frac{PQ}{P^V V} = \frac{\mu}{\mu} = 1$$

  for every firm. A revenue elasticity therefore carries no information about the markup, a point developed by Bond et al. (2021).

- A markup ratio above one must cover fixed and overhead costs (Proposition 1.13). If technology has shifted toward fixed costs, such as software and overhead, μ rises with no

rise in profits. Which costs count as variable, cost of goods sold or also overhead, matters for the trend. A shift of the population toward firms with larger fixed costs or lower costs of goods sold moves the average markup by composition alone (Asker and Nocke, 2021, p. 258). De Loecker, Eeckhout and Unger reply that the rise in markups "is not merely to offset a rise in overhead costs" (quoted in Asker and Nocke, 2021, p. 258, n. 205). They find that markups rose by more than overhead costs, and that the excess markups are highest for the firms with high overhead costs. Their measure of profits rose too, as did market value as a share of sales.

- The average depends on the weights. A revenue-weighted mean rises when sales move toward large firms with high markups, even if no firm's markup changes.
- The relation between markups and concentration across industries is subject to every problem of Section 1.4.

Descriptive evidence on concentration itself gives a modern version of the Demsetz pattern of Section 1.5.1. Ganapati (2021) examines detailed firm-level Census data for 1972–2012. As reported by Asker and Nocke (2021, p. 259), increases in concentration are positively correlated with productivity and with real output growth. They are uncorrelated with price changes and with overall payroll, and they are negatively correlated with labor's share of revenue. Concentration rose where output and productivity grew, without the price increases that the market-power reading would predict. This fits the efficiency reading better than the market-power reading, although, as Section 1.5.1 showed, it cannot rule out market power.

Berry et al. (2019), to whom Asker and Nocke (2021, p. 259, n. 206) point for an IO perspective on this literature, develop the last point of the bulleted list above. Their argument, summarized in Section 1.5.3, is that different changes in primitives can produce the same correlation between concentration and markups, with very different positive and normative implications (Berry et al., 2019, p. 47). Following Bresnahan (1989), they hold that the effect of concentration cannot be interpreted without demand, the marginal costs of firms and the nature of oligopolistic competition (Berry et al., 2019, p. 48). They regard the production approach as persuasive evidence that markups have risen, although the size and causes of the rise remain open (Berry et al., 2019, p. 49). Because industries are so heterogeneous, they argue that careful industry studies are also needed. They call for many more such studies (Berry et al., 2019, pp. 50 and 53).

A demand-side study of one large industry models these three objects and reaches a contrasting answer.

The US automobile industry. Grieco et al. (2024), GMY below, ask whether market power in the US new-car market rose between 1980 and 2018, a period over which the production approach reports rising markups. We cite the author manuscript on hand, whose title page is dated July 5, 2023. Its table and figure numbers may differ from those of the published article. Product data from Ward's Automotive give the sales, list prices and characteristics of new cars and light trucks. An observation is a make-model-year, such as the 1987 Honda Accord, and the sample has 9,694 of them (Table I). The market size is the number of US households divided by 2.5. The divisor reflects that a household owns nearly two cars and keeps each for about five years. Survey data add the demographics of buyers and the models they name as their second choices.

Model and identification. Demand is a random coefficients logit of the kind developed in Chapter 8. Household i in year t obtains from model j the utility

$$u_{ijt} = x_{jt}\beta_i - \alpha_i p_{jt} + \xi_{jt} + \epsilon_{ijt}$$

in our sign convention for price (their equation 1). The tastes (α_i, β_i) depend on demographics drawn from the Current Population Survey and on normal taste shocks (equations 3 and 4). Manufacturers set the prices of all their models in a static Nash-Bertrand game each year. The first-order conditions are those of Proposition 1.37 (their equation 6). GMY solve them for the marginal cost of every model at the estimated demand parameters, as in (1.73). The price instrument is the real exchange rate of the country where the model is built, lagged one year and taken from the Penn World Table. It moves with local labor costs and with the nominal exchange rate, so it shifts the cost of supplying the US market. Average unobserved quality and the value of the outside good both move the total share of new cars each year. The year effects alone cannot separate them. GMY follow Pakes et al. (1993) and assume that, for models sold in two consecutive years without a redesign, the change in ξ_{jt} has mean zero (their equation 2).

Estimation is by the generalized method of moments (GMM) in three steps (their Section 5). The first matches micro moments, such as the average price paid by each income quintile and the correlation of characteristics between first and second choices. The second regresses the estimated mean utilities on characteristics, price, make and year dummies by two-stage least squares with the exchange-rate instrument. The third applies the continuing-model restriction to the estimated year effects. Standard errors come from a bootstrap of the micro data.

Table 1.4: Markups, concentration and welfare in the US new-car market

Panel A. Baseline estimates

	1980	2018	Source
Median Lerner index	0.325	0.185	Figure VIa, p. 2
Share-weighted mean Lerner index	0.42	0.22	Table VII
Share-weighted mean Lerner index, log price	0.32	0.27	p. 21
Herfindahl index (HHI points)	2661	1132	Table VII
Consumers' share of total surplus	0.62	0.82	p. 2

Panel B. Hypothetical cartels in 2018 (Table VII)

Cartel members	Mean Lerner index	HHI points
None (2018 baseline)	0.22	1132
GM, Ford and Toyota	0.26	2546
Top three and Fiat	0.35	3724
Top four and Honda	0.39	4819
Top five and Nissan	0.46	6000

Notes: The Lerner index is $\frac{p-mc}{p}$, with marginal costs implied by Nash-Bertrand pricing. Means are weighted by market shares. Total surplus is the sum of consumer surplus, producer surplus and deadweight loss, which the authors call efficient surplus. In Panel B, parent companies join the cartel in order of 2018 sales, and Fiat is the parent of Chrysler. Source: Grieco, Murry and Yurukoglu (2024), author manuscript (title page dated July 5, 2023), with the table, figure and page numbers of that manuscript.

Results. Table 1.4 collects the main numbers. The median Lerner index fell from 0.325 in 1980 to 0.185 in 2018, and the share-weighted mean fell from 0.42 to 0.22 (Figure VIa and Table VII). Markups fell across the distribution, for every vehicle style and for imported as well as domestic models (Figures VI and VII). Demand became more elastic. The share-weighted average own-price elasticity was −4.23 in 1985 and −5.36 in 2015, and the market elasticity moved from −1.07 to −1.29 (Table V). Concentration fell as well, and consumers gained. The share of total surplus going to consumers rose from 0.62 to 0.82, and consumer surplus per household rose by roughly $8,000 (p. 2). GMY attribute the gain mainly to better product

quality and better production technology.

Two checks address the main threats to this conclusion. With log price in utility in place of price, the mean Lerner index still falls, from 0.32 to 0.27 (p. 21). The supply side assumes Nash-Bertrand pricing throughout, so a move toward collusion could hide rising market power. Under fixed alternative conduct, collusion among the three US manufacturers or among all firms, markups still decline (Figure X). Panel B of Table 1.4 asks how large a cartel in 2018 would have to be to restore the 1980 mean of 0.42. Only a cartel of the six largest parent companies exceeds it. GMY judge that a cartel of that scale would hardly escape the notice of antitrust authorities (p. 27).

Comparison with the production approach. GMY compare their series with the auto-industry estimates of De Loecker et al. (2020) in their Section 5.6 and Figure XI. They also restate the economy-wide rise from 1.21 to 1.61 in the sales-weighted ratio of price to marginal cost (p. 28), which matches the figures above. The two auto series differ in level and in trend, although both are fairly flat after 1995. GMY give three reasons why the production approach may fail in this industry. First, cost of goods sold includes fixed manufacturing overhead under US accounting rules, so it is not the freely chosen input that Proposition 1.30 requires. Second, the output elasticity is estimated from revenue in place of physical output, as in the critique of Bond et al. (2021). It is also pooled with firms in many other manufacturing industries that share its two-digit code. Third, Compustat covers only listed firms. Several manufacturers that sell in the US never appear in it, and its revenues include sales outside the US and of other products.

The next example shows why a markup, even a correctly measured one, is a poor guide to welfare when products improve.

Example 1.31 (Quality, markups and consumer surplus)**.** This example follows Grieco et al. (2024, p. 26, n. 13). A monopolist sells one product with constant marginal cost mc to M consumers, who may instead choose an outside good. Consumer i obtains utility $\xi - \alpha p + \epsilon_i$ from the product and ϵ_{i0} from the outside good. The shocks are type-I extreme value, and ξ measures quality. Let $v = \xi - \alpha p$. The share of buyers and its price derivative are

$$s = \frac{e^{v}}{1 + e^{v}}, \qquad \frac{\partial s}{\partial p} = -\alpha s(1 - s).$$

The first-order condition $s + (p - mc)\frac{\partial s}{\partial p} = 0$ gives the dollar markup

$$p - mc = \frac{1}{\alpha(1 - s)}.$$

Now raise quality and hold mc fixed. Since $\mathrm{d}s = s(1-s)\,\mathrm{d}v$ and $\mathrm{d}v = \mathrm{d}\xi - \alpha\,\mathrm{d}p$, differentiating the markup equation gives

$$\mathrm{d}p = \frac{\mathrm{d}s}{\alpha(1-s)^2} = \frac{s}{\alpha(1-s)}\left(\mathrm{d}\xi - \alpha\,\mathrm{d}p\right).$$

Collect the terms in $\mathrm{d}p$, using $1 + \frac{s}{1-s} = \frac{1}{1-s}$:

$$\frac{\mathrm{d}p}{1-s} = \frac{s}{\alpha(1-s)}\,\mathrm{d}\xi \quad \Longrightarrow \quad \frac{\mathrm{d}p}{\mathrm{d}\xi} = \frac{s}{\alpha} > 0.$$

The dollar markup rises one for one with price. The Lerner index rises too, because

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left(\frac{p-mc}{p}\right) = \frac{mc}{p^2}\frac{\mathrm{d}p}{\mathrm{d}\xi} > 0.$$

Yet the net utility of the product rises as well:

$$\frac{\mathrm{d}v}{\mathrm{d}\xi} = 1 - \alpha\frac{\mathrm{d}p}{\mathrm{d}\xi} = 1 - s > 0.$$

Consumer surplus is $\frac{M}{\alpha}\ln(1+e^v)$ up to a constant, by the log-sum formula of Section 7.6.1, so it rises with v. A better product raises the markup, by either measure, and consumer surplus at the same time.

The data of GMY show the converse case. Better cars were also costlier to build. Over 1980 to 1999, average shares and their price derivatives were stable while average prices rose (their Section 5.4.1 and Figure VIII). For a single-product firm the first-order condition gives

$$\frac{p-mc}{p} = -\frac{1}{p}\,s\left(\frac{\partial s}{\partial p}\right)^{-1}$$

(their equation 7). Stable shares and derivatives keep the dollar margin fixed, so a higher price lowers the Lerner index. A counterfactual that holds observed characteristics at their 1980 distribution removes the rise in marginal cost and much of the fall in markups (Figure IX). In both directions the lesson is the one GMY draw. A markup is a poor measure of performance over long periods in which products change (p. 2). Chapter 8 develops the model behind such studies, and Appendix C estimates simpler demand models on the replication data of GMY.

The SCP paradigm and its critics leave one lesson for the rest of the book. Cross-industry correlations between margins and concentration cannot separate demand, cost and conduct, because all three determine both variables at once. The response is to study one industry at a time, with a model of its demand, its costs and the conduct of its firms. Section 1.6 turns to that response.

1.6 The New Empirical Industrial Organization

The cross-industry program of Section 1.3 asked a single regression to separate demand, cost and conduct across hundreds of industries. From the late 1970s the field moved in the opposite direction. Researchers studied one industry at a time, wrote down an explicit model of its demand, cost and conduct, and estimated the conduct of firms as a parameter. Bresnahan (1989) named this program the *New Empirical Industrial Organization* (NEIO) and gave it its first systematic statement. This section presents the origins of the NEIO, its principles, its workhorse model and its treatment of conduct. Section 1.7 then asks which features of the data reveal market power. Figure 1.5 places the main contributions in time.

1.6.1 Industry studies before the NEIO

Industry studies are older than the SCP paradigm. From the 1930s economists wrote detailed case studies of single industries. These studies described pricing, capacity and rivalry with care. They made little attempt to generalize beyond the industry at hand, and the theory

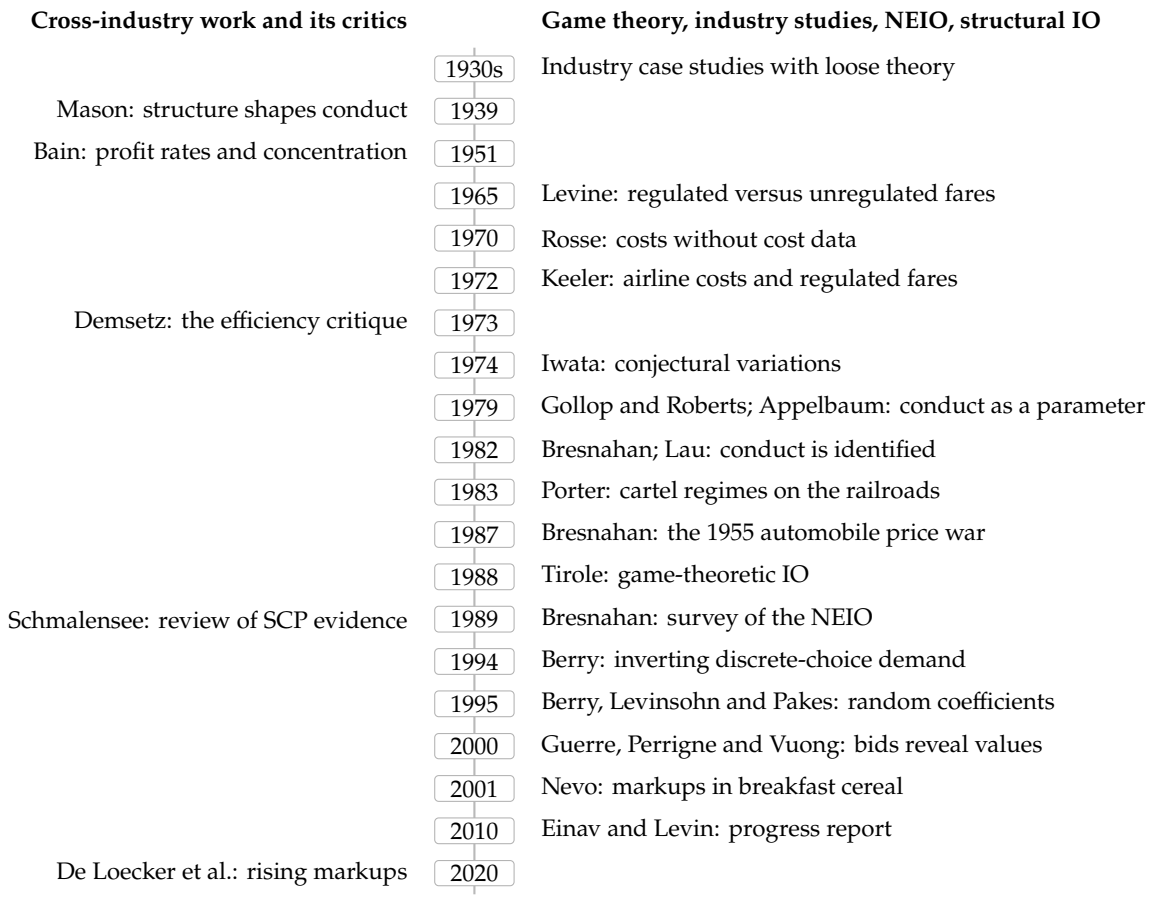

Figure 1.5: A timeline of empirical industrial organization. Left: the cross-industry tradition, its critics and its recent revival (Mason, 1939; Bain, 1951; Demsetz, 1973; Schmalensee, 1989; De Loecker et al., 2020). Right: game-theoretic IO, single-industry work, the NEIO and the structural demand and supply models that followed (Tirole, 1988; Levine, 1965; Rosse, 1970; Keeler, 1972; Iwata, 1974; Gollop and Roberts, 1979; Appelbaum, 1979; Bresnahan, 1982; Lau, 1982; Porter, 1983a; Bresnahan, 1987, 1989; Berry, 1994; Berry et al., 1995; Guerre et al., 2000; Nevo, 2001; Einav and Levin, 2010). Rows are in chronological order and are not drawn to scale.

behind them was loose. A case study could document that prices were high and stable. It could rarely say whether this reflected market power, high costs or something else.

The clearest successes came in regulatory economics. Levine (1965) compared air fares between Los Angeles and San Francisco with fares in markets regulated by the Civil Aeronautics Board. Purely intrastate carriers on this route, such as Pacific Southwest Airlines, were outside the Board's economic jurisdiction. The California Public Utilities Commission, their only regulator, could not control entry (Levine, 1965, pp. 1430–1431). The jet coach fare on this 350-mile route was about 3.9 cents per mile. The national average jet coach fare was about 5.5 cents per mile, over longer stages that are cheaper to operate (Levine, 1965, p. 1433). Keeler (1972) estimated an airline cost function from interstate data and adjusted it to the operating practices of the California intrastate carriers (Keeler, 1972, pp. 400–401). He used seating densities matching those of Pacific Southwest Airlines and a 60 percent load factor, below what the California carriers had achieved (Keeler, 1972, pp. 405–406, 415 and 417). The resulting cost-based fares came within 3 percent of actual fares on two California intrastate routes. Among the 30 densest routes in 1968, regulated coach fares exceeded these cost-based fares by 20 to 95 percent, and the markup tended to rise with distance (Keeler, 1972, p. 416 and Table 6). Both studies shaped the case for airline deregulation in the late 1970s, the starting point of Chapter 9. Their method compared prices with a competitive benchmark that the data supplied directly, either an unregulated market or an estimate of cost.

Rosse (1970) took a route that anticipated the NEIO. His title, which promises cost estimates "without using cost data" (Section 1.2.3), states the central idea of the later literature. He studied local newspapers, each treated as a monopolist, and inferred marginal cost from the firm's pricing condition once demand had been estimated. The application needed care because a newspaper sells two products. It sells circulation to readers and space to advertisers, and the demand on each side depends on the other.

Let Q^c denote circulation, Q^a the column inches of advertising and Q^e the column inches of editorial content. The circulation price P^c is the average price per subscription copy and the advertising price P^a is the average price per inch. Suppressing demand shifters and error terms, the inverse demands are

$$P^a = P^a(Q^a, Q^c), \qquad P^c = P^c(Q^a, Q^c, Q^e). \tag{1.40}$$

Advertisers pay more to reach more readers, so $\frac{\partial P^a}{\partial Q^c} > 0$. The newspaper chooses (Q^a, Q^c, Q^e) to maximize

$$\Pi = P^a(Q^a, Q^c)\, Q^a + P^c(Q^a, Q^c, Q^e)\, Q^c - C(Q^a, Q^c, Q^e).$$

The marginal revenue of a product is the derivative of the firm's entire revenue with respect to that product's quantity. For circulation, with $mc^c = \frac{\partial C}{\partial Q^c}$, the first-order condition is

$$P^c + Q^c \frac{\partial P^c}{\partial Q^c} + Q^a \frac{\partial P^a}{\partial Q^c} - mc^c = 0.$$

Solving for the circulation price gives the two-sided pricing condition (Bresnahan, 1989, eq. 6c)

$$P^c = mc^c - Q^c \frac{\partial P^c}{\partial Q^c} - Q^a \frac{\partial P^a}{\partial Q^c}. \tag{1.41}$$

The second term is the usual monopoly markup. The third term is new. It is the extra advertising revenue that one more reader generates, and it lowers the circulation price. To

see its size, divide (1.41) by P^c. Define the inverse demand elasticities $f^c = -\frac{\partial \ln P^c}{\partial \ln Q^c} > 0$ and $f^{ac} = \frac{\partial \ln P^a}{\partial \ln Q^c} > 0$. Then

$$\begin{aligned}\frac{P^c - mc^c}{P^c} &= -\frac{Q^c}{P^c}\frac{\partial P^c}{\partial Q^c} - \frac{Q^a}{P^c}\frac{\partial P^a}{\partial Q^c} \\ &= f^c - \frac{P^a Q^a}{P^c Q^c} \cdot \frac{Q^c}{P^a}\frac{\partial P^a}{\partial Q^c} = f^c - \frac{P^a Q^a}{P^c Q^c} f^{ac}.\end{aligned}$$

The circulation price lies below marginal cost whenever $\frac{P^a Q^a}{P^c Q^c} f^{ac} > f^c$. This happens when advertising revenue is large relative to circulation revenue and advertisers value readers highly. Most newspaper revenue comes from advertising (Bresnahan, 1989, p. 1037), so a reader price below marginal cost is a natural outcome. A markup test applied to circulation alone would find price below marginal cost and could wrongly conclude that newspapers have no market power. The theory of two-sided platforms later generalized this logic (Rochet and Tirole, 2003; Armstrong, 2006).

Rosse estimated the demand system (1.40) jointly with the pricing conditions. The cross-equation restrictions between demand and marginal revenue then deliver marginal cost from the condition that marginal cost equals marginal revenue. This let him treat marginal cost flexibly, for example by allowing transitory shocks to firm size to separate short-run from long-run marginal cost. The approach is only as good as the estimated marginal revenue. A linear demand curve may fit the data well and still give a poor estimate of its slope at the observed point (Bresnahan, 1989, p. 1021).

Two developments turned such isolated studies into a research program. The first was the critique of SCP regressions developed in Sections 1.4 and 1.5. The second was the game theory revolution of the 1980s, which gave the field sharp models of product differentiation, entry, pricing strategies and asymmetric information (Tirole, 1988). Models proliferated so quickly that prominent members of the field lamented their overabundance (Fisher, 1989; Peltzman, 1991). Einav and Levin (2010, p. 146) note a lasting effect of this abundance. Because predictions depended on fine details of preferences, information and commitment, empirical researchers learned to take the institutional details of each market seriously. A single industry, studied with an explicit model, was the natural place to do so.

Tirole (1988, Introduction) tells this history as two waves of interest in the field. The first was the empirical Harvard tradition of Section 1.3. Alongside it, the "Chicago tradition" of Aaron Director and George Stigler stressed rigorous theory and the empirical identification of competing theories. It also took a permissive view of vertical restraints and predatory pricing, treating collusion as the main offense, and it distrusted government intervention more than the Harvard tradition did. By the early 1970s many felt that theory served more to explain statistical results or to buttress positions than to investigate markets systematically. Joskow (1975, p. 273) wrote that "the important messages are being carried by the informal theories, stories, and behavioral observations." The formal models, in his phrase, were "trotted out ex-post" to show that some formal apparatus could explain what was observed. Tirole attributes the second, mainly theoretical, wave, which started in the 1970s, to three causes. On the demand side, researchers were dissatisfied with the limits of cross-section work. On the supply side, leading theorists entered a field they had long ignored, and noncooperative game theory became its standard tool. Game theory also made progress in two areas central to IO, dynamics and asymmetric information. Tirole saw the new intra-industry studies of Porter (1983a) and Bresnahan (1987) as a sign that theory would soon feed back into empirical work (note 8).

1.6.2 Principles of the NEIO

Bresnahan (1989, p. 1012) summarizes the new approach in four ideas.

1. Price-cost margins are not observed. Economic marginal cost cannot be read from accounting data. The analyst infers it from firm behavior, uses differences between closely related markets to trace the effects of changes in marginal cost, or quantifies market power without measuring cost at all.
2. Industries have important idiosyncrasies. Institutional detail affects conduct, and it affects the measurement strategy even more. Comparative statics across industries are therefore suspect unless the markets are closely related.
3. Firm and industry conduct are unknown parameters. The behavioral equations by which firms set prices and quantities are estimated, and their parameters map into the notions of conduct of oligopoly theory.
4. The inference is explicit about its alternatives. The set of hypotheses is stated in advance. It includes the hypothesis of no strategic interaction, typically perfect competition, and the data can select it.

The NEIO defined itself against three maintained hypotheses of the SCP paradigm (Bresnahan, 1989, pp. 1012–1013). The first was that economic price-cost margins can be observed in accounting data. The second was that cross-industry differences in structure can be captured by a few observable measures, such as concentration ratios. The third was that empirical work should estimate the reduced-form relation between structure and performance. The gridlock over the meaning of high accounting profits, described in Section 1.5.1, showed where these hypotheses led. No cross-industry regression could tell the market-power reading from the efficiency reading, because both predict the same correlation.

The NEIO kept what the SCP paradigm had added to the field, namely systematic statistical evidence. It combined that evidence with the attention to a single industry that marked the older case studies. In Bresnahan's words, the NEIO at its best takes "the best from the two great empirical IO traditions" (Bresnahan, 1989, p. 1013). A typical NEIO paper is first of all an econometric model of one industry, with economic theory guiding both the specification and the inference.

In practice these ideas translate into a recognizable research design.

- The unit of study is one industry, observed either as a time series or as a cross-section of geographic markets. Observations are similar to one another, so fewer factors are omitted than in a cross-section of industries.
- Knowledge of the institutions guides the specification: which inputs matter, how the market clears, whether firms choose prices or quantities, and which prices are list prices and which are transaction prices.
- Economic costs are inferred from pricing decisions rather than read from accounts. The inversion $\hat{c} = p\left(1 - \frac{1}{\hat{\varepsilon}^R}\right)$ of Corollary 1.11 is the simplest example.
- Conduct is a parameter with an explicit interpretation (Section 1.6.4).
- External validity is claimed qualitatively. Some industries are studied as laboratories, for example ketchup, yogurt, laundry detergents or cement, and their value lies in mechanisms that travel to other markets. Others matter in their own right, for example

health care, education, automobiles or airlines, and the specific numbers carry policy weight.

Einav and Levin (2010, p. 147) make the same point about generality. The lasting lessons of industry studies tend to be qualitative insights, such as the finding that entry can have large effects on prices, or methods that apply in many settings.

A last principle concerns data. Economists in the field had long felt starved of appropriate data. The early NEIO studies show this view to be false (Bresnahan, 1989, p. 1025). The dissertations of Rosse, Bresnahan and Suslow built their data from public industry sources, without relying on government statistics for the endogenous variables. Porter's railroad data, discussed next, also came from industry records.

1.6.3 Bresnahan's stylized model

Most NEIO studies of homogeneous-good industries share one econometric structure. We present it in general form, following Bresnahan (1989, Section 2.1) in the notation of this book, and then sketch Porter's study of a railroad cartel as an illustration.

Variables and equations. Firms are indexed by $i = 1, \ldots, N$ and observations, usually time periods, by t. The industry sells a single product, so industry output $Q_t = \sum_i q_{it}$ is well defined. Demand has no intertemporal links from durability, habits or learning. The endogenous variables are the market price P_t and each firm's output q_{it}, or only Q_t when firm data are missing. Price-cost margins are not observed. The exogenous variables are demand shifters Y_t, factor prices W_{it} paid by firm i, and other cost shifters Z_{it}, such as fixed factors in a short-run cost function. Three sets of unknown parameters describe demand (γ), cost (Γ) and conduct (ϑ). The econometric errors u_t^d and u_{it}^c may enter nonlinearly and need not be scalars. The model has five parts.

$$P_t = P(Q_t, Y_t, \gamma, u_t^d), \tag{1.42}$$

$$C_{it} = C(q_{it}, W_{it}, Z_{it}, \Gamma, u_{it}^c), \tag{1.43}$$

$$mc_{it} = C_q(q_{it}, W_{it}, Z_{it}, \Gamma, u_{it}^c), \tag{1.44}$$

$$P_t = C_q(q_{it}, W_{it}, Z_{it}, \Gamma, u_{it}^c) - P_Q(Q_t, Y_t, \gamma, u_t^d)\, q_{it}\, \vartheta_{it}. \tag{1.45}$$

Equation (1.42) is the inverse demand curve, (1.43) the cost function and (1.44) marginal cost, where $C_q = \frac{\partial C}{\partial q}$. Equation (1.45) is the *supply relation* of firm i, with $P_Q = \frac{\partial P}{\partial Q} < 0$ the slope of inverse demand. Solving the demand equation and the N supply relations together gives the reduced forms

$$P_t = P^*(W_t, Z_t, Y_t, \Theta, u_t), \qquad q_{it} = q_i^*(W_t, Z_t, Y_t, \Theta, u_t), \tag{1.46}$$

where $\Theta = (\gamma, \Gamma, \vartheta)$ collects all parameters, u_t all errors, and W_t and Z_t the shifters of all firms. Equations (1.42) to (1.46) are Bresnahan's equations (1) to (5) and (5′). We write Θ where Bresnahan writes Ω, because Ω is the ownership matrix in this book, and γ where he writes δ.

The supply relation. The supply relation states that marginal cost equals a "perceived" marginal revenue. For a monopolist, $P + P_Q\, Q$ is marginal revenue. In (1.45) the term $-P_Q\, q_{it}\, \vartheta_{it}$ is the wedge between price and marginal cost, and $\vartheta_{it} \geq 0$ indexes how far the conduct of firm i departs from price taking. The value $\vartheta_{it} = 0$ is price taking. The value $\vartheta_{it} = 1$ is Cournot conduct and, with a single firm, monopoly. Bresnahan calls it a supply relation because outside perfect competition firms have no *supply curve*, that is, no function $Q = S(P)$ that solves

$P = mc(Q)$ (Bresnahan, 1989, fn. 6). A firm with market power chooses its output in response to the whole demand curve, including its slope, so the same price can go with different outputs.

Equation (1.45) seems to contain marginal cost, which the NEIO treats as unobserved. The contradiction is only apparent. In the model, marginal cost is a function of the unknown parameters Γ, and it can be computed only after Γ has been estimated. Most methods estimate Γ and ϑ in the same econometric step. A conduct parameter that varies freely by firm and period would overparameterize the model. Bresnahan writes it this way only to nest all known oligopoly theories, and every application restricts how ϑ_{it} varies.

Remark 1.32 (Firm-level and industry conduct). Bresnahan uses one symbol for two normalizations of conduct, and we keep them apart. The firm-level parameter ϑ_{it} in (1.45) equals $1 + r_i$ in the conjectural-variations notation of Section 1.2.5. It is 0 for price taking, 1 for Cournot and N for symmetric collusion. The industry parameter θ of this book weights each firm's conduct by its squared share, $\theta = \sum_i s_i^2 \vartheta_i$, as derived in Proposition 1.33 below. It is 0 for price taking, *HHI* for Cournot and 1 for collusion. With symmetric firms, $q_{it} = \frac{Q_t}{N}$ and $s_i = \frac{1}{N}$, so

$$\theta = \sum_{i=1}^{N} \frac{1}{N^2} \vartheta = \frac{\vartheta}{N}.$$

Symmetric Cournot ($\vartheta = 1$) gives $\theta = \frac{1}{N}$ and symmetric collusion ($\vartheta = N$) gives $\theta = 1$, the convention used throughout the book.

The core econometric methods are those for simultaneous equations, since P_t and q_{it} (or Q_t) are jointly determined. Some studies estimate (1.42) and (1.45) directly as structural equations, which is attractive because the conduct parameters are the object of interest. Studies that lack price, quantity or firm-level data estimate reduced forms such as (1.46) or aggregate the supply relations to the industry level.

An illustration: the Joint Executive Committee

Bresnahan (1989) develops the stylized model alongside one application, Porter's (1983a) study of a nineteenth-century railroad cartel. We sketch that study here and draw out what it teaches about the NEIO. The full case study, with the theory of Green and Porter (1984) behind it and later reanalyses, appears in Chapter 13.

The Joint Executive Committee (JEC) was a legal cartel that controlled eastbound freight shipments from Chicago to the Atlantic seaboard (Porter, 1983a, p. 302). Porter asks whether its prices switched between collusive and price-war regimes, as trigger-price theories of collusion predict. The data are weekly records from the first week of 1880 to the sixteenth week of 1886, which gives 328 observations. Quantity Q_t is the tonnage of grain shipped by members, and price P_t is the grain rate in dollars per 100 pounds (Porter, 1983a, Table 2). Demand has constant elasticity and shifts down when the Great Lakes are open to shipping. The supply relation is the industry version of (1.45), derived in Proposition 1.33 below. Conduct takes a collusive value θ^c in some weeks, and Porter normalizes conduct during price wars to the Bertrand value $\theta^w = 0$. He treats each week's regime as an unobserved draw, collusive with a constant probability ω, and estimates the system by maximum likelihood. We write ω to keep π for profit. Demand is inelastic, with an estimated elasticity of $\hat{\varepsilon} = 0.80$ (Porter, 1983a, Table 3). With the lakes closed, predicted prices are 0.2780 dollars in collusive weeks and 0.1673 in price-war weeks (Porter, 1983a, Table 4). Collusion thus raised price by 66 percent and lowered quantity by 33 percent (Porter, 1983a, p. 310). The implied collusive conduct

parameter is $\hat{\theta}^c = 0.336$, which Porter calls roughly consistent with Cournot behavior (Porter, 1983a, p. 309). Section 13.3 develops the model and estimates.

Bresnahan (1989, p. 1018) summarizes these findings in three statements. First, successful collusion raised price by about 40 percent. This is the 0.40 reported for Porter in Table 1.7. It measures the gap from the collusive price, since $1 - \frac{0.1673}{0.2780} = 0.40$. Porter's 66 percent measures the same gap from the price-war price. Second, the implied conduct was about as anticompetitive as Cournot. Only the gap between the regimes is identified, because conduct during wars and the cost intercept enter the supply relation together. The Cournot reading therefore rests on the unidentified assumption that price-war conduct was price taking (his fn. 10). Third, the cartel broke down 28 percent of the time.

What the illustration teaches. Bresnahan sees three advantages in this structural approach (Bresnahan, 1989, p. 1018). First, every parameter has an economic meaning, so implausible estimates are diagnostic. Porter's demand elasticity is an example. With $\hat{\varepsilon} = 0.80 < 1$, industry marginal revenue is negative, so the collusive weeks cannot reflect static joint profit maximization (Porter, 1983a, p. 308). A conduct parameter of one would imply a Lerner index of $\frac{1}{0.8} = 1.25$, which is impossible with positive marginal cost. Second, if the interpretation of conduct is right, the link between the estimates and oligopoly theory is clear. Third, because the model is structural, the reason why the data identify conduct can be stated. Section 1.7 takes up this third point.

Bresnahan also notes what the specification leaves out (Bresnahan, 1989, p. 1025). A single constant probability ω tells us how often the cartel broke down. It cannot tell us what triggered breakdowns or what ended them, which is where theories of collusion disagree. Answering that question needs a state-dependent switching probability. Bresnahan doubts that the data can discriminate among the theories. A test of whether there are two regimes uses every week of data, but a test of what starts and stops price wars has as many observations as there are price wars.

1.6.4 Conduct as a parameter

The stylized model treats conduct as an unknown parameter. This subsection derives the industry supply relation in general form and lists the values of conduct implied by standard theories. It then surveys how the literature specified conduct and explains how the estimates should and should not be read.

Proposition 1.33 (Industry supply relation)**.** *Consider a homogeneous good with differentiable inverse demand $P(Q)$, $P'(Q) < 0$, and N firms with differentiable costs $C_i(q_i)$. Firm i chooses q_i to maximize $P(Q)\,q_i - C_i(q_i)$, where $Q = q_i + Q_{-i}$ and the conjectural variation $r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$ of Section 1.2.5 is treated as a constant. Assume an interior solution with every firm active, and let $mc_i = C_i'(q_i)$, $s_i = \frac{q_i}{Q}$ and $\varepsilon = -\frac{P}{Q\,P'(Q)}$. Then:*

(i) Each firm satisfies the supply relation $P = mc_i - P'(Q)\,q_i\,(1 + r_i)$.

(ii) The industry satisfies

$$P = \overline{mc} - P'(Q)\,Q\,\theta, \qquad \overline{mc} = \sum_{i=1}^{N} s_i\,mc_i, \qquad \theta = \sum_{i=1}^{N} s_i^2(1 + r_i). \tag{1.47}$$

(iii) Equivalently, $\frac{P - \overline{mc}}{P} = \frac{\theta}{\varepsilon}$, and average marginal cost can be recovered as $\overline{mc} = P + \theta\,Q\,P'(Q) = P\left(1 - \frac{\theta}{\varepsilon}\right)$.

Proof. (i) The derivative of firm i's profit is

$$\frac{\mathrm{d}}{\mathrm{d}q_i}\Big[P(Q)\,q_i - C_i(q_i)\Big] = P(Q) + q_i\,P'(Q)\,\frac{\mathrm{d}Q}{\mathrm{d}q_i} - C_i'(q_i) = P + q_i\,P'(Q)\,(1+r_i) - mc_i,$$

because $\frac{\mathrm{d}Q}{\mathrm{d}q_i} = 1 + \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i} = 1 + r_i$. Setting it to zero and solving for P gives (i). (ii) Multiply (i) by s_i and sum over i:

$$\sum_i s_i P = \sum_i s_i\,mc_i - P'(Q)\sum_i s_i\,q_i(1+r_i),$$
$$P = \overline{mc} - P'(Q)\,Q\sum_i s_i^2(1+r_i),$$

using $\sum_i s_i = 1$ and $q_i = s_i Q$. (iii) Subtract $\overline{mc}$ from both sides of (1.47) and divide by P:

$$\frac{P-\overline{mc}}{P} = -\frac{Q\,P'(Q)}{P}\,\theta = \frac{\theta}{\varepsilon}.$$

Solving (1.47) for $\overline{mc}$ gives the last statement. □

Proposition 1.33 extends Proposition 1.17 to marginal costs that vary with output. It shows that one number, θ, summarizes industry conduct for the purpose of the industry markup, whatever the heterogeneity across firms. Table 1.5 lists the values implied by standard theories. The inversion in part (iii) is the conduct-adjusted version of Corollary 1.11. It is how the NEIO turns an estimated demand curve and an assumed or estimated θ into an estimate of marginal cost.

Table 1.5: Conduct implied by standard oligopoly theories

Conduct	$r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$	$\vartheta_i = 1 + r_i$	$\theta = \sum_i s_i^2(1+r_i)$	$\frac{P-\overline{mc}}{P}$
Perfect competition	-1	0	0	0
Cournot	0	1	HHI	$\frac{HHI}{\varepsilon}$
Symmetric Cournot	0	1	$\frac{1}{N}$	$\frac{1}{N\varepsilon}$
Collusion (joint profit maximum)	$\frac{1-s_i}{s_i}$	$\frac{1}{s_i}$	1	$\frac{1}{\varepsilon}$
Symmetric collusion	$N-1$	N	1	$\frac{1}{\varepsilon}$
Clarke-Davies, $\kappa \in [0,1]$	$\kappa\frac{1-s_i}{s_i}$	$\frac{\kappa+(1-\kappa)s_i}{s_i}$	$\kappa + (1-\kappa)HHI$	$\frac{\kappa+(1-\kappa)HHI}{\varepsilon}$

Notes: s_i are output shares, $HHI = \sum_i s_i^2$, and ε is the market elasticity of demand. Under collusion each firm acts as if rivals match its output in proportion to their shares, so $1 + r_i = \frac{1}{s_i}$ and $\theta = \sum_i s_i = 1$. With constant marginal costs, the collusion rows require equal costs across active firms. With rising marginal costs, they equalize marginal costs across firms. The Clarke-Davies row is Proposition 1.17: $s_i^2(1+r_i) = (1-\kappa)s_i^2 + \kappa s_i$, and summing gives $\kappa + (1-\kappa)HHI$. Perfect competition requires rising marginal cost for an interior solution.

How the literature specified conduct

Bresnahan (1989, Section 2.2) sorts the early studies into four groups by how they wrote the supply relation. The groups differ in language more than in substance.

Supply relations from a single theory. The first group derives ϑ_{it} from one explicit theory. The simplest case is monopoly or Cournot, where $\vartheta_{it} = 1$ for all firms and periods (Bresnahan, 1989, eq. 6):

$$P_t = C_q(q_{it}, W_{it}, Z_{it}, \Gamma, u^c_{it}) - P_Q(Q_t, Y_t, \gamma, u^d_t)\, q_{it}.$$

With several firms this gives one estimating equation per firm. Rosse's newspapers, with the two-sided condition (1.41), belong here.

Bertrand pricing is the other static noncooperative model. With a homogeneous product and flat marginal cost it is indistinguishable from perfect competition, so applications use differentiated products. Bresnahan (1981a) estimates such a model on the 1977 and 1978 cross-sections of American automobiles. Products are ordered on a one-dimensional quality index χ_j, with neighbors $j-1$ and $j+1$. Consumers differ in a scalar taste for quality. A consumer with taste ν who buys product j at price p_j gets $\nu\chi_j - p_j$, so she prefers j to $j+1$ exactly when $\nu < \frac{p_{j+1}-p_j}{\chi_{j+1}-\chi_j}$. (Here ν is a taste for quality. Dividing utility by ν gives the equivalent form with a consumer-specific price sensitivity used in Chapter 6.) With tastes spread uniformly with density γ_0, demand is

$$q_j = \gamma_0 \left(\frac{p_{j+1} - p_j}{\chi_{j+1} - \chi_j} - \frac{p_j - p_{j-1}}{\chi_j - \chi_{j-1}} \right) + u^d_j, \tag{1.48}$$

and quality is a hedonic function of observed characteristics x_j, such as length, weight and horsepower,

$$\chi_j = f(x_j, \gamma_1) + u^\chi_j. \tag{1.49}$$

These are Bresnahan's equations (7) and (8). Prices are manufacturer-to-dealer list prices, which equal transaction prices for most sales, and quantities are model-year production. A firm f owning the set of products $\mathcal{J}_f$ chooses prices to maximize $\sum_{k\in\mathcal{J}_f}(p_k - mc_k)\, q_k$. Differentiating (1.48),

$$\frac{\partial q_j}{\partial p_j} = -\gamma_0 \left(\frac{1}{\chi_{j+1} - \chi_j} + \frac{1}{\chi_j - \chi_{j-1}} \right), \qquad \frac{\partial q_{j+1}}{\partial p_j} = \frac{\gamma_0}{\chi_{j+1} - \chi_j}, \qquad \frac{\partial q_{j-1}}{\partial p_j} = \frac{\gamma_0}{\chi_j - \chi_{j-1}}.$$

Let $\Omega_{jk} = 1$ if the same firm sells j and k, and $\Omega_{jk} = 0$ otherwise. The matrix Ω is the *ownership matrix*, which returns in Section 1.8.1. The first-order condition $q_j + \sum_{k\in\mathcal{J}_f}(p_k - mc_k)\frac{\partial q_k}{\partial p_j} = 0$ becomes the supply relation

$$q_j = \gamma_0(p_j - mc_j) \left(\frac{1}{\chi_{j+1} - \chi_j} + \frac{1}{\chi_j - \chi_{j-1}} \right) - \Omega_{j,j+1}\, \gamma_0\, \frac{p_{j+1} - mc_{j+1}}{\chi_{j+1} - \chi_j} - \Omega_{j,j-1}\, \gamma_0\, \frac{p_{j-1} - mc_{j-1}}{\chi_j - \chi_{j-1}}, \tag{1.50}$$

the counterpart of Bresnahan's equation (6″). Marginal cost depends on the characteristics of the product. The markup of product j is large when its neighbors are far away in quality space. Bresnahan (1981a) finds large price-cost margins on the larger cars, which are also much farther apart in quality space. The obvious weakness is the restrictive demand system. Bresnahan probes it through the residuals, firm dummies and the quality error in (1.49). Chapter 6 develops the vertical model in full.

A second class of single theories gives firms different roles. In the *Stackelberg* model, firms $2, \ldots, N$ follow Cournot supply relations and the leader, firm 1, internalizes their reaction. Its supply relation is

$$P_t = C_q(q_{1t}, W_{1t}, Z_{1t}, \Gamma, u^c_{1t}) - P_Q(Q_t, Y_t, \gamma, u^d_t)\, q_{1t}\,(1 + \theta_S), \tag{1.51}$$

where θ_S is the derivative of the followers' total output with respect to q_1, obtained by solving their supply relations. A linear example shows what θ_S looks like. Let $P = a - bQ$ and let the $N-1$ followers have constant marginal cost c. Follower j's Cournot condition is $a - bQ - bq_j = c$. Summing over the followers, with $Q = q_1 + Q_F$ and Q_F their total output,

$$(N-1)(a-c) - (N-1)\,b\,(q_1 + Q_F) - b\,Q_F = 0,$$
$$Q_F = \frac{(N-1)(a - c - b\,q_1)}{Nb}.$$

Hence $\theta_S = \frac{\mathrm{d}Q_F}{\mathrm{d}q_1} = -\frac{N-1}{N}$, and the leader's firm-level conduct is $\vartheta_1 = 1 + \theta_S = \frac{1}{N}$. The leader behaves more aggressively than a Cournot firm because each unit it adds displaces part of the followers' output.

The *dominant-firm* model is closely related. Suslow (1986) estimates it for Alcoa in the interwar period, when Alcoa was the only producer of new aluminum and a fringe of firms recycled scrap. The fringe takes price as given, so its supply relation is a supply curve. Write it as $Q_{ft} = S(P_t, W_{ft}, Z_{ft}, \Gamma, u^c_{ft})$, the inverse of $P_t = C_q(Q_{ft}, \dots)$. Bresnahan's equations (10) and (10′) are these two forms. The dominant firm faces the residual demand $q_1 = Q(P) - S(P)$, where $Q(P)$ is market demand. Its slope is

$$\frac{\mathrm{d}P}{\mathrm{d}q_1} = \frac{1}{Q'(P) - S_P} = \frac{P_Q}{1 - P_Q S_P},$$

where $P_Q = \frac{1}{Q'(P)} < 0$ and $S_P = \frac{\partial S}{\partial P} \geq 0$. The first-order condition $P + q_1 \frac{\mathrm{d}P}{\mathrm{d}q_1} = mc_1$ can be written in the form of (1.45):

$$P_t = mc_{1t} - P_Q\, q_{1t}\,(1 + S_D), \qquad S_D = \frac{P_Q S_P}{1 - P_Q S_P} \in (-1, 0]. \tag{1.52}$$

These are Bresnahan's equations (11) and (11′). With no fringe response ($S_P = 0$) the leader is a monopolist on its residual demand and $S_D = 0$. As the fringe supply becomes perfectly elastic, $S_D \to -1$ and the leader becomes a price taker. In elasticity form, with s_1 the leader's share and e_S the fringe supply elasticity, $P_Q S_P = -\frac{(1-s_1)e_S}{\varepsilon}$, and

$$\frac{P - mc_1}{P} = \frac{s_1}{\varepsilon}\,(1 + S_D) = \frac{s_1}{\varepsilon + (1 - s_1)\,e_S}.$$

In Suslow's data Alcoa's marginal cost is shifted by its accounting average variable cost, which does not enter the fringe supply. The fringe supply is shifted by the stock of aluminum available for recycling. She estimates S_D to be small, so Alcoa had considerable market power despite the fringe (Bresnahan, 1989, p. 1023). She identifies Alcoa as the leader from the structure of the industry, a monopoly in new aluminum facing many recyclers.

Dynamic theories of collusion form the last part of this group. Stigler (1964) argued that cartels held together by self-interest should sometimes break down. Firms cannot always tell whether a fall in their sales reflects secret price cutting, so suspicion leads to price wars even without cheating. Green and Porter (1984) formalized this idea. Firms observe the market price but not rivals' outputs, and a low price triggers a reversion to Cournot behavior for a fixed period. The cartel chooses the collusive output, the trigger price and the length of punishment to maximize expected profit. It does not push price to the monopoly level, because a higher price raises the gain from cheating. Abreu et al. (1986) find more profitable designs

in which both the start and the end of a price war are triggered, so wars have random length and endogenous severity. Rotemberg and Saloner (1986) let demand fluctuate. When current demand does not predict future demand, the gain from defecting is largest in booms, so the cartel must lower its price in booms. All these theories imply that ϑ_{it} varies over time. They differ in the predicted timing of the regimes, which is why Porter's constant ω cannot tell them apart. Chapter 12 develops these models.

Testing a small set of theories. A second group estimates the supply relations of a few distinct theories and tests among them. Bresnahan (1987) uses the vertical model (1.48) for the American automobile industry in the mid-1950s. Under joint profit maximization, $\Omega_{jk} = 1$ for every pair of neighbors in (1.50), because industry marginal revenue counts every product. Under Bertrand pricing Ω_{jk} follows actual ownership. Non-nested tests favor collusion in 1954 and 1956 and Bertrand competition in 1955, the year of a large expansion of output and a fall in prices. A temporary breakdown of collusion thus explains part of the 1955 boom. Chapter 6 treats this paper as a case study. Geroski (1983) and Roberts (1984) test leader-follower theories on the coffee-roasting data of Gollop and Roberts (1979). The smaller roasters behave as price-taking followers. The leading firms behave less competitively than Cournot firms. They stop short of maximizing joint profits, even given the fringe (Bresnahan, 1989, p. 1026).

The difference between estimating a continuous ϑ and choosing among a few theories is purely econometric (Bresnahan, 1989, p. 1026). A researcher who estimates ϑ on a continuum tests theories with nested tests, and may find a value between two theories. A researcher who specifies a few theories uses non-nested tests.

Conjectural-variations language. A third group writes conduct as a conjectural variation, a firm's "expectation" of how rivals' outputs respond to its own. Starting with Iwata (1974), these papers write the supply relation as

$$P_t = C_q(\cdot) - P_Q(\cdot)\, q_{it} \left(1 + r_i(q_{it}, Q_{-i,t}, Z_{it}, \Phi)\right), \tag{1.53}$$

where the parameters Φ let conjectures depend on firm size and other variables. Iwata asked where the Japanese plate glass industry lay between competition and monopoly. He assumed, unlike most later work, that accounting data reveal margins. Gollop and Roberts (1979) let conjectures differ across firms in coffee roasting, and Spiller and Favaro (1984) and Gelfand and Spiller (1987) continued this emphasis on heterogeneous conduct in banking.

Equation (1.53) differs from (1.45) only in replacing ϑ_{it} by $1 + r_i(\cdot)$. As a matter of logic the two are identical, since $\vartheta_{it} - 1 = r_i(\cdot)$ nests the same models. Bresnahan puts it strongly: saying what the conjectural variation is and saying which theory of oligopoly holds in the data are the same statement (Bresnahan, 1989, p. 1027). The practical differences are two. Conjectural-variation papers allow all values of r_i, and they stress the link between firm size and conduct.

Aggregate data and average conduct. A fourth group has only industry data. It writes the supply relation in aggregate form (Bresnahan, 1989, eq. 16),

$$P_t = C_q(Q_t, W_t, Z_t, \Gamma, u_t^c) - P_Q(Q_t, Y_t, \gamma, u_t^d)\, Q_t\, \theta_t, \tag{1.54}$$

as in Appelbaum (1979) and Porter's study. Under the null of price taking ($\theta_t = 0$), C_q is industry marginal cost. With market power, firms generally have different marginal costs in equilibrium. Cournot firms with different costs have different margins (Cowling and Waterson, 1976), so a stable industry marginal cost curve need not exist. Proposition 1.33 gives the right reading. The aggregate $\theta_t = \sum_i s_{it}^2 \vartheta_{it}$ weights each firm's conduct by its squared share, and

$\frac{P-C_q}{P}$ is the share-weighted average markup. Some authors claimed that oligopoly theory implies identical conduct across firms (Appelbaum, 1982; Lopez, 1984). Bresnahan rejects this claim, since nothing in oligopoly theory forces firms to behave alike.

What an estimated conjecture means

The language of conjectures invites a misreading (Bresnahan, 1989, pp. 1027–1029). Suppose we read (1.53) as the first-order condition of a firm that expects rivals' outputs to depend on its own:

$$\max_{q_i} \; P\Big(q_i + \sum_{j \neq i} Q_j(q_i)\Big)\, q_i - C(q_i), \qquad 1 + r_i = \frac{\mathrm{d}q_i}{\mathrm{d}q_i} + \sum_{j \neq i} \frac{\mathrm{d}Q_j}{\mathrm{d}q_i}. \tag{1.55}$$

For Cournot conduct ($r_i = 0$) and price taking ($r_i = -1$) the reading is harmless. A Cournot firm can be described as expecting rivals' outputs to stay fixed, and a competitive firm as expecting price to stay fixed.

The trouble arises near collusion. Let all N firms have the same costs and the collusive conjecture $1 + r_i = N$. Each supply relation becomes

$$P = C_q(\cdot) - P_Q(\cdot)\, N\, q_i, \tag{1.56}$$

which is the first-order condition for maximizing the joint profit of all N firms. Read literally, $r_i = N - 1$ says that each firm expects every rival to match any change in its output one for one, $\frac{\mathrm{d}Q_j}{\mathrm{d}q_i} = 1$. Repeated games give a different account of the same outcome. Firms produce their share of the collusive output because they expect a deviation to trigger a general breakdown of restraint. The matching behavior is never observed. It is the threat that keeps it off the equilibrium path.

Bresnahan therefore separates two objects: (i) what firms believe will happen if they deviate, and (ii) what firms do as a result of those beliefs. Estimated conjectures measure only (ii). If they are stable over time and breakdowns are rare, they measure the average collusiveness of conduct. They carry no information about what would happen if one firm expanded output on its own, which is the sense of "conjectural variation" in theoretical work. The only thing they reveal about expectations is that the expectations suffice to deter departures from the normal arrangement (Bresnahan, 1989, fn. 19). For the same reason Bresnahan rejects reading the slope of $r_i(\cdot)$ in own output as evidence of "mutual forbearance".

A second interpretive issue concerns firm size. Models with different conjectures for different size classes produce an equilibrium size distribution even among identical firms. A competing explanation is that firms differ in cost. Separating the two requires firm-specific cost functions, and in particular a comparison of the marginal costs of large and small firms at the same output (Bresnahan, 1989, p. 1030 and fn. 20).

Every specification is a test of price taking

Appelbaum (1979) observed that setting every conduct parameter to zero in (1.45), or every r_i to -1, imposes price taking. Every specification of conduct, theoretical or not, therefore nests the competitive model. Its estimation is a test of price-taking behavior, the title of Appelbaum's paper, against an alternative in which firms raise price above marginal cost. This is the advance that the NEIO claims over the SCP paradigm (Bresnahan, 1989, p. 1031). When price taking is rejected, it is rejected against specific theories of market power. The interpretation of the result is then clear, and only econometric problems can cloud the inference.

Two cautions carry over to later chapters. First, an estimated θ is a reduced summary of behavior, as the discussion of conjectures shows. Corts (1999) shows that when firms collude dynamically, the estimated θ tracks how the markup responds to demand shocks at the margin. It can then differ greatly from the average markup that it is meant to measure. His Proposition 1 (p. 233) states the condition exactly, for linear demand, constant marginal cost and a symmetric equilibrium. Let q^* be equilibrium output per firm and Y a demand shifter. The estimate equals the elasticity-adjusted Lerner index that θ is meant to measure if and only if

$$\frac{P - mc}{q^*} = \frac{\frac{\mathrm{d}(P-mc)}{\mathrm{d}Y}}{\frac{\mathrm{d}q^*}{\mathrm{d}Y}}.$$

The margin per unit of output must equal the marginal response of the margin to output along demand-driven movements. Under efficient supergame collusion this condition fails. The estimated conduct parameter then understates market power unless demand shocks are fully permanent. When the shocks are completely transitory, it may detect no market power at all, even if average margins are near the monopoly level (p. 245). Chapter 3 develops this critique. Second, the theory of the conduct parameter, including its links to conjectural variations and pass-through, appears in Chapter 2.

1.7 How the data identify market power

A structural model states the class of hypotheses among which the data choose. This makes a central question answerable (Bresnahan, 1989, p. 1031). Why do the data identify the inference of market power? Which implication of perfect competition has been rejected when market power is measured? The question does not arise in the SCP paradigm, which takes margins to be observed. In the NEIO margins are estimated, so we must ask which features of the data and which natural experiments reveal them. Bresnahan distinguishes four classes of arguments: comparative statics in demand, comparative statics in cost, direct estimation of marginal cost, and supply shocks. A fifth, comparative statics in industry structure, is familiar in its logic but still lacked a sound identification argument in 1989. This section explains each, then turns to differentiated products and to what the NEIO learned.

1.7.1 The identification question

The question is this. Given equilibrium prices and quantities from different but similar markets, under what conditions can we identify conduct, or test for market power, without observing demand and cost? A linear model shows the difficulty. Let demand and marginal cost be

$$Q_t = a_0 + a_1 P_t + a_2 Y_t + u_t^d, \qquad mc_t = b_0 + b_1 Q_t + b_2 W_t + u_t^c, \tag{1.57}$$

with $a_1 < 0$, a demand shifter Y_t and a cost shifter W_t. The slope of inverse demand is $\frac{1}{a_1}$, so the supply relation of Proposition 1.33 is $P_t = mc_t - \theta \frac{Q_t}{a_1}$. Substituting marginal cost,

$$P_t = b_0 + \left(b_1 - \frac{\theta}{a_1} \right) Q_t + b_2 W_t + u_t^c. \tag{1.58}$$

The cost shifter W_t is excluded from demand, so it identifies (a_0, a_1, a_2). The demand shifter Y_t is excluded from the supply relation, so it identifies b_0, b_2 and the slope $b_1 - \frac{\theta}{a_1}$. The two

parameters b_1 and θ enter only through this slope. A competitive industry with steep marginal cost and a monopoly with flatter marginal cost produce the same data. When demand shifts out, price rises in both, either because marginal cost rises with output or because of market power. Demand shifts that move the curve in parallel cannot tell the two apart. Chapter 3 develops this observational equivalence in detail, with figures, and shows how Bresnahan (1982) breaks it. The next subsection previews the general arguments.

1.7.2 Five identification arguments

Comparative statics in demand

The first argument, due to Bresnahan (1982) and Lau (1982), uses demand shifters that change the slope of demand. Bresnahan (1989, Section 3.1) presents it in a simple version. Errors are additive, conduct θ is constant, and the slope of inverse demand depends on the demand shifters but not on quantity. The demand equation and the aggregate supply relation (1.54) become

$$P_t = P(Q_t, Y_t, \gamma) + u_t^d, \tag{1.59}$$

$$P_t = C_q(Q_t, W_t, Z_t, \Gamma) + u_t^c - P_Q(Y_t, \gamma)\, Q_t\, \theta. \tag{1.60}$$

Demand (1.59) has one endogenous regressor, Q_t, and the cost shifters provide instruments, so γ can be estimated. Call the estimate $\hat{\gamma}$ and form the constructed variable $\hat{P}_{Q,t} = P_Q(Y_t, \hat{\gamma})$. Then consider

$$P_t = C_q(Q_t, W_t, Z_t, \Gamma) + u_t^c - \hat{P}_{Q,t}\, Q_t\, \theta. \tag{1.61}$$

Equations (1.59) to (1.61) are Bresnahan's (17) to (19). Bresnahan calls the two-step procedure too ugly for anyone to use, but it shows why better estimators identify θ.

Equation (1.61) has two endogenous variables: Q_t, which enters cost, and $\hat{P}_{Q,t}Q_t$, whose coefficient is θ. Two conditions are needed to estimate θ. First, the two variables must not be perfectly collinear. If the slope of demand does not depend on Y_t, then $\hat{P}_{Q,t}$ is a constant and $\hat{P}_{Q,t}Q_t$ is proportional to Q_t. This is exactly the linear model above. Second, there must be instruments for both endogenous variables. Both conditions hold when Y_t has two elements, one that enters the slope P_Q and one that does not. A linear example is the inverse demand

$$P_t = \gamma_0 + \gamma_1 Y_{1t} + (\gamma_2 + \gamma_3 Y_{2t})\, Q_t + u_t^d,$$

in which Y_{1t} shifts demand and Y_{2t} rotates it. Lau (1982) gives a general sufficient condition. The parameter θ is identified if the inverse demand function cannot be written as $P(Q, Y) = \tilde{P}(Q, h(Y))$ for a scalar index h. With a single demand shifter the index form holds trivially, with $h(Y) = Y$, so identification requires at least two demand shifters.

Remark 1.34 (Why a single demand index is not enough). Suppose $P(Q, Y) = \tilde{P}(Q, h(Y))$ with scalar h, and ignore errors. Fix W and let $Q^*(h, W)$ be the equilibrium quantity of a model with conduct $\theta > 0$ and marginal cost $C_q(Q, W)$. Assume Q^* is strictly monotone in h, with inverse $h = H(Q, W)$. Define a new marginal cost $mc^\dagger(Q, W) = \tilde{P}(Q, H(Q, W))$, which depends only on cost variables. Consider a competitive industry with this marginal cost, and assume its equilibrium is unique. For any (h, W), the quantity $Q^*(h, W)$ satisfies $\tilde{P}(Q, h) = mc^\dagger(Q, W)$ because $H(Q^*(h, W), W) = h$. The competitive model therefore reproduces every equilibrium of the model with market power, and θ is not identified without restrictions on cost. With two demand shifters this construction fails. Two values of Y can produce the same equilibrium quantity with different slopes of demand. Competition then predicts the same price for both, while market power predicts different prices.

The economics is simple (Bresnahan, 1989, p. 1033). Suppose the demand shifters could rotate the demand curve around the equilibrium point. Under perfect competition nothing happens, because supply and demand still cross at the same point. Under monopoly or any oligopoly theory, the change in the elasticity of demand shifts perceived marginal revenue, and price and quantity respond. Market power has an idiosyncratic comparative static, and the data can detect it.

Applications need a natural experiment that changes the slope of demand. In Just and Chern (1980) the market power lies on the buying side. A concentrated processing industry buys tomatoes from many farmers, and the adoption of a mechanical harvester changed the elasticity of supply. The logic is the same as for sellers. In Bresnahan (1981a, 1987) elasticities depend on how close products are in quality space. More generally, one shifter might measure the size of the economy, such as national income, and a second the price of a substitute. The method stands or falls with the estimated demand elasticities. Critics offered other readings of the tomato harvester, and the automobile results depend on the ordering of products in quality space.

A second route uses the structure of cost. Suppose marginal cost is homogeneous of degree one in factor prices, as it is whenever it is derived from a cost function. Then every term of marginal cost involves a factor price. Any term in the supply relation that does not involve a factor price must belong to the markup (Bresnahan, 1989, p. 1034). For example, if $C_q(Q, W) = \sum_k W_k \, g_k(Q)$, the supply relation

$$P_t = \sum_k W_{kt} \, g_k(Q_t) - \theta \, Q_t \, P_Q(Q_t, Y_t, \gamma) + u_t^c$$

identifies θ from the one term that no factor price multiplies. This is how Appelbaum (1979, 1982) obtained identification. The argument leans heavily on the functional form of marginal cost and on observing the true marginal price of every input, capital in particular. The defense is robustness to other functional forms, to quasi-fixed capital and labor, and to economic rather than accounting costs of capital. Chapter 3 gives the full treatment of identification through demand, with figures and estimation.

Comparative statics in cost

Panzar and Rosse (1987) propose two ideas. The first is to estimate a reduced form and to focus on the coefficients of factor prices. The second is that a reduced-form revenue equation can be estimated even where price and quantity are not observed. Let firm i's equilibrium revenue be

$$R_{it} = R^*(W_{it}, Z_{it}, Y_t, \Theta, u_t), \tag{1.62}$$

obtained by solving demand and the supply relations for price and quantity and multiplying them. The *Panzar-Rosse statistic* is the sum of the elasticities of reduced-form revenue with respect to all factor prices,

$$\psi = \sum_k \frac{\partial R^*}{\partial W_k} \frac{W_k}{R^*}. \tag{1.63}$$

Equations (1.62) and (1.63) are Bresnahan's (20) and (21), where the statistic is called H_R. It needs little data on endogenous variables, but it needs every variable that shifts cost or demand. Revenue also avoids a quality correction. If the product is better in some markets, price per unit overstates the true price there, but revenue is unaffected.

For an elementary monopolist, which chooses one quantity, ψ has a definite sign. Let $R(Q,Y) = Q\,P(Q,Y)$ be revenue as a function of output, so that R_Q is marginal revenue. Let $Q^*(W)$ solve $R_Q(Q) = C_Q(Q,W)$, and let equilibrium revenue be $R^*(W) = R(Q^*(W))$. Differentiating the first-order condition with respect to W_k,

$$R_{QQ}\,\frac{\partial Q^*}{\partial W_k} = C_{QQ}\,\frac{\partial Q^*}{\partial W_k} + C_{QW_k} \quad\Longrightarrow\quad \frac{\partial Q^*}{\partial W_k} = \frac{C_{QW_k}}{R_{QQ} - C_{QQ}}.$$

Then $\frac{\partial R^*}{\partial W_k} = R_Q \frac{\partial Q^*}{\partial W_k}$. Because C is homogeneous of degree one in W, so is C_Q, and Euler's theorem gives $\sum_k W_k C_{QW_k} = C_Q$. At the optimum $C_Q = R_Q$. Hence

$$\psi = \frac{1}{R^*}\sum_k W_k\,R_Q\,\frac{C_{QW_k}}{R_{QQ} - C_{QQ}} = \frac{R_Q\,C_Q}{(R_{QQ} - C_{QQ})\,R^*} = \frac{(R_Q)^2}{(R_{QQ} - C_{QQ})\,R^*} \le 0, \tag{1.64}$$

since the second-order condition requires $R_{QQ} - C_{QQ} < 0$. This is Bresnahan's equation (23). The intuition is direct. A one percent increase in all factor prices raises marginal cost by one percent, and a monopolist's revenue always falls when its costs rise. Otherwise its output was too large before the increase. Panzar and Rosse (1987) show that the result holds for a monopolist with many choice variables, including several outputs, quality or advertising.

A second hypothesis also has a sharp prediction. In long-run competitive equilibrium with free entry, every firm produces at the minimum of its average cost. A proportional increase in all factor prices raises minimum average cost in the same proportion and leaves the efficient scale unchanged. Firm revenue, the product of the two, rises in the same proportion, so $\psi = 1$. Industry output falls through exit. In this case demand shifters should not enter the revenue equation, which gives a second testable restriction (Bresnahan, 1989, p. 1037 and fn. 30).

The statistic does not discriminate perfectly. It need not be positive when firms are not monopolists, although Panzar and Rosse (1987) show that it is positive in some models of oligopoly and monopolistic competition. A negative ψ can also arise for reasons other than monopoly, so false findings of monopoly are possible. The applications use cross-sections of similar local markets. Rosse and Panzar (1977) study newspapers in local media markets and reject monopoly even for newspapers that are alone in their market, which points to competition from other media. Shaffer (1982) studies banks in New York State in 1979 and rejects both monopoly and long-run competition. These studies are convincing to the extent that the cross-section reflects long-run equilibria and every cost shifter is measured and correctly entered. Chapter 3 proves the results above and discusses the test further.

A per-unit tax is the cleanest cost shifter, because it enters marginal cost one for one and is observed. Sumner (1981) builds a test of monopoly pricing on state cigarette excise taxes. Let a firm face a residual demand elasticity $\varepsilon^R > 1$ that is constant over the sample. Its marginal cost is $mc = X\phi + E + R$, where X contains observed cost factors, E unobserved ones and R the tax per pack. Marginal revenue equals marginal cost when

$$P = \frac{\varepsilon^R}{\varepsilon^R - 1}\,mc$$

(his equations 1 and 2, with his elasticity $\eta = -\varepsilon^R$). Multiplying out and absorbing the factor $\frac{\varepsilon^R}{\varepsilon^R - 1}$ into the coefficients of X gives his estimating equation (4), for state i in year t,

$$P_{it} = X_{it}\phi + \rho R_{it} + U_{it}, \qquad \rho = \frac{\varepsilon^R}{\varepsilon^R - 1} = \frac{P}{mc}. \tag{1.65}$$

Sumner calls the tax coefficient θ. We write ρ because the coefficient is a pass-through rate that equals the ratio of price to marginal cost. It differs from the conduct parameter θ of Section 1.6.4. Competition with constant marginal cost implies $\rho = 1$. The data are 1,200 state-years, for 47 states and the District of Columbia over 1954–1978, and the estimator is OLS. With state and year dummies in X_{it}, $\hat{\rho} = 1.074$ (0.013). With the national consumer price index in place of the dummies, $\hat{\rho} = 1.029$ (0.011), and a variance-components model gives 1.069 (0.013) (Table 1, p. 1017). Sumner reports implied firm elasticities of 13.5, 34.5 and 14.5 in absolute value. Every estimate is significantly above one, so atomistic competition is rejected. Yet the firm elasticities lie far above the industry elasticities of 0.3 to 0.8 found in other studies (p. 1017), so an effective cartel is rejected too. The reported elasticities equal $\frac{1}{\hat{\rho}-1}$, and Chapter 3 compares them with the exact inversion of (1.65) in its full treatment of the paper.

Sullivan (1985) and Ashenfelter and Sullivan (1987) extend the idea to settings where market price and quantity are observed. Let all firms share a constant marginal cost c, and let firm i satisfy the supply relation $P = c - P'(Q)\, q_i\, (1 + r_i)$. Solving for output and summing over firms,

$$q_i = \frac{P - c}{-P'(Q)\,(1 + r_i)} \quad \Longrightarrow \quad Q = \frac{P - c}{-P'(Q)} \sum_i \frac{1}{1 + r_i} = (P - c)\, \frac{\varepsilon\, Q}{P} \sum_i \frac{1}{1 + r_i},$$

using $-\frac{1}{P'(Q)} = \frac{\varepsilon Q}{P}$. Dividing by Q gives $\sum_i (1 + r_i)^{-1} = \frac{1}{\varepsilon L}$, where $L = \frac{P-c}{P}$. Now let $E_P = \frac{\mathrm{d} \ln P}{\mathrm{d} \ln c}$ and $E_Q = \frac{\mathrm{d} \ln Q}{\mathrm{d} \ln c}$ be the elasticities of the reduced forms with respect to marginal cost. A cost shift moves the equilibrium along a fixed demand curve, so $\varepsilon = -\frac{E_Q}{E_P}$. Hence

$$\sum_i \frac{1}{1 + r_i} = -\frac{E_P}{E_Q\, L} \;\geq\; -\frac{E_P}{E_Q}, \tag{1.66}$$

where the inequality uses $L \leq 1$, which holds when marginal cost is nonnegative. Bresnahan's equation (25) states the first relation as a weak inequality, which is all the test needs. The left side equals 1 under collusion, N under Cournot and infinity under perfect competition. The right side can be estimated from cost shifts alone. If $-\frac{E_P}{E_Q}$ exceeds one, the data reject collusion. No value of the bound can reject competition. Sullivan uses a panel of American states and years for cigarettes, with state excise taxes as the cost shifter. Assuming that costs are at least as large as taxes tightens the bound, and he rejects the hypothesis that prices are set as if by a cartel. Ashenfelter and Sullivan (1987) use year-to-year tax changes within a state in a nonparametric version. Their tests indicate that monopoly and the other simple models without at least a moderate amount of competition predict poorly how excise tax changes affect cigarette prices, sales and revenues (p. 483). They also find some evidence that tax increases do not consistently raise prices and lower sales. The main questions are whether the cost shifters proxy for other variables and whether their link to marginal cost is known. Taxes are strong on the second count.

Why do cost shifts give only inequalities while demand shifts can deliver an estimate of conduct (Bresnahan, 1989, p. 1039)? The conduct parameter lives in the supply relation. A demand shift traces out the supply relation, which is the object we want. A cost shift traces out the demand curve. It sheds light on the supply relation only indirectly.

Estimating marginal cost more directly

The previous arguments use only price and quantity as endogenous variables. A third approach estimates marginal cost from cost or factor-demand data, using the duality between cost and

production (Bresnahan, 1989, Section 3.3). Gollop and Roberts (1979) and Appelbaum (1979, 1982) add the demands for inputs, typically labor, capital and materials, to the system. By Shephard's lemma (Appendix B) the factor demands are the derivatives of the cost function with respect to factor prices. With X_{it} the vector of input demands, the system is

$$\begin{aligned} P_t &= P(Q_t, Y_t, \gamma, u_t^d), \\ P_t &= C_q(q_{it}, W_{it}, Z_{it}, \Gamma, u_{it}^c) - P_Q(Q_t, Y_t, \gamma, u_t^d)\, q_{it}\, \vartheta_{it}, \\ X_{it} &= C_W(q_{it}, W_{it}, Z_{it}, \Gamma, u_{it}^c), \end{aligned} \tag{1.67}$$

Bresnahan's equations (26) to (28). The cost parameters Γ appear in both the supply relation and the factor demands. Because C is homogeneous of degree one in W, the factor demands taken together depend on all its parameters. Every parameter of marginal cost is then estimated from the factor demands, and the supply relation is left to identify conduct.

A Cobb-Douglas example makes this concrete. Let $C(q, W) = A\, q^{\frac{1}{\rho}} \prod_k W_k^{\beta_k}$ with $\sum_k \beta_k = 1$, where ρ measures returns to scale and A, ρ and β_k are local symbols. Shephard's lemma gives

$$X_k = \frac{\partial C}{\partial W_k} = \beta_k \frac{C}{W_k} \quad \Longrightarrow \quad \ln X_k = \ln(\beta_k A) + \frac{1}{\rho} \ln q + \sum_l \beta_l \ln W_l - \ln W_k,$$

so regressions of input quantities on output and factor prices identify (A, ρ, β). Marginal cost is then known, $mc = \frac{C}{\rho\, q}$, and the supply relation $P = mc - \theta\, Q\, P_Q$ identifies θ once demand is estimated.

The method's success turns on how well marginal cost is estimated. Functional form can be checked by trying several forms and by using knowledge of the technology. Two problems remain. A demand equation for capital requires splitting capital into the price and the quantity of capital services, so the accounting criticisms of the SCP paradigm return. If all inputs are treated as variable, the estimated margins are relative to long-run marginal cost.

Hall (1988), circulated in 1986, offers a related index-number approach. Marginal cost is in principle observable as the change in input spending when output changes and nothing else does. Under constant returns, input demands are proportional to output, so $\frac{\Delta \ell}{\Delta Q} = \frac{\ell}{Q}$ for labor ℓ with wage W_ℓ. Labor's share of cost is $s_\ell = \frac{W_\ell \ell}{C}$. Then

$$\frac{W_\ell\, \Delta \ell}{s_\ell\, \Delta Q} = \frac{W_\ell\, \ell}{s_\ell\, Q} = \frac{C}{Q} = mc.$$

The labor input alone thus reveals average incremental cost, which equals marginal cost when marginal cost is flat. Short-run marginal cost is unlikely to be flat, and labor's share must still be computed. Hall applied the idea to aggregate data. Section 1.5.4 returns to its modern descendant, the production approach to markups. Bresnahan notes two regularities in practice. None of the factor-demand papers used industry detail to defend its maintained hypotheses. Conversely, none of the other NEIO papers used factor demands to improve its estimates of marginal cost, although the two approaches are complements.

Supply shocks and regime switching

The fourth argument identifies changes in conduct from the shape of the distribution of the data (Bresnahan, 1989, Section 3.4). Suppose conduct takes two values, θ^w during price wars

and $\theta^c > \theta^w$ during collusion. Two supply relations then hold in the data:

$$\begin{aligned} P_t &= C_q(\cdot) - P_Q(Y_t, \gamma)\, Q_t\, \theta^w \qquad \text{during price wars,} \\ P_t &= C_q(\cdot) - P_Q(Y_t, \gamma)\, Q_t\, \theta^c \qquad \text{during collusion,} \end{aligned} \tag{1.68}$$

Bresnahan's equations (29) and (30). Collusion occurs with probability ϖ. The analyst does not know whether two regimes exist, let alone which weeks belong to which.

Fix the exogenous variables. In each regime, price and quantity are random because of the errors, and the two regimes have different centers. A linear version shows this. Let inverse demand be $P = a - bQ + u^d$ and marginal cost $mc = c_0 + c_1 Q + u^c$. In regime $j \in \{w, c\}$ the supply relation is $P = c_0 + c_1 Q + \theta^j b Q + u^c$, and equating it with demand gives

$$Q^j = \frac{a - c_0 + u^d - u^c}{b(1 + \theta^j) + c_1}, \qquad P^j = a - b\, Q^j + u^d.$$

Since $\theta^c > \theta^w$, mean quantity is lower and mean price higher under collusion. The joint distribution of (P, Q) given the exogenous variables is a mixture with two modes, one near each regime's mean. Switching regressions and other mixture methods can detect the two modes, estimate ϖ, and classify observations. Figure 1.6 illustrates with simulated data. The emphasis differs from the previous arguments. There, identification came from comparative statics in observed exogenous variables. Here it comes from a component of the error, assumed to take two values, that enters the system as a supply shock.

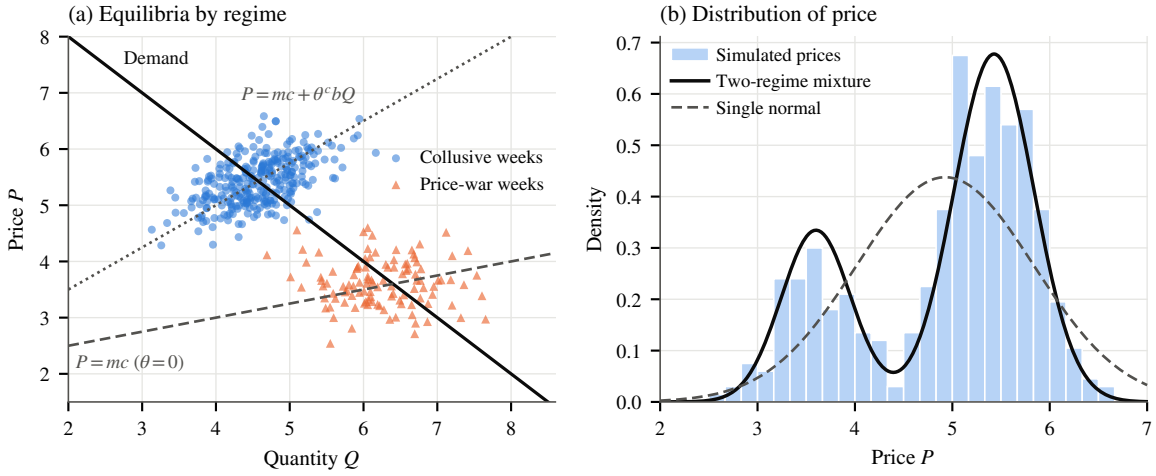

Figure 1.6: Identification of conduct regimes from the distribution of the data. The simulated market has inverse demand $P = 10 - Q + u^d$ and marginal cost $mc = 2 + 0.25\,Q + u^c$, observed for 400 weeks. Conduct is collusive ($\theta^c = 0.5$) with probability $\varpi = 0.7$ and competitive ($\theta^w = 0$) otherwise, with $u^d \sim N(0, 0.8^2)$ and $u^c \sim N(0, 0.4^2)$. Panel (a) colors each week by its true regime, which the analyst does not observe, and draws the deterministic demand curve and the two supply relations. Panel (b) shows the distribution of price that the analyst sees. The two-regime mixture fits it, while a single normal distribution does not. All values are illustrative.

The main threat to this inference is that some other unobserved shock moves the supply relation. Because the identifying variation is an error component, nothing in the procedure guarantees the conduct interpretation. Unrecorded changes in factor prices or technology could produce the same pattern, and Porter had no factor-price data. Bresnahan finds the conduct

interpretation likely in the railroad case for two reasons. The regime shifts move price and quantity by about 50 percent, and contemporary sources discuss cartel adherence extensively. An alternative is to fix the sample split in advance and estimate θ^c and θ^w separately, as Bresnahan (1987) does. This needs prior information but allows a more direct check that the apparent supply shocks reflect conduct. Chapter 13 returns to these issues with Porter (1983a) and Ellison (1994).

Comparative statics in industry structure

The fifth argument relates price to the number of firms or to concentration across similar local markets. Its logic is familiar, but Bresnahan (1989, p. 1032) judges that it still awaited its identification arguments. Section 1.5.2 presented these studies and the six difficulties Bresnahan raises. In the language of this section, all of them come back to the aggregate supply relation (1.39), which is Proposition 1.33(ii) applied market by market. A lower price in markets with more firms can mean lower average conduct θ or lower average marginal cost $\overline{mc}$. Price and quantity data alone cannot apportion the change between the two. A change in entry regulation, as in Spiller and Favaro (1984), offers cleaner variation because it moves structure for a reason unrelated to costs. The arguments of this section can then separate the two channels, for example by checking whether demand rotations identify a lower θ after deregulation.

Synthesis

Table 1.6 summarizes the arguments. Their variety reflects the variety of data across industry studies (Bresnahan, 1989, Section 3.6). Each industry offers different information and institutional detail, and therefore different defenses of different methods. The variety also reflects how many comparative statics of markets with market power have no counterpart in competitive markets.

1.7.3 Market power with product differentiation

Product differentiation raises short-run and long-run questions (Bresnahan, 1989, Section 4). In the short run the set of products and their attributes are fixed, and we ask how much market power existing differentiation confers. The question has two parts. As products become more distinct, each firm's profit depends less on rivals' prices, which the own- and cross-price elasticities of demand measure. As products become more distinct, each firm also responds less to rivals' moves, which requires a model of competitive interaction.

The conceptual issues resemble those of the homogeneous-good case, but measurement is much harder. Suppose an industry has J products and we assume constant elasticities and symmetric cross effects. Demand still has J own-price elasticities, J income elasticities and $\frac{J(J-1)}{2}$ cross-price elasticities. With $J = 100$ products this is

$$J + J + \frac{J(J-1)}{2} = 100 + 100 + 4{,}950 = 5{,}150$$

elasticities, and few industries have fewer than 100 products. Multi-product firms may also have economies of scope. Prior information from trade journals and marketing studies becomes indispensable, and how it is used varies from industry to industry.

Table 1.6: How the data identify market power

Argument	Exogenous variation	What is identified	Key maintained assumption	Applications	Full treatment
Comparative statics in demand	Demand shifters that rotate demand (Y_t entering P_Q)	Conduct θ and the slope of marginal cost separately	Correct demand specification; demand not of the form $\tilde{P}(Q, h(Y))$	Just and Chern (1980); Bresnahan (1981a, 1987)	Chapter 3
Homogeneity of marginal cost	Factor prices	θ from terms not multiplied by factor prices	Marginal cost homogeneous of degree one in observed factor prices	Appelbaum (1979, 1982)	Chapter 3
Comparative statics in cost	All factor prices, or taxes	Sign of ψ; bound on $\sum_i (1 + r_i)^{-1}$	All cost shifters measured; long-run equilibrium (for ψ); known link to marginal cost	Rosse and Panzar (1977); Shaffer (1982); Sullivan (1985); Ashenfelter and Sullivan (1987)	Chapter 3
Direct estimation of marginal cost	Factor prices with input quantities	Marginal cost from factor demands, then θ	Cost-function form; correct price of capital services	Gollop and Roberts (1979); Appelbaum (1982); Hall (1988)	Section 1.5.4
Supply shocks	Unobserved two-valued shock to the supply relation	Frequency and size of regime changes in conduct	No other unobserved shifts in the supply relation	Porter (1983a); Lee and Porter (1984)	Chapter 13
Comparative statics in structure	Number of firms or concentration across local markets	Reduced-form price and structure relation	Structure exogenous; average cost unrelated to structure	Graham et al. (1983); Spiller and Favaro (1984)	Section 1.5.2
Residual demand	Cost shifters specific to one firm	Elasticity of the firm's residual demand	Firm's costs move independently of rivals' costs	Baker and Bresnahan (1988)	Chapter 3

Notes: The first six rows follow the classification of Bresnahan (1989, Section 3) and are introduced in Section 1.7.2. The last row is the summary-statistic approach of his Section 4, introduced in Section 1.7.3. The last column gives the place in this book where each argument is developed in full.

The most common shortcut treats the products as close substitutes, uses a price index as the observed price, and proceeds as for a homogeneous good. Bresnahan warns that this can attribute to conduct what is due to product differentiation (Bresnahan, 1989, p. 1046). The next example makes the warning precise.

Example 1.35 (Differentiation that looks like conduct)**.** Let J symmetric single-product firms set prices in a Bertrand equilibrium with constant marginal cost. Let $\varepsilon_{\text{own}} > 0$ be each product's own-price elasticity (as a positive number) and $\varepsilon_{\text{cross}} \geq 0$ the cross-price elasticity between any two products. The pricing rule of Proposition 1.9 gives each firm the Lerner index $L = \frac{1}{\varepsilon_{\text{own}}}$. An analyst who treats the products as one homogeneous good measures the market elasticity when all prices move together,

$$\varepsilon = \varepsilon_{\text{own}} - (J-1)\,\varepsilon_{\text{cross}},$$

and reads conduct from $\frac{P-mc}{P} = \frac{\theta}{\varepsilon}$. The apparent conduct parameter is

$$\tilde{\theta} = \varepsilon L = \frac{\varepsilon_{\text{own}} - (J-1)\,\varepsilon_{\text{cross}}}{\varepsilon_{\text{own}}} = 1 - (J-1)\,D, \qquad D = \frac{\varepsilon_{\text{cross}}}{\varepsilon_{\text{own}}}.$$

With symmetric quantities, D is the *diversion ratio* between two products, the fraction of the sales lost by one product that go to another when its price rises (Chapter 4). So $\tilde{\theta}$ is the fraction of lost sales that leave the industry. It lies between zero and one although no firm colludes. With $J = 4$, $\varepsilon_{\text{own}} = 4$ and $\varepsilon_{\text{cross}} = 1$ we get $\varepsilon = 1$, $L = 0.25$ and $\tilde{\theta} = 0.25$. This is exactly the value of symmetric Cournot with four firms, produced by differentiated Bertrand competition.

To study differentiation directly, the analyst must reduce the dimension of the problem. Bresnahan describes three ways.

Modeling product choice. The first models how consumers choose among products, which yields demand systems with few parameters. Discrete-choice models (see McFadden, 1984), such as the nested logit, fit industries in which trade sources describe distinct segments with much closer competition inside than across them. Spatial models of differentiation fit industries without clear segment boundaries. In such industries, products A and B can both matter for C without A mattering for B. Spatial models reduce the parameter count by localizing competition, and discrete-choice models do it by grouping. A multinomial logit without nests is the limiting case in which the whole industry is one segment and competition is symmetric. Bresnahan's spatial model of automobiles is an example (Bresnahan, 1981a, 1987). Any such model is only as convincing as the information used to specify it, and the localized-versus-segmented distinction matters most. Schmalensee (1985b) proposes a test of localization based on how the prices and quantities of brands move together. In ready-to-eat breakfast cereals he decisively rejects the model in which all brands compete equally, although he doubts the covariance restrictions that identify the pattern of localization. Chapters 6 to 8 develop the modern versions of this approach.

Aggregating products. The second approach aggregates similar products until only a few elasticities remain. Gelfand and Spiller (1987) aggregate many types of bank loans into two and estimate a two-by-two system. Their model lets each bank's profit in one market depend on rivals' strategies in both, an interdependence they write in conjectural-variations form. Slade (1987) studies "majors" and "independents" among gasoline stations in Vancouver. Suslow (1986) aggregates output into the dominant firm's product and the fringe's product. The

dominant firm's marginal revenue then depends on the substitutability of the two products, the market elasticity and the fringe supply elasticity.

Estimating a summary statistic: residual demand. The third approach, due to Baker and Bresnahan (1985, 1988), estimates only the summary statistic that measures one firm's market power. Consider the seller of product 1, facing the inverse demand

$$P_1 = P^1(Q_1, P_2, \ldots, P_J, Y, \gamma), \tag{1.69}$$

where $P_2, \ldots, P_J$ are the prices of competing products. The parameter vector γ contains the cross effects of all $J-1$ rivals, so it can be very long. Each rival product $j = 2, \ldots, J$ has its own demand equation like (1.69) and a supply relation

$$P_j = C_q^j(Q_j, W_j, Z_j, \Gamma_j) - \frac{\partial P^j}{\partial Q_j} Q_j \vartheta_j, \qquad j = 2, \ldots, J. \tag{1.70}$$

These $2(J-1)$ equations can be solved for the rivals' prices and quantities as functions of Q_1 and the exogenous variables, $P_j = P_j^*(Q_1, W_{-1}, Z_{-1}, \Gamma_{-1}, \vartheta_{-1}, Y, \gamma)$. Here W_{-1} and Z_{-1} are the rivals' cost shifters, and Q_1 remains because only the rivals' equations have been solved. Substituting into (1.69) gives the *residual demand curve* of product 1,

$$P_1 = P^1\big(Q_1, P_2^*(\cdot), \ldots, P_J^*(\cdot), Y, \gamma\big) \equiv P^R(Q_1, W_{-1}, Z_{-1}, \Gamma_{-1}, \vartheta_{-1}, Y, \gamma). \tag{1.71}$$

Equations (1.69) to (1.71) are Bresnahan's (31), (4^d) and (32). By the chain rule, the elasticity of residual inverse demand is

$$-\frac{1}{\varepsilon_1^R} = \frac{\partial \ln P^R}{\partial \ln Q_1} = \frac{\partial \ln P^1}{\partial \ln Q_1} + \sum_{j=2}^{J} \frac{\partial \ln P^1}{\partial \ln P_j} \frac{\partial \ln P_j^*}{\partial \ln Q_1}.$$

The first term is the direct effect of firm 1's output on its price. The sum adds the effect of rivals' price responses. Substituting out the rivals' prices loses a great deal of information, since the separate elements of γ can no longer be estimated. That loss matters little for the question at hand. The slope of P^R tells us how much power firm 1 has over its price after all rivals have adjusted. Suppose product 1 is a perfect substitute for rival products sold by price takers at constant cost. Then P^R equals the lowest rival cost and does not respond to Q_1, so $\frac{1}{\varepsilon_1^R} = 0$.

Residual demand can be estimated only if firm 1's costs move independently of its rivals' costs (Bresnahan, 1989, fn. 43). Its own cost shifters then serve as instruments for Q_1, while the rivals' cost shifters enter (1.71) directly. International markets offer natural experiments, since exchange-rate movements change the relative costs of producers in different countries. The residual elasticity summarizes a firm's market power, but it does not reveal the sources of that power. It equals the Lerner index only under particular conduct, which is why Bresnahan leaves residual-demand studies out of his summary table. The approach complements the aggregation approach, which estimates every elasticity but only for a few products. Chapter 3 treats Baker and Bresnahan (1988) and its application to brewing in depth.

Market definition and policy. These techniques bear on market definition in antitrust. Antitrust often asks whether a single firm has market power, or whether a group of firms would have it if they acted together. Section 1.2.1 quoted Bresnahan's remark that these questions are well posed even where computing shares in a relevant market is senseless. Residual demand answers the first question directly. Scheffman and Spiller (1987) extend it to a group of firms,

which answers the second. Baker and Bresnahan (1985) ask how much steeper the residual demand of two merging firms would be after the merger. If the two sell close substitutes and few other firms sell similar products, each firm is an important brake on the other, and the merger steepens the curve. The Panzar-Rosse statistic gives a related answer. A rejection of monopoly for a firm or group means that it cannot be treated as acting in isolation. Chapter 11 develops merger analysis with differentiated products.

Differentiation in the long run. In the long run firms add products, change attributes or perceptions, and new firms enter with new products or imitations. Theory offers many strategic hypotheses: preemption by reputation for quality, preemption by filling the product space, and coordination of product choices to soften competition. In 1989 essentially nothing empirical was known about any of them (Bresnahan, 1989, p. 1050). The same passage contains the welfare point of Section 1.2.4. Under the Chamberlin tangency every firm prices above marginal cost, so short-run market power says little about efficiency until we know how new products and new firms are supplied.

1.7.4 What the NEIO learned

The case-study character of the NEIO raises questions of interpretation (Bresnahan, 1989, Section 5). How general are the results, and what do they reveal about market power in the economy as a whole? The SCP paradigm aimed to estimate a map from structure to conduct and performance. Such a map would be valuable, for example to guide merger policy, which acts on structure. A single industry study reveals at most one point on it. By 1989 NEIO studies covered more than a dozen industries. Table 1.7 reproduces the estimated Lerner indices that Bresnahan collected.

Table 1.7: Estimated Lerner indices from early NEIO studies

Author	Industry	L
Lopez (1984)	Food processing	0.504
Roberts (1984)	Coffee roasting	0.055 / 0.025[a]
Appelbaum (1982)	Rubber	0.049[c]
Appelbaum (1982)	Textile	0.072[c]
Appelbaum (1982)	Electrical machinery	0.198[c]
Appelbaum (1982)	Tobacco	0.648[c]
Porter (1983a)	Railroads	0.40[b]
Slade (1987)	Retail gasoline	0.10
Bresnahan (1981a)	Automobiles (1970s)	0.1 / 0.34[d]
Suslow (1986)	Aluminum (interwar)	0.59
Spiller and Favaro (1984)	Banks "before"[e]	0.88 / 0.21[f]
Spiller and Favaro (1984)	Banks "after"[e]	0.40 / 0.16[f]

Notes: $L = \frac{P-mc}{P}$. [a]Largest and second-largest firm, respectively. [b]When the cartel was succeeding (0 in reversionary periods). [c]At the sample midpoint. [d]Varies by type of car, larger in the standard and luxury segments. [e]Uruguayan banks before and after entry deregulation. [f]Large firms / small firms. Panzar-Rosse and Sullivan studies are excluded because they yield only tests of, or bounds on, conduct. Residual-demand studies are excluded because the residual elasticity equals the Lerner index only in special cases.
Source: Bresnahan (1989), Table 17.1.

From this evidence Bresnahan draws three guarded conclusions (Bresnahan, 1989, pp. 1052–1053).

Conclusion A. Some concentrated industries have a great deal of market power, in the sense of high price-cost margins. Several entries in Table 1.7 exceed 0.4. The industries cannot be matched systematically to census concentration measures, because many data sets were collected by the authors. A glance at the list shows that they come overwhelmingly from the concentrated end of the spectrum.

Two reasons warn against generalizing. First, researchers who invent a method for detecting market power apply it first where they expect to find it. They choose concentrated industries, known or suspected cartels, or industries where earlier case studies suggested anticompetitive conduct. Second, the data often come from trade journals, regulators or court records. Industries with excellent trade journals are industries in which firms know a lot about their rivals, an information structure that favors collusion. Suslow could use the trial record on Alcoa because Alcoa was suspected of market power. More sources of data, from more industries, were needed.

Conclusion B. One significant cause of high margins is anticompetitive conduct. The studies separate conduct, the behavioral rules by which firms set prices, from performance, the price-cost margin. They do not find small departures from price taking combined with very steep demand. Several find conduct well toward the collusive end, for example Porter (1983a) and Bresnahan (1987), which both find explicit collusion. Conduct is not uniform. Roberts (1984) classifies most coffee roasters as a price-taking fringe, while the largest firms behave less competitively without reaching the profit maximum given the fringe.

Conclusion C. The new methods had taught little about the relation between market power and industry structure. The studies cover only the concentrated end of the range, so they reveal the structure-performance map over a narrow interval. Few of them address the causes of market power. Long-lived market power suggests that entry fails to discipline conduct, yet the studies hardly discuss entry.

The sources of market power. Bresnahan closes by pointing to the causes of market power as the frontier (Bresnahan, 1989, Section 6). Entry, predation, entry deterrence and long-run strategic competition had received little empirical work with explicit theoretical foundations. Burns (1986) studies the American tobacco trust and finds that its acquisitions of competitors became cheaper after episodes of predatory pricing. The study relies on a nineteenth-century documentary record that modern firms would not leave. The open problem was to find the empirical implications of predation when predatory acts must be inferred. On entry, Rosse and Panzar (1977) add to demand and the supply relations an entry condition for the marginal firm, $P = LRAC(W, Y)$, with $LRAC$ long-run average cost. Bresnahan and Reiss (1990) model the entry decisions of the first two firms in a market with an integer number of firms. They use 149 geographically isolated American markets for new car dealers. A second entrant faces nearly the same costs and opportunities as the first, and its entry does not lower the monopoly dealer's margins by much. Both papers argue that cross-sections of closely related markets are the right samples for studying entry. Section 1.8.5 takes up the sequel by Bresnahan and Reiss (1991).

Bresnahan's final assessment is optimistic about measurement and modest about explanation. By abandoning accounting measures of performance, the NEIO produced a new kind of evidence of substantial market power, immune to the standard criticisms of earlier work. Its studies are detailed enough that alternative explanations can be confronted and rebutted.

In his words, "we know that there is market power out there, and need to know a lot more about exactly where" (Bresnahan, 1989, p. 1055). Its causes and systematic predictors remained essentially unknown.

The program that followed kept the NEIO's commitment to single industries and explicit models. Its main change was on the demand side. Classic analyses of market power, such as Porter (1983a), Bresnahan (1987) and Nevo (2001), supply the basic toolkit (Einav and Levin, 2010, p. 151). That toolkit combines demand and supply in an equilibrium analysis of imperfect competition. Modern work replaces the conduct parameter with explicit models of differentiated-product competition and estimates rich demand systems with instruments. Section 1.8 describes this structural workflow.

1.8 Empirical IO today

The previous sections traced how the field moved from cross-industry regressions to studies of single industries with explicit models of conduct. This section describes what empirical research in industrial organization looks like after that transition. We follow the progress report of Einav and Levin (2010), which maps the modern field, and we add the formal content that a survey essay leaves implicit.

Einav and Levin summarize the state of the field in a few sentences (p. 147). Most influential research looks to economic theory for guidance, especially in modeling the behavior of firms. Studies frequently focus on a single industry or market. They pay careful attention to institutional specifics, to the measurement of key variables and to econometric identification. Advocates argue that, when it succeeds, this approach combines the conceptual clarity of theory with convincing empirical measurement.

There is no recipe, but most papers share a few themes (p. 148). A study usually begins with a theory of market equilibrium, which can be more or less explicit. The theory then plays one of three roles. It supplies optimization or equilibrium conditions from which we infer unobserved parameters. It delivers testable predictions. Or it helps us interpret estimated causal effects. In every case the institutional details of the market matter, and one broad lesson from looking across industries is that they can matter a great deal.

Industry studies have drawbacks as well (p. 147). They can lead to narrow analyses, and researchers are often reluctant to generalize their findings to markets with different institutions. The broader lessons therefore tend to be qualitative insights, or methods that can be applied in other settings. Critics also argue that models resting heavily on equilibrium assumptions can obscure the link between the estimated parameters and the variation in the data. We return to this debate in Section 1.8.6.

The section has six parts. Section 1.8.1 sets out the structural workflow that organizes most of the book. Sections 1.8.2 and 1.8.3 discuss demand estimation and the measurement of market power. Section 1.8.4 shows that auctions are pricing problems governed by the same first-order logic. Section 1.8.5 turns to entry, market structure and dynamics, with a full case study of Bresnahan and Reiss (1991). Section 1.8.6 discusses the debate between structural and design-based empirical work.

1.8.1 The structural workflow: demand, supply, counterfactuals

A large share of modern empirical IO follows a three-step workflow. We first estimate demand. We then combine the demand estimates with a model of pricing to recover marginal

costs. Finally we use the estimated demand and costs to solve for the equilibrium under a counterfactual policy or market structure. This subsection states the canonical model behind the workflow, derives its central equation and illustrates the three steps. Later chapters develop each step in full.

The canonical model

Consider a market with J inside products and an outside good $j = 0$. (When several markets $t = 1, \dots, T$ appear, we add the subscript t.) Product j has price p_j, a row vector of observed characteristics x_j and an unobserved demand shock ξ_j, which we call *unobserved product quality*. Market size is M, the quantity of product j is q_j, and its market share is $s_j = \frac{q_j}{M}$. Each firm f owns a set of products $\mathcal{J}_f$, and every product has exactly one owner.

Assumption 1.36 (Canonical static model)**.**

(i) Market shares are $s_j = s_j(p, x, \xi; \gamma)$ for $j = 1, \dots, J$. Here $p = (p_1, \dots, p_J)^\top$ is the price vector, x and ξ collect the characteristics and demand shocks of all products, and γ is a finite-dimensional vector of demand parameters. Each s_j is continuously differentiable in p.

(ii) Product j has a constant marginal cost $mc_j = c(w_j, \omega_j; \Gamma)$, where w_j is a vector of observed cost shifters, ω_j is an unobserved cost shock and Γ is a vector of cost parameters. Fixed costs do not affect prices.

(iii) Firms choose prices simultaneously. Each firm sets the prices of its own products to maximize their joint profit, taking the prices of rival products as given. We call this *multi-product Bertrand-Nash* pricing.

(iv) The equilibrium is interior, so it satisfies the first-order conditions, and the matrix $\Omega \odot \Delta^\top$ defined below is invertible at the equilibrium prices.

Two matrices summarize conduct and demand. The ownership matrix Ω, met with the vertical model in Section 1.6.4, is the $J \times J$ matrix with $\Omega_{jk} = 1$ if products j and k have the same owner and $\Omega_{jk} = 0$ otherwise. It is symmetric and has ones on the diagonal. The matrix of share derivatives Δ has (j, k) element $\Delta_{jk} = \frac{\partial s_j}{\partial p_k}$, so row j collects the effects of all prices on the share of product j. The symbol $\odot$ denotes the element-wise (Hadamard) product.

Proposition 1.37 (Multi-product pricing and implied marginal costs)**.** *Under Assumption 1.36, equilibrium prices satisfy the system of J first-order conditions*

$$s + (\Omega \odot \Delta^\top)(p - mc) = 0, \tag{1.72}$$

where s, p and mc are J-vectors. Equivalently, markups and marginal costs are

$$p - mc = -(\Omega \odot \Delta^\top)^{-1} s, \qquad mc = p + (\Omega \odot \Delta^\top)^{-1} s. \tag{1.73}$$

Proof. Firm f earns

$$\pi_f = \sum_{k \in \mathcal{J}_f} (p_k - mc_k)\, M s_k(p) - C_f,$$

where C_f is its fixed cost. Take a product $j \in \mathcal{J}_f$. The price p_j enters the margin of product j and the shares of every product. By the product rule,

$$\frac{\partial \pi_f}{\partial p_j} = M s_j + M \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j}.$$

Setting this derivative to zero and dividing by $M > 0$ gives

$$s_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j} = 0.$$

The ownership matrix lets us replace the sum over the firm's products by a sum over all products:

$$s_j + \sum_{k=1}^{J} \Omega_{jk} \frac{\partial s_k}{\partial p_j} (p_k - mc_k) = 0.$$

The derivative in this sum is $\frac{\partial s_k}{\partial p_j} = \Delta_{kj} = (\Delta^\top)_{jk}$. The coefficient on $(p_k - mc_k)$ in the condition for product j is therefore $\Omega_{jk}(\Delta^\top)_{jk} = (\Omega \odot \Delta^\top)_{jk}$. Stacking the J conditions gives (1.72). Premultiplying (1.72) by $(\Omega \odot \Delta^\top)^{-1}$ and rearranging gives (1.73). □

The transpose has a simple origin. The condition for p_j involves the effect of p_j on the shares of the firm's other products. These effects form column j of Δ, which is row j of $\Delta^\top$. Because Ω is symmetric, $\Omega \odot \Delta^\top = (\Omega \odot \Delta)^\top$, and some references write the system in that form.

Remark 1.38 (Special cases and conduct). With single-product firms, Ω is the identity matrix. Condition j then reads $s_j + \Delta_{jj}(p_j - mc_j) = 0$, so

$$p_j - mc_j = -s_j \left(\frac{\partial s_j}{\partial p_j} \right)^{-1} = -q_j \left(\frac{\partial q_j}{\partial p_j} \right)^{-1},$$

which is the dollar markup of Proposition 1.9 applied to the residual demand q_j. A cartel that maximizes the joint profit of all products sets every element of Ω equal to one. Intermediate cases put a weight between zero and one on rival products. In this sense Ω plays the role in differentiated-product markets that the conduct parameter θ plays in the homogeneous-good supply relation $P = \overline{mc} - \theta P'(Q)Q$ of Proposition 1.33. Equation (1.73) also shows that markups depend only on shares, share derivatives and conduct. Once demand is known and conduct is assumed, marginal costs follow from observed prices without any cost data.

Example 1.39 (Same data, two conduct assumptions)**.** Two symmetric products sell at $p_1 = p_2 = 2$ with shares $s_1 = s_2 = 0.2$. Suppose demand estimates give own-price derivatives $\frac{\partial s_j}{\partial p_j} = -0.4$ and cross-price derivatives $\frac{\partial s_k}{\partial p_j} = 0.1$ (per dollar). The numbers are illustrative.

If the products have different owners, Ω is the identity and each markup is $p_j - mc_j = \frac{0.2}{0.4} = 0.5$. Implied marginal cost is 1.5 and the Lerner index is 0.25.

If one firm owns both products, (1.72) becomes

$$\begin{pmatrix} 0.2 \\ 0.2 \end{pmatrix} + \begin{pmatrix} -0.4 & 0.1 \\ 0.1 & -0.4 \end{pmatrix} \begin{pmatrix} p_1 - mc_1 \\ p_2 - mc_2 \end{pmatrix} = 0.$$

By symmetry both markups equal some m, and each row reads $0.2 - 0.4m + 0.1m = 0$. Hence $m = \frac{0.2}{0.3} = \frac{2}{3}$, implied marginal cost is $\frac{4}{3}$ and the Lerner index is $\frac{1}{3}$. The diversion ratio from product 1 to product 2 (Example 1.35), the fraction of the sales lost by product 1 after a price increase that go to product 2, is $D_{12} = -\frac{\partial s_2}{\partial p_1}\left(\frac{\partial s_1}{\partial p_1}\right)^{-1} = \frac{0.1}{0.4} = \frac{1}{4}$. In this symmetric case the joint-ownership markup equals the single-product markup divided by $1 - D_{12}$:

$$m = \frac{0.2}{0.4 - 0.1} = \frac{0.5}{1 - \frac{1}{4}} = \frac{2}{3}.$$

The same prices and demand estimates thus imply different marginal costs under different conduct assumptions. With independent cost data we could tell the two models apart. This is the logic of the conduct tests in Section 1.8.3, and diversion ratios return in Chapters 4 and 11.

The three steps

Figure 1.7 displays the workflow. Each step uses the output of the previous one.

Step 1. Estimate demand. We estimate γ from data on shares, prices and characteristics, usually across many markets. Firms observe ξ_j when they set prices, and (1.73) shows that markups depend on shares. Prices are therefore correlated with ξ_j, and least squares estimates of price sensitivity are biased. The remedy is a set of instruments z_j that satisfy $\mathbb{E}[\xi_j \mid z_j] = 0$ and move prices (Section 1.8.2).

Step 2. Recover marginal costs or test conduct. Given $\hat{\gamma}$, we compute $\hat{\Delta}$ and the implied costs $\widehat{mc} = p + (\Omega \odot \hat{\Delta}^\top)^{-1}s$. With a cost specification $mc_{jt} = w_{jt}\Gamma + \omega_{jt}$, the supply-side estimating equation is

$$p_{jt} + \left[(\Omega_t \odot \hat{\Delta}_t^\top)^{-1}s_t\right]_j = w_{jt}\Gamma + \omega_{jt}, \tag{1.74}$$

which we estimate by least squares or instrumental variables, or jointly with demand by the generalized method of moments. Alternatively we compare the implied costs under several conduct assumptions with direct cost information.

Step 3. Solve for a counterfactual equilibrium. We solve

$$s(p'; \hat{\gamma}) + \left(\Omega' \odot \Delta(p'; \hat{\gamma})^\top\right)(p' - mc') = 0 \tag{1.75}$$

for the new price vector p'. A merger changes the ownership matrix to Ω'. A per-unit tax t changes costs to $mc' = \widehat{mc} + t$. A new product enlarges the choice set. The demand model then delivers changes in consumer welfare, and the cost estimates deliver changes in profits.

The following example runs the three steps on the campus coffee shop of Example 1.12. It shows that two demand models that agree at the observed data can disagree sharply about a counterfactual.

Example 1.40 (A tax on campus coffee)**.** In Example 1.12 the shop charges $p = 4$ and we estimate its residual demand elasticity as $\hat{\varepsilon}^R = 2.5$ with standard error 0.5. The numbers are illustrative. If the shop sets a monopoly price, Corollary 1.11 gives

$$\hat{c} = p\left(1 - \frac{1}{\hat{\varepsilon}^R}\right) = 4\left(1 - \frac{1}{2.5}\right) = 2.40.$$

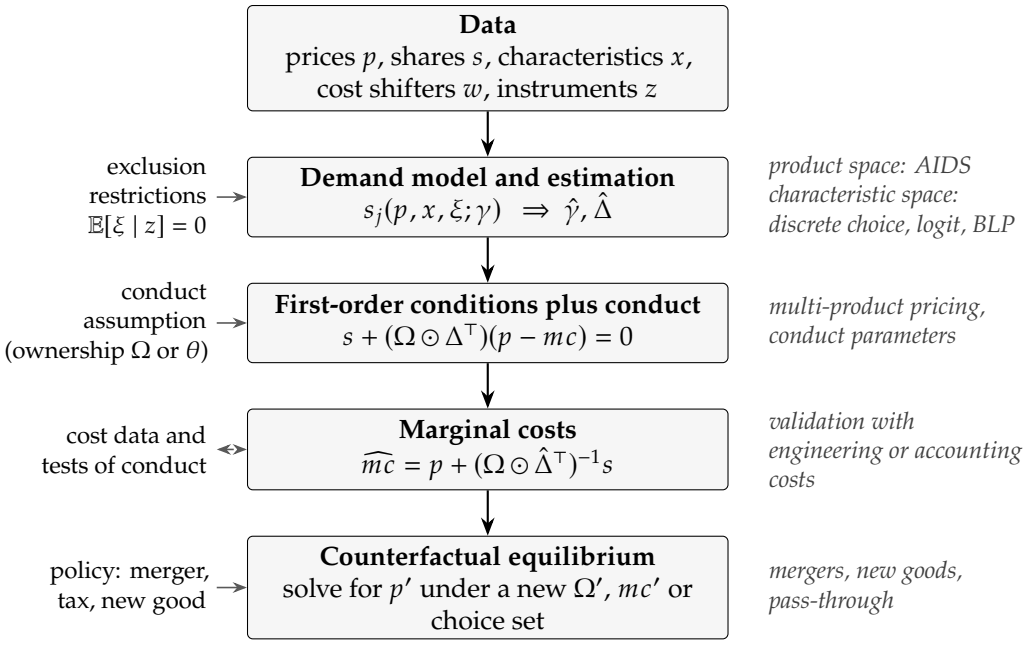

Figure 1.7: The structural workflow. Solid arrows show the flow of estimates. Inputs on the left are assumptions or outside information. Notes on the right name the models used at each step. Demand models are developed in Chapters 5 to 8, pricing and conduct in Chapters 3 and 4, and counterfactuals in Chapters 10 and 11, with pass-through theory in Chapter 2.

Suppose the university now levies a tax of $t = 0.30$ on every coffee sold, paid by the shop. How much does the price rise?

Pass-through in general. With the tax, the shop maximizes $(p - c - t)Q(p)$, and its first-order condition is

$$Q(p) + (p - c - t)\, Q'(p) = 0.$$

This condition defines the price as a function of t. Differentiating both sides with respect to t, and writing $\rho = \frac{\mathrm{d}p}{\mathrm{d}t}$ for *pass-through*, gives

$$Q'(p)\rho + (\rho - 1)\, Q'(p) + (p - c - t)\, Q''(p)\rho = 0.$$

Collecting the terms in ρ gives

$$\rho = \frac{Q'(p)}{2Q'(p) + (p - c - t)\, Q''(p)}. \tag{1.76}$$

Pass-through depends on the curvature Q'' of demand. The elasticity at the observed point does not pin down the curvature. Chapter 2 develops this formula in full.

Constant-elasticity demand. Let $Q(p) = Ap^{-\varepsilon^R}$ with $\varepsilon^R = 2.5$. The pricing rule is $p = \frac{\varepsilon^R}{\varepsilon^R - 1}(c + t)$, so

$$\rho = \frac{\varepsilon^R}{\varepsilon^R - 1} = \frac{2.5}{1.5} = \frac{5}{3} \approx 1.67.$$

The price rises from $\frac{5}{3} \times 2.40 = 4.00$ to $\frac{5}{3} \times 2.70 = 4.50$. The increase of 0.50 exceeds the tax.

Linear demand. Let $Q(p) = A - Bp$. The monopoly price is $p = \frac{1}{2}\left(\frac{A}{B} + c\right)$. Matching $p = 4$ with $c = 2.40$ requires $\frac{A}{B} = 5.6$. The elasticity at the observed point is then

$$\frac{Bp}{A - Bp} = \frac{p}{\frac{A}{B} - p} = \frac{4}{1.6} = 2.5,$$

the same as before. So the two models fit the price, the elasticity and the implied marginal cost equally well. With $Q'' = 0$, (1.76) gives $\rho = \frac{1}{2}$. The new price is $\frac{1}{2}(5.6 + 2.70) = 4.15$, an increase of 0.15.

Perfect competition. With price-taking firms and flat marginal cost, $p = c + t$ and the price rises by exactly 0.30.

Sampling uncertainty. Under constant elasticity the predicted price change is $\frac{\varepsilon^R}{\varepsilon^R - 1} t$. Its derivative with respect to ε^R is $-\frac{t}{(\varepsilon^R - 1)^2}$. By the delta method (Appendix A),

$$\operatorname{se}(\widehat{\Delta p}) \approx \frac{t}{(\hat{\varepsilon}^R - 1)^2} \operatorname{se}(\hat{\varepsilon}^R) = \frac{0.30}{2.25} \times 0.5 \approx 0.067.$$

The same calculation gives $\operatorname{se}(\hat{\rho}) \approx \frac{0.5}{2.25} \approx 0.22$, so an approximate 95 percent confidence interval for ρ is $[1.23, 2.10]$. The predicted increase ranges from 0.15 to 0.50 across models, a spread far wider than the sampling error within one model. Functional form is a substantive assumption in counterfactual work. Chapter 3 returns to this point in the tax pass-through test of Sumner (1981) and its critiques.

The second step deserves a caution. Inferring marginal costs from first-order conditions is elegant and needs no cost data, but it rests on the assumption that firms set profit-maximizing prices. Einav and Levin warn that the approach "can be a bit too seductive" (p. 151). Researchers sometimes discard available cost data because they are imperfect, even when the data could be informative or at least complementary. A few studies combine direct and indirect cost measurement to cross-check the analysis and test the hypothesis of equilibrium pricing. Examples are Nevo (2001) for breakfast cereal (Chapter 8) and Hortaçsu and Puller (2008) for the Texas electricity market. Chapter 3 treats two classic validations, Genesove and Mullin (1998) for sugar and Wolfram (1999) for British electricity. Wolfram measures marginal cost directly from the fuel costs and efficiencies of power plants. She finds prices above marginal cost yet well below the predictions of Cournot and supply-function models of the two dominant generators (p. 805). Of three explanations, regulatory constraints, the threat of entry and financial contracts, she finds more support for the first two than for contracts (p. 806).

1.8.2 Demand estimation

Most studies of imperfect competition begin by estimating demand. Demand is interesting in its own right (Einav and Levin, 2010, p. 148). It tells us what consumers value and how they substitute between products as prices or product offerings change. It is the input for the welfare effects of mergers and new products, and for measuring how information or advertising affect choices. Demand elasticities are also the key input for measuring market power, as Proposition 1.37 shows. Many advances in this area are econometric models that can be applied in many markets, and even outside markets.

The dimensionality problem

Einav and Levin illustrate the problem with the pricing of the iPhone (p. 148). Some consumers simply prefer the iPhone to comparable phones, and consumers who value its interface differ from those who value a rival's link to corporate email. Apple also sells several versions, and consumers can delay their purchase and wait for prices to fall. Apple's pricing incentives therefore depend on a whole set of elasticities, which describe how customers shift their purchases when Apple changes its price schedule.

A flexible demand system needs many parameters. Consider the linear system

$$q_j = a_j + \sum_{k=1}^{J} b_{jk}\, p_k + x_j\beta + \xi_j, \qquad j = 1, \ldots, J, \tag{1.77}$$

which has J^2 price coefficients b_{jk} (p. 149). With $J = 50$ products there are 2,500 of them. Identification requires distinct variation in each of the J prices. Attractive sources of variation, such as cost shocks, often move all prices together. Suppose, for example, that every price responds to a single cost shifter z through $p_k = \pi_k z + v_k$. Substituting into (1.77) gives the reduced form

$$q_j = a_j + \Big(\sum_{k=1}^{J} b_{jk}\pi_k\Big)z + x_j\beta + \xi_j + \sum_{k=1}^{J} b_{jk}v_k.$$

The shifter identifies only the combination $\sum_k b_{jk}\pi_k$ in each equation, one number for J unknowns. Idiosyncratic shocks have the opposite problem: they move a few prices and leave the effects of the others unidentified.

Demand modeling has therefore centered on a trade-off between flexible substitution patterns and the limited variation in typical data (p. 149). There are two main strategies.

(a) *Segments in product space.* We divide products into groups and restrict substitution across groups while allowing flexibility within them. Hausman (1997) divides ready-to-eat cereals into adult, family and kids' segments. With S equal segments of $\frac{J}{S}$ products, a linear system with unrestricted within-segment coefficients has $S\left(\frac{J}{S}\right)^2 = \frac{J^2}{S}$ of them, plus S^2 segment-level coefficients. For $J = 30$ and $S = 3$ this is $300 + 9$ parameters instead of 900. Chapters 5 and 10 develop the approach.

(b) *Characteristic space.* We describe each product by a few characteristics and let consumers trade off price against those characteristics in a way that is common across products. Berry et al. (1995) describe cars by size, horsepower and fuel efficiency, plus a quality characteristic ξ_j that the researcher does not observe. A typical utility function is

$$u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j + \epsilon_{ij}, \tag{1.78}$$

where consumer i has taste coefficients β_i and price coefficient α_i, and ϵ_{ij} is an idiosyncratic shock. The number of parameters depends on the number of characteristics and does not grow with J. Chapters 6 to 8 develop the approach.

These techniques are the main source of the policy footprint described in Section 1.1. They underlie market definition and merger simulation in antitrust, damages in litigation, and the treatment of new goods in the Consumer Price Index (Chapters 10 and 11).

Simultaneity and instruments

Demand models are estimated from individual choice data or from aggregate prices and market shares (p. 149). Prices respond to demand shocks, which creates a simultaneity problem. It is the imperfect competition analogue of the textbook simultaneity of supply and demand, and researchers address it with instrumental variables. The simplest case shows the structure. If utility (1.78) has common coefficients $\beta_i = \beta$ and $\alpha_i = \alpha$, and ϵ_{ij} is type-I extreme value, the market shares invert to the linear estimating equation

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt} \tag{1.79}$$

of Berry (1994), derived in Chapter 7. Firms set higher prices for products with high ξ_{jt}, so $\text{Cov}(p_{jt}, \xi_{jt}) > 0$. Least squares then biases the estimate of α toward zero and makes demand look less elastic than it is. Estimation instead uses moment conditions $\mathbb{E}[z_{jt}\xi_{jt}] = 0$ for instruments z_{jt}.

Because independent movements in many prices are rare, the most popular instruments exploit restrictions across the equations of the demand system (pp. 149–150).

(a) *Prices of the same product in other markets.* The instrument for p_{jt} is, for example, $z_{jt} = \frac{1}{T-1}\sum_{t' \neq t} p_{jt'}$. The idea is that, conditional on observed demand characteristics, prices of the same product are correlated across markets because of common costs. The exclusion restriction requires the demand shocks to be uncorrelated across markets, $\text{Cov}(\xi_{jt}, \xi_{jt'}) = 0$ for $t \neq t'$. A national advertising campaign would violate it. Hausman (1997) and Nevo (2001) use such instruments, which we call *Hausman instruments*.

(b) *Characteristics of competing products.* The instruments are functions such as $\sum_{k \notin \mathcal{J}_f} x_k$ and $\sum_{k \in \mathcal{J}_f, k \neq j} x_k$, which proxy for the closeness of competition and so shift markups. The exclusion restriction requires that the characteristics be uncorrelated with ξ. We call these *BLP instruments*.

Neither solution is perfect, and the source of price variation and its strength must be evaluated in each application (p. 150). Return to the iPhone. Rivals that introduce touch screens compete harder with Apple and lead it to cut the iPhone's price, so rivals' characteristics move the iPhone's price. But suppose the rivals were responding to the surprisingly high demand for iPhones, a high ξ. Then the rivals' characteristics are correlated with ξ, and the exclusion restriction fails. Einav and Levin's own assessment is that many applications are careful about the statistical conditions behind identification. They are often thin, however, in explaining the precise source of identifying variation, in arguing why the conditions hold, and in reporting first-stage regressions and other diagnostics (p. 150). We ask these three questions of every demand estimate in the case studies of later chapters.

Experiments and models

Proprietary data and experiments sanctioned by firms are increasingly available (p. 150). Lewis and Reiley (2009) analyze a large-scale experiment that randomized consumers' exposure to internet advertising by a large retailer and then tracked their purchases. The study measures the effect of advertising on purchases. It shows what new data technologies and cooperating firms make possible.

Experimental measurement is not a panacea, however (p. 150). An experiment measures the response to one specific change in prices or information. A model of consumer choice links different behavioral responses to common underlying parameters, and it translates responses into statements about welfare. Two examples illustrate the point. Hendel and Nevo (2006) show that short-run elasticities mislead when consumers stockpile storable goods during sales. Their model relates short-run responses to the long-run elasticities that determine the price effects of a merger. Cohen and Einav (2007) show how choices of insurance deductibles reveal risk preferences under the assumption that consumers maximize expected utility. Better data will make estimated responses more precise and more convincing, and these estimates will complement the demand models of this book.

1.8.3 Market power and pricing

How far market outcomes reflect market power, or implicit or explicit collusion, is a central question of the field. We met the three classic analyses that Einav and Levin single out (p. 151) at the end of Section 1.7.4. They are Porter (1983a) on the railroad cartel of the 1880s, Bresnahan (1987) on the automobile industry and Nevo (2001) on breakfast cereal. The first two estimate conduct in the NEIO manner. The third shows the modern form of the toolkit.

Underlying each study is a model of market equilibrium. The most common one is Bertrand-Nash price competition with differentiated products. In equilibrium each firm sets price equal to marginal cost plus a markup that depends on the semi-elasticity of its demand, taking rivals' prices as given. This is Proposition 1.37. With estimates of demand and costs, these conditions let us compute equilibrium prices. They also let us test noncooperative pricing against alternatives such as collusion. Because accounting data rarely measure economic marginal cost (Section 1.1), a typical study estimates demand, computes the optimal markup and subtracts it from the observed price, as Rosse (1970) did. This is Step 2 of the workflow.

Testing conduct

The same logic turns conduct into a testable hypothesis. Let $m = 1, \dots, \bar{m}$ index a menu of conduct models, each with its own matrix Ω^m. Examples are single-product pricing, pricing by the actual multi-product owners and joint profit maximization. Model m implies the markup vector $b^m = -(\Omega^m \odot \hat{\Delta}^\top)^{-1} s$ and the cost vector $mc^m = p - b^m$. There are two ways to confront the menu with data. The first compares the implied margins with direct measures of cost or margin. Nevo (2001) compares the margins implied by the three models above with accounting margins in the cereal industry. The second specifies costs as $mc_{jt} = w_{jt}\Gamma + \omega_{jt}$ and writes, for each model,

$$p_{jt} - b^m_{jt}(\hat{\gamma}) = w_{jt}\Gamma + \omega^m_{jt}, \qquad \mathbb{E}\left[\omega^m_{jt} \mid z_{jt}\right] = 0 \text{ under model } m. \tag{1.80}$$

Only the true model satisfies the moment condition. Instruments that move markups differently across models, such as changes in rivals' products or in ownership, give the comparison power. Bresnahan (1987) uses non-nested (Cox) tests to compare collusive and competitive models of automobile pricing in 1954, 1955 and 1956 (Chapter 6). The homogeneous-good version, with the conduct parameter θ, is the subject of Chapter 3.

Beyond traditional product markets

The basic framework supports a wide range of analyses (p. 151). Early industry studies focused on distinguishing unilateral market power from collusion and on the price and welfare effects of mergers, taxes and new goods. Later work added search costs, price discrimination, retail sales, consumer stockpiling, adverse selection and nonprice strategies for attracting customers. Einav and Levin give three examples (p. 152).

- Ellison and Ellison (2009) study how an internet price comparison engine affects competition among online retailers. Carefully documented price variation shows that the engine's price ranking makes consumers extremely price sensitive. Retailers then have an incentive to *obfuscate*, that is, to manipulate consumer search so as to soften otherwise cut-throat price competition.

- Gentzkow and Shapiro (2010) construct a measure of newspaper "slant" and estimate consumer demand for slant from variation in the distribution areas of local newspapers. They use the estimated demand in a model of the slant chosen by newspaper owners.
- Einav et al. (2012) use discrete shifts in pricing to estimate the demand for subprime auto loans. They embed the estimates in a model of loan pricing to study screening and credit terms set by a lender with market power.

Detailed data and transparent identification matter in these studies. Yet their results are most interesting through the lens of a theoretical model (p. 152). Any empirical result applies to one setting at one time, and markets differ a great deal. What makes these studies meaningful beyond their setting is that they illuminate mechanisms. Manipulation of consumer search, catering to ideological preferences and pricing under asymmetric information also operate in other markets.

The same methods changed antitrust practice, which moved from concentration ratios and Herfindahl-Hirschman indices to econometric studies of the industry under review (Section 1.1). The Department of Justice and the Federal Trade Commission use such studies to define markets and to assess the likely price effects of a merger or the risk of collusion. These exercises draw on academic research and in turn motivate new empirical models (p. 152 and Chapter 11).

1.8.4 Auctions as pricing problems

Many intermediate goods are traded in *bidding markets*. Firms and governments solicit bids to procure goods and services, and they use auctions to sell resources in limited supply. The connection between bidding markets and price competition is very close, although it is not always appreciated (Einav and Levin, 2010, pp. 152–153). Empirical methods for auctions parallel the framework of the previous subsections (Athey and Haile, 2006; Hendricks and Porter, 2007). A bidder trades off a higher probability of winning against a higher margin if she wins. A firm posting a price trades off higher sales against a higher margin. The next proposition makes the parallel exact.

Assumption 1.41 (Single-agent pricing problems)**.**

(i) Agents are risk neutral. Each bidder knows her own cost or value, and the costs or values of different bidders are independent (independent private values).

(ii) Each agent takes as given the demand curve or the distribution of rival bids that she faces. In a Bayesian Nash equilibrium this distribution is the one induced by the rivals' bidding strategies.

(iii) The relevant distribution functions are differentiable with positive densities, ties occur with probability zero, and the optimum is interior.

Proposition 1.42 (One markup rule for prices and bids)**.** *Under Assumption 1.41:*

(i) A firm with constant marginal cost c facing residual demand $Q(p)$, with $Q' < 0$, maximizes $(p - c)Q(p)$. Its optimal price satisfies

$$p = c - \frac{Q(p)}{Q'(p)}. \tag{1.81}$$

(ii) In a procurement auction won by the lowest of N bids, a bidder with cost c faces $N - 1$ rivals whose bids are independent draws from a distribution G with density g. She wins with probability

$\big(1-G(b)\big)^{N-1}$, *maximizes* $(b-c)\big(1-G(b)\big)^{N-1}$, *and her optimal bid satisfies*

$$b = c + \frac{1-G(b)}{(N-1)\,g(b)}. \tag{1.82}$$

(iii) In a first-price sale auction with N bidders, a bidder with value v faces $N-1$ rivals whose bids are independent draws from a distribution G with density g. She wins with probability $G(b)^{N-1}$, maximizes $(v-b)G(b)^{N-1}$, and her optimal bid satisfies

$$v = b + \frac{G(b)}{(N-1)\,g(b)}. \tag{1.83}$$

In each case the margin equals the reciprocal of the semi-elasticity of the probability of trade (or of quantity) with respect to the agent's own price.

Proof. (i) The first-order condition is $Q(p)+(p-c)Q'(p)=0$. Dividing by $-Q'(p)>0$ gives $p-c=-\frac{Q(p)}{Q'(p)}$, which is (1.81) and Proposition 1.9.

(ii) Differentiating $(b-c)\big(1-G(b)\big)^{N-1}$ with respect to b and setting the result to zero gives

$$\big(1-G(b)\big)^{N-1} - (b-c)(N-1)\big(1-G(b)\big)^{N-2}g(b) = 0.$$

Dividing by $(N-1)\big(1-G(b)\big)^{N-2}g(b)>0$ gives $b-c=\frac{1-G(b)}{(N-1)g(b)}$, which is (1.82).

(iii) Differentiating $(v-b)G(b)^{N-1}$ with respect to b and setting the result to zero gives

$$-G(b)^{N-1} + (v-b)(N-1)\,G(b)^{N-2}g(b) = 0.$$

Dividing by $(N-1)G(b)^{N-2}g(b)>0$ gives $v-b=\frac{G(b)}{(N-1)g(b)}$, which is (1.83).

For the last claim, let $D(x)$ be the quantity sold or the probability of trade at the agent's price x. A seller maximizes $(x-c)D(x)$ with $D'<0$, and the first-order condition gives $x-c=-\frac{D(x)}{D'(x)}=\left|\frac{\mathrm{d}\ln D(x)}{\mathrm{d}x}\right|^{-1}$. In case (i), $D=Q$. In case (ii), $D=(1-G)^{N-1}$, so $-\frac{D'}{D}=\frac{(N-1)g}{1-G}$. A buyer maximizes $(v-x)D(x)$ with $D'>0$, and the first-order condition gives $v-x=\frac{D(x)}{D'(x)}=\left(\frac{\mathrm{d}\ln D(x)}{\mathrm{d}x}\right)^{-1}$. In case (iii), $D=G^{N-1}$, so $\frac{D'}{D}=\frac{(N-1)g}{G}$. □

Table 1.8 lines up the three problems. Rules (ii) and (iii) are mirror images of each other. Einav and Levin state the procurement rule and rule (i) side by side in their footnote 3 (p. 153). Their G is the distribution of the lowest rival bid, which we write $G_{\min}$. All $N-1$ rivals bid above b exactly when the lowest rival bid does, so $1-G_{\min}(b)=\big(1-G(b)\big)^{N-1}$. Rule (ii) then reads $b=c+\frac{1-G_{\min}(b)}{g_{\min}(b)}$, their form. In the same way, rule (iii) reads $v=b+\frac{G_{\max}(b)}{g_{\max}(b)}$, where $G_{\max}(b)=G(b)^{N-1}$ is the distribution of the highest rival bid. The proposition describes a single bidder's best response. That the first-order condition characterizes equilibrium bidding when every bidder uses an increasing strategy is shown in Chapter 14.

From bids to values

The proposition is the basis of the estimator of Guerre et al. (2000). Rosse inferred costs from prices. In the same way, we can infer values or costs from bids (p. 153). In a posted-price

Table 1.8: Posted prices and auctions as one pricing problem

	Posted price	Procurement auction	First-price sale auction
Choice	price p	bid b	bid b
Objective	$(p-c)Q(p)$	$(b-c)\big(1-G(b)\big)^{N-1}$	$(v-b)G(b)^{N-1}$
"Demand" faced	residual demand $Q(p)$	probability $\big(1-G(b)\big)^{N-1}$ that all rivals bid more	probability $G(b)^{N-1}$ that all rivals bid less
Inversion	$c = p + \frac{Q(p)}{Q'(p)}$	$c = b - \frac{1-G(b)}{(N-1)g(b)}$	$v = b + \frac{G(b)}{(N-1)g(b)}$
What we estimate	demand system, with instruments for price	distribution of bids	distribution of bids
Main confounder	demand shocks ξ correlated with price	unobserved auction heterogeneity	unobserved auction heterogeneity
Origin	Rosse (1970)	Guerre et al. (2000)	Guerre et al. (2000)

Notes: c is marginal cost, v is the bidder's value, G and g are the distribution function and density of each rival's bid, and N is the number of bidders. Each inversion follows from Proposition 1.42.

market, the inversion $\hat{c} = p + \frac{Q(p)}{\hat{Q}'(p)}$ requires an estimate of demand, which in turn requires instruments. In a first-price auction the object playing the role of demand is the distribution of rival bids. That distribution is observed directly: every bid in a sample of comparable auctions is a draw from G. The estimator has two steps.

(1) Estimate G and g from the pooled bids of auctions with the same number of bidders and similar observed characteristics, for example by kernel methods.

(2) Compute a *pseudo-value* for each bid,

$$\hat{v}_i = b_i + \frac{\hat{G}(b_i)}{(N-1)\,\hat{g}(b_i)}, \tag{1.84}$$

and estimate the distribution of values from the pseudo-values.

No instrument is needed because, under independent private values and symmetric equilibrium, the bids that generate G are the bids we observe. The analogue of the demand shock ξ is *unobserved auction heterogeneity*, a feature of the object that bidders see and the researcher does not. It shifts all bids in an auction together and breaks the simple inversion. Chapter 15 treats it, including the deconvolution approach of Krasnokutskaya (2011).

Example 1.43 (The inversion with uniform values)**.** Let values be independent and uniform on $[0,1]$ with N bidders. The symmetric equilibrium of the first-price auction, derived in Chapter 14, is $b(v) = \frac{N-1}{N}v$. Bids are then uniform on $\left[0, \frac{N-1}{N}\right]$, so

$$G(b) = \frac{Nb}{N-1}, \qquad g(b) = \frac{N}{N-1}.$$

Substituting into (1.83) gives

$$b + \frac{G(b)}{(N-1)g(b)} = b + \frac{\frac{Nb}{N-1}}{(N-1)\frac{N}{N-1}} = b + \frac{b}{N-1} = \frac{N}{N-1}\,b = v.$$

The inversion recovers the value exactly. The bidder's margin is $v - b = \frac{v}{N}$, which falls as the number of bidders grows. It mirrors the Cournot Lerner index $\frac{1}{N\varepsilon}$ of Proposition 1.15.

Applications

Auctions also offer a laboratory for strategic behavior under asymmetric information. Einav and Levin describe four lines of work (pp. 153–154), which later chapters develop.

- Athey et al. (2011) study U.S. Forest Service timber sales. In the 1980s the Forest Service used both sealed-bid and open ascending auctions, in some cases choosing the format at random. Regressions exploiting this variation show that sealed-bid auctions attract more small bidders, shift the allocation toward them and can raise revenue. A private-value model with endogenous participation and bidders of different sizes and technologies matches these patterns. The authors use the estimated model to assess bidder competitiveness, including the possibility of collusion in some auctions. Theory translates bids into values that support predictions out of sample, and the variation in format provides a sharp test (p. 154). The paper is a deep dive in Chapter 15.
- Hendricks and Porter (1988) study federal auctions of offshore oil leases on the Outer Continental Shelf. They focus on sales from 1959 to 1969 of "drainage" tracts, which lie next to tracts where deposits have been found. The owner of the neighboring lease has extra information about a drainage tract, whereas newly opened "wildcat" tracts favor no bidder. The outcomes differ sharply across the two cases, and the better-informed neighbors earn profits in the way the theory of asymmetric information predicts. With the later work of Hendricks et al. (2003), this study provides some of the sharpest evidence for equilibrium models of asymmetric information.
- Search advertising auctions combine auction methods with large data sets and field experiments. Varian (2009) infers advertisers' values from Google data under optimal bidding and estimates the division of surplus. Ostrovsky and Schwarz (2009) use a calibrated model of equilibrium bidding to derive optimal reserve prices for Yahoo!'s sponsored search auctions. They implement the reserve prices in a large field experiment and track the resulting increase in revenue. Theory makes predictions "before the fact" or "outside the data" (p. 154).
- In restructured wholesale electricity markets, generators bid to supply power. Borenstein et al. (2002) analyze the California market. They argue that the price spike of the summer of 2000 was due in large part to the exercise of market power, rather than to higher production costs.

1.8.5 Market structure and dynamics

A classic question dates back at least to Bain's work in the 1950s (Einav and Levin, 2010, p. 154). It asks how the set of firms in an industry and their capabilities affect competition, innovation and other outcomes. It leads to a second question: what determines the set of firms, and which barriers to entry keep markets imperfectly competitive? Entry, market structure and dynamics lie outside the main scope of this edition. We nevertheless treat the entry model of Bresnahan and Reiss (1991) in some detail. It gives a clean modern answer to the question that the SCP regressions of Section 1.3 tried to answer.

Entry events

One approach studies specific episodes of entry or exit (pp. 154–155). Goolsbee and Syverson (2008) study how incumbent airlines respond when Southwest Airlines threatens to enter

a route. Fares fall sharply, and the decline begins before Southwest enters. It starts once Southwest operates at both endpoints of the route, which makes entry probable. We cite the working-paper version (NBER Working Paper 11072, revised August 2008). According to its abstract, over half of Southwest's total effect on incumbent fares occurs before Southwest starts flying the route (Chapter 9 treats airline entry). Ellison and Ellison (2011) test for strategic entry deterrence by pharmaceutical incumbents just before their patents expire. Their test exploits variation in market size. Deterrence is unnecessary in very small markets, which attract no entrants, and impossible in very large ones, which attract entrants anyway. Strategic investment can therefore be nonmonotone in market size, whereas investment without a deterrence motive is monotone under their conditions. The working-paper version (NBER Working Paper 13069, 2007) studies drugs that lost patent protection between 1986 and 1992. In it, incumbents in markets of intermediate size advertise less and are more likely to cut advertising just before expiry.

Entry thresholds: theory

A second approach, pioneered by Bresnahan and Reiss (1991), also relies on variation in market size. It adds the assumption that markets are in long-run equilibrium (p. 155). The idea, which also appears in Sutton (1991), is that variable profits scale with the size of the market while fixed costs do not.

Assumption 1.44 (Entry with market-size scaling)**.**

(i) Market demand is $Q = M\,d(p, X)$, where M is the number of consumers, d is the demand of a representative consumer and X shifts it. Doubling M doubles demand at every price.

(ii) The N active firms are symmetric. In the post-entry equilibrium they charge p_N and share demand equally. Industry variable profit per consumer, $v_N = \big(p_N - AVC\big)\,d(p_N, X)$, depends on N but not on M, where AVC is average variable cost.

(iii) Every firm pays the same fixed cost $F > 0$.

(iv) Entry does not raise industry variable profit per consumer, which stays positive: $0 < v_{N+1} \le v_N$ for all N.

(v) Entry is free. Firms enter as long as an entrant earns nonnegative profit.

Under these assumptions each of N firms earns

$$\Pi_N(M) = \frac{M}{N}\,v_N - F. \tag{1.85}$$

We define the *entry threshold* M_N^* as the market size at which N firms just break even, and the *per-firm threshold* $\tau_N = \frac{M_N^*}{N}$ as the number of consumers each firm needs.

Proposition 1.45 (Entry thresholds)**.** *Under Assumption 1.44:*

(i) N firms break even if and only if $M \ge M_N^*$, where $M_N^* = \frac{NF}{v_N}$.

(ii) The thresholds are strictly increasing: $M_1^* < M_2^* < M_3^* < \cdots$.

(iii) The free-entry number of firms is the unique N^* with $\Pi_{N^*}(M) \ge 0 > \Pi_{N^*+1}(M)$. Equivalently, $N^* = N$ if and only if $M_N^* \le M < M_{N+1}^*$, and $N^* = 0$ if $M < M_1^*$.

(iv) The per-firm threshold is $\tau_N = \frac{F}{v_N}$*, and the* entry threshold ratio *is*

$$\frac{\tau_{N+1}}{\tau_N} = \frac{v_N}{v_{N+1}} \geq 1, \tag{1.86}$$

with equality if and only if the entry of firm $N+1$ *leaves variable profit per consumer unchanged.*

Proof. (i) From (1.85), $\Pi_N(M) \geq 0$ if and only if $\frac{Mv_N}{N} \geq F$. Multiplying by $\frac{N}{v_N} > 0$ gives $M \geq \frac{NF}{v_N} = M_N^*$.

(ii) Because $v_{N+1} \leq v_N$,

$$M_{N+1}^* = \frac{(N+1)F}{v_{N+1}} \geq \frac{(N+1)F}{v_N} > \frac{NF}{v_N} = M_N^*.$$

(iii) With N firms in the market, free entry requires two conditions. Incumbents must not lose money, so $\Pi_N(M) \geq 0$. A further entrant must lose money, so $\Pi_{N+1}(M) < 0$. By part (i) the two conditions are $M \geq M_N^*$ and $M < M_{N+1}^*$. By part (ii) the intervals $[M_N^*, M_{N+1}^*)$ are disjoint and cover $[M_1^*, \infty)$, so exactly one N satisfies both. If $M < M_1^*$, a monopolist loses money and no firm enters.

(iv) Dividing M_N^* by N gives $\tau_N = \frac{F}{v_N}$. Taking the ratio for $N+1$ and N gives $\frac{\tau_{N+1}}{\tau_N} = \frac{v_N}{v_{N+1}}$, which is at least one by Assumption 1.44(iv) and equals one exactly when $v_{N+1} = v_N$. □

The ratio in (1.86) measures how competition changes as firms enter. Suppose it takes 800 residents to support one dentist, the illustration of Einav and Levin (p. 155). If a second dentist neither lowers margins nor changes entry costs, a town of 1,600 can support two dentists. If the second dentist intensifies competition, two dentists need more than 1,600 residents. Einav and Levin state the model in their footnote 4 as $\pi(n) = S\, q(p_n)(p_n - c)$ and $\pi(n) > F > \pi(n+1)$, where S is market size and $q(p)$ is "the share of potential customers who purchase." In our notation $S = M$. Because $\pi(n)$ is the profit of one firm, we read $q(p_n)$ as the share of potential customers who buy from a given firm. This reading is ours, and with it $\pi(n) = \frac{M}{n} v_n$.

Remark 1.46 (What the ratio does and does not reveal). The ratio measures the change in conduct as N grows. It says nothing about the level of conduct. A perfect cartel earns the monopoly variable profit per consumer whatever the number of members, so v_N is constant and every ratio equals one. Perfect competition among firms with U-shaped average costs also gives ratios of one, because each firm needs enough customers to produce at minimum efficient scale. At the other extreme, homogeneous Bertrand competition with constant marginal cost gives $v_N = 0$ for $N \geq 2$, so no duopoly ever forms. This case lies outside Assumption 1.44(iv), which requires $v_N > 0$. We read its thresholds as $M_N^* = \infty$ for $N \geq 2$. A ratio near one after a few entrants is therefore consistent with competition or with collusion. Bresnahan and Reiss acknowledge that without price or quantity data they cannot tell the two apart (working paper, p. 8, fn. 8).

Remark 1.47 (Heterogeneous entrants). Let later entrants pay higher fixed costs F_N, because they are less efficient or face entry barriers. Repeating the proof gives $\tau_N = \frac{F_N}{v_N}$ and

$$\frac{\tau_{N+1}}{\tau_N} = \frac{F_{N+1}}{F_N} \cdot \frac{v_N}{v_{N+1}}.$$

A ratio above one can then reflect costlier entrants as well as tougher competition. Other departures shift the ratios too. A monopolist that price discriminates earns more per customer, which lowers τ_1 and raises $\frac{\tau_2}{\tau_1}$. Product differentiation softens competition and lowers τ_N relative to τ_1. Separating these channels requires maintained assumptions about costs.

Example 1.48 (Entry thresholds under Cournot competition)**.** Let per-capita demand be $d(p) = \frac{a-p}{b}$, so market inverse demand is $p = a - b\frac{Q}{M}$. Firms have constant marginal cost $c < a$ and compete in quantities. Firm i maximizes $\left(a - b\frac{Q}{M} - c\right) q_i$, with first-order condition

$$a - b\frac{Q}{M} - c - b\frac{q_i}{M} = 0.$$

In the symmetric equilibrium $q_i = \frac{Q}{N}$. Substituting and solving gives

$$Q = \frac{MN(a-c)}{b(N+1)}, \qquad p_N = \frac{a+Nc}{N+1}, \qquad p_N - c = \frac{a-c}{N+1}.$$

Per-capita demand is $d(p_N) = \frac{Q}{M} = \frac{N(a-c)}{b(N+1)}$, so

$$v_N = (p_N - c)\, d(p_N) = \frac{N(a-c)^2}{b(N+1)^2}.$$

Proposition 1.45 then gives

$$M_N^* = \frac{NF}{v_N} = \frac{Fb(N+1)^2}{(a-c)^2}, \qquad \frac{\tau_{N+1}}{\tau_N} = \frac{v_N}{v_{N+1}} = \frac{N(N+2)^2}{(N+1)^3}.$$

The ratios are $\frac{9}{8} = 1.125$ for the second firm, $\frac{32}{27} \approx 1.185$ for the third, $\frac{75}{64} \approx 1.172$ for the fourth and $\frac{144}{125} = 1.152$ for the fifth, and they tend to one as N grows. A duopoly needs $\frac{9}{4}$ times the market of a monopoly. Figure 1.8 plots the profit lines. Linear Cournot competition thus implies a gradual decline in margins, with ratios a little above one for every entrant.

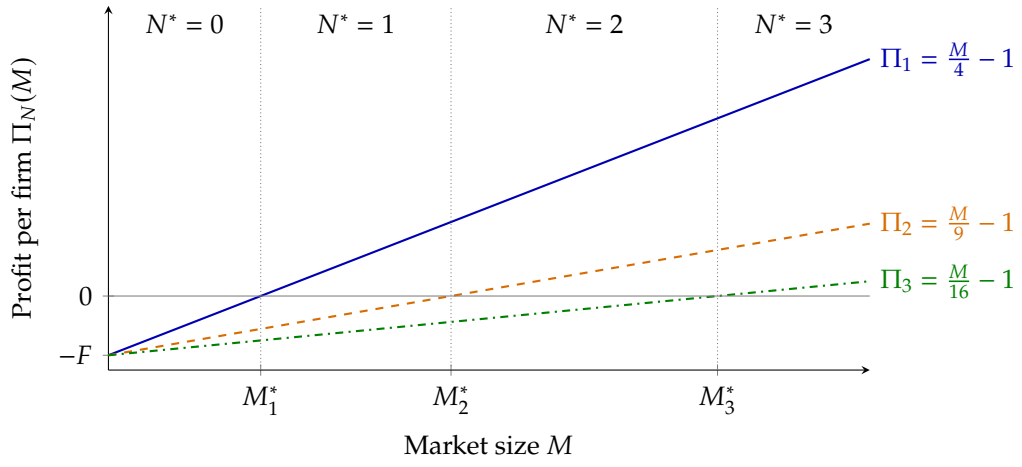

Figure 1.8: Entry thresholds under linear Cournot competition (Example 1.48) with the normalization $\frac{(a-c)^2}{b} = 1$ and $F = 1$. Profit per firm is $\Pi_N = \frac{M}{(N+1)^2} - 1$. Each line crosses zero at the threshold $M_N^* = (N+1)^2$, and the bands show the free-entry number of firms N^*.

Bresnahan and Reiss (1991): entry into isolated markets

Question. How much does entry change competition in a concentrated market? Theories give conflicting answers. Contestability says that the threat of entry alone disciplines incumbents, while many entry-barrier theories say that only actual entry matters. Bresnahan and Reiss (1991) propose to measure the effect of each additional entrant from the relation between market size and the number of firms. The numbers below come from the working-paper version of the article (Stanford GSB Research Paper 1061).

Setting and data. The sample consists of 202 geographically isolated local markets in the United States. The typical market is a county seat in the western United States, and the population of the central town approximates market size. The towns lie at least 25 miles from the nearest town of 1,000 people or more, and towns within 100 miles of a city of 100,000 are excluded. Isolation makes it easy to count all competitors. The authors keep only industries whose sellers offer a narrowly defined product or service and can all be identified. Five survive their data requirements: doctors, dentists, druggists, plumbers and tire dealers. Firms are counted from telephone books and trade sources and checked by visits. Practices that share an address and a telephone number count as one firm. In the sample, mean town population is 3,740, ranging from 120 to 45,090, and the mean number of dentists is 2.6 (working paper, Table 2). Of the 202 markets, 32 have no dentist, 67 have one and 39 have two (Table 1).

Model and estimating equations. The empirical model generalizes (1.85) by letting market size, variable profit and fixed costs depend on observables. The parameter names below are ours, because the paper's symbols clash with the notation of this book. In market t the profit of each of N firms is

$$\Pi_{Nt} = M_t(\lambda)\, V_N(X_t) - F_N(W_t) + u_t. \tag{1.87}$$

The profit shock u_t is standard normal and independent across markets and of the observables. It is common to all firms in a market. Market size is

$$M_t(\lambda) = TownPop_t + \lambda_1 NearbyPop_t + \lambda_2 PosGrowth_t + \lambda_3 NegGrowth_t + \lambda_4 Commuters_t,$$

with the coefficient on town population normalized to one. The other terms are population within ten miles, the positive and negative parts of town growth between 1970 and 1980, and residents who commute to work outside the county. Per-firm variable profit per consumer and fixed costs are

$$V_N(X_t) = \eta_1 + X_t\beta^V - \sum_{n=2}^{N} \eta_n, \qquad F_N(W_t) = \zeta_1 + \zeta_L W_{Lt} + \sum_{n=2}^{N} \zeta_n,$$

The vector X_t contains county demographics such as per capita income. The variable W_{Lt} is the value of farmland, a proxy for the cost of capital. The parameter η_n measures the fall in each firm's variable profit per consumer when the n-th firm enters, and ζ_n the increase in fixed cost. Because V_N is per firm, $V_N = \frac{v_N}{N}$ in the notation of Proposition 1.45. Each industry has 19 parameters: four λs, four coefficients in β^V, five ηs and six ζs.

Estimator. Write $\bar\Pi_{Nt} = M_t V_N - F_N$ for the deterministic part of profit. The equilibrium number of firms is $N_t = N$ when $\Pi_{Nt} \geq 0 > \Pi_{N+1,t}$, that is, when $-\bar\Pi_{Nt} \leq u_t < -\bar\Pi_{N+1,t}$. With $\bar\Pi_{1t} \geq \bar\Pi_{2t} \geq \cdots$ and Φ the standard normal distribution function, this event has probability

$$\mathbb{P}(N_t = N) = \Phi\big(-\bar\Pi_{N+1,t}\big) - \Phi\big(-\bar\Pi_{Nt}\big) = \Phi\big(\bar\Pi_{Nt}\big) - \Phi\big(\bar\Pi_{N+1,t}\big)$$

for $N = 1, \ldots, 4$. The end categories have $\mathbb{P}(N_t = 0) = 1 - \Phi(\bar{\Pi}_{1t})$ and $\mathbb{P}(N_t \geq 5) = \Phi(\bar{\Pi}_{5t})$. The parameters maximize the ordered probit log-likelihood

$$\ell = \sum_t \sum_{N=0}^{5} \mathbf{1}\{N_t = N\} \ln \mathbb{P}(N_t = N \mid M_t, X_t, W_t).$$

The authors impose $\bar{\Pi}_{N+1} \leq \bar{\Pi}_N$ by setting an η_N or ζ_N to zero where necessary. In the doctors' model, for example, $\eta_3 = \eta_5 = 0$. At the sample means of the covariates, the entry thresholds are

$$M_N^* = \frac{\zeta_1 + \zeta_L \bar{W}_L + \sum_{n=2}^{N} \zeta_n}{\eta_1 + \bar{X}\beta^V - \sum_{n=2}^{N} \eta_n}, \tag{1.88}$$

the market size at which $\bar{\Pi}_N = 0$, and the per-firm thresholds are $\tau_N = \frac{M_N^*}{N}$.

Identification. Market size is the excluded variable. It multiplies variable profit and leaves fixed costs unchanged, so the way the distribution of N_t shifts with population traces out the thresholds. The normalizations fix the units of market size (town residents) and the scale of profit (unit variance of u_t). The thresholds are ratios, so they do not depend on the scale normalization. The parameters η_n and ζ_n are separately identified only because η_n interacts with market size and ζ_n does not. In practice the data barely separate falling variable profits from rising fixed costs, and many individual estimates have large standard errors (working paper, pp. 16 and 20). The thresholds depend only on the ratio of fixed costs to variable profits, and restricting the cost parameters changes them little (working paper, p. 21). Five assumptions are maintained. Firms within an industry differ only through the entry-order terms η_n and ζ_n, and one profit shock is common to all firms in a market. Population is exogenous to the number of firms, and isolation captures every competitor. Markets are in long-run equilibrium. With a single cross-section, sunk and fixed costs cannot be distinguished (working paper, fn. 5).

Main results. Table 1.9 reproduces the estimated thresholds. A monopoly tire dealer or druggist needs about 500 people in town, and a monopoly doctor or dentist between 700 and 900. A monopoly plumber needs about 1,430 people, twice the dentist threshold and 1.6 times the doctor threshold (Table 1.9). The per-firm ratios decline with N. For doctors, dentists, druggists and tire dealers, the second firm needs roughly 1.8 to 2.0 times the customers of a monopolist, while plumbers' ratios stay near one throughout. For the third firm the ratio is near one for doctors and plumbers (1.10 and 1.00), 1.28 for tire dealers and 1.58 for druggists. For dentists Table 4 prints 0.79, while the printed thresholds imply 1.10. For the fourth and fifth firms the ratios lie between 0.94 and 1.14 in every industry, so the decline stops abruptly after the first few entrants. Likelihood ratio tests cannot reject $\tau_3 = \tau_4 = \tau_5$ except for dentists. They reject $\tau_1 = \cdots = \tau_5$ in all five industries, so the variation in the first two thresholds is not sampling noise. Figure 1.9 redraws the paper's Figure 4, which plots $\frac{\tau_5}{\tau_N}$ against N.

Robustness. Using "four or more firms" as the top category extends the analysis to eight industries. The thresholds of the original five change little, and heating contractors and barbers show the same pattern. Auto dealers are the exception, with a per-firm ratio for the fourth dealer well above one (working paper, pp. 18–19). The authors attribute this to product differentiation. Most dealer triopolies pit the three domestic manufacturers against one another, and the fourth dealer is typically the first intrabrand competitor. The hypothesis of equal fixed costs across entrants is rejected for every industry except plumbers, but imposing it barely moves the thresholds. Restricting the sample to very isolated markets, at least 40 miles from the

Table 1.9: Entry thresholds in five retail and professional industries

Panel A. Thresholds and per-firm threshold ratios

	Threshold M_N^* (thousands)					Ratio $\frac{\tau_{N+1}}{\tau_N}$			
Industry	$N=1$	2	3	4	5	$\frac{\tau_2}{\tau_1}$	$\frac{\tau_3}{\tau_2}$	$\frac{\tau_4}{\tau_3}$	$\frac{\tau_5}{\tau_4}$
Doctors	0.88	3.49	5.78	7.72	9.14	1.98	1.10	1.00	0.95
Dentists	0.71	2.54	4.18	5.43	6.41	1.78	0.79	0.97	0.94
Druggists	0.53	2.12	5.04	7.67	9.39	1.99	1.58	1.14	0.98
Plumbers	1.43	3.02	4.53	6.20	7.47	1.06	1.00	1.02	0.96
Tire dealers	0.49	1.78	3.41	4.74	6.10	1.81	1.28	1.04	1.03

Panel B. Likelihood ratio tests of equal per-firm thresholds

	$\tau_4=\tau_5$		$\tau_3=\tau_4=\tau_5$		$\tau_2=\cdots=\tau_5$		$\tau_1=\cdots=\tau_5$	
Industry	LR	df	LR	df	LR	df	LR	df
Doctors	1.12	1	6.20	3	8.33	4	45.06*	6
Dentists	1.59	1	12.30*	2	19.13*	4	36.67*	5
Druggists	0.43	2	7.13	4	65.28*	6	113.92*	8
Plumbers	1.99	2	4.01	4	12.07	6	15.62*	7
Tire dealers	3.59	2	4.24	3	14.52*	5	20.89*	7

Notes: Thresholds are evaluated at sample means with (1.88), using the baseline ordered probit estimates, and are measured in thousands of people. The per-firm threshold is $\tau_N = \frac{M_N^*}{N}$. Ratios are as printed in the source. The printed thresholds imply $\frac{\tau_3}{\tau_2} = 1.10$ for dentists, and all other ratios match the thresholds up to rounding. In Panel B, LR is the likelihood ratio statistic and df its degrees of freedom. An asterisk marks a statistic above the 5 percent cutoff of the chi-squared distribution with the stated degrees of freedom. Source: Bresnahan and Reiss (1991), Table 4 (working-paper version, Research Paper 1061).

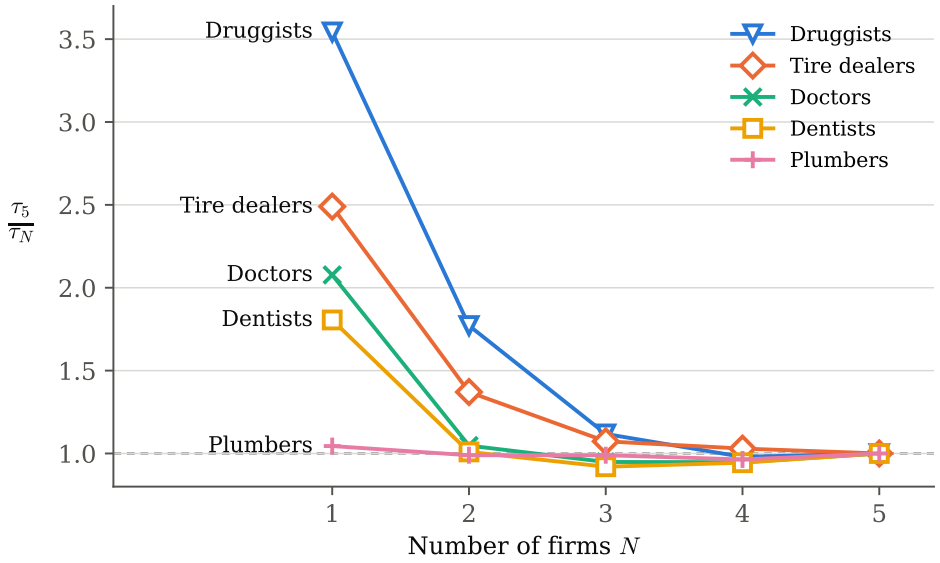

Figure 1.9: Ratio of the per-firm threshold for five firms to the per-firm threshold for N firms, $\frac{\tau_5}{\tau_N}$, by industry. A value near one means that the N-th firm needs about as many customers as the fifth. From $N = 3$ on, the ratios lie between 0.92 and 1.12 in every industry. Redrawn from the thresholds in Table 1.9. Source: Bresnahan and Reiss (1991), Figure 4 (working-paper version).

next town of 1,000 people, leaves 157 markets and similar ratios. Treating every county with fewer than 10,000 residents in 1980 as a market, isolated or not, sharply reduces the estimated effect of the second and third doctors and dentists. This is what we would expect if customers in less isolated towns shop elsewhere, and it supports the strict market definition.

Interpretation. Under the maintained hypotheses that firms in each industry offer similar services with similar technologies and costs, the results say that entry beyond the third firm changes margins very little. Most of the competitive effect of entry is felt in highly concentrated markets, with the second and third entrants. The authors were surprised. They had expected margins, or entry barriers, to erode gradually. Through the lens of Example 1.48 the pattern is sharper than linear Cournot competition implies. Cournot predicts a second-firm ratio of 1.125 and ratios above one for every later entrant. Four of the industries instead show second-firm ratios between 1.78 and 1.99, and every industry shows ratios close to one from the fourth firm on. In the words of Einav and Levin, competition appears to "kick in relatively quickly" with just a few firms and then does not ramp up with further entry (p. 155).

Critiques. Bresnahan and Reiss list the main caveats themselves. Without prices, quantities and the timing of entry, they cannot say whether markets with three or more firms are competitive, only that conduct stops changing (Remark 1.46). Ratios above one can reflect costlier later entrants as well as falling margins (Remark 1.47). Professionals with low opportunity costs might seek out isolated monopolies, which would raise the monopoly ratios for reasons unrelated to competition. Einav and Levin add a critique of the literature that followed (pp. 155–156). One might have expected researchers to look for other identifying variation, such as differences in fixed costs or entry restrictions, or to gather data on prices and costs. Instead, most follow-up work developed econometric methods that allow firm heterogeneity or relax parametric restrictions (Berry, 1992; Berry and Tamer, 2006), often applying the original identifying assumptions where they are less compelling. This produced a rich literature on identification and estimation that has not necessarily brought us closer to the original question.

Contribution. The paper shows how sparse data, used with theory and a clean design, can answer an important question. Counts of firms in markets of different sizes reveal how competition varies with the number of firms. The entry model gets around missing data on prices and quantities, which is one reason it has been so influential (p. 160). It also reframes the SCP question. Concentration is treated as an equilibrium outcome driven by an exogenous shifter, market size, and the relation between the two identifies how conduct changes with structure.

Remark 1.49 (Market size and concentration). If the per-firm thresholds converge to a finite limit τ_∞, concentration vanishes in large markets. Because τ_N is nondecreasing, $M < M^*_{N^*+1} = (N^*+1)\tau_{N^*+1} \leq (N^*+1)\tau_\infty$ by Proposition 1.45(iii). Hence $N^* > \frac{M}{\tau_\infty} - 1$, which grows without bound with M. This argument treats fixed costs as exogenous. Sutton (1991) shows that the conclusion fails when firms can raise demand through sunk outlays such as advertising or research and development. Such endogenous sunk costs escalate with market size, and concentration can stay bounded away from zero however large the market becomes.

Industry dynamics

Many questions about market structure are dynamic (Einav and Levin, 2010, p. 156). Do new industries follow a common life cycle of entry and consolidation? How do firm and industry growth vary with market characteristics? Are mergers followed quickly by entry, and how do

industries adapt to booms and recessions? A dynamic view can also temper static intuition. Higher concentration reduces static welfare, but the prospect of market power can create strong incentives to innovate.

The literature has two strands (p. 156). The first looks across industries for robust patterns of survival, turnover and growth. Its main finding is the large heterogeneity across establishments even within narrow industries. This finding shaped theoretical models of industry dynamics (Hopenhayn, 1992), which in turn inspired work on firm heterogeneity in international trade (Melitz, 2003). The link between entry, exit and firm characteristics also entered the study of productivity through Olley and Pakes (1996). The second strand builds models of dynamic equilibrium in single industries, often in the framework of Ericson and Pakes (1995). Benkard (2004) applies such a model to commercial aircraft, where learning by doing lowers costs dramatically. Equilibrium prices can lie below marginal cost early in a product's life, because extra output speeds learning. The prospect of market power is what motivates firms to move down the learning curve. Consumers gain from lower prices both early on and later, when costs are lower. Newer methods estimate sunk costs, learning and adjustment frictions from panel data on firms or local markets (Aguirregabiria and Mira, 2007; Bajari et al., 2007; Pakes et al., 2007). Aguirregabiria et al. (2021) survey this work in Volume 4 of the Handbook of Industrial Organization. Their chapter lays out the Markov perfect equilibrium framework, the data typically available, identification and estimation, and applications to innovation, mergers, regulation, investment, advertising and dynamic pricing (Ho et al., 2021a, Preface, pp. xvi–xvii).

Remark 1.50 (Why learning can push prices below marginal cost). A two-period monopolist faces demand $Q(p)$ in each period and discounts the future by a factor δ. The first-period cost is c_1. Learning makes the second-period cost $c_2(Q_1)$ fall with first-period output, so $c_2' < 0$. Let $\pi_2(c_2)$ be the optimal second-period profit. By the envelope theorem $\pi_2'(c_2) = -q_2$, where q_2 is second-period output. The firm chooses p_1 to maximize $(p_1 - c_1)Q(p_1) + \delta\,\pi_2\big(c_2(Q(p_1))\big)$. The first-order condition is

$$Q(p_1) + (p_1 - c_1)Q'(p_1) + \delta\,\pi_2'(c_2)\,c_2'(Q_1)\,Q'(p_1) = 0.$$

Substituting $\pi_2' = -q_2$ and dividing by $-Q'(p_1) > 0$ gives

$$p_1 = \big(c_1 - \delta q_2 |c_2'|\big) - \frac{Q(p_1)}{Q'(p_1)}.$$

The firm prices off an effective marginal cost that is lower than c_1 by the discounted value of learning. If learning is strong enough, $p_1 < c_1$.

The data available for such models often pale in comparison with the ambitious questions asked, so researchers fill the gaps with strong assumptions (p. 156). Einav and Levin view this work as "a quantitative theory exercise" (pp. 156–157). It sheds light on dynamic competition in a model with reasonable parameter values. They do not see this as a problem. It is hard to imagine a clean research design that could pin down the long-run effect on innovation of a change in the patent system. When the entire history of an industry is a single data point, quasi-experimental variation is rare, and models are the only way to study such questions.

1.8.6 Structural and design-based approaches

Thirty years ago empirical IO resembled other applied fields (Einav and Levin, 2010, p. 157). Industrial organization economists ran cross-industry regressions and faced endogeneity,

omitted variables and reverse causality, much as labor economists running wage regressions did. Since then IO has moved in a distinctive direction. It turned toward single industries, where measurement and identification are cleaner, and toward analyses framed by an economic theory of the industry. In the same journal issue, Angrist and Pischke (2010) describe a parallel move in applied microeconomics toward randomized experiments and quasi-experiments. They also criticize empirical IO, and Einav and Levin reply. The exchange clarifies the stance of this book.

Clean measurement versus the object of interest

No one disagrees about the ideal (p. 157). Every researcher would like to define an object of interest and then design the perfect experiment to measure it. Without that ideal, researchers face trade-offs, and a common one is between the cleanness of a measurement and how well the measured object proxies for the object of interest. Einav and Levin illustrate it with cereal (pp. 157–158). Suppose the object of interest is the $J \times J$ matrix of price elasticities $E = [\varepsilon_{jk}]$.

- The standard IO approach controls for shifts in demand and assumes that the remaining correlation of prices across cities reflects costs, as with the Hausman instruments of Nevo (2001). Within the demand model this identifies all of E. The assumption may fail.
- A design-based alternative looks for an episode that moved one price for an explicable and plausibly exogenous reason. An example would be a week in which the pricing algorithm for Froot Loops malfunctioned and produced an unintended sale. Such an episode credibly identifies one column of E, the responses $\varepsilon_{j,\mathrm{FL}}$ of all products to the price of Froot Loops. To learn the rest of E we must extrapolate, for instance by assuming that a change in the price of Frosted Flakes, or of any cereal, would have analogous effects.

Neither approach is ideal. The first relies on a questionable identifying assumption but frames the exercise directly in terms of the object of interest. The second measures a few entries convincingly but reaches the object of interest only through a questionable extrapolation. Einav and Levin argue that evaluating entire research approaches in the abstract paints too simple a picture (p. 158). The right resolution depends on the question, the data and how compelling a rationale theory provides for the assumptions. There is room for many approaches, even to the same question, and careful work from different angles is often complementary.

Theory, transparency and mechanisms

Angrist and Pischke favor measurement strategies uncontaminated by restrictions from an economic model, partly on grounds of transparency. Einav and Levin call the implied link between theory and obscurity "a false equivalence" (p. 158). A model derived from theory can be exposited with perfect clarity, and a linear regression can be exposited with perfect obscurity. It is more natural to start with a research question and ask how much theory can say about it. Standard theory says little about student behavior in third-grade classrooms, the setting of Angrist and Pischke's class-size example. There a statistical approach that exploits variation across thousands of roughly parallel classrooms is attractive. Industrial organization is largely about firms and markets, which is the other side of the contrast quoted in Section 1.1 (pp. 158–159). Moreover, the interesting question is often a mechanism rather than a single causal effect. Markets differ greatly, so importing particular numbers across markets is rarely compelling. Empirical work generalizes best by building support for principles of strategic interaction and market functioning that apply across industries.

The merger example

Angrist and Pischke chose merger evaluation as their example. They dismiss merger simulation as needlessly indirect and ask why there has not been more retrospective analysis of past mergers. Einav and Levin answer that the point is good at one level and misses the point at another (p. 159). If the Department of Justice had to review a merger of Microsoft and Yahoo!, the price effects of past airline or office-supply mergers would be of little use. It is far more useful to lay out a clear framework for the potential effects of that merger and to add the best available evidence. Chapter 11 presents retrospective studies and merger simulations side by side, and it shows how each disciplines the other.

The bottom line is that economic theory and the search for compelling identifying variation are allies (p. 159). The applied work that Einav and Levin find most exciting rests on careful measurement from data with good variation and then frames the analysis in a coherent economic model. The model gives a way to think about how the industry works and, potentially, to draw conclusions about policy or general principles. The case studies of this book are chosen and presented with that standard in mind.

Methods, applications and the questions IO asks

Einav and Levin also voice concerns about the field itself (pp. 159–160). Their main concern is that too little effort goes into compelling applications relative to new econometric methods. Better methods are valuable if they are eventually used in compelling ways and do not become an end in themselves. In demand estimation, researchers may have tolerated imperfect price variation because the main contribution was a method that applies more broadly. Data limitations explain part of the current balance. Some of the most influential methods were responses to scarce data. The entry model of Bresnahan and Reiss (1991) gets around missing data on prices and quantities, and the demand model of Berry et al. (1995) needs only market-level data. As firms collect vast amounts of data on customers, prices, quantities and locations, richer data may substitute for methods and shift effort toward applications.

A related danger applies to all empirical strategies: the elegance of a solution can pull researchers toward less important questions (p. 160). Einav and Levin use eBay as an example. Viewed as a laboratory for elegant auction methods, eBay invites the study of ever narrower submarkets. Broader questions, such as why eBay succeeded as an institution or how it competes with Amazon and other platforms, would then go unasked. Researchers should "resist the temptation of grabbing a hammer and letting it pull them toward a limited set of nails" (p. 160).

The last concern is about scope. Schmalensee's review of the cross-industry literature concluded that it had taught us little about how markets work (Section 1.5.3). After two decades of industry studies, we know a lot about specific industries such as automobiles, airlines, electricity, and cement and concrete. This knowledge is extremely disaggregated and does not easily accumulate across industries. As a result, IO has ceded many important questions about the overall organization of production to trade and macroeconomics. Einav and Levin suggest that "it may be time to reclaim them" (p. 160). The debate over rising markups in Section 1.5.4 is one place where IO economists are doing so, and it shows how hard the cross-industry questions remain.

1.9 Roadmap of the book

The book has four parts and three appendices. Every chapter follows the order of this introduction: theory in general form first, then case studies that show how the theory meets data. Table 1.10 lists, for each chapter, its central question, its main models and tools, and the papers it treats as full case studies. Readings that are not case studies receive shorter treatments in the same chapters.

1.9.1 The four parts

Part I treats market power, its theory and its measurement. This chapter introduced the questions, the SCP tradition and its failure, the NEIO response and the structural workflow. Chapter 2 develops the theory that the rest of the book uses. It covers monopoly pricing, Cournot and Bertrand competition, conjectural variations and the conduct parameter, pass-through and welfare. Chapter 3 asks whether market power can be detected and measured in homogeneous-good industries. It covers tax pass-through tests, the Panzar-Rosse statistic, residual demand, the identification of conduct by demand rotations, and direct validations against cost data. Chapter 4 turns to differentiated products. It derives multi-product Bertrand pricing and diversion ratios, discusses existence and uniqueness of equilibrium, and contrasts product space with characteristic space.

Part II is about demand estimation. Chapter 5 estimates demand in product space with the Almost Ideal Demand System, multi-stage budgeting and Hausman instruments. Chapter 6 builds the foundations of discrete choice, including the vertical model and the pure characteristics model. Chapter 7 covers the logit and nested logit, the Berry inversion and instruments for price. Chapter 8 develops the random coefficients logit of Berry, Levinsohn and Pakes, its estimation and its supply side. Chapter 9 applies these tools to airline hubs and entry. Chapter 10 measures the value of new goods and the bias in price indexes that ignore them.

Part III is about competition policy. Chapter 11 covers horizontal mergers. It treats market definition, the theory of mergers in Cournot and differentiated-product models, upward pricing pressure, merger simulation and retrospective studies. Chapter 12 develops the theory of collusion in repeated games, with demand fluctuations, imperfect monitoring, private information and communication. Chapter 13 studies how real cartels operated and how collusion can be detected in prices and bids.

Part IV is about auctions. Chapter 14 develops the theory of single-object auctions, from independent private values to the affiliated values model of Milgrom and Weber. Chapter 15 asks what bid data reveal about values and costs. It covers identification, the estimator of Guerre, Perrigne and Vuong, unobserved heterogeneity and entry.

Three appendices support the main text. Appendix A collects the econometric tools: instrumental variables, the generalized method of moments, maximum likelihood and simulation estimators, the delta method, nonparametric estimation, and event studies. Appendix B collects the mathematical tools: the envelope and implicit function theorems, duality, extreme value algebra, order statistics, contraction mappings, log-concavity and affiliation. Appendix C contains worked problems with full solutions. Two simulated markets recur there as running examples. One has 25 logit products sold by five owners. The other has 100 markets drawn from a pool of ten products, and each market offers between four and nine of them. It is generated from a random-coefficients logit with a cost shifter, and on it the vertical, logit and random-coefficients estimators are compared.

Table 1.10: Roadmap of the book

Chapter	Central question	Main models and tools	Case studies in depth
Part I. Market power: theory and measurement			
1. Introduction	How do we learn about market power and its causes?	SCP regressions, the Cournot link between margins and concentration, the conduct parameter, the structural workflow	Bresnahan and Reiss (1991), Grieco et al. (2024) (and substantive treatments of Bresnahan (1989) and Einav and Levin (2010))
2. Pricing theory	How do demand, cost and conduct determine prices?	Monopoly pricing, Cournot and Bertrand oligopoly, conjectural variations, pass-through, welfare	None
3. Measuring market power	Can we detect and measure market power with homogeneous goods?	Tax pass-through tests, Panzar-Rosse statistic, residual demand, identification of conduct by rotations	Sumner (1981), Corts (1999), Genesove and Mullin (1998), Wolfram (1999)
4. Differentiated oligopoly	How do multi-product firms price differentiated goods?	Multi-product Bertrand-Nash pricing, ownership matrix, diversion ratios, existence and uniqueness, location models	None
Part II. Demand estimation			
5. AIDS	How do we estimate flexible demand in product space?	Duality, AIDS, multi-stage budgeting, Hausman instruments, welfare	Deaton and Muellbauer (1980a), Hausman et al. (1994), Chaudhuri et al. (2006)
6. Discrete choice	How do individual choices aggregate to market demand?	Random utility, vertical model, pure characteristics model, hedonic approach	Bresnahan (1987), Berry and Pakes (2007)
7. Logit	How do we estimate logit demand with endogenous prices?	Logit, Berry inversion, instruments, nested logit	Berry (1994), Einav (2007), Hendel (1999)
8. BLP	How do we obtain realistic substitution from market-level data?	Random coefficients logit, contraction mapping, GMM, supply side, micro moments	Berry et al. (1995), Nevo (2000a), Nevo (2001), Berry et al. (2004a), Goldberg (1995)
9. Airlines	Why are fares high at hubs, and how does entry discipline them?	Fare regressions, event studies, discrete choice with consumer types and hub costs	Borenstein (1989), Whinston and Collins (1992), Berry et al. (2006)
10. New goods	What is a new good worth to consumers?	Virtual prices, compensating variation, logit welfare, micro moments	Hausman (1997), with the comment by Bresnahan (1997); Trajtenberg (1989), Petrin (2002), Gentzkow (2007)
Part III. Competition policy			
11. Mergers	When do horizontal mergers raise prices?	Market definition, Cournot merger analysis, upward pricing pressure, merger simulation, retrospectives	Farrell and Shapiro (1990), Farrell and Shapiro (2010), Nevo (2000b), Björnerstedt and Verboven (2016), Miller and Weinberg (2017)
12. Collusion: theory	How can firms sustain collusion without enforceable contracts?	Repeated games, optimal punishments, demand fluctuations, imperfect monitoring, private information, communication	Green and Porter (1984), Rotemberg and Saloner (1986), Athey et al. (2004a), Harrington and Skrzypacz (2011)
13. Collusion: evidence	How did cartels operate, and how can we detect them?	Regime-switching supply relations, tests of price-war theories, bidding rings, tests for bid rigging	Porter (1983a), Ellison (1994), Porter and Zona (1993), Asker (2010)
Part IV. Auctions			
14. Auction theory	How do rules and information shape bids and revenue?	Private and affiliated values, first- and second-price equilibrium, revenue equivalence, reserve prices, linkage principle	Milgrom and Weber (1982)
15. Auction empirics	What do bids reveal about values and costs?	Order-statistic inversion, the GPV estimator, unobserved heterogeneity, entry, timber auctions	Athey and Haile (2002), Athey and Haile (2007), Guerre et al. (2000), Krasnokutskaya (2011), Athey et al. (2011)

Notes: The last column lists the papers treated as full case studies, following the structure described in Section 1.9.3. Each chapter also gives shorter treatments of the other readings in its scope.

1.9.2 Reading paths

The chapters build on one another, but several shorter paths through the book work well.

- A reader interested in antitrust and merger analysis can read Chapters 2 to 4, 7, 8 and 11. This path runs from pricing theory and the measurement of market power to the demand models that merger simulation requires.
- A reader interested in demand estimation can read Chapters 5 to 10, after Section 1.8.1 and the multi-product pricing of Chapter 4.
- A reader interested in collusion can read Chapters 2, 3, 12 and 13.
- A reader interested in auctions can read Chapters 14 and 15, after Section 1.8.4. The bid-rigging material of Chapter 13 is a natural complement.

1.9.3 Prerequisites and conventions

We assume graduate training in microeconomic theory and econometrics. On the theory side the reader should know consumer theory and duality, and Nash, subgame perfect and Bayesian Nash equilibrium. On the econometric side the reader should know least squares, instrumental variables, the generalized method of moments and maximum likelihood. Appendices A and B fill gaps. For the theory of industrial organization at greater length, Tirole (1988) remains the standard reference. For surveys of recent work, including topics outside this edition, the reader can turn to Volumes 4 and 5 of the Handbook of Industrial Organization (Ho et al., 2021b,a). Their Preface describes every chapter (Ho et al., 2021a, pp. xv–xxi). The first five chapters review econometric methods that continue the NEIO program, Chapters 6 to 9 review theory, and Chapters 10 to 17 apply both to policy questions and to particular sectors. Table 1.11 lists the chapters and the parts of this book that each one extends.

Notation is fixed across chapters. Markets are indexed by t and products by j, with $j = 0$ the outside good. Firms are indexed by f in differentiated-product models and by i in homogeneous-good models, and consumers by i in discrete choice models. Market shares are s_{jt}, marginal costs mc_{jt}, the price elasticity of demand $\varepsilon > 0$, the conduct parameter θ and the ownership matrix Ω. Mean utility is $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, and auctions use v for values, b for bids and G for the distribution of bids. When a chapter must depart from this notation, or rename the symbols of a paper, it says so at first use.

Each case study follows the same order. We state the economic question and why it matters, the institutional setting and the data. We then write the model and the exact estimating equations, the estimator, the instruments and the identification argument. We reproduce the key results in a table, citing the table number in the original paper, and discuss robustness, interpretation, the critiques raised in the literature and the paper's contribution. Every chapter ends with exercises and with bibliographic notes that place its papers in context.

1.10 Bibliographic notes

The structure-conduct-performance tradition begins with Mason (1939) and the cross-industry studies of Bain (1951, 1956). The Introduction of Tirole (1988) tells its history, together with the Chicago tradition and the theoretical wave that followed (Joskow, 1975). Schmalensee (1989) is the standard review of its evidence, and Weiss (1989) collects the price-concentration studies of local markets. Demsetz (1973) stated the efficiency critique, and Schmalensee (1987) tests it

Table 1.11: The chapters of the Handbook of Industrial Organization, Volumes 4 and 5

Chapter	Authors	Topic	Extends
Volume 4: econometric methods (Chapters 1 to 5) and theory (Chapters 6 to 9)			
1	Berry and Haile	Foundations of demand estimation	Chapters 6 to 8
2	Gandhi and Nevo	Demand and supply in differentiated-products industries, opening with Bresnahan (1987)	Chapters 6, 8 and 11
3	De Loecker and Syverson	Productivity, and the production approach to market power	Section 1.5.4
4	Aguirregabiria, Collard-Wexler and Ryan	Dynamic games	Section 1.8.5
5	Kline, Pakes and Tamer	Moment inequalities and partial identification	Section 1.8.5
6	Gavazza and Lizzeri	Frictions in product markets	Not covered
7	Jullien, Pavan and Rysman	Two-sided markets, pricing and network effects	Section 1.6.1
8	Bergemann and Ottaviani	Information markets and nonmarkets	Not covered
9	Lee, Whinston and Yurukoglu	Contracting in vertical markets	Not covered
Volume 5: applications to policy questions and sectors			
10	Agarwal and Budish	Market design	Chapter 14
11	Hortaçsu and Perrigne	Empirical perspectives on auctions	Chapter 15
12	Asker and Nocke	Collusion, mergers and related antitrust issues	Chapters 11 to 13
13	Bryan and Williams	Innovation: market failures and public policies	Not covered
14	Einav, Finkelstein and Mahoney	Selection markets	Section 1.8.3
15	Clark, Houde and Kastl	Financial markets	Not covered
16	Handel and Ho	Health care markets	Section 1.5.3
17	Kellogg and Reguant	Energy and environmental markets	Section 1.8.4

Notes: Chapter titles are abbreviated. "Extends" names the chapter or section of this book that the Handbook chapter continues. Source: Ho et al. (2021a, Preface, pp. xv–xxi).

against the collusion hypothesis. Hopenhayn (1992) shows that high entry costs can produce the pattern Demsetz reported in a competitive model, and Levenstein and Suslow (2006) place the debate within the study of cartels. Salinger (1990) revisited the debate with a panel of industries, using annual cross sections and long differences. The measurement problems of accounting margins are analyzed by Fisher and McGowan (1983). The Cournot foundation of the margin-concentration relation is due to Cowling and Waterson (1976), with the conduct generalization of Clarke and Davies (1982). Section 5.5 of Tirole (1988) links concentration indices to industry profitability, and Encaoua and Jacquemin (1980) give the axioms that define them.

The New Empirical Industrial Organization is surveyed by Bresnahan (1989), whose chapter remains the best statement of its principles and of its identification arguments. Its antecedents include Rosse (1970), and its central identification results are Bresnahan (1982) and Lau (1982) for demand rotations and Panzar and Rosse (1987) for comparative statics in cost. Porter (1983a) is the classic application to a cartel. Chapter 3 develops these results, the tax tests of Sumner (1981) and Ashenfelter and Sullivan (1987), and the critique by Corts (1999).

Modern empirical IO is surveyed by Einav and Levin (2010). Volumes 4 and 5 of the Handbook of Industrial Organization (Ho et al., 2021b,a) survey its methods and applications chapter by chapter, and Table 1.11 maps each chapter to this book. Among them, De Loecker and Syverson (2021) treat productivity and the production approach to markups, and Aguirregabiria et al. (2021) treat dynamic games. Asker and Nocke (2021) cover collusion and mergers, and Handel and Ho (2021) cover health care. Tirole (1988) remains the standard treatment of the theory. The demand models behind the structural workflow start with Berry (1994) and Berry et al. (1995), and the parallel approach to auctions starts with Guerre et al. (2000). Bresnahan and Reiss (1991) is the founding paper of the empirical entry literature, and Sutton (1991) gives the theory of endogenous sunk costs.

The debate over rising markups starts with De Loecker et al. (2020), who build on the production approach of Hall (1988) and De Loecker and Warzynski (2012). Section 3.8 of Asker and Nocke (2021) summarizes their findings and the measurement questions they raise, and Ganapati (2021) documents how concentration relates to productivity, output and prices. Berry et al. (2019) give the IO perspective on that debate, which Handel and Ho (2021) apply to health care and Autor et al. (2020) connect to the labor share. Bond et al. (2021) analyze the use of revenue data. Grieco et al. (2024) study one industry from the demand side and find that markups in the US new-car market fell after 1980 while consumer surplus rose. The exchange between Angrist and Pischke (2010) and Einav and Levin (2010) sets out the case for and against structural models in applied microeconomics.

1.11 Exercises

1. *Measuring the market power of one seller.* A coffee shop on a university campus sets a single price for a cup of coffee.

   (a) Describe the data and the variation in prices you would need to estimate the elasticity of the shop's residual demand. Explain why a regression of its daily sales on its daily price would not, in general, estimate that elasticity.

   (b) Suppose you have such an estimate. Explain what you could conclude about marginal cost from Corollary 1.11, and which maintained assumption the conclusion rests on.

   (c) Consider three events: a per-unit tax on coffee sold on campus, a rise in the world price

of coffee beans, and the opening of a rival cafe in the same building. For each event, say which primitive (demand, cost or conduct) it moves. Then explain what the observed response of price would reveal.

(d) Suppose the shop is the monopolist of Example 1.31, with $\alpha = 0.5$ per dollar and a share $s = 0.4$ of potential customers. It improves its coffee at no change in marginal cost. Compute the change in price and in net utility v per unit of quality. Explain why a regulator who saw the Lerner index rise would be wrong to conclude that customers lost.

2. *Concentration and mergers.*

(a) Construct two share vectors with the same four-firm concentration ratio CR_4 and different Herfindahl indices, and two with the same Herfindahl index and different CR_4. Compute the numbers equivalent N^{eq} of each.

(b) Firms i and j merge, and the merged firm keeps the share $s_i + s_j$. Show that the merger lowers the numbers equivalent from $\frac{1}{HHI}$ to $\frac{1}{HHI + 2s_i s_j}$, and compute both for $s_i = 0.2$, $s_j = 0.1$ and $HHI = 0.15$.

(c) Consider symmetric Cournot competition with linear demand among four firms with equal constant marginal costs. Two firms merge, and the merged firm has the same marginal cost as before. Compute the predicted change in the Herfindahl index from part (b) and the actual change in the new Cournot equilibrium. Explain the difference.

(d) Show that the entropy index $\sum_i s_i \ln s_i$ rises when share moves from a smaller to a larger firm, as Remark 1.6 requires. Then construct a transfer between two firms that leaves CR_4 unchanged and raises HHI.

3. *Conduct and the slope of the SCP regression.* Industries $k = 1, \dots, n$ share a common market elasticity ε. Each industry is either Cournot ($\kappa_k = 0$) or perfectly collusive ($\kappa_k = 1$), so that by Proposition 1.17 its margin is $L_k = \frac{\kappa_k + (1 - \kappa_k) HHI_k}{\varepsilon}$.

(a) Suppose HHI_k is uniform on $[0, 1]$ and $\mathbb{P}(\kappa_k = 1 \mid HHI_k = h) = 1 - h$, because collusive industries attract entry. Use Proposition 1.24(i) to compute the probability limit of the OLS slope of L_k on HHI_k.

(b) Compare your answer with $\mathbb{E}\left[\frac{1 - \kappa_k}{\varepsilon}\right]$, the slope that random assignment of concentration would deliver. Explain the sign of the bias.

(c) The regression in (a) suggests that concentration does not affect margins. Yet the margin of every Cournot industry rises with concentration at the rate $\frac{1}{\varepsilon}$. Explain the discrepancy.

4. *Free entry and the cross-industry correlation.* Use the free-entry Cournot model of Section 1.4.3 with a continuous number of firms.

(a) Derive N^*, HHI^* and L^* as functions of (a, c, b, F).

(b) Compute the equilibrium for four industries: $(a, c, b, F) = (10, 2, 1, 1)$, $(10, 2, 1, 4)$, $(10, 4, 1, 1)$ and $(14, 2, 1, 1)$.

(c) Pair the first industry with each of the other three. For each pair, compute the slope of the line through the two points (HHI^*, L^*). Compare these slopes with the slope $\frac{\mathrm{d}L}{\mathrm{d}HHI}$

of each industry's own causal curve (1.24) at its equilibrium. Which pairs, if any, reveal a causal effect of concentration?

5. *Efficiency and concentration.* Inverse demand is $P = 10 - Q$, and three Cournot firms have marginal costs $(2, 3, 4)$.

   (a) Use Proposition 1.27 to compute the price, total output, each firm's output and share, the Herfindahl index, industry variable profit and consumer surplus.

   (b) Replace the costs by $(1.5, 3, 4.5)$. Verify that all firms stay active and recompute every quantity in (a). Which change, and by how much does total surplus change?

   (c) Return to the costs $(2, 3, 4)$. The two lowest-cost firms merge and produce at the lower of their two costs. Compute the new equilibrium. Compare the actual change in the Herfindahl index with the share-based prediction $2s_1s_2$, and compute the changes in price and consumer surplus.

   (d) What do (b) and (c) imply for a regulator who observes only concentration and industry profits?

6. *Measurement error, fixed effects and accounting margins.*

   (a) Show that the Census price-cost margin equals the Lerner index whenever variable cost (payroll and materials) is linear in output, whatever the cost of capital. Derive the probability limit of the OLS slope in a regression of PCM_k on HHI_k that omits $\frac{K_k}{S_k}$, and sign the bias when capital intensity rises with concentration.

   (b) In the setting of Proposition 1.26, let the total variance of true concentration across industry-years be 0.04, of which 90 percent is between industries, so that $\sigma^2_{\tilde{H}} = 0.004$. Let $\sigma^2_u = 0.002$ and $T = 5$. Compute the reliability ratio of the pooled OLS estimator and of the within estimator, and the probability limit of each when $\beta_1 = 0.5$ and the pooled estimator is otherwise valid.

   (c) Explain why the gain from removing industry fixed effects can be smaller than the loss from attenuation.

7. *Identification of conduct in a linear model.* Consider the linear model (1.57) with supply relation (1.58).

   (a) Show that a monopoly ($\theta = 1$) with marginal cost slope b_1 and a competitive industry ($\theta = 0$) with marginal cost slope $b_1 - \frac{1}{a_1}$ generate the same joint distribution of (P_t, Q_t) given (Y_t, W_t).

   (b) Now let demand be $Q_t = a_0 + (a_1 + a_3 Y_t)P_t + a_2 Y_t + u_t^d$ with $a_3 \neq 0$. Derive the supply relation implied by Proposition 1.33. Show that it contains two regressors, Q_t and $\frac{Q_t}{a_1 + a_3 Y_t}$, that are not collinear.

   (c) Explain which exogenous variables can serve as instruments for the two regressors in (b), and why the argument fails when $a_3 = 0$. Relate your answer to Remark 1.34.

8. *Entry thresholds and conduct.* Work under Assumption 1.44.

   (a) Show that if the N firms in every market collude perfectly, every entry threshold ratio $\frac{\tau_{N+1}}{\tau_N}$ equals one. Show that homogeneous Bertrand competition with constant marginal cost and $F > 0$ never supports two firms.

(b) In the linear Cournot model of Example 1.48, let the N-th entrant pay the fixed cost $F_N = F + (N-1)\Delta$ with $\Delta \geq 0$. Use Remark 1.47 to compute $\frac{\tau_2}{\tau_1}$, and find the ratio $\frac{\Delta}{F}$ that matches the dentist ratio in Table 1.9.

(c) Use the dentist thresholds in Table 1.9 to compute $\frac{\tau_2}{\tau_1}$ and $\frac{\tau_3}{\tau_2}$. Compare them with the linear Cournot ratios. What do they suggest about how competition changes with the second and the third dentist?

(d) Explain why per-firm ratios equal to one from the fourth firm on do not show that markets with four or more firms are competitive. Which additional data would settle the question?

Chapter 2

The Theory of Pricing and Market Power

What determines how far price exceeds marginal cost? This chapter develops the theory that answers the question for a homogeneous good. The gap depends on the demand curve that firms face, on their costs, on the number of firms and on the way they compete. Each of these forces has a precise expression, and we derive them one at a time. The chapter is a theory chapter, but it is written for empirical use. Every result in it is a building block of an estimating equation or a counterfactual later in the book.

The reason is that every empirical method in Part I of the book inverts a pricing first-order condition. Demand estimates supply the elasticity. A model of conduct supplies the rule that turns the elasticity into a markup. Marginal cost is then what remains of the price. Counterfactual work runs the same logic forward. The analyst changes a tax, a cost or the ownership of firms and solves the first-order conditions for the new equilibrium. To judge an empirical study we must know which theoretical result each of these steps relies on, and what happens when that result fails.

The chapter proceeds from one firm to many. Section 2.1 recalls the measures of margins and concentration from Chapter 1. Section 2.2 studies a single seller and derives the two forms of the pricing rule that recur throughout the book, the dollar markup and the Lerner rule. It also prices several products at once, which is the starting point for multi-product firms in oligopoly. Section 2.3 collects the tools from game theory that the rest of the chapter uses: Nash equilibrium, reaction functions and subgame perfection. Sections 2.4 to 2.6 move to several firms. Cournot competition links margins to the Herfindahl index, free entry makes the number of firms an equilibrium outcome, and Bertrand competition shows that two firms can suffice for the competitive price. Section 2.7 nests these models in a single supply relation indexed by a conduct parameter θ, the object that Chapter 3 estimates. Section 2.8 studies how prices respond to cost shocks and taxes. Section 2.9 measures the social cost of market power. Section 2.10 asks why firms that would gain from collusion often fail to achieve it. It treats the information theory of Stigler (1964) in detail and previews the repeated-game models that formalized it. Section 2.11 carries the pricing logic over to differentiated products.

The chapter also collects the formal results that later chapters cite. Proposition 1.15 proved the Cournot relation between margins and concentration. Section 2.4 adds existence, uniqueness and comparative statics. Chapter 3 takes the supply relation of Section 2.7 and the pass-through formulas of Section 2.8 as given and asks which data identify conduct. Chapter 4 extends the pricing rules to multi-product firms. Chapter 11 builds on the Cournot comparative

statics, on pass-through and on the welfare trade-off of Section 2.9.5. Chapter 12 develops the repeated games previewed in Section 2.10.3. The worked problems on Cournot competition, entry, collusion and tax pass-through in Appendix C apply the results of this chapter.

A few conventions hold throughout. Firms are indexed by $i = 1, \dots, N$, with outputs q_i, industry output $Q = \sum_i q_i$ and market shares $s_i = \frac{q_i}{Q}$. Inverse demand is $P(Q)$ and direct demand is $Q(p)$. The market elasticity $\varepsilon = -Q'(p)\frac{p}{Q(p)}$ is a positive number. Marginal cost is c (or c_i) when it is constant and $C_i'(q_i)$ otherwise. Symbols with a meaning confined to one section are introduced where they are used and flagged as local. The mathematical tools we rely on, namely the implicit function theorem, the envelope theorem and log-concavity, are collected in Appendix B.

2.1 Measuring market power: markups, margins and concentration

Every question in this chapter concerns the gap between price and marginal cost. Section 1.2.3 and Section 1.2.2 defined the measures of that gap, and the measures of market structure, that the rest of the book uses. This section recalls them in the notation of this chapter and adds the algebra that later sections need.

2.1.1 Market power and margins

We use the definitions of Definition 1.8. A firm has market power if it can profitably set a price above its marginal cost. The benchmark is the price-taking firm, which treats the price p as given and chooses its output q to maximize $pq - C(q)$. At an interior optimum it produces where $p = C'(q)$, so the gap we wish to measure is zero. In this chapter c denotes a constant marginal cost. When marginal cost varies with output, every measure below applies with c replaced by $C'(q)$.

With price p and marginal cost $c > 0$, the four measures of Definition 1.8 are the dollar markup $p - c$, the Lerner index $L = \frac{p-c}{p}$, the markup ratio $\mu = \frac{p}{c}$ and the markup rate $\mu - 1 = \frac{p-c}{c}$. The Lerner index and the markup ratio carry the same information, as (1.5) shows:

$$L = \frac{p-c}{p} = 1 - \frac{c}{p} = 1 - \frac{1}{\mu} = \frac{\mu - 1}{\mu},$$
$$\frac{1}{\mu} = 1 - L, \qquad \text{so} \qquad \mu = \frac{1}{1-L}.$$

When $0 < c \le p$, the Lerner index lies in $[0, 1)$ and $\mu \ge 1$. A price 25 percent above marginal cost has $\mu = 1.25$ and $L = \frac{0.25}{1.25} = 0.20$. Market power is a statement about the margin on the last unit sold. It says nothing directly about profit, which also depends on fixed costs. The dollar markup is measured in currency, while L and μ are pure numbers. The dollar markup is the natural object in the pricing first-order condition (Section 2.2). The Lerner index is the natural object when we compare industries, because it does not depend on units.

Remark 2.1 (Positive margins are not evidence of rents). Consider a firm with constant marginal cost c and fixed cost F that sells q units at price p. Its profit is $\pi = (p - c)q - F$. Dividing by revenue pq gives

$$\frac{\pi}{pq} = \frac{p-c}{p} - \frac{F}{pq} = L - \frac{F}{pq}.$$

The profit margin on sales equals the Lerner index minus the share of revenue absorbed by fixed costs. Under free entry profit is driven to zero, and then

$$p = c + \frac{F}{q}, \qquad L = \frac{F}{pq} > 0.$$

A firm that earns no economic rent therefore has a strictly positive Lerner index whenever it has fixed costs. Such a firm needs a positive margin to survive. Evidence of high markups must be weighed against fixed and sunk costs before it can be read as evidence of excess profit. The same point runs through the recent debate on rising markups (De Loecker et al., 2020), which Chapter 1 reviews. Section 2.5 shows that free entry ties the Cournot markup exactly to the fixed cost.

Measured margins raise a further problem. Accounting data report average rather than marginal cost, allocate common costs by convention, and use accounting depreciation. Margins computed from them are not $\frac{p-c}{p}$, as Chapter 1 explains. For this reason the methods in this book usually infer marginal cost from behavior (Section 2.2.4).

2.1.2 Concentration

Market structure is summarized by the concentration measures of Definition 1.3. Consider N firms that sell a homogeneous good, with outputs q_i, industry output $Q = \sum_{i=1}^{N} q_i$ and market shares $s_i = \frac{q_i}{Q}$. We write $s_{(1)} \geq s_{(2)} \geq \cdots \geq s_{(N)}$ for the shares in decreasing order. The m-firm concentration ratio is $CR_m = \sum_{i=1}^{m} s_{(i)}$, and the Herfindahl-Hirschman index is $HHI = \sum_{i=1}^{N} s_i^2$, quoted in HHI points as $10{,}000 \times HHI$. Its numbers equivalent $\frac{1}{HHI}$ is the number of equal-sized firms that would produce the same index. Chapter 1 writes it as N^e. In this chapter N^e instead denotes the free-entry number of firms (Section 2.5).

By Lemma 1.4, the index decomposes as

$$HHI = \frac{1}{N} + N\sigma_s^2, \qquad \sigma_s^2 = \frac{1}{N}\sum_{i=1}^{N}\left(s_i - \frac{1}{N}\right)^2,$$

where σ_s^2 is the cross-firm variance of shares around their mean $\frac{1}{N}$. Hence $\frac{1}{N} \leq HHI \leq 1$. The term $\frac{1}{N}$ reflects the number of firms, and the term $N\sigma_s^2$ reflects the inequality of their sizes. Corollary 2.28 uses the decomposition to show that cost differences raise concentration in a Cournot market with general demand.

The index also has a simple rule for mergers. Suppose firms i and j combine and every share stays at its premerger value. The merged firm then has share $s_i + s_j$, and the index changes by

$$\Delta HHI = (s_i + s_j)^2 - s_i^2 - s_j^2 = 2s_i s_j. \tag{2.1}$$

A merger of firms with 20 and 10 percent of the market raises the index by $2 \times 0.2 \times 0.1 = 0.04$, or 400 HHI points. Merger guidelines use this formula as a screen (Chapter 11). It holds shares fixed, which no equilibrium model implies. Remark 2.36 shows that in symmetric Cournot competition the formula overstates the change in concentration whenever more than two firms are present.

The Herfindahl index belongs to a wider family. Encaoua and Jacquemin (1980) ask which indices deserve to be called measures of concentration (Tirole, 1988, sec. 5.5). They require three properties of an index $R(s_1, \ldots, s_N)$: symmetry in the shares, the Lorenz condition, and

no rise with the number of equal-sized firms. Remark 1.6 states these properties and shows that every index of the form

$$R(s_1, \dots, s_N) = \sum_{i=1}^{N} s_i \, h(s_i), \tag{2.2}$$

with h nondecreasing and $s\,h(s)$ convex, satisfies them. The symbols R and h are local to this subsection. The Herfindahl index has $h(s) = s$, and the entropy index $\sum_i s_i \ln s_i$ has $h(s) = \ln s$. The ratio CR_m satisfies the three properties, but it is not of the form (2.2). It satisfies the Lorenz condition only weakly, since a small transfer between two of the m largest firms leaves CR_m unchanged. The properties rank distributions of shares, but they do not say what an index measures. The Cournot model links the Herfindahl index to margins and profits (Section 2.4.4), and Stigler's model links it to the detection of secret price cuts (Section 2.10.2).

Every concentration index presupposes a market. The analyst must choose the set of products and the geographic area within which shares are computed. With differentiated products this choice is often contestable, and Chapters 4 and 11 discuss how demand estimates can discipline it.

2.2 Monopoly pricing

A single seller facing a downward-sloping demand curve is the simplest setting with market power. Its pricing rule reappears in every later model, because each firm in an oligopoly behaves as a monopolist on its own residual demand. This section derives the rule and states the conditions under which it characterizes the optimum. It then shows how the rule can be inverted to recover marginal cost and works through the demand curves that recur in applied work.

2.2.1 The pricing problem

Assumption 2.2 (Monopoly)**.** A single firm faces market demand $Q(p)$, which is twice continuously differentiable with $Q(p) > 0$ and $Q'(p) < 0$ on the relevant range of prices. Marginal cost is a constant $c \geq 0$. The firm chooses p to maximize profit $\pi(p) = (p - c)Q(p)$.

Differentiating profit gives the first-order condition

$$\pi'(p) = Q'(p)(p - c) + Q(p) = 0. \tag{2.3}$$

A small price increase has two effects. It raises revenue on the $Q(p)$ units still sold, and it loses the margin $p - c$ on the $-Q'(p)$ units that customers no longer buy. At the optimum the two effects balance. The second-order condition for a local maximum is

$$\pi''(p) = Q''(p)(p - c) + 2Q'(p) < 0. \tag{2.4}$$

Lemma 2.3 (Second-order condition and uniqueness)**.** *Let Assumption 2.2 hold.*

(i) At any price satisfying (2.3), the second-order condition (2.4) holds if and only if $Q(p)Q''(p) < 2Q'(p)^2$.

(ii) The inequality in (i) holds whenever $\ln Q$ *is concave at* p.

(iii) If $\ln Q$ *is concave on the whole range of prices, at most one price satisfies (2.3), and such a price maximizes profit.*

Proof. For (i), the first-order condition gives $p - c = -\frac{Q(p)}{Q'(p)}$. Substituting into $\pi''(p)$,

$$\begin{aligned}\pi''(p) &= -\frac{Q(p)Q''(p)}{Q'(p)} + 2Q'(p) \\ &= \frac{2Q'(p)^2 - Q(p)Q''(p)}{Q'(p)}.\end{aligned}$$

The denominator is negative, so $\pi''(p) < 0$ if and only if the numerator is positive. For (ii), the second derivative of $\ln Q$ is

$$\frac{\mathrm{d}^2 \ln Q(p)}{\mathrm{d}p^2} = \frac{Q(p)Q''(p) - Q'(p)^2}{Q(p)^2}.$$

Concavity makes it nonpositive, so $QQ'' \le (Q')^2 < 2(Q')^2$. For (iii), define $m(p) = -\frac{Q(p)}{Q'(p)} > 0$ and factor the derivative of profit as

$$\pi'(p) = Q'(p)\left[(p - c) - m(p)\right].$$

Since $\frac{1}{m(p)} = -\frac{\mathrm{d}\ln Q(p)}{\mathrm{d}p}$, concavity of $\ln Q$ makes $\frac{1}{m}$ nondecreasing and hence m nonincreasing. The bracket $h(p) = p - c - m(p)$ is then strictly increasing, so it has at most one zero. Because $Q' < 0$, profit rises where $h < 0$ and falls where $h > 0$. A zero of h is therefore a global maximum. □

A function whose logarithm is concave is called *log-concave*. Linear and exponential demand curves are log-concave. So is any demand curve $Q(p) = M[1 - G(p)]$ generated by a distribution G of willingness to pay with a log-concave density (Appendix B). Constant-elasticity demand is log-convex, so Lemma 2.3(ii) does not cover it, and Example 2.10 checks the conditions directly.

Tirole (1988, sec. 1.1.1.4) locates the difficulty in revenue. Revenue $R(p) = pQ(p)$ has second derivative $R''(p) = 2Q'(p) + pQ''(p)$. The first term is negative, and the second is nonpositive when demand is concave. With constant marginal cost, $\pi''(p) = 2Q'(p) + (p - c)Q''(p)$ is then negative at every $p \ge c$, so concave demand makes profit concave on the relevant range. Convex demand can make revenue, and with it profit, fail to be concave, which is why Lemma 2.3 works with the weaker property of log-concavity.

The first-order condition can be arranged in two ways, and the book uses both throughout. Proposition 1.9 stated both for residual demand. We repeat the two short steps because later sections build on each. For the first arrangement, divide (2.3) by $-Q'(p) > 0$ and solve for the margin:

$$\begin{aligned}-(p - c) - \frac{Q(p)}{Q'(p)} &= 0, \\ p - c &= -\frac{Q(p)}{Q'(p)}.\end{aligned}$$

We call the right side the dollar markup $m(p)$ and record

$$p - c = m(p) \equiv -\frac{Q(p)}{Q'(p)} = \frac{1}{-\frac{\mathrm{d}\ln Q(p)}{\mathrm{d}p}}. \tag{2.5}$$

The quantity $-\frac{\mathrm{d}\ln Q}{\mathrm{d}p} = -\frac{Q'(p)}{Q(p)}$ is the *semi-elasticity* of demand, the proportional fall in quantity per dollar of price increase. The dollar markup is its reciprocal. If a one-dollar price increase loses 5 percent of sales, the markup is 20 dollars. Equation (2.5) involves only the demand curve, evaluated at the optimal price. Marginal cost affects the markup only through the choice of that price.

For the second arrangement, divide (2.5) by p:

$$\frac{p-c}{p} = -\frac{Q(p)}{p\,Q'(p)} = \frac{1}{\varepsilon(p)}, \qquad \varepsilon(p) = -Q'(p)\frac{p}{Q(p)} > 0. \tag{2.6}$$

This is the *Lerner rule*, also called the *inverse elasticity rule*. The Lerner index of a monopolist equals the inverse of the price elasticity of demand at the chosen price. Multiplying by p and collecting the terms in p expresses price as a multiple of cost:

$$\begin{aligned} p - c &= \frac{p}{\varepsilon}, \\ p\left(1 - \frac{1}{\varepsilon}\right) &= c, \\ p &= \frac{\varepsilon}{\varepsilon - 1}\, c. \end{aligned} \tag{2.7}$$

Both (2.5) and (2.7) are fixed-point conditions, because m and ε generally depend on p. They become explicit pricing formulas only for special demand curves (Section 2.2.5).

Proposition 2.4 (A monopolist prices on the elastic part of demand)**.** *Under Assumption 2.2, any price that satisfies* (2.3) *has* $p > c$ *and* $\varepsilon(p) \geq 1$*. If* $c > 0$*, then* $\varepsilon(p) > 1$*.*

Proof. By (2.5), $p - c = m(p) > 0$, because $Q > 0$ and $Q' < 0$. Hence $p > c \geq 0$, so the Lerner index satisfies $0 < L \leq 1$, with $L < 1$ when $c > 0$. By (2.6), $\frac{1}{\varepsilon} = L$. Therefore $\varepsilon \geq 1$, and $\varepsilon > 1$ when $c > 0$. □

The intuition is direct. Where demand is inelastic, a small price increase raises revenue and reduces output, which lowers cost. Both effects raise profit, so no such price can be optimal. With zero marginal cost the monopolist maximizes revenue and sets $\varepsilon = 1$.

It is often convenient to let the firm choose output. Let $P(Q)$ be inverse demand. The firm chooses Q to maximize $P(Q)Q - cQ$, and the first-order condition equates marginal revenue to marginal cost:

$$MR(Q) = P(Q) + QP'(Q) = c. \tag{2.8}$$

Factoring out the price gives

$$MR(Q) = P(Q)\left[1 + \frac{QP'(Q)}{P(Q)}\right] = P(Q)\left[1 - \frac{1}{\varepsilon}\right].$$

The second step uses $P'(Q) = \frac{1}{Q'(p)}$ at $p = P(Q)$, so that $\frac{QP'(Q)}{P(Q)} = \frac{Q}{pQ'(p)} = -\frac{1}{\varepsilon}$. Setting $MR = c$ gives (2.7) again. The price and quantity formulations are equivalent, and we move between them freely.

Remark 2.5 (Rising marginal cost). With a convex cost function $C(Q)$, profit is $pQ(p) - C(Q(p))$, and the first-order condition becomes $Q'(p)\left[p - C'(Q(p))\right] + Q(p) = 0$. Every formula above

holds with c replaced by marginal cost at the optimal output. The second derivative of profit becomes

$$\pi''(p) = Q''(p)\,\big[p - C'(Q)\big] + 2Q'(p) - C''(Q)\,Q'(p)^2.$$

The last term is nonpositive, so rising marginal cost makes the second-order condition easier to satisfy.

One comparative static needs none of the conditions above. A higher marginal cost never lowers the monopoly price, whatever the shapes of demand and cost. The proof compares two optima directly and is an example of a *revealed-preference argument*: each optimum must do at least as well as the other choice under its own cost.

Lemma 2.6 (The monopoly price does not fall when marginal cost rises)**.** *Let inverse demand $P(Q)$ be nonincreasing, and let C_1 and C_2 be differentiable cost functions with $C_2'(q) > C_1'(q)$ for every $q > 0$. Let q_k be an output that maximizes $P(q)q - C_k(q)$, and let $p_k = P(q_k)$, for $k = 1, 2$. Then $q_1 \geq q_2$ and $p_1 \leq p_2$.*

Proof. Under C_1 the firm could have sold q_2 at the price p_2. Under C_2 it could have sold q_1 at p_1. So

$$p_1 q_1 - C_1(q_1) \geq p_2 q_2 - C_1(q_2),$$
$$p_2 q_2 - C_2(q_2) \geq p_1 q_1 - C_2(q_1).$$

Adding the two inequalities cancels the revenues and leaves

$$\big[C_2(q_1) - C_2(q_2)\big] - \big[C_1(q_1) - C_1(q_2)\big] \geq 0,$$

which by the fundamental theorem of calculus reads

$$\int_{q_2}^{q_1} \big[C_2'(x) - C_1'(x)\big]\,\mathrm{d}x \geq 0.$$

The integrand is positive. If $q_1 < q_2$ the integral would be negative, so $q_1 \geq q_2$. Since P is nonincreasing, $p_1 = P(q_1) \leq P(q_2) = p_2$. □

The argument is that of Tirole (1988, sec. 1.1.1.1, eqs. (1.2) to (1.5)). It needs no second-order condition, no differentiability of demand and no uniqueness of the optimum. With constant marginal costs $c_1 < c_2$ it says that the monopoly price is nondecreasing in c. Proposition 2.69 gives the rate of increase when demand is smooth.

2.2.2 Residual demand and the dominant firm

Nothing in the derivation of (2.5) and (2.6) requires the firm to be alone in its market. Any firm that sets its price against a given demand curve obeys the same rules. The *residual demand* of a firm is the quantity it sells at each of its own prices, given how its rivals behave. Its *residual elasticity* ε^R is the elasticity of that curve. The *market elasticity* ε is the elasticity of total industry demand. A firm with market power satisfies $\frac{p-c}{p} = \frac{1}{\varepsilon^R}$, and the two elasticities coincide only for a monopolist.

The residual elasticity depends on how rivals respond. In a Cournot market (Section 2.4), rivals hold their total output Q_{-i} fixed, so firm i faces the residual inverse demand $P(q_i + Q_{-i})$. A change in q_i then changes industry output one for one, and

$$\varepsilon_i^R = -\frac{\mathrm{d}q_i}{\mathrm{d}p}\,\frac{p}{q_i} = -\frac{\mathrm{d}Q}{\mathrm{d}p}\,\frac{p}{Q}\cdot\frac{Q}{q_i} = \frac{\varepsilon}{s_i}. \tag{2.9}$$

A firm with a small share faces very elastic residual demand even when market demand is inelastic. At the other extreme, a firm whose rivals sell the same good at a fixed price faces infinitely elastic residual demand above that price (Section 2.6). The next example derives the residual elasticity when rivals are price takers.

Example 2.7 (Dominant firm with a competitive fringe)**.** A *dominant firm* sets the price, and a *competitive fringe* of small price-taking firms supplies $S(p)$ at each price, with $S'(p) \geq 0$. The dominant firm's residual demand is

$$Q_d(p) = Q(p) - S(p).$$

Let $s_d = \frac{Q_d}{Q}$ be the dominant firm's share and $\varepsilon_f = S'(p)\frac{p}{S(p)} \geq 0$ the elasticity of fringe supply. Differentiating gives $Q_d'(p) = Q'(p) - S'(p)$, so

$$\begin{aligned} \varepsilon^R = -Q_d'(p)\,\frac{p}{Q_d} &= -Q'(p)\,\frac{p}{Q}\cdot\frac{Q}{Q_d} + S'(p)\,\frac{p}{S}\cdot\frac{S}{Q_d} \\ &= \frac{\varepsilon}{s_d} + \varepsilon_f\,\frac{1-s_d}{s_d}. \end{aligned}$$

The second line uses $\frac{Q}{Q_d} = \frac{1}{s_d}$ and $\frac{S}{Q_d} = \frac{1-s_d}{s_d}$. The Lerner rule then gives the dominant firm's margin,

$$L_d = \frac{1}{\varepsilon^R} = \frac{s_d}{\varepsilon + \varepsilon_f(1-s_d)}. \tag{2.10}$$

Landes and Posner (1981) proposed this formula as a guide to inferring market power from market shares in antitrust cases. It shows that a large share alone does not imply a large margin. Take $s_d = 0.7$ and $\varepsilon = 2$. With an unresponsive fringe ($\varepsilon_f = 0$), $L_d = \frac{0.7}{2} = 0.35$. With $\varepsilon_f = 10$, the residual elasticity is $\frac{2}{0.7} + 10 \cdot \frac{0.3}{0.7} \approx 7.14$ and $L_d = \frac{0.7}{2+3} = 0.14$. The margin falls by 60 percent although the share is unchanged. What limits the dominant firm is the elasticity of the demand it faces, and that elasticity depends on how quickly rivals expand.

The residual elasticity is the object that a firm's pricing reveals. Chapter 3 shows how Baker and Bresnahan (1988) estimate the residual demand curve of a single firm directly.

2.2.3 Multiproduct monopoly

A firm that sells several products sets each price with an eye on the others. Let a monopolist sell products $j = 1, \ldots, J$ at prices $p = (p_1, \ldots, p_J)$. Demand for product j is $q_j(p)$, the cost of the output vector is $C(q_1, \ldots, q_J)$, and $mc_j = \frac{\partial C}{\partial q_j}$ is the marginal cost of product j. The firm maximizes

$$\pi(p) = \sum_{k=1}^{J} p_k\, q_k(p) - C\big(q_1(p), \ldots, q_J(p)\big).$$

Differentiating with respect to p_j gives the first-order condition (Tirole, 1988, sec. 1.1.2, eq. (1.6))

$$q_j + \sum_{k=1}^{J} p_k \frac{\partial q_k}{\partial p_j} = \sum_{k=1}^{J} mc_k\,\frac{\partial q_k}{\partial p_j}, \qquad j = 1, \ldots, J. \tag{2.11}$$

The left side is the marginal revenue from raising p_j, including the revenue that the price change moves to the firm's other products. The right side is the change in total cost. Collecting the terms product by product gives

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + \sum_{k \neq j}(p_k - mc_k)\frac{\partial q_k}{\partial p_j} = 0. \tag{2.12}$$

With independent demands, $\frac{\partial q_k}{\partial p_j} = 0$ for $k \neq j$, and each product obeys the single-product rule (2.6). Products with less elastic demand then carry higher markups, the simplest form of Ramsey pricing.

The Lerner rule with cross effects. Let costs be separable, $C = \sum_k C_k(q_k)$, so that mc_k depends on q_k alone. Write $|\varepsilon_{jj}| = -\frac{\partial q_j}{\partial p_j}\frac{p_j}{q_j}$ for the own-price elasticity, $\varepsilon_{kj} = \frac{\partial q_k}{\partial p_j}\frac{p_j}{q_k}$ for the cross elasticity of product k with respect to the price of j, and $R_j = p_j q_j$ for the revenue of product j. Dividing (2.12) by q_j and substituting $\frac{\partial q_j}{\partial p_j} = -|\varepsilon_{jj}|\frac{q_j}{p_j}$ and $\frac{\partial q_k}{\partial p_j} = \varepsilon_{kj}\frac{q_k}{p_j}$,

$$1 - |\varepsilon_{jj}|\,\frac{p_j - mc_j}{p_j} + \sum_{k \neq j}(p_k - mc_k)\,\frac{\varepsilon_{kj}\,q_k}{p_j q_j} = 0.$$

Solving for the Lerner index of product j gives

$$\frac{p_j - mc_j}{p_j} = \frac{1}{|\varepsilon_{jj}|} + \sum_{k \neq j}\frac{(p_k - mc_k)\,q_k\,\varepsilon_{kj}}{R_j\,|\varepsilon_{jj}|}. \tag{2.13}$$

This is Tirole's formula. He defines the cross elasticity with the opposite sign, so his version has a minus sign in front of the sum. Suppose the other products earn positive margins. If they are *substitutes* for product j ($\varepsilon_{kj} > 0$), the sum is positive and the Lerner index of j exceeds $\frac{1}{|\varepsilon_{jj}|}$. If they are *complements* ($\varepsilon_{kj} < 0$), the Lerner index falls short of $\frac{1}{|\varepsilon_{jj}|}$. It can even be negative, so that product j is sold below marginal cost to raise the demand for the others.

Tirole interprets the formula through the biases of a decentralized firm. Suppose the firm were run by J independent divisions, each maximizing the profit $p_j q_j - C_j(q_j)$ of its own product. Each division would set the single-product markup $\frac{1}{|\varepsilon_{jj}|}$. With substitutes, a higher p_j raises the sales of the other divisions, and division j ignores the margins it creates for them. The divisions are then de facto competitors, and each prices too low from the point of view of the firm. With complements, each division prices too high. Joint pricing internalizes these externalities between divisions. Section 2.11 shows that the same first-order condition, written with diversion ratios, governs multiproduct firms in oligopoly.

Example 2.8 (Perfect complements)**.** A firm sells nuts (product 1) and bolts (product 2), which are used one for one, so demand depends only on the total price: $q_1 = q_2 = D(p_1 + p_2)$ (Tirole, 1988, Exercise 1.5). Then $\frac{\partial q_k}{\partial p_j} = D'(p_1 + p_2)$ for both j and k. Writing $\bar{P} = p_1 + p_2$, condition (2.12) for either product reads

$$D(\bar{P}) + (\bar{P} - mc_1 - mc_2)\,D'(\bar{P}) = 0.$$

This is the monopoly condition (2.3) for a single composite good with price $\bar{P}$ and marginal cost $mc_1 + mc_2$. Only the total price is determined. Compare two separate monopolists, one

for each product. Each sets $D(\bar{P}) + (p_j - mc_j)D'(\bar{P}) = 0$, so $p_j - mc_j = m(\bar{P})$, with m the dollar markup of (2.5). Adding the two conditions gives $\bar{P} - mc_1 - mc_2 = 2m(\bar{P})$, twice the markup $m(\bar{P})$ that the integrated firm charges at its own price. When m is nonincreasing, as under log-concave demand, separate pricing therefore leads to a higher total price.

Intertemporal applications. The same logic applies to one good sold at two dates, since the good at each date is a separate product (Tirole, 1988, sec. 1.1.2). Let $\delta \in (0, 1)$ be the firm's discount factor, as in Section 2.10.3 and Chapter 12. The symbol differs from the mean utility δ_j of the logit demand in Example 2.73 and later chapters. With *goodwill*, a lower first-period price raises second-period demand. Demand is $q_1 = D_1(p_1)$ in period 1 and $q_2 = D_2(p_2, p_1)$ in period 2, with $\frac{\partial D_2}{\partial p_1} < 0$. First-period demand does not depend on p_2, so the firm charges the monopoly price of (2.6) in period 2, given the goodwill it has built. In period 1 it charges less than the static monopoly price. To see this, let $S(p_1) = p_1 D_1(p_1) - C_1(D_1(p_1))$ be first-period profit and $V(p_1)$ the maximized second-period profit. By the envelope theorem (Appendix B),

$$V'(p_1) = (p_2 - mc_2)\,\frac{\partial D_2}{\partial p_1} < 0,$$

since the second-period margin is positive. Let p^s maximize S and p^* maximize $S + \delta V$. Optimality gives $S(p^s) \geq S(p^*)$ and $S(p^*) + \delta V(p^*) \geq S(p^s) + \delta V(p^s)$. Adding the two inequalities gives $V(p^*) \geq V(p^s)$, and since V is decreasing, $p^* \leq p^s$. The inequality is strict at an interior optimum. There $S'(p^s) = 0$ and $\delta V'(p^s) < 0$. A small price cut from p^s therefore raises $S + \delta V$. The firm sacrifices current profit to raise future demand.

With *learning by doing*, first-period output lowers second-period cost. Let the second-period cost be $C_2(q_2, q_1)$ with $\frac{\partial C_2}{\partial q_1} < 0$, and let $V(q_1)$ be the maximized second-period profit. The firm chooses q_1 to maximize $P_1(q_1)q_1 - \tilde{C}(q_1)$, with the effective cost $\tilde{C}(q_1) = C_1(q_1) - \delta V(q_1)$. By the envelope theorem, its marginal cost is

$$\tilde{C}'(q_1) = C_1'(q_1) + \delta\,\frac{\partial C_2}{\partial q_1} < C_1'(q_1).$$

First-period marginal revenue therefore falls short of current marginal cost. By Lemma 2.6, which compares two cost functions for the same demand, the first-period price lies weakly below the myopic monopoly price. Tirole adds that with stationary demand and costs that fall with experience, output grows over time.

2.2.4 Inferring marginal cost from prices

The pricing rule can be read backward. If demand is known and the firm behaves as a monopolist, the first-order condition determines marginal cost from the observed price and quantity:

$$\hat{c} = p + \frac{Q(p)}{\hat{Q}'(p)} = p\left(1 - \frac{1}{\hat{\varepsilon}}\right). \tag{2.14}$$

Here $\hat{Q}'(p)$ and $\hat{\varepsilon}$ are estimates of the demand slope and elasticity at the observed price. The first form follows from (2.5) and the second from (2.6). No cost data are needed. This inversion is the core of the *New Empirical Industrial Organization* (NEIO), the approach based on studies of single industries that Bresnahan (1989) surveys. Bresnahan lists as its first premise that price-cost margins are not observable, so that the analyst infers marginal cost from firm

behavior (p. 1012). He quotes the title of Rosse (1970), "Estimating Cost Function Parameters without Using Cost Data," as a statement of the program (p. 1014).

Bresnahan's stylized model makes the inversion econometric. Observation t has inverse market demand $P(Q_t, Y_t, \epsilon_{dt})$, with demand shifters Y_t and a demand error ϵ_{dt}. Firm i has marginal cost $MC(q_{it}, W_{it}, Z_{it}, \epsilon_{cit})$, with factor prices W_{it}, other cost shifters Z_{it} and a cost error ϵ_{cit}. Both functions are known up to unknown parameters. In our notation, his supply relation (eq. (4), p. 1016) is

$$P_t = MC(q_{it}, W_{it}, Z_{it}, \epsilon_{cit}) - \theta_{it}\, q_{it}\, \frac{\partial P(Q_t, Y_t, \epsilon_{dt})}{\partial Q}. \tag{2.15}$$

With a single firm and $\theta_{it} = 1$, the second term is $-QP'(Q)$, and (2.15) says that marginal revenue equals marginal cost. With $\theta_{it} = 0$ it is the competitive supply curve $P = MC$. Bresnahan stresses that marginal cost enters as a function of unknown parameters, never as an accounting datum. Demand, cost and conduct parameters are estimated together. Section 2.7 develops the conduct parameter θ, and Chapter 3 studies how data identify it. With conduct θ the inversion becomes $\hat{c} = p + \theta \frac{Q}{\hat{Q}'(p)}$.

Two features of (2.14) matter in practice. The first is that the implied cost inherits the sampling error of the demand estimate, most strongly when demand is close to unit elastic. Differentiating (2.14) with respect to the elasticity gives $\frac{\partial \hat{c}}{\partial \hat{\varepsilon}} = \frac{p}{\hat{\varepsilon}^2}$. By the delta method (Appendix A),

$$\operatorname{se}(\hat{c}) \approx \frac{p}{\hat{\varepsilon}^2} \operatorname{se}(\hat{\varepsilon}).$$

Take $p = 10$ and $\operatorname{se}(\hat{\varepsilon}) = 0.25$. At $\hat{\varepsilon} = 2$ the implied cost is 5, with a standard error of about 0.63. At $\hat{\varepsilon} = 1.25$ it is 2, with a standard error of 1.6. An estimated elasticity below one implies a negative marginal cost, which is inconsistent with monopoly pricing (Proposition 2.4). Chapter 3 returns to this point for industries with inelastic demand, such as electricity.

The second feature is that the inverted costs can be related to observed cost shifters. Suppose marginal cost is $mc_t = w_t\psi + \omega_t$, with a row vector of cost shifters w_t, coefficients ψ and an unobserved cost shock ω_t. Substituting (2.14) gives the regression

$$p_t + \frac{Q_t}{\hat{Q}'(p_t)} = w_t\psi + \omega_t. \tag{2.16}$$

The left side is computed from data and estimated demand. If marginal cost also rises with output, Q_t enters the right side. Output is correlated with the cost shock ω_t, so it must be instrumented, typically with demand shifters. The additive cost shock is what makes the estimating equation linear in ψ. Chapter 4 extends the inversion to firms that sell several differentiated products, where the markup involves the full matrix of demand derivatives.

2.2.5 Worked demand families

Four families of demand curves recur in applied work. Each gives an explicit monopoly price, and each implies a different relation between cost and price. Figure 2.1 illustrates the linear case.

Example 2.9 (Linear demand)**.** Let $P(Q) = a - bQ$ with $a > c \geq 0$ and $b > 0$, so that $Q(p) = \frac{a-p}{b}$. Marginal revenue is $a - 2bQ$. Setting it equal to c and solving,

$$\begin{aligned} a - 2bQ &= c, \\ Q^m &= \frac{a-c}{2b}, \\ p^m = a - bQ^m &= a - \frac{a-c}{2} = \frac{a+c}{2}. \end{aligned}$$

Since $Q'(p) = -\frac{1}{b}$, the elasticity at price p is $\varepsilon(p) = \frac{1}{b} \cdot \frac{p}{Q(p)} = \frac{p}{a-p}$. At the monopoly price,

$$\varepsilon(p^m) = \frac{\frac{a+c}{2}}{\frac{a-c}{2}} = \frac{a+c}{a-c}, \qquad L = \frac{p^m - c}{p^m} = \frac{a-c}{a+c} = \frac{1}{\varepsilon(p^m)}.$$

The dollar markup is $m(p) = -\frac{Q(p)}{Q'(p)} = a - p$, which falls one for one with price. At the optimum it equals $\frac{a-c}{2}$, so each dollar of marginal cost raises the monopoly price by fifty cents. With $a = 10$, $b = 1$ and $c = 2$, we obtain $Q^m = 4$, $p^m = 6$, $\varepsilon(p^m) = \frac{3}{2}$ and $L = \frac{2}{3}$.

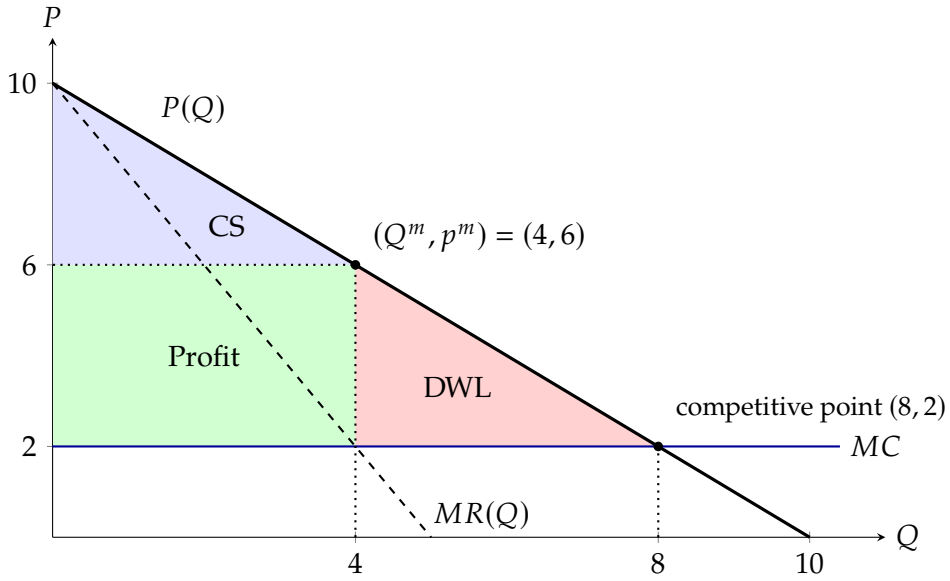

Figure 2.1: Monopoly with linear demand $P(Q) = 10 - Q$, marginal revenue $MR(Q) = 10 - 2Q$ and constant marginal cost $MC = 2$. The monopolist sells $Q^m = 4$ at $p^m = 6$, while price taking would give the point $(8, 2)$. The shaded areas are consumer surplus (CS), profit, and the deadweight loss (DWL) of pricing above marginal cost. Section 2.9.1 defines these areas formally. The Lerner index is $L = \frac{6-2}{6} = \frac{2}{3}$, which equals $\frac{1}{\varepsilon(p^m)} = \frac{2}{3}$ because $\varepsilon(p^m) = \frac{6}{4} = \frac{3}{2}$.

Example 2.10 (Constant-elasticity demand)**.** Let $Q(p) = Ap^{-\varepsilon}$ with $A > 0$ and a constant $\varepsilon > 0$. The elasticity is the same at every price:

$$-Q'(p)\,\frac{p}{Q(p)} = \varepsilon A p^{-\varepsilon-1} \cdot \frac{p}{Ap^{-\varepsilon}} = \varepsilon.$$

If $\varepsilon > 1$, (2.7) is an explicit pricing formula, $p^m = \frac{\varepsilon}{\varepsilon-1}c$. The Lerner index is the constant $\frac{1}{\varepsilon}$, and price is proportional to cost. The dollar markup $m(p) = \frac{p}{\varepsilon}$ rises with price, so a one-dollar

increase in cost raises price by $\frac{\varepsilon}{\varepsilon-1} > 1$ dollars. This demand curve is log-convex, so we check optimality directly. Here $\frac{QQ''}{(Q')^2} = \frac{\varepsilon+1}{\varepsilon}$, which is below 2 exactly when $\varepsilon > 1$. The function $h(p) = p - c - \frac{p}{\varepsilon} = p\left(1 - \frac{1}{\varepsilon}\right) - c$ is then strictly increasing, so the argument of Lemma 2.3(iii) shows that p^m is the unique optimum. If $\varepsilon \le 1$, revenue $Ap^{1-\varepsilon}$ does not fall as price rises while cost falls, so profit rises at every price and no optimal price exists. Tirole (1988, Exercise 1.4) extends the result to any convex cost function. With constant-elasticity demand and $\varepsilon > 1$, profit is then quasi-concave in price.

Example 2.11 (Exponential demand)**.** Let $Q(p) = e^{\frac{a-p}{b}}$ with $b > 0$, or equivalently $P(Q) = a - b \ln Q$. Then $Q'(p) = -\frac{1}{b}Q(p)$, so the semi-elasticity is the constant $\frac{1}{b}$ and the dollar markup is $m(p) = -\frac{Q(p)}{Q'(p)} = b$ at every price. The monopoly price is

$$p^m = c + b.$$

A monopolist facing this demand charges a fixed dollar margin whatever its cost, so each dollar of cost passes fully into price, exactly as under perfect competition. The elasticity $\varepsilon(p) = \frac{p}{b}$ rises with price. Since $\ln Q = \frac{a-p}{b}$ is linear, and hence weakly concave, Lemma 2.3 applies.

Example 2.12 (The Bulow-Pfleiderer family)**.** Consider demand curves of the form

$$Q(p) = B\,|\bar{p} - p|^g, \qquad B > 0, \tag{2.17}$$

on the range $p < \bar{p}$ when $g > 0$, and on the range $p > \bar{p}$ when $g < 0$. When $g > 0$, the parameter $\bar{p}$ is the choke price, the highest willingness to pay. Bulow and Pfleiderer (1983) identified this family as the one with constant pass-through of cost to price (Section 2.8). Genesove and Mullin (1998) write it as $Q = \beta(\alpha - P)^\gamma$ and use it for the demand for refined sugar (Chapter 3). They motivate it by noting that linear and log-linear demand, the usual choices in industry studies, impose strong restrictions on the monopoly pricing rule.

In both cases $\frac{\mathrm{d}\ln Q}{\mathrm{d}p} = -\frac{g}{\bar{p}-p}$. Hence the dollar markup and the elasticity are

$$m(p) = \frac{\bar{p} - p}{g}, \qquad \varepsilon(p) = \frac{p}{m(p)} = \frac{gp}{\bar{p} - p},$$

both positive on the relevant range. The first-order condition $p - c = m(p)$ is linear in p:

$$\begin{aligned} g(p - c) &= \bar{p} - p, \\ (1 + g)p &= \bar{p} + gc, \\ p^m &= \frac{\bar{p} + gc}{1 + g}. \end{aligned}$$

The monopoly price is affine in cost, with slope $\frac{g}{1+g}$. Substituting p^m into $\varepsilon(p)$ gives the elasticity at the optimum, $\varepsilon(p^m) = \frac{\bar{p}+gc}{\bar{p}-c}$. The family nests the cases above.

- With $g = 1$, $\bar{p} = a$ and $B = \frac{1}{b}$, demand is linear and $p^m = \frac{a+c}{2}$.
- With $g = 2$, demand is quadratic and convex, and $p^m = \frac{\bar{p}+2c}{3}$.
- With $\bar{p} = 0$ and $g < 0$, demand is $Q = Bp^g$, which has constant elasticity $\varepsilon = -g$. Then $p^m = \frac{gc}{1+g} = \frac{\varepsilon}{\varepsilon-1}c$, which requires $g < -1$.

- Let $\bar{p} \to \infty$ and $g \to \infty$ with $\lambda_s = \frac{g}{\bar{p}}$ held fixed, and set $B = A\bar{p}^{-g}$ for a constant $A > 0$. Then
$$Q(p) = A\left(1 - \frac{p}{\bar{p}}\right)^g = A\left(1 - \frac{\lambda_s p}{g}\right)^g \to Ae^{-\lambda_s p}.$$
The limit is exponential demand with semi-elasticity λ_s. The monopoly price converges to
$$p^m = \frac{\frac{\bar{p}}{g} + c}{\frac{1}{g} + 1} \to c + \frac{1}{\lambda_s},$$
which matches Example 2.11 with $b = \frac{1}{\lambda_s}$.

In inverse form, the case $g > 0$ reads $P(Q) = a - bQ^\gamma$ with $a = \bar{p}$, $b = B^{-\gamma}$ and $\gamma = \frac{1}{g}$. The symbol γ is local to this family. The second-order condition holds automatically when $g > 0$, because $\ln Q$ is then concave. When $g < 0$, $\frac{QQ''}{(Q')^2} = 1 - \frac{1}{g}$, which is below 2 exactly when $g < -1$, the condition found above. The family returns in Sections 2.7 and 2.8 and in Chapter 3.

2.3 Games and equilibrium

A monopolist solves a decision problem. With two or more firms, each firm's best choice depends on what its rivals do, and we need a rule that predicts the outcome of this interdependence. This section collects the tools from noncooperative game theory that the rest of the chapter uses. They are Nash equilibrium in pure and mixed strategies, reaction functions, and subgame perfection in games that unfold in stages. We follow Tirole (1988, ch. 11 and the introduction to Part II), which presents these tools for industrial organization. Fudenberg and Tirole (1991) give a complete treatment.

2.3.1 Nash equilibrium

Definition 2.13 (Normal-form game)**.** A *normal-form game* has players $i = 1, \dots, N$. Player i chooses an *action* a_i from a set A_i and receives the payoff $\pi_i(a)$, where $a = (a_1, \dots, a_N)$ is the *action profile*. We write a_{-i} for the actions of the players other than i, and (a_i', a_{-i}) for the profile in which player i switches to a_i' while the others keep a_{-i}.

In the games of this chapter the players are firms, the actions are outputs or prices, and the payoffs are profits. All players choose at the same time, and the structure of the game is common knowledge. A *pure strategy* picks one action with certainty. A *mixed strategy* σ_i is a probability distribution over A_i. Players randomize independently, and payoffs under mixed strategies are expected values of pure-strategy payoffs. A pure strategy is the special case of a distribution that puts probability one on a single action.

Definition 2.14 (Best response and Nash equilibrium)**.** Player i's *best response* to a_{-i} is the set $BR_i(a_{-i}) = \arg\max_{a_i \in A_i} \pi_i(a_i, a_{-i})$. A *pure-strategy Nash equilibrium* is a profile a^* such that
$$\pi_i(a_i^*, a_{-i}^*) \geq \pi_i(a_i, a_{-i}^*) \qquad \text{for every player } i \text{ and every } a_i \in A_i, \tag{2.18}$$
that is, $a_i^* \in BR_i(a_{-i}^*)$ for every i. A *mixed-strategy Nash equilibrium* is a profile of distributions $(\sigma_1^*, \dots, \sigma_N^*)$ that satisfies (2.18) with distributions in place of actions and expected payoffs in place of payoffs.

In a Nash equilibrium each player's choice is optimal given the choices of the others, and each player anticipates those choices correctly. No player can gain by changing its own action alone. Mixed equilibria have one further property that we use repeatedly. A player who randomizes must be indifferent among all actions in the support of its distribution. If one of them paid strictly more, moving probability toward it would raise the expected payoff. The indifference conditions therefore pin down the rivals' distributions. In *matching pennies*, two players each choose heads or tails. Player 1 wins one dollar from player 2 when the choices match and loses one dollar otherwise. No pure equilibrium exists. In the mixed equilibrium each player chooses heads with probability $\frac{1}{2}$, the only probability that leaves the opponent indifferent (Tirole, 1988, sec. 11.2).

Theorem 2.15 (Existence of Nash equilibrium)**.** *Suppose that each action set A_i is a nonempty, compact and convex subset of a Euclidean space. Suppose also that each payoff $\pi_i(a)$ is continuous in a and quasi-concave in a_i. Then a pure-strategy Nash equilibrium exists. In particular, a game with finitely many players and finitely many actions has a mixed-strategy Nash equilibrium.*

Proof sketch. The first statement is the special case of Debreu (1952) given in Tirole (1988, sec. 11.6.1). The standard argument applies Kakutani's fixed-point theorem (Theorem B.147) to the joint best-response correspondence $a \mapsto BR_1(a_{-1}) \times \cdots \times BR_N(a_{-N})$. By Berge's maximum theorem, continuity and compactness make this correspondence nonempty valued with a closed graph. Quasi-concavity makes its values convex. A fixed point of the correspondence is a Nash equilibrium (see also Corollary B.148). For the second statement, a mixed strategy of player i is a point in the simplex of distributions over its finite action set, which is compact and convex. The expected payoff is linear, hence quasi-concave, in the player's own mixture. It is a polynomial, hence continuous, in the profile of mixtures. The first statement therefore applies to the game in mixed strategies (Nash, 1950). □

Both assumptions of the theorem can fail in oligopoly models. Without quasi-concavity, best responses can jump, and a pure equilibrium may fail to exist (Remark 2.25). Continuity fails in the price games of Section 2.6, because a firm's sales jump when its price crosses a rival's price. With capacity constraints, pure equilibria may then fail to exist (Section 2.6.2). For games with discontinuous payoffs, Dasgupta and Maskin (1986) give conditions for a pure equilibrium when payoffs are quasi-concave and for a mixed equilibrium when they are not (Tirole, 1988, sec. 11.6.1).

2.3.2 Reaction functions

Most models in this chapter have one-dimensional actions and smooth payoffs. Take two firms with actions $a_1, a_2 \in \mathbb{R}$ and twice continuously differentiable profits, and suppose each profit is strictly concave in the firm's own action. The first-order condition $\frac{\partial \pi_i}{\partial a_i}(a_i, a_j) = 0$ then defines firm i's *reaction function* $R_i(a_j)$, its unique best response to a_j at an interior optimum. A Nash equilibrium is a pair with $a_1^* = R_1(a_2^*)$ and $a_2^* = R_2(a_1^*)$, an intersection of the two reaction curves. Differentiating the identity $\frac{\partial \pi_i}{\partial a_i}(R_i(a_j), a_j) = 0$ with respect to a_j gives

$$\frac{\partial^2 \pi_i}{\partial a_i^2} R_i'(a_j) + \frac{\partial^2 \pi_i}{\partial a_i \, \partial a_j} = 0,$$

so the slope of the reaction function is

$$R_i'(a_j) = -\frac{\frac{\partial^2 \pi_i}{\partial a_i \, \partial a_j}}{\frac{\partial^2 \pi_i}{\partial a_i^2}} \tag{2.19}$$

(Tirole, 1988, introduction to Part II, eq. (5)). The denominator is negative, so the slope of the reaction function has the sign of the cross-partial derivative. Following Bulow et al. (1985), actions are *strategic substitutes* when the cross-partial is negative and *strategic complements* when it is positive. Quantities are often substitutes and prices often complements (Section 2.4.2 and Remark 2.50).

Reaction functions are a device for finding equilibria. They do not describe behavior in a simultaneous-move game, since no firm observes its rival's choice before it acts. The reaction function states what a firm would do if it learned that its rival had changed its action (Tirole, 1988, introduction to Part II). The point returns in the critique of conjectural variations (Section 2.7.4).

2.3.3 Subgame perfection

Several models in this chapter unfold over time. Firms enter and then compete (Section 2.5), build capacity and then set prices (Section 2.6.2), or play the same game repeatedly (Section 2.10.3). An *extensive-form game* describes such a situation. It specifies the order of moves, the actions available at each move, what each player knows when it moves, and the payoffs at the end of each path of play. The points at which a player moves but cannot tell apart form one of its *information sets*. A strategy is a complete plan of action. It specifies a move at every point where the player could be called upon to act, including points that are never reached when the plan is followed.

Nash equilibrium is too permissive in these games, because it can rest on threats that a player would not carry out. Consider an entrant that either stays out or enters. Staying out gives the entrant 0 and the incumbent 2. After entry, the incumbent either accommodates, which gives both firms 1, or fights, which gives the entrant -1 and the incumbent 0. The profile in which the entrant stays out and the incumbent plans to fight is a Nash equilibrium. Given the plan to fight, entry would earn -1. Given that entry does not occur, the plan costs the incumbent nothing. Yet the threat is not credible, because after entry the incumbent earns 1 by accommodating and 0 by fighting.

Definition 2.16 (Subgame-perfect equilibrium)**.** A *subgame* is a part of an extensive-form game that begins at a point where the mover knows the entire history of play, and that contains every later move. It does not split an information set, so two points that a player cannot tell apart are both inside the subgame or both outside it. A *subgame-perfect equilibrium* is a strategy profile that induces a Nash equilibrium in every subgame (Selten, 1965).

The whole game is one of its subgames, so a subgame-perfect equilibrium is a Nash equilibrium. Perfection adds the requirement that strategies remain optimal off the equilibrium path. In games of *perfect information*, where every mover knows all earlier actions, subgame-perfect equilibria are found by *backward induction* (Kuhn, 1953). We solve the last mover's problem at each of its decision points and replace those points by the resulting payoffs. We then repeat the step until we reach the first move. In the entry game the incumbent accommodates after entry. The entrant anticipates this and enters, and this is the unique subgame-perfect equilibrium (Tirole, 1988, secs. 11.3 and 11.3.1).

Most games in this book have *almost perfect information*. Play proceeds in stages, players move simultaneously within a stage, and everyone observes all earlier stages. Backward induction then works stage by stage. The last stage is solved as a Nash equilibrium after every history. Each earlier stage is then solved as a game whose payoffs are the equilibrium payoffs of the stages that follow. The two-stage entry game of Definition 2.37 and the capacity game of Proposition 2.52 are solved in this way. The second-stage equilibrium gives a reduced-form payoff for each first-stage choice, and the first stage is a game in those payoffs. Repeated games are the other leading case, and Section 2.10.3 states the two results on them that the chapter uses.

2.4 Cournot oligopoly with N firms

The Cournot model is the workhorse model of oligopoly with a homogeneous good. It delivers the link between concentration and margins that motivated a generation of empirical work (Chapter 1). Its comparative statics underlie the analysis of entry, mergers and cost pass-through in later sections and chapters. This section develops the model for N firms with general demand and asymmetric convex costs. We prove existence and uniqueness, derive the relation between margins and concentration, solve the linear case in closed form and sign the comparative statics.

2.4.1 The game

Definition 2.17 (Cournot game)**.** N firms produce a homogeneous good. Firm i chooses an output $q_i \geq 0$. All firms choose simultaneously and have complete information. Given the output vector $q = (q_1, \dots, q_N)$, industry output is $Q = \sum_i q_i$, the market price is $P(Q)$, and firm i's profit is

$$\pi_i(q) = P(Q)\, q_i - C_i(q_i).$$

A *Cournot equilibrium* is a Nash equilibrium in quantities (Definition 2.14), an output vector q^* such that $\pi_i(q_i^*, q_{-i}^*) \geq \pi_i(q_i, q_{-i}^*)$ for every firm i and every $q_i \geq 0$.

Here q_{-i} is the vector of rivals' outputs and $Q_{-i} = Q - q_i$ is their total. Firm i's profit depends on its rivals only through Q_{-i}, so we also write it as $\pi_i(q_i, Q_{-i})$.

Assumption 2.18 (Cournot regularity)**.**

(C1) Inverse demand P is twice continuously differentiable on $[0, \infty)$, with $P'(Q) < 0$ for every Q.

(C2) For every $Q > 0$, $P'(Q) + QP''(Q) < 0$. Equivalently, $P'(Q) + qP''(Q) < 0$ for every $q \in [0, Q]$.

(C3) Each cost function C_i is twice continuously differentiable, nondecreasing and convex on $[0, \infty)$, so that $C_i' \geq 0$ and $C_i'' \geq 0$.

(C4) There is $\bar{Q} > 0$ with $P(\bar{Q}) \leq \min_i C_i'(0)$, and $P(0) > C_i'(0)$ for at least one firm i.

Condition (C1) says that demand slopes down. In (C2), the two forms are equivalent because $P' + qP''$ is linear in q and negative at $q = 0$, so it is negative on $[0, Q]$ if and only if it is negative at $q = Q$. We show below that (C2) makes each firm's marginal revenue fall when its rivals produce more. Condition (C3) allows constant or rising marginal cost. Condition (C4)

says that no firm wants to produce once industry output reaches $\bar{Q}$, while at least one firm would produce if no one else did.

Remark 2.19 (Interpreting (C2)). Define the *curvature* of inverse demand as $\chi(Q) = -\frac{QP''(Q)}{P'(Q)}$. Since $P' < 0$, (C2) is the condition $\chi(Q) < 1$ at every Q. Linear demand has $\chi = 0$, and every concave inverse demand has $\chi \le 0$, so both satisfy (C2). The family $P = a - bQ^{\gamma}$ of Example 2.12 with $b, \gamma > 0$ has $\chi = 1 - \gamma < 1$ and also satisfies it. Constant-elasticity demand $P(Q) = \left(\frac{Q}{A}\right)^{-\frac{1}{\varepsilon}}$ has $\chi = 1 + \frac{1}{\varepsilon} > 1$ and violates it. For this demand, the inequality $P'(Q) + q_i P''(Q) < 0$ holds if and only if $s_i\left(1 + \frac{1}{\varepsilon}\right) < 1$. The arguments below therefore apply at equilibria in which no firm's share exceeds $\frac{\varepsilon}{1+\varepsilon}$. Novshek (1985) shows that a condition of the type in (C2), namely that each firm's marginal revenue falls when its rivals' output rises, guarantees existence of an equilibrium even without convex costs. Curvature also governs pass-through (Section 2.8).

2.4.2 Best responses and strategic substitutes

Firm i takes Q_{-i} as given and chooses q_i. Its *best response* $BR_i(Q_{-i})$ is the output that maximizes $\pi_i(q_i, Q_{-i})$.

Lemma 2.20 (Concavity and best responses)**.** *Under Assumption 2.18, $\pi_i(q_i, Q_{-i})$ is strictly concave in q_i for every $Q_{-i} \ge 0$. The best response is unique and is characterized by the conditions*

$$P(Q) + q_i P'(Q) - C_i'(q_i) \le 0, \qquad q_i \ge 0, \qquad q_i\left[P(Q) + q_i P'(Q) - C_i'(q_i)\right] = 0, \tag{2.20}$$

with $Q = q_i + Q_{-i}$. Where $BR_i(Q_{-i}) > 0$, the best response is differentiable with slope

$$BR_i'(Q_{-i}) = -\frac{P'(Q) + q_i P''(Q)}{2P'(Q) + q_i P''(Q) - C_i''(q_i)} \in (-1, 0). \tag{2.21}$$

Proof. The derivative of profit with respect to own output is

$$\frac{\partial \pi_i}{\partial q_i} = P(Q) + q_i P'(Q) - C_i'(q_i).$$

Differentiating again and grouping terms,

$$\frac{\partial^2 \pi_i}{\partial q_i^2} = 2P'(Q) + q_i P''(Q) - C_i''(q_i) = \left[P'(Q) + q_i P''(Q)\right] + \left[P'(Q) - C_i''(q_i)\right].$$

The first bracket is negative by (C2), because $q_i \le Q$. The second is negative by (C1) and (C3). So profit is strictly concave in q_i. For $q_i \ge \bar{Q}$ we have $Q \ge \bar{Q}$, and then $\frac{\partial \pi_i}{\partial q_i} < P(\bar{Q}) - C_i'(0) \le 0$ by (C4). A maximizer therefore exists on $[0, \bar{Q}]$. Strict concavity makes it unique and makes the Kuhn-Tucker conditions (2.20) necessary and sufficient.

Where $BR_i > 0$, the first-order condition holds with equality. Write it as $G(q_i, Q_{-i}) = 0$ with $G(q_i, Q_{-i}) = P(q_i + Q_{-i}) + q_i P'(q_i + Q_{-i}) - C_i'(q_i)$. Its partial derivatives are

$$\frac{\partial G}{\partial q_i} = 2P' + q_i P'' - C_i'' < 0, \qquad \frac{\partial G}{\partial Q_{-i}} = P' + q_i P''.$$

By the implicit function theorem (Appendix B), $BR_i'(Q_{-i}) = -\left(\frac{\partial G}{\partial q_i}\right)^{-1} \frac{\partial G}{\partial Q_{-i}}$, which is (2.21). Both the numerator and the denominator are negative. The denominator equals the numerator plus the negative term $P' - C_i''$, so the ratio $\frac{P' + q_i P''}{2P' + q_i P'' - C_i''}$ lies in $(0, 1)$. Hence $BR_i' \in (-1, 0)$. □

The cross-partial derivative of profit is $\frac{\partial^2 \pi_i}{\partial q_i \partial Q_{-i}} = P'(Q) + q_i P''(Q) < 0$. More output by rivals therefore lowers firm i's marginal profit. The slope (2.21) is the general formula (2.19), with this cross-partial in the numerator and the own second derivative $2P' + q_i P'' - C_i''$ in the denominator. In the terminology of Bulow et al. (1985), quantities are *strategic substitutes*: a more aggressive strategy by one firm lowers its rivals' marginal profits (p. 489). Best responses slope down as a result. The bound $BR_i' > -1$ adds that a firm offsets only part of a rival's expansion. When rivals produce one more unit, firm i contracts by less than one unit, and industry output rises. This property drives every comparative static below. With linear demand $P = a - bQ$ and constant cost c_i, the best response is $BR_i(Q_{-i}) = \max\left\{0, \frac{a - c_i - bQ_{-i}}{2b}\right\}$, with slope $-\frac{1}{2}$ where positive.

2.4.3 Existence and uniqueness

An equilibrium solves N best-response conditions simultaneously. Because each firm's profit depends on its rivals only through their total output, the system reduces to a single equation in industry output. Szidarovszky and Yakowitz (1977) and Novshek (1985) use this reduction, and Vives (1999) develops it for general aggregative games. The device is the following function.

Definition 2.21 (Replacement function)**.** For $Q \in [0, \bar{Q}]$, the *replacement function* $\tilde{q}_i(Q)$ of firm i is the output that satisfies the conditions (2.20) when industry output equals Q:

$$\tilde{q}_i(Q) = 0 \text{ if } P(Q) \le C_i'(0), \qquad P(Q) + \tilde{q}_i(Q)P'(Q) = C_i'(\tilde{q}_i(Q)) \text{ otherwise.}$$

The replacement function gives the output that firm i would choose if it knew that industry output, including its own, would equal Q. It is well defined. Let $G_i(q, Q) = P(Q) + qP'(Q) - C_i'(q)$. For fixed Q, G_i is strictly decreasing in q, because $\frac{\partial G_i}{\partial q} = P'(Q) - C_i''(q) < 0$. It also tends to $-\infty$ as $q \to \infty$, because $G_i(q, Q) \le P(Q) + qP'(Q)$. So when $G_i(0, Q) = P(Q) - C_i'(0) > 0$ there is exactly one positive root. By construction, q_i is a best response to Q_{-i} if and only if $q_i = \tilde{q}_i(q_i + Q_{-i})$.

Lemma 2.22 (Properties of replacement functions)**.** *Under Assumption 2.18, the following hold for each firm i.*

(i) $\tilde{q}_i$ is continuous on $[0, \bar{Q}]$ and $\tilde{q}_i(\bar{Q}) = 0$. If $\tilde{q}_i(Q) = 0$, then $\tilde{q}_i(Q') = 0$ for every $Q' \ge Q$.

(ii) At any Q with $0 < \tilde{q}_i(Q) \le Q$, $\tilde{q}_i$ is differentiable and

$$\tilde{q}_i'(Q) = -\frac{P'(Q) + \tilde{q}_i(Q)P''(Q)}{P'(Q) - C_i''(\tilde{q}_i(Q))} < 0. \tag{2.22}$$

(iii) The set $R_i = \{Q \in [0, \bar{Q}] : \tilde{q}_i(Q) \le Q\}$ is a closed interval that contains $\bar{Q}$, and $\tilde{q}_i$ is nonincreasing on R_i.

Proof. (i) Where $P(Q) > C_i'(0)$, the root of $G_i(\cdot, Q)$ is continuous in Q by the implicit function theorem, since $\frac{\partial G_i}{\partial q} < 0$. Because $C_i'(q) \ge C_i'(0)$, at the root we have $0 = G_i \le P(Q) - C_i'(0) + \tilde{q}_i(Q)P'(Q)$, which gives the bound

$$\tilde{q}_i(Q) \le \frac{P(Q) - C_i'(0)}{-P'(Q)}.$$

The bound tends to zero as $P(Q)$ falls to $C_i'(0)$, so $\tilde{q}_i$ is continuous at the point where it reaches zero. By (C4), $P(\bar{Q}) \le C_i'(0)$, so $\tilde{q}_i(\bar{Q}) = 0$. Since P is decreasing, $P(Q) \le C_i'(0)$ implies $P(Q') \le C_i'(0)$ for every $Q' \ge Q$.

(ii) At such a Q, $G_i(\tilde{q}_i(Q), Q) = 0$ with $\frac{\partial G_i}{\partial q} = P' - C_i'' < 0$ and $\frac{\partial G_i}{\partial Q} = P'(Q) + \tilde{q}_i(Q)P''(Q)$. The latter is negative by (C2), because $\tilde{q}_i(Q) \le Q$. The implicit function theorem gives (2.22), a ratio of two negative numbers with a minus sign in front.

(iii) The set R_i is closed because $\tilde{q}_i$ is continuous, and it contains $\bar{Q}$ because $\tilde{q}_i(\bar{Q}) = 0$. Take $Q' \in R_i$ and suppose that some $Q'' > Q'$ lies outside R_i. Let Q° be the largest point of $[Q', Q'']$ in R_i. Then $Q^\circ < Q''$, and continuity forces $\tilde{q}_i(Q^\circ) = Q^\circ$, with $\tilde{q}_i(Q) > Q$ on $(Q^\circ, Q'']$. If $Q^\circ = 0$, then $\tilde{q}_i(0) = 0$ and by (i) $\tilde{q}_i \equiv 0$, a contradiction. So $\tilde{q}_i(Q^\circ) = Q^\circ > 0$, and by (ii) the function $\tilde{q}_i(Q) - Q$ has derivative below -1 at Q°. It is therefore negative just above Q°, which contradicts the choice of Q°. Hence R_i is an interval. On R_i, $\tilde{q}_i$ is strictly decreasing where it is positive, by (ii), and it stays at zero once it reaches zero, by (i). So it is nonincreasing on R_i. □

Proposition 2.23 (Existence and uniqueness of Cournot equilibrium)**.** *Under Assumption 2.18, a Cournot equilibrium exists and is unique. Industry output Q^* is the unique root in $(0, \bar{Q})$ of*

$$\Phi(Q) \equiv \sum_{i=1}^{N} \tilde{q}_i(Q) - Q = 0, \tag{2.23}$$

and firm i produces $q_i^* = \tilde{q}_i(Q^*)$. Moreover, $\Phi(Q) > 0$ for $0 \le Q < Q^*$ and $\Phi(Q) < 0$ for $Q^* < Q \le \bar{Q}$.

Proof. We proceed in four steps.

1. *Equilibria are roots of Φ.* By Lemma 2.20, q^* is an equilibrium if and only if every q_i^* satisfies (2.20) at $Q^* = \sum_j q_j^*$. If $Q^* \le \bar{Q}$, this says exactly that $q_i^* = \tilde{q}_i(Q^*)$ for every i, and summing gives $\Phi(Q^*) = 0$. Equilibrium output cannot be zero, because the firm with $P(0) > C_i'(0)$ in (C4) would then gain by producing. It cannot be at least $\bar{Q}$ either. Any firm with $q_i^* > 0$ would then satisfy $C_i'(q_i^*) = P(Q^*) + q_i^* P'(Q^*) < P(\bar{Q}) \le C_i'(0)$, which contradicts (C3). So all outputs would be zero, a contradiction. Conversely, every root $Q^* \in (0, \bar{Q})$ of Φ yields the equilibrium $q_i^* = \tilde{q}_i(Q^*)$.

2. *Location of roots.* At a root, $\tilde{q}_i(Q^*) \le \sum_j \tilde{q}_j(Q^*) = Q^*$ for every i, so Q^* lies in $R = \bigcap_i R_i$. By Lemma 2.22(iii), R is a closed interval $[Q_0, \bar{Q}]$.

3. *Uniqueness.* Each $\tilde{q}_i$ is nonincreasing on R, and $-Q$ is strictly decreasing, so Φ is strictly decreasing on R and has at most one root there.

4. *Existence and sign.* The firm k of (C4) has $\tilde{q}_k(0) > 0$, so $0 \notin R_k$ and $Q_0 > 0$. Let j be a firm with $\min R_j = Q_0$. Continuity gives $\tilde{q}_j(Q_0) = Q_0$, so $\Phi(Q_0) \ge \tilde{q}_j(Q_0) - Q_0 = 0$. For $Q < Q_0$, $Q \notin R_j$, so $\Phi(Q) \ge \tilde{q}_j(Q) - Q > 0$. At the other end, $\Phi(\bar{Q}) = -\bar{Q} < 0$. The intermediate value theorem yields a root in $[Q_0, \bar{Q})$. Strict monotonicity on R and positivity below Q_0 give the sign pattern. □

Figure 2.2 illustrates the construction for a linear market with three firms. With $P(Q) = 10 - Q$ and constant costs c_i, the condition $P(Q) + qP'(Q) = c_i$ reads $10 - Q - q = c_i$, so $\tilde{q}_i(Q) = \max\{0, 10 - c_i - Q\}$. With costs $(1, 2, 3)$ the replacement functions are $9 - Q$, $8 - Q$ and $7 - Q$ where positive. For $Q \le 7$ their sum is $24 - 3Q$, and setting it equal to Q gives $Q^* = 6$ and outputs $(3, 2, 1)$. Firm 1's replacement function exceeds Q for $Q < 4.5$, so $R = [4.5, 9]$, with $\bar{Q} = 9$ because $P(9) = 1$ equals the lowest marginal cost.

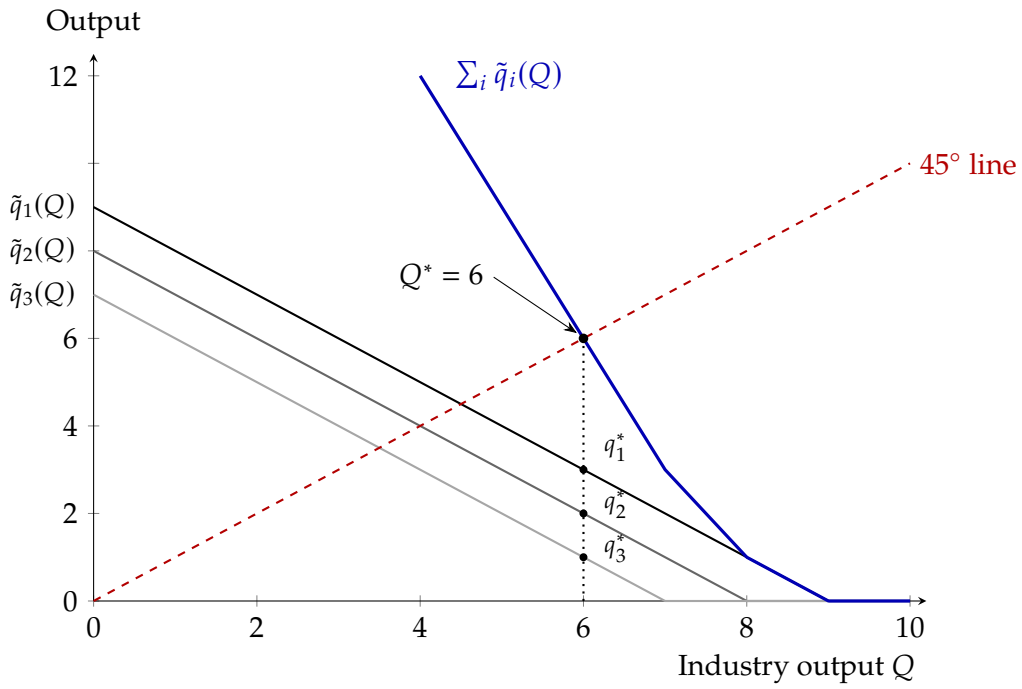

Figure 2.2: Replacement functions for $P(Q) = 10 - Q$ and constant marginal costs $(1, 2, 3)$. Each firm's replacement function $\tilde{q}_i(Q) = \max\{0, 10 - c_i - Q\}$ is the output that is optimal for firm i when industry output is Q. Their sum, $24 - 3Q$ for $Q \le 7$, crosses the 45° line once, at $Q^* = 6$. The equilibrium outputs $(3, 2, 1)$ are read off the individual replacement functions at Q^*.

Remark 2.24 (Why uniqueness matters). Empirical work uses equilibrium conditions in two ways. Estimation evaluates first-order conditions at the observed prices and quantities, for example to invert them for marginal cost as in (2.14). It never has to solve for an equilibrium, so multiplicity does no harm there. Counterfactuals, such as the effect of a merger or a tax, must solve for the new equilibrium. If several solutions exist, the analyst needs a rule for selecting one, and conclusions can depend on that rule. Proposition 2.23 rules this out for homogeneous-good Cournot markets that satisfy (C1) to (C4). Merger simulations in practice often compute the new equilibrium by iterating on the first-order conditions from the premerger prices, which selects an equilibrium close to the status quo. Chapter 4 gives the corresponding conditions for differentiated-products price competition.

Remark 2.25 (Other routes to existence and uniqueness). Theorem 2.15 gives a second proof of existence. Under Assumption 2.18, restrict each firm to the compact and convex set $[0, \bar{Q}]$. Profit $\pi_i(q)$ is continuous, and by Lemma 2.20 it is strictly concave, hence quasi-concave, in q_i. The theorem yields an equilibrium of the restricted game, and it is also an equilibrium of the original game. The proof of Lemma 2.20 shows that $\frac{\partial \pi_i}{\partial q_i} < 0$ whenever $q_i \ge \bar{Q}$, so no output above $\bar{Q}$ does better than $\bar{Q}$ itself. This route needs only quasi-concavity of profit in own output, but it is silent on uniqueness. The replacement-function proof of Proposition 2.23 gives both.

Tirole (1988, sec. 5.7.1) reviews the other approaches. Szidarovszky and Yakowitz (1977) assume that profit is concave in own output, which holds when costs are convex and inverse demand is concave. Profit need not be concave when demand is sufficiently convex. Friedman (1983) and Roberts and Sonnenschein (1977) give robust examples in which no pure-strategy

equilibrium exists even with convex costs. Without concavity, reaction functions can jump. McManus (1964) and Roberts and Sonnenschein (1976) prove existence for symmetric firms with convex costs. Convex costs ensure that the common reaction function jumps only upward, and only a downward jump can prevent a symmetric equilibrium. Novshek (1985) works with the condition discussed in Remark 2.19. For uniqueness with two firms and strictly concave profits, a sufficient condition is that $|BR_i'| < 1$ for both firms on the relevant range. The reaction curves then cross at most once. Lemma 2.20 shows that (C1) to (C3) deliver this bound, since $BR_i' \in (-1, 0)$.

2.4.4 Markups and concentration

In this subsection each firm has a constant marginal cost c_i. Firm i's Lerner index is $L_i = \frac{P-c_i}{P}$, and the *share-weighted industry Lerner index* is $\bar{L} = \sum_i s_i L_i$. The market elasticity at industry output Q is $\varepsilon = -\frac{P(Q)}{QP'(Q)}$.

Proposition 2.26 (Cowling and Waterson)**.** *In a Cournot equilibrium with constant marginal costs, every active firm satisfies*

$$L_i = \frac{P - c_i}{P} = \frac{s_i}{\varepsilon}, \tag{2.24}$$

and the share-weighted industry Lerner index satisfies

$$\bar{L} = \sum_{i=1}^{N} s_i L_i = \frac{HHI}{\varepsilon}. \tag{2.25}$$

Proof. This is Proposition 1.15. Each active firm satisfies the first-order condition $P(Q) + q_i P'(Q) = c_i$, and the algebra in that proof turns it into (2.24). Inactive firms have $s_i = 0$ and add nothing to either sum, so summing $s_i L_i$ over the active firms gives (2.25). □

The result is due to Cowling and Waterson (1976). It agrees with the monopoly rule applied to residual demand. By (2.9), firm i's residual elasticity is $\varepsilon_i^R = \frac{\varepsilon}{s_i}$, so (2.24) reads $L_i = \frac{1}{\varepsilon_i^R}$. Each Cournot firm is a monopolist on the demand left to it by its rivals. Since $L_i < 1$ whenever $c_i > 0$, every active firm has $s_i < \varepsilon$. Cournot firms can therefore operate where market demand is inelastic, provided that each firm's share is below the market elasticity. A monopolist never can (Proposition 2.4).

Corollary 2.27 (Symmetric firms)**.** *Suppose Assumption 2.18 holds and $c_i = c$ for all i. Then the unique Cournot equilibrium is symmetric and interior, with $q_i^* = \frac{Q^*}{N}$ for every firm. The formulas of Corollary 1.16 hold, in particular $HHI = \frac{1}{N}$ and $L = \frac{P-c}{P} = \frac{1}{N\varepsilon}$.*

Proof. With identical costs, all firms have the same replacement function, so by Proposition 2.23 they produce the same output $\tilde{q}(Q^*)$. Hence $q_i^* = \frac{Q^*}{N}$, which is positive because $Q^* > 0$. Every firm is active with share $\frac{1}{N}$, so Corollary 1.16(i) applies. Equivalently, substitute $s_i = \frac{1}{N}$ and $HHI = \frac{1}{N}$ into (2.25). □

The symmetric formula shows how the number of firms disciplines margins. Proposition 2.34 below shows that price approaches marginal cost as N grows. Read literally, (2.25) suggests that margins should rise with concentration across industries, with slope $\frac{1}{\varepsilon}$. The next two results show why that reading needs care.

Corollary 2.28 (Efficient firms are large)**.** *In a Cournot equilibrium with constant marginal costs, every active firm has share*

$$s_i = \varepsilon \frac{P - c_i}{P} = \varepsilon \left(1 - \frac{c_i}{P}\right), \tag{2.26}$$

so lower-cost firms have larger shares. If all N firms are active, let $\sigma_c^2 = \frac{1}{N}\sum_i (c_i - \tilde{c})^2$ be the variance of costs around their simple average $\tilde{c} = \frac{1}{N}\sum_i c_i$. Then

$$HHI = \frac{1}{N} + N \frac{\varepsilon^2}{P^2}\sigma_c^2, \qquad \bar{L} = \frac{1}{N\varepsilon} + N \frac{\varepsilon}{P^2}\sigma_c^2. \tag{2.27}$$

Proof. Equation (2.26) rearranges (2.24). It makes each share an affine function of the firm's cost with slope $-\frac{\varepsilon}{P}$, so $\sigma_s^2 = \frac{\varepsilon^2}{P^2}\sigma_c^2$. Substituting into (1.3) gives the expression for HHI, and dividing it by ε gives $\bar{L}$ by (2.25). □

With linear demand $P = a - bQ$, the elasticity is $\varepsilon = \frac{P}{bQ}$, so $\frac{\varepsilon}{P} = \frac{1}{bQ}$ and (2.27) reduces to Proposition 1.27(ii).

Corollary 2.28 is an identity that holds at the equilibrium, since ε and P are themselves equilibrium outcomes. It shows that dispersion in costs raises concentration and the average margin together, with no change in the way firms compete. Large firms earn high margins because they are efficient. This is the formal content of the efficiency critique of Demsetz (1973), which Chapter 1 develops in the context of cross-industry regressions.

The identity also has an industry-profit form (Tirole, 1988, eq. (5.14) and Exercise 5.6). With constant marginal costs, industry variable profit is

$$\Pi = \sum_i (P - c_i)\, q_i = \sum_i \frac{s_i P}{\varepsilon}\, q_i = \frac{PQ}{\varepsilon} \sum_i s_i^2,$$

where the second step uses (2.24) and the third uses $q_i = s_i Q$. Dividing by revenue PQ gives

$$\frac{\Pi}{PQ} = \frac{HHI}{\varepsilon}. \tag{2.28}$$

Suppose consumers spend a fixed amount E on the good, so that demand is $Q = \frac{E}{p}$. The elasticity is then one and revenue equals E at every price, so $\Pi = E\,HHI$. In this case the Herfindahl index measures industry profit exactly, up to a constant (Tirole's eq. (5.15)).

Bertrand competition gives a sharp contrast (Tirole, 1988, sec. 5.5). With symmetric firms, the Bertrand price and industry profit do not depend on the number of firms (Proposition 2.48), so profitability and concentration are unrelated. In Cournot competition, profitability falls with the number of firms. With asymmetric costs, the lowest-cost Bertrand firm prices at the second-lowest cost and takes the whole market (Section 2.6.1). Concentration then takes its highest value under any index that satisfies the Encaoua-Jacquemin properties, and the efficient firm earns a positive profit. Under both models, intrinsic cost asymmetries raise concentration and profitability together, which is the argument of Demsetz (1973).

Example 2.29 (Cost asymmetry raises concentration and profit)**.** Let $Q = 1 - p$, and let two Cournot firms have costs $c_1 = c - d$ and $c_2 = c + d$, with $d \geq 0$ and $1 - c - 3d > 0$ (Tirole, 1988, Exercise 5.7). Example 2.31 with $a = b = 1$ gives

$$q_1 = \frac{1 - c + 3d}{3}, \qquad q_2 = \frac{1 - c - 3d}{3}, \qquad Q = \frac{2(1-c)}{3}, \qquad P = \frac{1 + 2c}{3}.$$

Industry output and price do not depend on d. A larger d moves share from firm 2 to firm 1, a mean-preserving spread. No index with the Encaoua-Jacquemin properties falls, and the Herfindahl index rises. Each firm earns $(P - c_i)q_i = q_i^2$, so industry profit is

$$\Pi = \frac{(1 - c + 3d)^2 + (1 - c - 3d)^2}{9} = \frac{2(1 - c)^2}{9} + 2d^2,$$

which also rises with d. Here $\Pi = Q^2\, HHI$, an instance of (2.28), since $\frac{PQ}{\varepsilon} = Q^2$ for this demand. Consumer surplus does not change, so total surplus rises with d as well.

Concentration can also be related to the scope for welfare gains. Dansby and Willig (1979) consider small changes $\mathrm{d}q_i$ in firms' outputs (Tirole, 1988, Exercise 5.8). Total surplus $\int_0^Q P(x)\,\mathrm{d}x - \sum_i C_i(q_i)$ then changes by

$$\mathrm{d}W = \sum_i \left[P - C_i'(q_i)\right]\mathrm{d}q_i.$$

Suppose the change is small in the sense that $\sum_i (\mathrm{d}q_i)^2 \le \eta^2$ for some $\eta > 0$. By the Cauchy-Schwarz inequality, the largest attainable gain is $\eta\left(\sum_i [P - C_i'(q_i)]^2\right)^{\frac{1}{2}}$. In Cournot equilibrium $P - C_i'(q_i) = -q_i P'(Q) = \frac{s_i P}{\varepsilon}$, so the largest gain is

$$\max \mathrm{d}W = \eta\, \frac{P}{\varepsilon} \sqrt{HHI}.$$

The potential gain from small output changes is proportional to the square root of the Herfindahl index. Dansby and Willig call such measures *industry performance gradient indexes*. Tirole adds two cautions. Concentration indices have no systematic relationship with the variables needed to assess changes in cost, demand or policy. They are also endogenous, so their correlations with performance have no causal interpretation.

Remark 2.30 (Margins and concentration are joint outcomes). Both sides of (2.25) are determined in equilibrium by the same primitives: demand, the cost distribution and, with entry, fixed costs. Industries with inelastic demand or large fixed costs tend to have both high margins and few firms. The identity therefore does not say that an exogenous rise in concentration raises margins, except when the number of symmetric firms changes exogenously. A regression of margins on *HHI* across industries omits the elasticity and the cost dispersion. Section 2.5 shows that with free entry the sign of the relation depends on which primitive varies across industries, and Chapter 1 discusses the regressions.

The first-order conditions can also be aggregated into an industry supply relation. Suppose all N firms are active. Summing the conditions $P + q_i P'(Q) = c_i$ over firms gives $NP + QP'(Q) = \sum_i c_i$, or

$$P = \tilde{c} - \frac{1}{N}\, QP'(Q), \qquad \tilde{c} = \frac{1}{N} \sum_i c_i. \tag{2.29}$$

Alternatively, multiply firm i's condition by s_i before summing. Using $\sum_i s_i = 1$ and $s_i q_i = s_i^2 Q$,

$$\sum_i s_i P + P'(Q) \sum_i s_i q_i = \sum_i s_i c_i,$$
$$P + P'(Q)\, Q\, HHI = \bar{c},$$

which gives

$$P = \bar{c} - HHI \cdot QP'(Q), \qquad \bar{c} = \sum_i s_i c_i. \tag{2.30}$$

Both relations have the form $P = MC - \theta\, QP'(Q)$ of the supply relation (2.15) written for the industry. The value of the conduct parameter depends on how industry marginal cost is defined. It is $\theta = \frac{1}{N}$ when MC is the simple average of costs, and $\theta = HHI$ when MC is the share-weighted average. In the three-firm example of Figure 2.2, $\tilde{c} = 2$ and $\bar{c} = \frac{5}{3}$, and both relations give $P = 4$. Section 2.7 generalizes this aggregation to arbitrary firm-level conduct.

Bresnahan (1989) discusses exactly this issue for studies that have only industry data (Section 2.2.4, p. 1030). Such studies estimate an aggregate relation $P_t = MC(Q_t, W_t, Z_t, \epsilon_{ct}) - \theta_t Q_t \frac{\partial P}{\partial Q}$ (his eq. (16)). Bresnahan notes that oligopoly firms generally have different marginal costs in equilibrium unless costs are identical and constant, so a stable industry marginal cost curve need not exist. He recommends following Cowling and Waterson (1976) and reading the aggregate θ_t as average conduct and $\frac{P-MC}{P}$ as the average markup. He also rejects the claim that theory implies equal conduct for all firms. Equations (2.29) and (2.30) make the averaging explicit.

2.4.5 The linear model in closed form

Example 2.31 (Linear Cournot)**.** Let $P(Q) = a - bQ$ with $b > 0$, and let firm i have constant marginal cost $c_i < a$ and fixed cost F, which does not affect output decisions. Suppose all firms are active. Firm i's first-order condition is

$$a - bQ - bq_i - c_i = 0, \qquad \text{so} \qquad bq_i = a - c_i - bQ.$$

Summing over the N firms and solving for Q,

$$bQ = Na - \sum_j c_j - NbQ,$$

$$Q^* = \frac{Na - \sum_j c_j}{b(N+1)}.$$

The price is

$$P^* = a - bQ^* = a - \frac{Na - \sum_j c_j}{N+1} = \frac{a + \sum_j c_j}{N+1},$$

and each firm's output follows from $bq_i = P^* - c_i$:

$$q_i^* = \frac{P^* - c_i}{b} = \frac{a - (N+1)c_i + \sum_j c_j}{b(N+1)}.$$

All firms are active if and only if $(N+1)c_i < a + \sum_j c_j$ for every i, that is, if every cost is below the equilibrium price. Profit is $\pi_i^* = (P^* - c_i)q_i^* - F = b(q_i^*)^2 - F$, because $P^* - c_i = bq_i^*$.

With symmetric costs $c_i = c$, these formulas become

$$P = \frac{a + Nc}{N+1}, \qquad q = \frac{a - c}{b(N+1)}, \qquad Q = \frac{N(a-c)}{b(N+1)}, \qquad \pi = \frac{(a-c)^2}{b(N+1)^2} - F.$$

The Lerner index is $L = \frac{P-c}{P}$, with $P - c = \frac{a-c}{N+1}$, so $L = \frac{a-c}{a+Nc}$. The index is $HHI = \frac{1}{N}$. The market elasticity at the equilibrium is

$$\varepsilon = \frac{P}{bQ} = \frac{a+Nc}{N+1} \cdot \frac{N+1}{N(a-c)} = \frac{a+Nc}{N(a-c)},$$

and indeed $\frac{HHI}{\varepsilon} = \frac{1}{N} \cdot \frac{N(a-c)}{a+Nc} = \frac{a-c}{a+Nc} = L$, as Corollary 2.27 requires.

For a numerical illustration take $a = 10$, $b = 1$ and costs $(c_1, c_2, c_3) = (1, 2, 3)$, the market of Figure 2.2. Then $\sum_j c_j = 6$, so $P^* = \frac{16}{4} = 4$ and $Q^* = \frac{30-6}{4} = 6$. Outputs are $q^* = (3, 2, 1)$ and shares are $\left(\frac{1}{2}, \frac{1}{3}, \frac{1}{6}\right)$, so

$$HHI = \frac{1}{4} + \frac{1}{9} + \frac{1}{36} = \frac{7}{18} \approx 0.389.$$

The market elasticity is $\varepsilon = \frac{P^*}{bQ^*} = \frac{2}{3}$, so demand is inelastic at the equilibrium. The firm Lerner indices are $(0.75, 0.50, 0.25)$, and each equals $\frac{s_i}{\varepsilon}$. The share-weighted index is

$$\bar{L} = \frac{1}{2} \cdot \frac{3}{4} + \frac{1}{3} \cdot \frac{1}{2} + \frac{1}{6} \cdot \frac{1}{4} = \frac{7}{12} \approx 0.583 = \frac{7}{18} \cdot \frac{3}{2} = \frac{HHI}{\varepsilon}.$$

Profits gross of fixed costs are $(9, 4, 1)$. Costs have variance $\sigma_c^2 = \frac{2}{3}$, and (2.27) gives $\frac{1}{3} + 3 \cdot \frac{4}{9} \cdot \frac{1}{16} \cdot \frac{2}{3} = \frac{1}{3} + \frac{1}{18} = \frac{7}{18}$, as it should.

Table 2.1 collects the symmetric closed forms for four cases: Cournot competition and perfect collusion, each with a fixed number of firms and with free entry. Under *perfect collusion* the firms maximize joint profit and split the output equally. Joint profit $(a - bQ - c)Q - NF$ is maximized at the monopoly output, so

$$Q = \frac{a-c}{2b}, \qquad P = \frac{a+c}{2}, \qquad q = \frac{a-c}{2bN}, \qquad \pi = \frac{(a-c)^2}{4bN} - F.$$

The Lerner index is $\frac{a-c}{a+c}$ for every N, while $HHI = \frac{1}{N}$. Collusion is not a Nash equilibrium of the one-shot game, and Section 2.10 discusses what sustains it. The free-entry columns treat the number of firms as continuous and set profit to zero. Section 2.5 derives them and uses the table to compare the relation between margins and concentration across the four cases.

2.4.6 Comparative statics

The replacement functions also deliver the comparative statics of the equilibrium. The sign pattern in Proposition 2.23 is the key. If a parameter change shifts Φ down at the old equilibrium output, the new root must lie to the left of the old one. If it shifts Φ up, the new root lies to the right. Within the interval R the replacement functions are nonincreasing, which pins down how individual outputs move.

Proposition 2.32 (An increase in one firm's cost)**.** *Let Assumption 2.18 hold, and write firm i's cost as $C_i(q) = c_i q + K_i(q)$ with K_i convex, so that c_i shifts its marginal cost up one for one. Suppose firm i is active in equilibrium, and let c_i rise. Then industry output Q^* falls and the price rises. Every rival's output weakly rises, strictly for rivals that are active after the change. Firm i's output falls. At an equilibrium in which no firm has $P(Q^*) = C_j'(0)$, the effects are differentiable, with*

$$\frac{\mathrm{d}Q^*}{\mathrm{d}c_i} = \frac{\frac{\partial \tilde{q}_i}{\partial c_i}}{1 - \sum_{j=1}^{N} \tilde{q}_j'(Q^*)} < 0, \qquad \frac{\partial \tilde{q}_i}{\partial c_i} = \frac{1}{P'(Q^*) - C_i''(q_i^*)} < 0, \tag{2.31}$$

Table 2.1: Closed forms for the linear market $P(Q) = a - bQ$ with symmetric firms

	Cournot		Perfect collusion	
	(i) Fixed N	(ii) Free entry	(iii) Fixed N	(iv) Free entry
Number of firms	N	$N^e = \frac{a-c}{\sqrt{bF}} - 1$	N	$N^m = \frac{(a-c)^2}{4bF}$
Price P	$\frac{a+Nc}{N+1}$	$c + \sqrt{bF}$	$\frac{a+c}{2}$	$\frac{a+c}{2}$
Output per firm q	$\frac{a-c}{b(N+1)}$	$\sqrt{\frac{F}{b}}$	$\frac{a-c}{2bN}$	$\frac{2F}{a-c}$
Industry output Q	$\frac{N(a-c)}{b(N+1)}$	$\frac{a-c-\sqrt{bF}}{b}$	$\frac{a-c}{2b}$	$\frac{a-c}{2b}$
Profit per firm π	$\frac{(a-c)^2}{b(N+1)^2} - F$	0	$\frac{(a-c)^2}{4bN} - F$	0
Lerner index L	$\frac{a-c}{a+Nc}$	$\frac{\sqrt{bF}}{c+\sqrt{bF}}$	$\frac{a-c}{a+c}$	$\frac{a-c}{a+c}$
HHI	$\frac{1}{N}$	$\frac{\sqrt{bF}}{a-c-\sqrt{bF}}$	$\frac{1}{N}$	$\frac{4bF}{(a-c)^2}$

Notes: Each firm has constant marginal cost $c < a$ and fixed cost $F > 0$. Perfect collusion means that the firms produce the monopoly output and split it equally. In columns (ii) and (iv) the number of firms is treated as continuous and set so that profit is zero, which requires $F \le \frac{(a-c)^2}{4b}$. With $a = 10$, $b = 1$, $c = 2$ and $F = 1$, column (ii) gives $N^e = 7$, $P = 3$ and $HHI = \frac{1}{7}$, and column (iv) gives $N^m = 16$ and $HHI = \frac{1}{16}$.

$$\frac{\mathrm{d}q_j^*}{\mathrm{d}c_i} = \tilde{q}_j'(Q^*)\,\frac{\mathrm{d}Q^*}{\mathrm{d}c_i} \ge 0 \;\; (j \ne i), \qquad \frac{\mathrm{d}q_i^*}{\mathrm{d}c_i} = \frac{\mathrm{d}Q^*}{\mathrm{d}c_i} - \sum_{j \ne i} \frac{\mathrm{d}q_j^*}{\mathrm{d}c_i} < 0, \qquad \frac{\mathrm{d}P}{\mathrm{d}c_i} = P'(Q^*)\,\frac{\mathrm{d}Q^*}{\mathrm{d}c_i} > 0.$$

Proof. Firm i's replacement function solves $P(Q) + qP'(Q) - c_i - K_i'(q) = 0$. The left side falls with c_i, so for each Q the root $\tilde{q}_i(Q)$ is nonincreasing in c_i, and strictly decreasing wherever it is positive. Rivals' replacement functions do not depend on c_i. Let Q^* be the old equilibrium output, so $\tilde{q}_i(Q^*) > 0$. After the increase, the new aggregate function satisfies $\Phi^{\text{new}}(Q^*) < \Phi(Q^*) = 0$. By the sign pattern of Proposition 2.23 applied to Φ^{new}, its root lies strictly below Q^*. So industry output falls, and the price rises because P is decreasing.

For a rival j, both the old and the new equilibrium outputs lie in R_j, which does not depend on c_i. Since $\tilde{q}_j$ is nonincreasing on R_j, the lower industry output weakly raises $q_j^* = \tilde{q}_j(Q^*)$. The increase is strict when j is active at the new equilibrium, because $\tilde{q}_j$ is strictly decreasing where it is positive. Firm i's output equals $Q^* - \sum_{j \ne i} q_j^*$, which falls because industry output falls and rivals' outputs rise.

For the derivatives, differentiate the identity $\sum_j \tilde{q}_j(Q^*(c_i); c_i) - Q^*(c_i) = 0$ with respect to c_i:

$$\left[\sum_j \tilde{q}_j'(Q^*) - 1\right] \frac{\mathrm{d}Q^*}{\mathrm{d}c_i} + \frac{\partial \tilde{q}_i}{\partial c_i} = 0.$$

Solving gives the first expression in (2.31). Differentiating firm i's first-order condition with respect to c_i at fixed Q gives $\left[P' - C_i''\right] \frac{\partial \tilde{q}_i}{\partial c_i} - 1 = 0$, which is the second. The denominator of $\frac{\mathrm{d}Q^*}{\mathrm{d}c_i}$ is at least one because $\tilde{q}_j' \le 0$, and its numerator is negative. The remaining derivatives follow from $q_j^* = \tilde{q}_j(Q^*)$, the adding-up identity and the chain rule. □

With linear demand and constant costs, every active firm has $\tilde{q}_j' = -1$ and $\frac{\partial \tilde{q}_i}{\partial c_i} = -\frac{1}{b}$. Then $\frac{\mathrm{d}Q^*}{\mathrm{d}c_i} = -\frac{1}{b(N+1)}$ and $\frac{\mathrm{d}P}{\mathrm{d}c_i} = \frac{1}{N+1}$, matching the closed form $P^* = \frac{a+\sum_j c_j}{N+1}$. A firm-specific cost shock moves the price by much less than the same shock applied to every firm. Section 2.8 develops this contrast.

A weaker statement about the firm's own response needs none of the regularity conditions. Given Q_{-i}, firm i is a monopolist on the residual inverse demand $P(q + Q_{-i})$. By Lemma 2.6, a higher marginal cost weakly lowers its optimal output for every Q_{-i}, whatever the shape of demand and cost. A cost increase therefore shifts firm i's reaction curve inward (Tirole, 1988, sec. 5.4). The equilibrium effects in Proposition 2.32 need more structure, namely best responses that slope down and an equilibrium that is unique.

The same argument measures how rivals respond when one firm's output changes for any reason. Hold q_i fixed and let the other firms play their replacement functions. Industry output then satisfies $Q = q_i + \sum_{j\neq i} \tilde{q}_j(Q)$. Write $\lambda_j = -\tilde{q}_j'(Q)$. Differentiating gives $\mathrm{d}Q = \mathrm{d}q_i - \sum_{j\neq i} \lambda_j \,\mathrm{d}Q$, so

$$\frac{\mathrm{d}Q}{\mathrm{d}q_i} = \frac{1}{1 + \sum_{j\neq i} \lambda_j}, \qquad \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i} = -\frac{\sum_{j\neq i} \lambda_j}{1 + \sum_{j\neq i} \lambda_j} \in (-1, 0]. \tag{2.32}$$

With linear demand and constant costs, $\lambda_j = 1$ for every active rival. If all $N-1$ rivals are active, they contract by $\frac{N-1}{N}$ units for each extra unit that firm i produces, and industry output rises by only $\frac{1}{N}$. Farrell and Shapiro (1990) define the same number $\lambda_j = -\frac{P' + q_j P''}{C_j'' - P'}$ and build their analysis of mergers in Cournot markets on it (Chapter 11). Dixit (1986) develops comparative statics for general oligopoly models along similar lines. Figure 2.3 shows the effect of a cost reduction in a linear duopoly.

Entry has the opposite effect on industry output, and it hurts every incumbent.

Proposition 2.33 (Entry)**.** *Suppose a firm $N+1$, with a cost function satisfying (C3), joins N incumbents, and (C4) holds for the enlarged set of firms. Then industry output weakly rises and the price weakly falls. Every incumbent's output and profit weakly fall. If the entrant is active in the new equilibrium, industry output strictly rises and the price strictly falls. The output and profit of every incumbent that was active before entry then fall strictly.*

Proof. Write Φ_N and Φ_{N+1} for the aggregate functions before and after entry, with roots Q_N^* and Q_{N+1}^*. Since $\Phi_{N+1} = \Phi_N + \tilde{q}_{N+1}$, we have $\Phi_{N+1}(Q_N^*) = \tilde{q}_{N+1}(Q_N^*) \geq 0$. By the sign pattern of Proposition 2.23, $Q_{N+1}^* \geq Q_N^*$. If the entrant is active after entry, the two roots cannot coincide, because $\Phi_{N+1}(Q_N^*) = \tilde{q}_{N+1}(Q_N^*) > 0$ would then contradict $\Phi_{N+1}(Q_{N+1}^*) = 0$. So the inequality is strict.

Both equilibrium outputs lie in R_i for each incumbent i, and $\tilde{q}_i$ is nonincreasing there, so $q_i^* = \tilde{q}_i(Q^*)$ weakly falls. Rivals' total output from i's point of view, $Q_{-i}^* = Q^* - q_i^*$, weakly rises. Firm i's equilibrium profit is the value function $V_i(Q_{-i}) = \max_{q\geq 0} \left[P(q + Q_{-i})\, q - C_i(q)\right]$. For every $q > 0$ the bracket falls with Q_{-i}, so V_i is nonincreasing. By the envelope theorem (Appendix B), $V_i'(Q_{-i}) = P'(Q)\, q_i^* \leq 0$, strictly when firm i is active. Hence incumbents' profits fall.

Now let the entrant be active, so that Q^* rises strictly. Take an incumbent with $\tilde{q}_i(Q_N^*) > 0$. Its replacement function is strictly decreasing where it is positive, so its output falls strictly. Then Q_{-i}^* rises strictly. Since V_i is nonincreasing and strictly decreasing near the old value of Q_{-i}, where firm i is active, its profit falls strictly. □

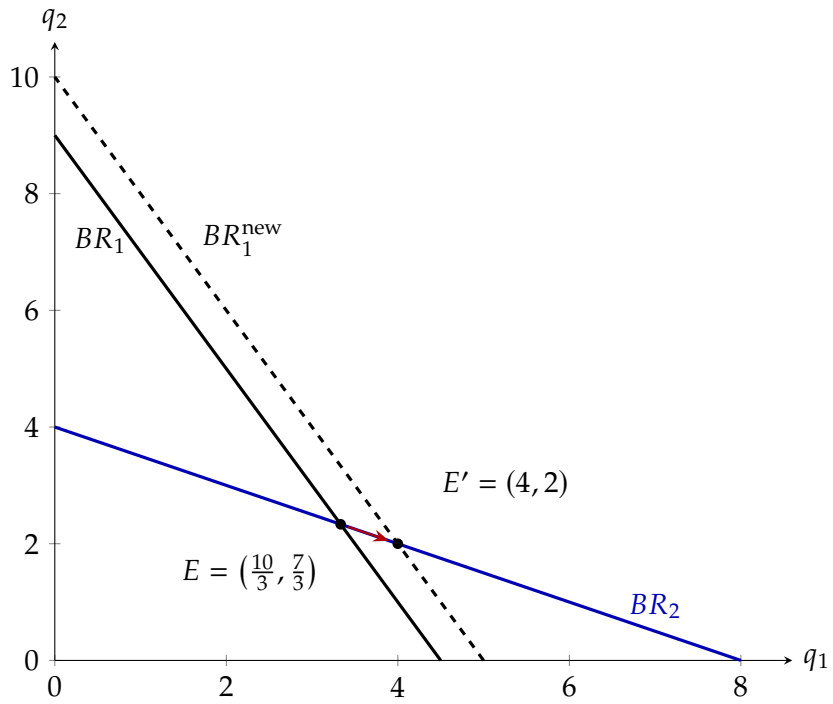

Figure 2.3: Best responses in a linear Cournot duopoly with $P(Q) = 10 - Q$, $c_1 = 1$ and $c_2 = 2$. Firm 1's best response is $q_1 = \frac{9-q_2}{2}$ and firm 2's is $q_2 = \frac{8-q_1}{2}$. They cross at $E = \left(\frac{10}{3}, \frac{7}{3}\right)$, where $P = \frac{13}{3}$. When c_1 falls to 0, firm 1's best response shifts out to the dashed line BR_1^{new}, $q_1 = \frac{10-q_2}{2}$. The new equilibrium $E' = (4, 2)$ has a larger firm 1, a smaller firm 2 and price $P = 4$, as Proposition 2.32 predicts.

With symmetric firms the effect of entry can be computed explicitly. Treat N as a continuous variable, and let q_N be the symmetric equilibrium output, which solves $P(Nq) + qP'(Nq) - C'(q) = 0$. Differentiating with respect to N,

$$P'\left(q + N\frac{\mathrm{d}q}{\mathrm{d}N}\right) + P'\frac{\mathrm{d}q}{\mathrm{d}N} + qP''\left(q + N\frac{\mathrm{d}q}{\mathrm{d}N}\right) - C''\frac{\mathrm{d}q}{\mathrm{d}N} = 0.$$

Collecting the terms in $\frac{\mathrm{d}q}{\mathrm{d}N}$,

$$\frac{\mathrm{d}q}{\mathrm{d}N}\left[N(P' + qP'') + P' - C''\right] = -q(P' + qP''),$$

so

$$\begin{aligned} \frac{\mathrm{d}q_N}{\mathrm{d}N} &= -\frac{q(P' + qP'')}{N(P' + qP'') + P' - C''} < 0, \\ \frac{\mathrm{d}(Nq_N)}{\mathrm{d}N} &= q + N\frac{\mathrm{d}q_N}{\mathrm{d}N} = \frac{q(P' - C'')}{N(P' + qP'') + P' - C''} > 0. \end{aligned} \tag{2.33}$$

The common denominator is negative by (C1) to (C3). The numerator of the first expression is positive and that of the second is negative, which gives the signs. These formulas are due to Seade (1980). They verify, for Cournot competition, the conditions that Mankiw and Whinston (1986) impose on the outcome of competition after entry (p. 51). Their Assumption 1 requires industry output Nq_N to rise with N toward a finite limit, which holds because $Nq_N < \bar{Q}$. Their Assumption 2 requires output per firm to fall with N, the *business-stealing effect*. Their Assumption 3 requires price to be at least marginal cost, and in Cournot $P - C'(q_N) = -q_N P' > 0$. Section 2.5 restates the three properties as conditions (E1) to (E3) of Assumption 2.39 and shows that they imply excessive entry.

As the number of firms grows, Cournot competition approaches perfect competition.

Proposition 2.34 (Convergence to competitive pricing)**.** *Consider N symmetric firms with constant marginal cost c, and suppose Assumption 2.18 holds for every N with the same $\bar{Q}$. Let P_N be the equilibrium price and $\mathcal{M} = \max_{Q\in[0,\bar{Q}]}|P'(Q)|$. Then*

$$0 < P_N - c \le \frac{\mathcal{M}\bar{Q}}{N},$$

so $P_N \to c$ as $N \to \infty$. If $c > 0$, the Lerner index $L_N = \frac{1}{N\varepsilon(P_N)}$ also tends to zero.

Proof. By Corollary 2.27, each firm produces $q_N = \frac{Q_N}{N}$, with $Q_N < \bar{Q}$ by Proposition 2.23. The first-order condition gives

$$P_N - c = -q_N P'(Q_N) = \frac{Q_N}{N}|P'(Q_N)| \le \frac{\bar{Q}\mathcal{M}}{N}.$$

The left side is positive because $q_N > 0$. If $c > 0$, then $L_N = \frac{P_N - c}{P_N} \le \frac{P_N - c}{c} \to 0$. □

Ruffin (1971) studies this convergence, and Novshek (1980) shows that Cournot equilibria with free entry approach the competitive outcome as firms become small relative to the market. In the linear case, $P_N - c = \frac{a-c}{N+1}$. With $c = 0$ the Lerner index $\frac{P_N - 0}{P_N}$ equals one for every N, even though the price itself converges to zero. This is why the second statement requires $c > 0$.

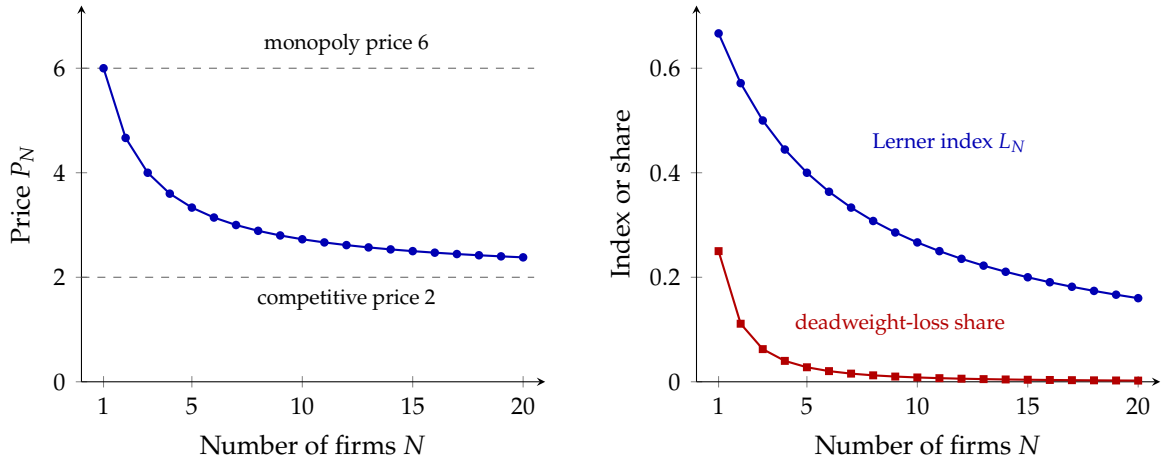

Figure 2.4: Symmetric linear Cournot market with $a = 10$, $b = 1$ and $c = 2$, for $N = 1, \dots, 20$. The left panel shows the price $P_N = \frac{10+2N}{N+1}$ between the monopoly price 6 and the competitive price 2. The right panel shows the Lerner index $L_N = \frac{8}{10+2N}$ and the deadweight loss as a share of maximal surplus, $\frac{1}{(N+1)^2}$ (Section 2.9).

Figure 2.4 shows the speed of convergence in a linear market. The deadweight loss falls with the square of $N + 1$, much faster than the Lerner index.

The deadweight-loss share in the figure follows from Table 2.1. Competitive output is $\frac{a-c}{b}$, so Cournot output falls short of it by $\frac{a-c}{b(N+1)}$, while price exceeds cost by $\frac{a-c}{N+1}$. The deadweight loss is the triangle $\frac{1}{2} \cdot \frac{a-c}{N+1} \cdot \frac{a-c}{b(N+1)} = \frac{(a-c)^2}{2b(N+1)^2}$. Dividing by the maximal surplus $\frac{(a-c)^2}{2b}$ gives $\frac{1}{(N+1)^2}$. Corollary 2.88 recovers this share as a special case of a formula for any conduct θ, and Section 2.9 treats welfare in general.

Remark 2.35 (Other competitive limits). Replicating firms is only one way to make an industry competitive. With fixed costs or increasing returns, adding potential firms need not add competition, because a limited market supports only a few viable firms (Tirole, 1988, sec. 5.7.1.3). Novshek and Sonnenschein (1978) instead allow free entry and shrink the minimum efficient scale. Let each firm have a U-shaped average cost with minimum c at output 1. Replace the cost function $C(q)$ by $C_\alpha(q) = \alpha\, C\left(\frac{q}{\alpha}\right)$, whose minimum efficient scale is α and whose minimum average cost is still c. Let $Q^* = Q(c)$ be the competitive output. Any free-entry Cournot equilibrium then has industry output in $[Q^* - \alpha, Q^*]$. If output exceeded Q^*, the price would be below c, and every active firm would lose money. If output fell short of $Q^* - \alpha$, an entrant producing α at average cost c would face a price above c and earn a profit. The equilibrium therefore becomes competitive as $\alpha \to 0$.

A large number of firms is not even necessary, as Hart (1979) pointed out. What matters is that each firm be small relative to its market, so that its own output has little effect on the price. Tirole's illustration is a monopolist with ten units of capacity and zero marginal cost. It faces ten consumers with unit demands and valuations $10, 9, \dots, 1$, and it maximizes revenue by withholding part of its capacity. If it can sell on ten identical islands of such consumers, it sells all ten units at the price 10 and causes no distortion.

Remark 2.36 (Mergers in the symmetric Cournot model). Suppose two of N symmetric Cournot firms with constant marginal cost merge, and the merged firm has the same cost as every other firm. The market then has $N - 1$ symmetric firms. Two consequences follow, and Chapter 11 treats both in full.

First, the actual change in concentration is

$$\Delta HHI = \frac{1}{N-1} - \frac{1}{N} = \frac{1}{N(N-1)}.$$

The formula (2.1) predicts $2 \cdot \frac{1}{N} \cdot \frac{1}{N} = \frac{2}{N^2}$. The prediction exceeds the actual change if and only if $2(N-1) > N$, that is, $N > 2$. With $N = 3$ the formula predicts 0.222, while the actual change is 0.167. The formula ignores the expansion of the nonmerging firms, which by Proposition 2.33 (read in reverse) produce more when a competitor disappears.

Second, the merger may be unprofitable. In the linear model each firm earns $\frac{(a-c)^2}{b(N+1)^2}$ before the merger, ignoring fixed costs, and the merged firm earns $\frac{(a-c)^2}{bN^2}$ afterwards. The merger is profitable for its participants if and only if

$$\frac{(a-c)^2}{bN^2} \geq \frac{2(a-c)^2}{b(N+1)^2} \iff (N+1)^2 \geq 2N^2 \iff N \leq \frac{1}{\sqrt{2}-1} = 1+\sqrt{2}.$$

Only a merger to monopoly from duopoly passes this test. With $N = 3$, the two insiders earn $\frac{2}{16} = 0.125$ in units of $\frac{(a-c)^2}{b}$ before the merger and $\frac{1}{9} \approx 0.111$ afterwards. The outsiders gain, because they expand while the price rises. This is the merger paradox of Salant et al. (1983). Farrell and Shapiro (1990) show that a Cournot merger that creates no synergies always raises the price, so cost savings are needed before consumers can gain (Chapter 11).

2.5 Free entry and the number of firms

Section 2.4 took the number of firms as given. In most industries the number of firms is itself an equilibrium outcome. Firms enter while the profit of one more entrant covers the cost of setting up, and they stay out once it does not. This section asks whether free entry delivers the number of firms that maximizes total surplus. The general answer, due to Mankiw and Whinston (1986), is that in homogeneous-good markets with imperfect competition free entry tends to produce too many firms. The reason is a *business-stealing externality*: an entrant takes sales from incumbents and counts them as its own profit, while society gains nothing from the transfer.

2.5.1 The two-stage entry game

Definition 2.37 (Two-stage entry game)**.** A large pool of identical potential entrants plays two stages. In stage 1 each potential entrant decides whether to enter. Entry requires a *set-up cost* $F > 0$, which is sunk once paid. In stage 2 the N entrants observe N and play an oligopoly game in output or prices. Each entrant has the cost function $C(q)$, with C continuous, $C(0) = 0$, $C' \geq 0$ and $C'' \geq 0$. The stage-2 game has a symmetric equilibrium in which each firm produces q_N and the price is $P(Nq_N)$. The *per-firm profit* with N entrants, net of the set-up cost, is

$$\pi_N = P(Nq_N)\, q_N - C(q_N) - F. \tag{2.34}$$

The solution concept is subgame-perfect equilibrium (Definition 2.16).

The definition leaves the stage-2 game open. It may be Cournot, Bertrand, a cartel, or any other game with a symmetric outcome. This generality is the main strength of the analysis that follows.

The *free-entry number of firms* N^e satisfies two conditions (Mankiw and Whinston, 1986, p. 50):

$$\pi_{N^e} \geq 0 \qquad \text{and} \qquad \pi_{N^e+1} < 0. \tag{2.35}$$

The first condition says that no entrant regrets entering. The second says that no outsider wishes to enter. A firm that is indifferent enters. When we treat N as a continuous variable, the two conditions collapse to the zero-profit condition $\pi_{N^e} = 0$.

Example 2.38 (Free entry in the linear Cournot market)**.** Let $P(Q) = a - bQ$ and $C(q) = cq$, with $a > c \geq 0$ and $b > 0$, and let the entrants play Cournot. Example 2.31 gives

$$q_N = \frac{a-c}{b(N+1)}, \qquad P - c = \frac{a-c}{N+1} = b\, q_N, \qquad \pi_N = \frac{(a-c)^2}{b(N+1)^2} - F.$$

Setting $\pi_{N^e} = 0$ and solving for N^e gives

$$(N^e+1)^2 = \frac{(a-c)^2}{bF} \qquad \Longrightarrow \qquad N^e = \frac{a-c}{\sqrt{bF}} - 1. \tag{2.36}$$

At least one firm enters when $F \leq \frac{(a-c)^2}{4b}$. Substituting $\frac{a-c}{N^e+1} = \sqrt{bF}$ into the Cournot formulas gives the free-entry outcome:

$$P^e = c + \sqrt{bF}, \qquad q^e = \sqrt{\frac{F}{b}}, \qquad Q^e = \frac{a-c-\sqrt{bF}}{b},$$
$$L^e = \frac{\sqrt{bF}}{c+\sqrt{bF}}, \qquad HHI^e = \frac{1}{N^e} = \frac{\sqrt{bF}}{a-c-\sqrt{bF}}.$$

They fill the free-entry column of Table 2.1. As a check, $(P^e - c)\, q^e = \sqrt{bF}\sqrt{\frac{F}{b}} = F$, so operating profit just covers the set-up cost.

The example makes two points. First, under free entry the price-cost margin equals $\sqrt{bF}$ exactly. Markups are what pays for fixed costs, which is the point of Remark 2.1. A positive Lerner index is therefore compatible with zero economic profit. Second, the margin does not depend on the demand intercept a. A higher intercept attracts more firms and leaves the margin unchanged, while concentration falls. Adding consumers is different. Scaling the number of consumers by M replaces b by $\frac{b}{M}$, so the free-entry margin $\sqrt{\frac{bF}{M}}$ falls as the market grows (Table 2.3).

2.5.2 The second-best planner and excess entry

Mankiw and Whinston (1986) compare N^e with the choice of a *second-best planner*. This planner chooses how many firms enter but cannot control how they compete after entry. The restriction reflects antitrust practice. Mankiw and Whinston (1986, p. 50) quote the observation of Scherer (1980, p. 525) that oligopolists who refrain from price competition, each deciding independently, do not break the law. The planner maximizes total surplus, ignoring income effects:

$$W(N) = \int_0^{Nq_N} P(x)\,\mathrm{d}x - N\,C(q_N) - NF. \tag{2.37}$$

The first term is gross consumer benefit, and the last two are production and set-up costs. Prices are transfers between consumers and firms, so they do not appear. Let N^o denote the maximizer of W (Mankiw and Whinston write N^*). With continuous N it satisfies $W'(N^o) = 0$.

Assumption 2.39 (Post-entry outcomes)**.** The symmetric stage-2 outcomes satisfy the following conditions (Mankiw and Whinston, 1986, p. 51).

(E1) Total output rises with N and stays bounded: $Nq_N > N'q_{N'}$ for all $N > N'$, and $\lim_{N\to\infty} Nq_N = Q_\infty < \infty$.

(E2) Per-firm output falls with N: $q_N < q_{N'}$ for all $N > N'$.

(E3) Price is not below marginal cost: $P(Nq_N) - C'(q_N) \geq 0$ for all N.

When N is continuous we also assume that q_N is differentiable, with $\frac{\mathrm{d}q_N}{\mathrm{d}N} < 0 < \frac{\mathrm{d}(Nq_N)}{\mathrm{d}N}$.

Condition (E2) is the *business-stealing effect*: an entrant lowers the equilibrium output of each incumbent. Proposition 2.33 and the derivatives (2.33) show that Cournot competition satisfies (E1) and (E2) under Assumption 2.18. Condition (E3) holds for any conduct between price taking and monopoly. Business stealing is closely related to quantities being strategic substitutes (Bulow et al., 1985), and Seade (1980) gives conditions for it under conjectural variations.

Proposition 2.40 (Excess entry)**.** *Suppose Assumption 2.39 holds and treat N as continuous, so that $\pi_{N^e} = 0$ and $W'(N^o) = 0$. Then $N^e \geq N^o$. If in addition $P(N^o q_{N^o}) - C'(q_{N^o}) > 0$, then $N^e > N^o$ (Mankiw and Whinston, 1986, Proposition 1).*

Proof. The proof has four steps.

Step 1. We differentiate welfare. By the fundamental theorem of calculus and the chain rule,

$$\frac{\mathrm{d}}{\mathrm{d}N}\int_0^{Nq_N} P(x)\,\mathrm{d}x = P(Nq_N)\,\frac{\mathrm{d}(Nq_N)}{\mathrm{d}N} = P(Nq_N)\left[q_N + N\frac{\mathrm{d}q_N}{\mathrm{d}N}\right].$$

The product rule gives $\frac{\mathrm{d}}{\mathrm{d}N}\left[NC(q_N)\right] = C(q_N) + NC'(q_N)\frac{\mathrm{d}q_N}{\mathrm{d}N}$. Hence

$$W'(N) = P(Nq_N)\left[q_N + N\frac{\mathrm{d}q_N}{\mathrm{d}N}\right] - C(q_N) - NC'(q_N)\frac{\mathrm{d}q_N}{\mathrm{d}N} - F. \tag{2.38}$$

Step 2. We regroup. The terms $P(Nq_N)q_N - C(q_N) - F$ add up to π_N. The remaining terms share the factor $N\frac{\mathrm{d}q_N}{\mathrm{d}N}$. Therefore

$$W'(N) = \pi_N + N\left[P(Nq_N) - C'(q_N)\right]\frac{\mathrm{d}q_N}{\mathrm{d}N}. \tag{2.39}$$

Step 3. We sign the wedge. By (E3) the bracket is nonnegative. By (E2) the derivative $\frac{\mathrm{d}q_N}{\mathrm{d}N}$ is negative. The second term of (2.39) is therefore nonpositive, and $W'(N) \leq \pi_N$ for every N. At $N = N^o$ this gives $0 = W'(N^o) \leq \pi_{N^o}$. The inequality is strict when the bracket is positive at N^o.

Step 4. Profit falls with entry. Differentiating (2.34) gives

$$\frac{\mathrm{d}\pi_N}{\mathrm{d}N} = \left[P(Nq_N) - C'(q_N)\right]\frac{\mathrm{d}q_N}{\mathrm{d}N} + q_N P'(Nq_N)\,\frac{\mathrm{d}(Nq_N)}{\mathrm{d}N}. \tag{2.40}$$

The first term is nonpositive by (E2) and (E3). The second is negative because $P' < 0$ and total output rises with N. So π_N is strictly decreasing. Since $\pi_{N^o} \geq 0 = \pi_{N^e}$, we conclude that $N^e \geq N^o$. If $\pi_{N^o} > 0$, then $N^e > N^o$. □

Equation (2.39) contains the whole economics of the result. The social value of a marginal entrant has two parts. The first is the entrant's own profit π_N, which is also its private value of entry. The second is the surplus lost on the output that incumbents give up. Entry shrinks incumbents' total output by $N\left|\frac{\mathrm{d}q_N}{\mathrm{d}N}\right|$. Each lost unit was worth P to consumers and cost C' to make, so each one destroys $P - C'$ of surplus. The entrant ignores this loss. The lower price that consumers pay on the remaining units is a transfer from incumbents, so it cancels in total surplus. Figure 2.5 plots the two values for the linear Cournot market.

Corollary 2.41 (Price-taking entrants)**.** *Suppose (E1) and (E2) hold and $P(Nq_N) = C'(q_N)$ for all N. Treating N as continuous, free entry yields the optimal number of firms, $N^e = N^o$ (Mankiw and Whinston, 1986, Corollary 1).*

Proof. With $P = C'$ the second term of (2.39) vanishes, so $W'(N) = \pi_N$ for all N. Hence $W'(N^o) = 0$ if and only if $\pi_{N^o} = 0$, and $N^o = N^e$. □

Business stealing still occurs under price taking, but the stolen units carry no surplus at the margin, since price equals marginal cost. In this case the second-best optimum is also the first-best optimum (Mankiw and Whinston, 1986, n. 6). If (E2) were reversed, so that entry raised incumbents' output, the wedge in (2.39) would be positive and free entry would produce too few firms (Mankiw and Whinston, 1986, n. 7).

Example 2.42 (Excess entry in the linear Cournot market)**.** Return to Example 2.38, which is Example 1 of Mankiw and Whinston (1986). The free-entry number of firms satisfies (2.36). To find N^o, compute the wedge in (2.39):

$$P - c = \frac{a-c}{N+1}, \qquad \frac{\mathrm{d}q_N}{\mathrm{d}N} = -\frac{a-c}{b(N+1)^2}, \qquad N\,[P-c]\,\frac{\mathrm{d}q_N}{\mathrm{d}N} = -\frac{N(a-c)^2}{b(N+1)^3}.$$

Adding π_N and collecting terms over the common denominator $b(N+1)^3$:

$$\begin{aligned} W'(N) &= \frac{(a-c)^2}{b(N+1)^2} - F - \frac{N(a-c)^2}{b(N+1)^3} \\ &= \frac{(a-c)^2\,[(N+1)-N]}{b(N+1)^3} - F \\ &= \frac{(a-c)^2}{b(N+1)^3} - F. \end{aligned}$$

W' is decreasing in N, so W is concave and its maximizer solves $W'(N^o) = 0$:

$$(N^o+1)^3 = \frac{(a-c)^2}{bF}. \tag{2.41}$$

Comparing (2.36) with (2.41) gives

$$N^e + 1 = (N^o+1)^{\frac{3}{2}}. \tag{2.42}$$

If the optimum has three firms, seven enter. If it has eight, twenty-six enter (Mankiw and Whinston, 1986, p. 52).

The gap in the number of firms overstates the welfare cost. Total output is $Q_N = \frac{N(a-c)}{b(N+1)}$, and (2.37) becomes

$$W(N) = (a-c)\,Q_N - \frac{b\,Q_N^2}{2} - NF.$$

The natural yardstick is the maximal surplus $\frac{(a-c)^2}{2b}$, the area between demand and marginal cost. Dividing $W(N)$ by this yardstick and using (2.41) shows that the welfare shares depend on the primitives only through N^o. Table 2.2 reports them. The losses are moderate and shrink as N^o grows, even though the excess number of firms explodes (Mankiw and Whinston, 1986, n. 8). Section 2.5.5 explains why. The policy lesson is still sharp. An entry tax, such as a licensing fee, would raise welfare in this market, and removing an artificial barrier to entry could lower it (Mankiw and Whinston, 1986, p. 53).

Table 2.2: Free entry versus the second-best number of firms in the linear Cournot market

		Free-entry N^e			Welfare loss (% of maximal surplus)	
N^o	F	continuous	integer	$W(N^o) - W(N^e)$	reported	recomputed
3	1.000	7.00	7	2.50	7.8	7.8
5	0.296	13.70	13	1.64	5.2	5.1
8	0.088	26.00	26	1.23	3.8	3.8

Notes: $P(Q) = a - bQ$ with $a - c = 8$ and $b = 1$, constant marginal cost c, Cournot competition after entry. The set-up cost $F = \frac{64}{(N^o+1)^3}$ makes N^o optimal, by (2.41). The maximal surplus is $\frac{(a-c)^2}{2b} = 32$. "Reported" is Mankiw and Whinston (1986, n. 8, p. 53). "Recomputed" uses the integer N^e and the script `figures/ch02/src/entry_welfare.py`. With the continuous $N^e = 13.70$ the middle loss is 5.7 percent. Rounding the set-up cost to $F = 0.3$ reproduces the printed 5.2 percent.

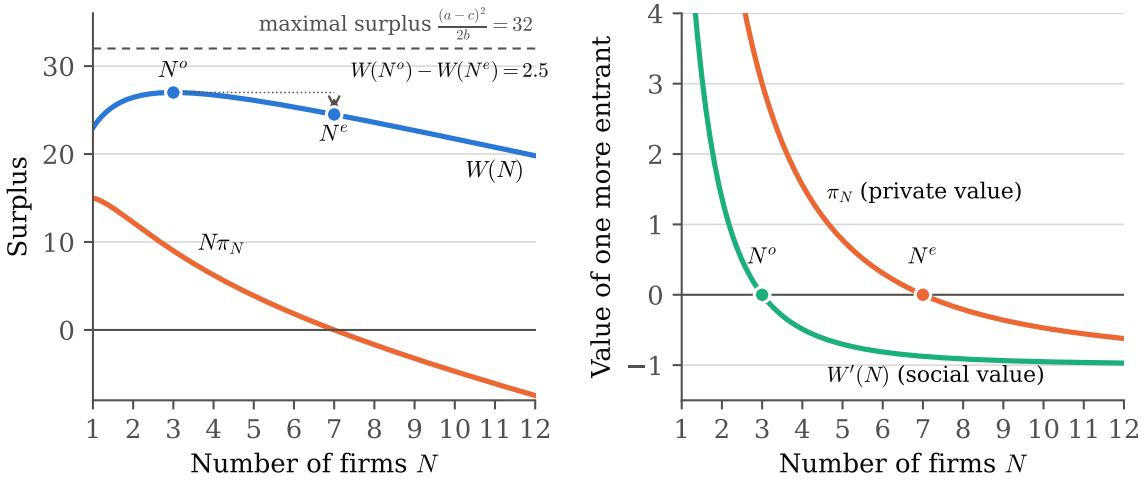

Figure 2.5: Excess entry in the linear Cournot market with $a - c = 8$, $b = 1$ and $F = 1$. In the left panel, total surplus $W(N)$ peaks at $N^o = 3$, while industry profit $N\pi_N$ reaches zero at $N^e = 7$. The welfare gap $W(3) - W(7) = 27 - 24.5 = 2.5$ is 7.8 percent of the maximal surplus of 32. In the right panel, the private value of entry π_N exceeds its social value $W'(N)$ by the business-stealing term in (2.39).

Example 2.43 (Free entry into a cartel)**.** Example 2 of Mankiw and Whinston (1986) keeps the linear market but lets the entrants form a cartel. Total output is the monopoly output $Q^m = \frac{a-c}{2b}$ for every N, and $q_N = \frac{Q^m}{N}$. Entry now steals business one for one, since $N\frac{\mathrm{d}q_N}{\mathrm{d}N} = -\frac{Q^m}{N} = -q_N$. Using $P^m - c = \frac{a-c}{2}$ in (2.39),

$$W'(N) = \pi_N - (P^m - c)\, q_N = \left[(P^m - c)\, q_N - F\right] - (P^m - c)\, q_N = -F.$$

Each extra firm adds nothing but a set-up cost, so the optimum has one firm whenever the market should be served. Free entry instead continues until $\pi_N = \frac{(a-c)^2}{4bN} - F = 0$, that is, until $N^m = \frac{(a-c)^2}{4bF}$. Total set-up costs $N^m F = \frac{(a-c)^2}{4b}$ then equal the monopoly profit. The whole monopoly rent is dissipated in duplicated set-up costs, as in the rent-seeking argument of Posner (1975) (see Section 2.9). Welfare falls to the consumer surplus at the monopoly price, $\frac{(a-c)^2}{8b}$, while one firm would give $\frac{3(a-c)^2}{8b} - F$. As $F \to 0$ the loss tends to $\frac{(a-c)^2}{4b}$, half of the maximal surplus (Mankiw and Whinston, 1986, n. 10).

2.5.3 The integer constraint

Treating N as continuous is convenient but can mislead. In the cartel example, monopoly profit is $\frac{(a-c)^2}{4b} - F$, and a monopoly is socially worth having when $\frac{3(a-c)^2}{8b} - F \geq 0$. When $\frac{(a-c)^2}{4bF} \in [\frac{2}{3}, 1)$ the second condition holds and the first fails. No firm enters, although one firm is optimal (Mankiw and Whinston, 1986, p. 53). A monopolist captures only part of the surplus its entry creates, so entry can be too low. With integers, the cartel example has excess entry only when $\frac{(a-c)^2}{4bF} \geq 2$ (Mankiw and Whinston, 1986, n. 11). The next result bounds the shortfall in general.

Proposition 2.44 (At most one firm too few)**.** *Suppose (E1) to (E3) of Assumption 2.39 hold, with N restricted to the integers and N^o the integer maximizer of W. Then $N^e \geq N^o - 1$ (Mankiw and Whinston, 1986, Proposition 2).*

Proof. The result is trivial when $N^o \leq 1$, so let $N^o \geq 2$ and write $Q_N = N q_N$ and $n = N^o$. The proof follows the appendix of Mankiw and Whinston (1986, p. 58). It first shows that $\pi_{n-1} \geq 0$ and then that π_N is nonincreasing in N.

Step 1. Optimality of n implies $W(n) \geq W(n-1)$. By (2.37) this reads

$$\int_{Q_{n-1}}^{Q_n} P(x)\,\mathrm{d}x - n\,C(q_n) + (n-1)\,C(q_{n-1}) \geq F.$$

Step 2. Write $\pi_{n-1} = P(Q_{n-1})\,q_{n-1} - C(q_{n-1}) - F$ and replace F by the larger quantity on the left of Step 1:

$$\pi_{n-1} \geq P(Q_{n-1})\,q_{n-1} - \int_{Q_{n-1}}^{Q_n} P(x)\,\mathrm{d}x + n\left[C(q_n) - C(q_{n-1})\right].$$

Step 3. Because P is decreasing and $Q_n > Q_{n-1}$ by (E1), the integral is at most $P(Q_{n-1})(Q_n - Q_{n-1})$. Moreover $q_{n-1} - (Q_n - Q_{n-1}) = n\,q_{n-1} - n\,q_n$. Hence

$$\pi_{n-1} \geq n\,P(Q_{n-1})\left(q_{n-1} - q_n\right) + n\left[C(q_n) - C(q_{n-1})\right].$$

Step 4. Convexity of C gives, for any two outputs q and q',

$$C(q') - C(q) \geq C'(q)\,(q' - q). \tag{2.43}$$

Applying it with $q = q_{n-1}$ and $q' = q_n$ yields

$$\pi_{n-1} \geq n \left[P(Q_{n-1}) - C'(q_{n-1})\right](q_{n-1} - q_n) \geq 0,$$

where the first factor is nonnegative by (E3) and the second is positive by (E2).

Step 5. For any N, the fact that $P(Q_N) \leq P(Q_{N-1})$ gives

$$\begin{aligned}\pi_N - \pi_{N-1} &= \left[P(Q_N)\, q_N - C(q_N)\right] - \left[P(Q_{N-1})\, q_{N-1} - C(q_{N-1})\right] \\ &\leq P(Q_{N-1})\left(q_N - q_{N-1}\right) - \left[C(q_N) - C(q_{N-1})\right] \\ &\leq \left[P(Q_{N-1}) - C'(q_{N-1})\right]\left(q_N - q_{N-1}\right) \leq 0,\end{aligned}$$

using (2.43) in the third line and (E2), (E3) for the sign.

Step 6. By (2.35), $\pi_{N^e+1} < 0$, and by Step 5 every $N \geq N^e + 1$ has negative profit. Step 4 shows that $\pi_{n-1} \geq 0$, so $n - 1 < N^e + 1$. Since both sides are integers, $n - 1 \leq N^e$. □

A shortfall of one firm can still be costly. In Example 3 of Mankiw and Whinston (1986), one firm in the linear market acts as a monopolist, while two firms play Bertrand and price at c. A duopolist earns $-F$, so at most one firm enters. A monopoly enters when $F \leq \frac{(a-c)^2}{4b}$. Welfare is $W(1) = \frac{3(a-c)^2}{8b} - F$ with one firm and $W(2) = \frac{(a-c)^2}{2b} - 2F$ with two. Duopoly is better when $F \leq \frac{(a-c)^2}{8b}$. The loss from one firm too few is then $\frac{(a-c)^2}{8b} - F$, which approaches 25 percent of the maximal surplus as $F \to 0$ (Mankiw and Whinston, 1986, pp. 53–54). Business stealing holds here only weakly, since $q_1 = q_2 = \frac{a-c}{2b}$.

2.5.4 Product diversity

With differentiated products a new entrant also adds variety. Following Spence (1976), Mankiw and Whinston (1986, pp. 54–55) write gross consumer benefit as $G\left(\sum_i \psi(q_i)\right)$, where q_i is firm i's output. The subutility ψ satisfies $\psi(0) = 0$, $\psi' > 0$ and $\psi'' \leq 0$, and G satisfies $G' > 0$ and $G'' < 0$. These assumptions say that consumers like variety and that the products are substitutes. (The symbols G and ψ are local to this subsection.) With N symmetric firms the planner solves

$$\max_N \; W(N) = G\left(N\psi(q_N)\right) - NC(q_N) - NF. \tag{2.44}$$

Consumer optimization sets each firm's price equal to the marginal benefit of its output, $p_N = G'\left(N\psi(q_N)\right)\psi'(q_N)$, so per-firm profit is

$$\pi_N = G'\left(N\psi(q_N)\right)\psi'(q_N)\, q_N - C(q_N) - F.$$

Differentiating (2.44), with arguments suppressed, gives

$$W'(N) = G'\left[N\psi'\frac{\mathrm{d}q_N}{\mathrm{d}N} + \psi\right] - C(q_N) - NC'\frac{\mathrm{d}q_N}{\mathrm{d}N} - F.$$

Adding and subtracting $G'\psi' q_N$ and regrouping yields the generalization of (2.39):

$$W'(N) = \pi_N + N\left[G'\psi' - C'\right]\frac{\mathrm{d}q_N}{\mathrm{d}N} + G'\left[\psi(q_N) - \psi'(q_N)\, q_N\right]. \tag{2.45}$$

The second term is the business-stealing wedge, now with price $G'\psi'$. It is negative when price exceeds marginal cost and entry contracts incumbents. The third term is new. $G'\psi$ is the

entrant's contribution to gross surplus, while $G'\psi' q_N$ is its revenue. Concavity and $\psi(0) = 0$ imply $\psi(q) \geq \psi'(q)\, q$, so the third term is nonnegative. It is the surplus from added variety that the entrant cannot appropriate. In the homogeneous case $\psi(q) = q$ and $G(Q) = \int_0^Q P(x)\,\mathrm{d}x$, the third term vanishes and (2.39) returns.

The two wedges push in opposite directions, so the sign of the entry bias is ambiguous. With $\psi(q) = q^{\varsigma}$ for some $\varsigma < 1$ and firms that take G' as given, the diversity term dominates for every N and entry is too low (Spence, 1976). Dixit and Stiglitz (1977) also show that monopolistic competition can produce too little entry. Replacing Spence's price taking with conjectural variations can reverse this result (Koenker and Perry, 1981). Mankiw and Whinston (1986, p. 55) also give a functional form, with a quadratic ψ and linear cost, in which business stealing dominates and entry is excessive. Demand substitutability is neither necessary nor sufficient for business stealing (Mankiw and Whinston, 1986, n. 14). Spatial models give further examples. In the circular city with linear transport costs, the free-entry number of firms is twice the optimum (Tirole, 1988, sec. 7.1.2), and Chapter 4 develops these location models.

2.5.5 Small set-up costs

Table 2.2 shows the loss from excess entry falling as set-up costs fall. The cartel example shows that this need not happen. There the loss tends to half of the maximal surplus as $F \to 0$. Mankiw and Whinston isolate what separates the two cases. Write W_F^o and W_F^e for welfare at the optimum and under free entry when the set-up cost is F, and $p_N = G'\left(N\psi(q_N)\right)\psi'(q_N)$ for the price.

Proposition 2.45 (Vanishing loss as set-up costs vanish)**.** *Suppose (E2) holds and, in addition, (i) p_N is decreasing in N and $\lim_{N\to\infty} N\psi(q_N) < \infty$, (ii) $p_N - C'(q_N) > 0$ for all N, and (iii) $\lim_{N\to\infty}\left[p_N - C'(q_N)\right] = 0$. Then $\lim_{F\to 0}\left(W_F^o - W_F^e\right) = 0$ (Mankiw and Whinston, 1986, Proposition 3).*

Proof sketch. Let $W^{\infty} = \lim_{N\to\infty}\left[G\left(N\psi(q_N)\right) - NC(q_N)\right]$. This limit is finite and is the best welfare attainable with no set-up cost, so $W^{\infty} \geq W_F^o \geq W_F^e$ for every F. It suffices to show that $W_F^e \to W^{\infty}$. First, $N_F^e \to \infty$ as $F \to 0$. Otherwise, for small enough F one more firm would earn $(p_N - \frac{C(q_N)}{q_N})\, q_N - F \geq (p_N - C'(q_N))\, q_N - F > 0$, using $C(q) \leq C'(q)\, q$ for convex C with $C(0) = 0$. Given $N_F^e \to \infty$, welfare under free entry converges to W^{∞} exactly when total set-up costs $N_F^e F$ vanish. The zero-profit condition bounds them:

$$N^e F \leq \left[p_{N^e} - \frac{C(q_{N^e})}{q_{N^e}}\right] N^e q_{N^e}.$$

As $N^e \to \infty$, per-firm output tends to zero because $N\psi(q_N)$ stays bounded. Average cost and marginal cost then both tend to $C'(0)$, so the bracket tends to $\lim\left[p_N - C'(q_N)\right] = 0$ by (iii). Total output $N^e q_{N^e}$ stays bounded, so $N^e F \to 0$. □

Two assumptions do the work. Price must exceed marginal cost for every finite N, which is (ii), and approach it as N grows, which is (iii). Mankiw and Whinston assume both and leave the post-entry game unspecified. Novshek (1980) derives (iii) for Cournot competition as efficient scale shrinks. Linear Cournot satisfies (ii) and (iii), which is why the losses in Table 2.2 decline. The cartel example violates (iii), since price stays at the monopoly level for every N. Example 3 satisfies (iii) but violates (ii). Price falls to marginal cost already at $N = 2$, so a second entrant cannot cover its set-up cost. The loss from having one firm too few therefore

persists as $F \to 0$ (Mankiw and Whinston, 1986, p. 57). The upshot is that regulating entry matters most in markets with large set-up costs and imperfect competition. It matters little where entry is cheap and competition is close to perfect.

2.5.6 Margins and concentration under fixed and free entry

Free entry changes how margins and concentration move together. With a fixed number of firms, concentration is a primitive and the Lerner index responds to it. With free entry, both are equilibrium outcomes driven by the same primitives. The linear market makes the point precisely, using the four columns of Table 2.1.

Example 2.46 (Lerner index and Herfindahl index in four regimes)**.** Let $P = a - bQ$, marginal cost c, set-up cost F, and $r \equiv \sqrt{bF}$.

Cournot with fixed N. Here $L = \frac{a-c}{a+Nc}$ and $HHI = \frac{1}{N}$. Substituting $N = \frac{1}{HHI}$ and multiplying numerator and denominator by HHI,

$$L = \frac{(a-c)\,HHI}{a\,HHI + c}, \qquad \frac{\mathrm{d}L}{\mathrm{d}HHI} = \frac{c(a-c)}{(a\,HHI + c)^2} > 0, \qquad \frac{\mathrm{d}^2L}{\mathrm{d}HHI^2} = -\frac{2ac(a-c)}{(a\,HHI + c)^3} < 0. \tag{2.46}$$

The relation is increasing and concave. It is causal, since N is set from outside.

Cournot with free entry. From Example 2.38, $L = \frac{r}{c+r}$ and $HHI = \frac{r}{a-c-r}$. These points lie on the curve (2.46) for the same (a, c), because

$$\frac{(a-c)\frac{r}{a-c-r}}{\frac{a\,r}{a-c-r} + c} = \frac{(a-c)\,r}{a\,r + c(a-c-r)} = \frac{(a-c)\,r}{(a-c)(r+c)} = \frac{r}{c+r}.$$

Both indices are now endogenous. A higher F or b raises r and moves the industry up along the curve. A higher a lowers HHI and leaves L unchanged. A higher c lowers L and raises HHI.

Collusion with fixed N. Here $L = \frac{a-c}{a+c}$ for every N, while $HHI = \frac{1}{N}$. The Lerner index does not depend on concentration at all.

Collusion with free entry. By Example 2.43, $N^m = \frac{(a-c)^2}{4bF}$, so $HHI = \frac{4bF}{(a-c)^2}$ and $L = \frac{a-c}{a+c}$. A higher F or b raises HHI only. A higher a raises L and lowers HHI, and a higher c does the reverse.

Finally, collusion attracts more entrants than Cournot competition. With $x = \frac{a-c}{\sqrt{bF}}$, (2.36) gives $N^e = x - 1$, while $N^m = \frac{x^2}{4}$. Then

$$N^m - N^e = \frac{x^2}{4} - x + 1 = \left(\frac{x}{2} - 1\right)^2 \geq 0.$$

The lesson is a theoretical one. The sign of a cross-industry relation between margins and concentration depends on which primitive varies across industries and on how firms compete. Points A and B in Figure 2.6 share every primitive and differ only in conduct. A sample that mixes Cournot and collusive industries pairs high margins with low concentration and can produce a flat or negative slope. A regression of L on HHI across industries therefore has no structural interpretation without a model of entry and conduct. Chapter 1 discusses these regressions, and Appendix C works through the full problem.

Table 2.3: Comparative statics of the Lerner and Herfindahl indices in the linear market

			Effect of a higher primitive on (L, HHI)			
Regime	L	HHI	F	b	a	c
Cournot, fixed N	$\frac{a-c}{a+Nc}$	$\frac{1}{N}$	$(0,0)$	$(0,0)$	$(+,0)$	$(-,0)$
Cournot, free entry	$\frac{\sqrt{bF}}{c+\sqrt{bF}}$	$\frac{\sqrt{bF}}{a-c-\sqrt{bF}}$	$(+,+)$	$(+,+)$	$(0,-)$	$(-,+)$
Collusion, fixed N	$\frac{a-c}{a+c}$	$\frac{1}{N}$	$(0,0)$	$(0,0)$	$(+,0)$	$(-,0)$
Collusion, free entry	$\frac{a-c}{a+c}$	$\frac{4bF}{(a-c)^2}$	$(0,+)$	$(0,+)$	$(+,-)$	$(-,+)$

Notes: $P = a - bQ$, constant marginal cost c, set-up cost F. Each cell gives the signs of the effects on L and HHI. Under free entry the number of firms is treated as continuous.

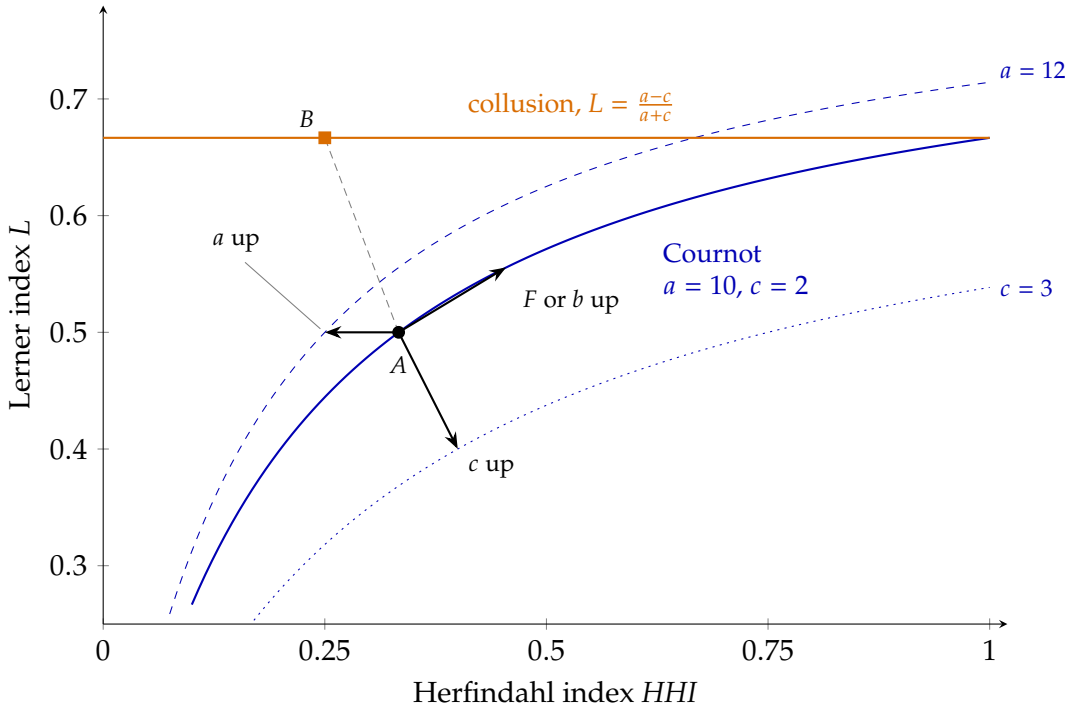

Figure 2.6: Lerner index against Herfindahl index in the linear market with $a = 10$, $c = 2$, $b = 1$. The solid curve is $L = \frac{8\,HHI}{10\,HHI+2}$, the Cournot relation (2.46). Point A is the Cournot free-entry outcome with $F = 4$ ($N^e = 3$). Arrows show the free-entry responses to higher F or b (along the curve), higher a (onto the dashed curve) and higher c (onto the dotted curve). Point B is the collusive free-entry outcome with the same primitives ($N^m = 4$). It has a higher margin and lower concentration than A.

2.6 Bertrand competition and capacity constraints

Cournot firms choose quantities and let the market set the price. Many firms instead post prices and serve whatever demand arrives. This section studies price competition with a homogeneous good. Its main result is stark: two firms suffice for the competitive price. We then show how capacity constraints undo the result and when quantity competition is the better description.

2.6.1 Price competition with a homogeneous good

Definition 2.47 (Bertrand game with a homogeneous good)**.** There are $N \geq 2$ firms with constant marginal costs c_i and no capacity limits. Market demand $Q(p)$ is continuous and nonincreasing. Firms choose prices $p_i \geq 0$ simultaneously. Let $p_{\min} = \min_i p_i$ and let k be the number of firms that charge $p_{\min}$. Each of these firms sells $\frac{Q(p_{\min})}{k}$, and every other firm sells nothing. Firm i earns $(p_i - c_i)\, q_i$, and each firm must serve all demand at its posted price.

These are the stage-game rules used for repeated price competition in Chapter 12. In the static game with symmetric costs the tie rule (equal split) does not affect equilibrium outcomes. It matters with asymmetric costs and for the collusive shares in the repeated game.

Proposition 2.48 (The Bertrand paradox)**.** *Suppose all firms have the same marginal cost c and $Q(c) > 0$. Then a pure-strategy Nash equilibrium exists. In every pure-strategy Nash equilibrium $p_{\min} = c$, at least two firms charge c, and every firm earns zero profit.*

Proof. Take any price profile and consider four exhaustive cases.

Case 1, $p_{\min} < c$. The firms charging $p_{\min}$ sell $\frac{Q(p_{\min})}{k} \geq \frac{Q(c)}{k} > 0$ at a loss. Any of them can raise its price above $p_{\min}$ and sell nothing, earning zero. So the profile is not an equilibrium.

Case 2, $p_{\min} > c$ and $Q(p_{\min}) > 0$. If $k \geq 2$, a firm at $p_{\min}$ earns $(p_{\min} - c)\frac{Q(p_{\min})}{k}$. By cutting its price to $p_{\min} - \eta$ it serves the whole market and earns at least $(p_{\min} - \eta - c)\, Q(p_{\min})$, because Q is nonincreasing. For small $\eta > 0$ this exceeds its current profit, since $k \geq 2$. If $k = 1$, any other firm earns zero and can charge a price $p' \in (c, p_{\min})$, earning $(p' - c)\, Q(p') \geq (p' - c)\, Q(p_{\min}) > 0$. Either way someone deviates.

Case 3, $p_{\min} > c$ and $Q(p_{\min}) = 0$. Every firm earns zero. By continuity of Q and $Q(c) > 0$ there is a price p' slightly above c with $Q(p') > 0$, and $p' < p_{\min}$ because Q is nonincreasing. A firm that deviates to p' earns $(p' - c)\, Q(p') > 0$.

Case 4, $p_{\min} = c$. If only one firm charges c, it earns zero. Let $p_{(2)} > c$ be the second-lowest price. By continuity it can raise its price to some $p' \in (c, p_{(2)})$ with $Q(p') > 0$ and earn a positive profit. So at least two firms must charge c. In that case every firm earns zero. A firm that raises its price sells nothing and still earns zero, and a firm that cuts below c makes a loss. No deviation is profitable, so any profile with at least two firms at c is an equilibrium. □

The paradox is the contrast with Section 2.4. A symmetric Cournot duopoly has industry conduct $\theta = \frac{1}{2}$ (Section 2.7). A Bertrand duopoly prices at marginal cost, so $\theta = 0$ even with two firms. The number of firms alone does not pin down margins. The mode of competition matters just as much. Two firms suffice for competitive pricing only under stark assumptions: identical products, constant marginal cost, no capacity limits, and a single round of play. Each assumption points to a resolution. Capacity constraints are the subject of Section 2.6.2. Product differentiation is the subject of Chapter 4. Repeated interaction is previewed in Section 2.10 and developed in Chapter 12.

Asymmetric costs. Let $c_1 < c_2 \le c_j$ for all $j \ge 3$, and let $p^m(c_1)$ be the monopoly price of a firm with cost c_1. If $p^m(c_1) \le c_2$, firm 1's cost advantage is *drastic*. It charges $p^m(c_1)$ and serves the market, while rivals price at or above their costs. If $p^m(c_1) > c_2$, firm 1 wants to price just below c_2. With continuous prices and an equal split of ties, there is no largest price below c_2, so a pure equilibrium fails to exist. Two standard modifications restore one. If ties go to the low-cost firm, then $p_1 = p_2 = c_2$ is an equilibrium in which firm 1 serves the market and earns $(c_2 - c_1)\,Q(c_2)$. If prices lie on a grid with step ι and c_2 on the grid, then $p_1 = c_2$ and $p_2 = c_2 + \iota$ is an equilibrium for small ι. In this equilibrium firm 2 avoids the weakly dominated choice of pricing at its own cost. Either way, the market price is

$$P = \min\left\{c_2,\ p^m(c_1)\right\}.$$

The efficient firm earns a margin limited by its rival's cost, with Lerner index $\frac{c_2 - c_1}{c_2}$ in the non-drastic case. Measured against the producing firm's marginal cost c_1, this market shows a positive conduct parameter $\theta = \varepsilon \frac{c_2 - c_1}{c_2}$, although firms play Bertrand. A positive estimated θ can thus reflect cost asymmetry as well as softer conduct.

Remark 2.49 (Increasing marginal cost). Let N symmetric firms have a strictly convex cost $C(q)$ with $C(0) = 0$, and keep the obligation to serve all demand at the posted price. Consider a common price p at which each firm sells $\frac{Q(p)}{N}$ and earns $u(p) = \frac{p\,Q(p)}{N} - C\left(\frac{Q(p)}{N}\right)$. Raising the price sells nothing and earns $C(0) = 0$. Undercutting slightly serves the whole market and earns close to $v(p) = p\,Q(p) - C(Q(p))$. For prices below the level that maximizes v, the common price p is an equilibrium if and only if

$$u(p) \ge 0 \qquad \text{and} \qquad u(p) \ge v(p).$$

Both conditions hold strictly at the competitive price p^*, defined by $p^* = C'\left(\frac{Q(p^*)}{N}\right)$. Write $q^* = \frac{Q(p^*)}{N}$. The first holds because average cost is below marginal cost for strictly convex C with $C(0) = 0$. For the second, apply (2.43) strictly:

$$v(p^*) - u(p^*) = p^*\left(Nq^* - q^*\right) - \left[C(Nq^*) - C(q^*)\right] < p^*\left(Nq^* - q^*\right) - C'(q^*)\left(Nq^* - q^*\right) = 0.$$

By continuity both inequalities also hold in an interval of prices around p^*. Pure equilibria therefore exist and form a continuum, with prices above and below the competitive level (Dastidar, 1995).

Without the obligation to serve, a firm sells only what it wishes at its posted price. Firm i's *competitive supply* $S_i(p)$ is defined by $p = C_i'(S_i(p))$, and a firm never sells more than $S_i(p)$. The natural candidate is then the competitive price p^*, with $S_1(p^*) + S_2(p^*) = Q(p^*)$ in a duopoly. Suppose rationing is *efficient*, so that the consumers with the highest willingness to pay are served first (Definition 2.51 below). Then p^* is not an equilibrium (Tirole, 1988, sec. 5.3.2). Let firm 2 charge p^* and sell $q_2^* = S_2(p^*)$, and write $q_1^* = S_1(p^*)$. If firm 1 raises its price to some p slightly above p^*, it serves the residual demand $Q(p) - q_2^*$, which is below $S_1(p)$. Its profit is $p\,[Q(p) - q_2^*] - C_1(Q(p) - q_2^*)$, whose derivative at p^* is

$$Q(p^*) - q_2^* + \left[p^* - C_1'(q_1^*)\right]Q'(p^*) = q_1^* > 0,$$

because $Q(p^*) - q_2^* = q_1^*$ and $p^* = C_1'(q_1^*)$. The units lost were sold at marginal cost, so the loss is of second order, while the higher price on the remaining units is a first-order gain. Equilibria then generally involve mixed strategies, and both firms' prices exceed the competitive price. Decreasing returns therefore soften price competition, and the capacity constraint of Section 2.6.2 is the extreme case.

Remark 2.50 (Strategic substitutes and complements). Bulow et al. (1985, p. 489) call a lower price or a higher quantity a "more aggressive" move. They classify competition by how a rival's aggressive move changes the *marginal* profit of the firm's own aggressive move. Choices are strategic substitutes when the rival's aggressive move lowers this marginal profit and *strategic complements* when it raises it. Equivalently, best responses slope down under substitutes and up under complements. Section 2.4.2 showed that quantities are substitutes in Cournot competition under Assumption 2.18. With differentiated products and linear demand $q_i = d_0 - d_1 p_i + d_2 p_j$, where $0 < d_2 < d_1$, profit $(p_i - c)\, q_i$ gives $\frac{\partial^2 \pi_i}{\partial p_i \partial p_j} = d_2 > 0$. A lower p_j therefore lowers $\frac{\partial \pi_i}{\partial p_i}$, which raises the marginal profit of cutting p_i. Prices are complements, and the best response $p_i = \frac{d_0 + d_1 c + d_2 p_j}{2 d_1}$ slopes up, with slope $\frac{d_2}{2 d_1} \in \left(0, \frac{1}{2}\right)$ as (2.19) predicts. Tirole (1988, sec. 11.2) uses the same linear demand, $q_i = 1 - b p_i + d p_j$, to illustrate Nash equilibrium in prices. The classification depends on demand as well as on the strategic variable. Bulow et al. (1985, p. 490) note that Cournot competition with constant-elasticity demand may yield strategic complements. Our derivation from Remark 2.19 gives the threshold. With constant-elasticity demand, $P' + q_i P'' = P'(1 - s_i \chi)$ with curvature $\chi = 1 + \frac{1}{\varepsilon}$. The cross-partial is therefore positive, and quantities are complements, when $s_i \left(1 + \frac{1}{\varepsilon}\right) > 1$.

2.6.2 Capacity constraints and rationing

Edgeworth (1925), in an article first published in Italian in 1897, observed that the Bertrand outcome collapses once firms cannot serve the whole market (Tirole, 1988, sec. 5.2.1). Let two firms have constant marginal cost c up to capacities k_1 and k_2, beyond which they cannot produce. Suppose $k_2 < Q(c)$ and both firms charge c. If firm 1 raises its price slightly, firm 2 cannot serve everyone who wants to buy at c. Some consumers turn to firm 1 at the higher price, and firm 1 earns a positive margin on them. So $p_1 = p_2 = c$ is no longer an equilibrium. When capacities are intermediate, no pure-strategy equilibrium exists at all. Firms undercut each other until one prefers to raise its price and serve the leftover demand, and the cycle repeats. The equilibrium of the static game is in mixed strategies (Levitan and Shubik, 1972). What a high-price firm can sell depends on which consumers the low-price firm serves.

Definition 2.51 (Rationing rules)**.** Let firm 1 charge $p_1 < p_2$ with capacity $k_1 < Q(p_1)$. A *rationing rule* gives the residual demand $Q_2(p_2)$ left for firm 2.

(i) Under *efficient rationing*, firm 1 serves the consumers with the highest willingness to pay first. Firm 2 faces

$$Q_2(p_2) = \max\left\{0,\ Q(p_2) - k_1\right\}.$$

(ii) Under *proportional rationing*, every consumer who wants to buy at p_1 is equally likely to be served by firm 1. The fraction $\frac{k_1}{Q(p_1)}$ of them is served. The unserved consumers are a random sample, so a fraction $1 - \frac{k_1}{Q(p_1)}$ of the demand at any price remains:

$$Q_2(p_2) = Q(p_2)\left(1 - \frac{k_1}{Q(p_1)}\right).$$

Efficient rationing maximizes consumer surplus given the capacities, since the units go to those who value them most. It also leaves the high-price firm the least demand. Proportional residual demand is larger because

$$Q(p_2)\left(1 - \frac{k_1}{Q(p_1)}\right) \geq Q(p_2) - k_1 \quad \Longleftrightarrow \quad \frac{Q(p_2)}{Q(p_1)}\, k_1 \leq k_1,$$

which holds because $Q(p_2) \leq Q(p_1)$. Figure 2.7 draws both residual demands. Efficient rationing shifts demand inward in parallel by k_1. Proportional rationing rotates it around the choke price.

Tirole (1988, sec. 5.3.1) interprets the two rules. Efficient rationing is the outcome if consumers can resell the good to each other at no cost, since such arbitrage moves the units to those who value them most. It also arises when identical consumers with downward-sloping demands are each rationed equally. Proportional rationing, also called randomized rationing, gives every consumer the same chance of being served. It leaves some low-value consumers with the bargain, and the high-price firm prefers it because its residual demand is larger. Many other rules are possible. Suppose rationing works through queues, and the most eager buyers also have the highest value of time. Then the least eager buyers may end up with the low price. In applications the rationing rule stands in for a model of consumer behavior, and the right rule depends on the market.

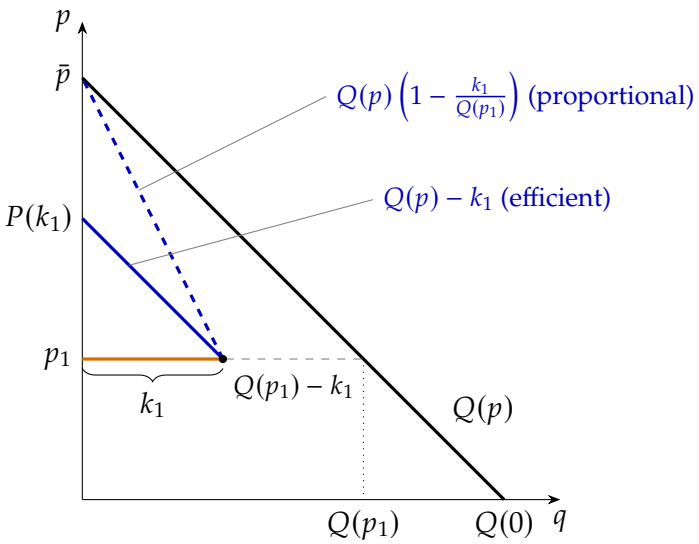

Figure 2.7: Residual demand of the high-price firm. Firm 1 charges p_1 and sells its capacity $k_1 < Q(p_1)$. Under efficient rationing firm 2 faces $Q(p) - k_1$ for $p > p_1$ (solid), a parallel inward shift of demand. Under proportional rationing it faces $Q(p)\left(1 - \frac{k_1}{Q(p_1)}\right)$ (dashed), which rotates demand around the choke price $\bar{p}$. Drawn for $Q(p) = 9 - p$, $p_1 = 3$ and $k_1 = 3$.

Kreps and Scheinkman (1983) turn Edgeworth's problem into a foundation for Cournot competition. Firms first choose capacities and then, having observed them, compete in prices. Write $r_\gamma(k)$ for the Cournot best response of a firm with constant marginal cost γ to rival output k.

Proposition 2.52 (Capacity commitment yields Cournot outcomes)**.** *Consider a duopoly in which firms first build capacities k_i at constant unit cost $c_k > 0$, then observe them and set prices. Production costs $c \geq 0$ per unit up to capacity. Suppose inverse demand is concave and residual demand follows efficient rationing. Then the game has a unique subgame-perfect equilibrium outcome. It coincides with the Cournot outcome of the one-stage game with marginal cost $c + c_k$ (Kreps and Scheinkman, 1983).*

A linear example shows the mechanism before the general argument (Tirole, 1988, sec. 5.3.2.1).

Example 2.53 (Capacity-constrained price competition with linear demand)**.** Let $Q(p) = 1 - p$, let capacity cost $c_k \in \left[\frac{3}{4}, 1\right]$ per unit, and let production cost nothing up to capacity. Rationing is efficient. No firm builds more than $\frac{1}{3}$. In the pricing stage a firm cannot earn more than the monopoly revenue $\max_p p(1-p) = \frac{1}{4}$. Its net profit is therefore at most $\frac{1}{4} - c_k k_i$, which is negative for $k_i > \frac{1}{3}$ because $c_k \geq \frac{3}{4}$.

Take capacities in $\left[0, \frac{1}{3}\right]$. We claim that both firms charging the market-clearing price $p^* = 1 - k_1 - k_2$ is an equilibrium of the pricing stage. A lower price gains nothing, since firm i already sells its whole capacity at p^*. At a higher price $p > p^*$, firm i sells the residual demand $q = 1 - p - k_j < k_i$. Its revenue pq is then $(1 - q - k_j)q$, the Cournot objective against rival output k_j. This objective is concave in q, and its derivative at $q = k_i$ is $1 - 2k_i - k_j \geq 0$. Revenue therefore rises on $[0, k_i]$, and the best choice is $q = k_i$, that is, the price p^*. The reduced-form profits after the pricing stage are

$$\Pi_i(k_i, k_j) = (1 - k_i - k_j)\, k_i - c_k k_i, \tag{2.47}$$

the profits net of capacity cost. This is Tirole's eq. (5.3). His eq. (5.2) is the same profit gross of capacity cost, $(1 - k_i - k_j)k_i$. The net profits are exactly the Cournot profits for outputs k_i and marginal cost c_k. The capacity stage is therefore a Cournot game. Its equilibrium has $k_1 = k_2 = \frac{1-c_k}{3} \leq \frac{1}{12}$ and price $p^* = \frac{1+2c_k}{3}$.

Two foundations for Cournot. Tirole (1988, sec. 5.3.4) separates two results. The pricing stage has an *exact Cournot reduced form* when, at every pair of capacities that can arise, its equilibrium profits equal the Cournot profits with quantities read as capacities. The two-stage game has a *Cournot outcome* when its subgame-perfect capacities and price coincide with the Cournot equilibrium. The first result implies the second, because the capacity stage is then the Cournot game. It also covers variants, such as capacities chosen in sequence. Example 2.53 has the exact reduced form. Proposition 2.52 claims only the Cournot outcome. In its general setting the reduced form is Cournot for small capacities only, and large capacities lead to mixed equilibria with other payoffs.

The pricing stage. To simplify, set the production cost to $c = 0$, as Tirole (1988, sec. 5.7.2.1) does, and assume $k_1 + k_2 < Q(0)$. Write $r(k) = r_0(k)$ for the output that maximizes $qP(q + k)$. Inverse demand is concave, so this objective is strictly concave in q. By Lemma 2.20, r is single-valued and decreasing, with slope in $(-1, 0)$.

Lemma 2.54 (Pure equilibria clear the market)**.** *In a pure-strategy equilibrium of the pricing stage, $p_1 = p_2 = P(k_1 + k_2)$, and both firms sell their capacities (Tirole, 1988, sec. 5.7.2.1, Lemma 1).*

Proof. Suppose first that $p_1 = p_2 = p > P(k_1 + k_2)$. Demand at p is below total capacity, so some firm i sells less than k_i. By charging $p - \eta$ it would serve the whole market and sell more, which raises its profit for small $\eta > 0$. Suppose next that $p_1 = p_2 = p < P(k_1 + k_2)$. Both firms ration their customers, and either one could raise its price slightly and still sell its capacity. Finally, suppose $p_i < p_j$. If firm i is capacity constrained, it can raise its price slightly and still sell k_i. Otherwise it serves all demand at p_i, and optimality requires p_i to be its unconstrained monopoly price, which is positive. Firm j then sells nothing, and it could earn a positive profit by charging $p_i - \eta$. Each case contradicts equilibrium. □

Lemma 2.55 (Pure equilibria lie below the reaction curves)**.** *In a pure-strategy equilibrium of the pricing stage, no firm charges less than $P(k_j + r(k_j))$ (Tirole, 1988, sec. 5.7.2.1, Lemma 2). Consequently, a pure-strategy equilibrium exists if and only if $k_i \leq r(k_j)$ for both firms, and it is then the market-clearing price $P(k_1 + k_2)$.*

Proof. By Lemma 2.54, both firms charge $p = P(k_1 + k_2)$ in a pure equilibrium. Suppose $p < P(k_j + r(k_j))$, which means $k_i > r(k_j)$. Let firm i deviate to $p' = P(k_j + r(k_j)) > p$. Firm j still sells k_j at p. Under efficient rationing firm i faces the residual demand $Q(p') - k_j = r(k_j) < k_i$, which it can serve. Its revenue becomes $r(k_j)P(r(k_j)+k_j)$, the largest Cournot revenue against k_j. This exceeds $k_i P(k_i + k_j)$, because $r(k_j)$ is the unique maximizer and $k_i \neq r(k_j)$. The deviation is profitable, a contradiction. Hence a pure equilibrium requires $k_i \leq r(k_j)$ for both firms.

Conversely, let $k_i \leq r(k_j)$ for both firms, and let both charge $p^* = P(k_1 + k_2)$. A price cut does not help firm i, because it already sells its whole capacity. At a price $p > p^*$, efficient rationing leaves firm i the residual demand $q = Q(p) - k_j < k_i$. Choosing p is therefore the same as choosing an output $q < k_i$ sold at $P(q + k_j)$. The revenue $qP(q + k_j)$ is the Cournot objective against k_j. It is concave in q and peaks at $r(k_j) \geq k_i$, so it rises on $[0, k_i]$. The best choice is $q = k_i$, which means charging p^*. □

In the pure-strategy region the reduced form is exactly Cournot. The Cournot capacities with capacity cost c_k lie in this region. Indeed $r_\gamma(k)$ solves $P(q + k) + qP'(q + k) = \gamma$, whose left side falls in q, so the best response falls when γ rises. Hence $r_{c_k}(k) < r(k)$ at every k where $r_{c_k}(k) > 0$.

Lemma 2.56 (The larger firm earns its Stackelberg-follower profit)**.** *Suppose $k_i > r(k_j)$ for at least one firm, so that the pricing stage has only mixed-strategy equilibria. Then the firm with the larger capacity, say firm i, earns*

$$F(k_j) = r(k_j)\, P\big(k_j + r(k_j)\big) \tag{2.48}$$

in every equilibrium (Tirole, 1988, sec. 5.7.2.1, Lemma 3).

Proof sketch. In a mixed equilibrium every price in a firm's support yields the same expected profit (Section 2.3.1). Consider the top of the support of the larger firm, and suppose that at this price it is undercut with probability one. It then sells along the efficient residual demand $Q(p) - k_j$, so choosing the price is the same as choosing a quantity against k_j. Optimality at the top of the support requires the quantity $r(k_j)$, which yields $F(k_j)$. Indifference across the support makes $F(k_j)$ the firm's equilibrium profit. Kreps and Scheinkman (1983) show that it is indeed the larger firm whose highest price is undercut for sure, and they construct the equilibrium distributions. Tirole sketches the argument. □

The name comes from the Stackelberg follower, which chooses its best response to the leader's output (Example 2.61). The key feature of (2.48) is that $F(k_j)$ does not depend on the larger firm's own capacity. Capacity beyond the pure region only adds cost.

The capacity stage. Let q^{**} be the symmetric Cournot output with marginal cost c_k, which maximizes $q\,[P(q + q^{**}) - c_k]$. We show that $k_1 = k_2 = q^{**}$ is an equilibrium of the capacity stage (Tirole, 1988, sec. 5.7.2.2). Let firm i choose q^{**}, and consider firm j's choice k. In the pricing stage the capacity cost is sunk, so each firm wants to sell more than it would if capacity were still to be paid for. In particular $r(q^{**}) > q^{**}$.

- Let $k \leq r(q^{**})$. The capacities then lie in the pure region. When $k \leq q^{**}$ this holds because $r(k) \geq r(q^{**}) > q^{**}$. When $q^{**} < k \leq r(q^{**})$, the slope bound $r' > -1$ gives $r(k) > r(q^{**}) - (k - q^{**}) \geq q^{**}$. Firm j therefore earns the Cournot profit $k\,[P(k + q^{**}) - c_k]$, which is at most $q^{**}[P(2q^{**}) - c_k]$ by the definition of q^{**}.
- Let $k > r(q^{**})$. The pricing stage is then in the mixed region, and firm j has the larger capacity. By Lemma 2.56 its net profit is $F(q^{**}) - c_k k$. Since $k > r(q^{**})$,

$$F(q^{**}) - c_k k < r(q^{**})\big[P\big(r(q^{**}) + q^{**}\big) - c_k\big] \leq q^{**}\big[P(2q^{**}) - c_k\big],$$

where the last step again uses the definition of q^{**}.

No deviation pays. The Cournot capacities therefore form an equilibrium of the capacity stage, and the price is $P(2q^{**})$. Proving that this outcome is unique takes more work (Kreps and Scheinkman, 1983).

Rationing and the cost of capacity. The result also depends on the rationing rule when capacity is cheap. Davidson and Deneckere (1986) study rules other than efficient rationing (Tirole, 1988, secs. 5.3.4 and 5.7.2.3). For virtually any such rule, the Cournot outcome cannot be an equilibrium of the two-stage game when the capacity cost is small. A first-order calculation at the Cournot point shows why. Let both firms hold the Cournot capacities q^{**} and charge $p^{**} = P(2q^{**})$, now with production cost $c \geq 0$. Let $Q_2(p_2)$ be firm 2's residual demand for p_2 just above p^{**}, with $Q_2(p^{**}) = q^{**}$. The capacity cost is sunk, so a small price increase changes firm 2's profit at the rate

$$A = q^{**} + (p^{**} - c)\, Q_2'(p^{**}).$$

The Cournot first-order condition with marginal cost $c + c_k$ gives $p^{**} - c - c_k = -q^{**}P'(2q^{**}) = \frac{q^{**}}{|Q'(p^{**})|}$. Substituting,

$$A = q^{**}\left(1 - \frac{|Q_2'(p^{**})|}{|Q'(p^{**})|}\right) - c_k\,|Q_2'(p^{**})|. \tag{2.49}$$

Efficient rationing has $Q_2' = Q'$, so $A = -c_k|Q'(p^{**})| < 0$, and a price increase does not pay. A rule whose residual demand responds less to price than market demand, $|Q_2'(p^{**})| < |Q'(p^{**})|$, makes the first term positive. For small enough c_k the rate A is then positive. Firm 2 gains by raising its price above the market-clearing level, and the Cournot capacities do not lead to the Cournot price. With price on the vertical axis, as in Figure 2.7, such a residual demand is steeper than market demand. Proportional rationing is such a rule. By Definition 2.51, it gives $Q_2(p) = Q(p)\big(1 - \frac{q^{**}}{Q(p^{**})}\big) = \frac{Q(p)}{2}$. Hence $Q_2' = \frac{Q'}{2}$ and $A = \frac{1}{2}\big(q^{**} - c_k|Q'(p^{**})|\big)$.

Costly capacity restores the Cournot form. Keep the demand $Q(p) = 1 - p$ and the zero production cost of Example 2.53, but let $c_k \in (0, 1)$. Then $q^{**} = \frac{1-c_k}{3}$ and $|Q'| = 1$, so under proportional rationing $A > 0$ if and only if $c_k < \frac{1}{4}$. Equivalently, the Cournot price $p^{**} = \frac{1+2c_k}{3}$ then lies below the monopoly price $\frac{1}{2}$. A firm that raises its price faces a scaled-down copy of market demand, $\frac{Q(p)}{2}$. Its best higher price is therefore the monopoly price whenever that price exceeds p^{**}. For $c_k \geq \frac{1}{4}$ the market-clearing price is at least $\frac{1}{2}$, and no firm wants to raise it. More generally, Tirole (1988, Exercise 5.2) shows that with this demand, proportional rationing and capacities below $\frac{1}{4}$, both firms charge the market-clearing price. The reduced form is then exactly Cournot again. The result is due to Beckmann (1967) for proportional rationing and to Levitan and Shubik (1972) for efficient rationing. The Kreps-Scheinkman foundation is thus a statement about timing and about the cost of capacity. It does not license Cournot competition in every market with capacity choice.

Further caveats. Tirole (1988, sec. 5.3.4) stresses that both foundations rest on strong assumptions. They are more likely to hold when the capacity cost is high. A large gap between ex ante and ex post costs then makes firms willing to dump their capacity on the market ex post. Price setting must be the last stage, with no later rounds of price competition and no product differentiation. Folding the two stages into a one-stage quantity game can also discard what actions reveal, for example when firms infer rivals' costs from their behavior. Finally, most firms do not face rigid capacity limits. Their cost curves rise beyond some output without the inverted L shape, so there is often no capacity level that gives the Cournot quantity a meaning.

The construction also needs rivals to observe capacities before they set prices. If capacities are not observed, the game is equivalent to one in which quantities and prices are chosen simultaneously (Tirole, 1988, sec. 5.7.2.4). Gertner (1985) studies this simultaneous game and allows increasing or decreasing returns. We follow Tirole and take a constant marginal cost c. In this game a firm produces before it learns whether it sells. No pure-strategy equilibrium exists, and the unique equilibrium is in mixed strategies. The symmetric equilibrium is easy to verify. Let $\bar{p}$ be the choke price, with $Q(\bar{p}) = 0$. Each firm draws its price from $F(p) = 1 - \frac{c}{p}$ on $[c, \bar{p})$, with the remaining probability $\frac{c}{\bar{p}}$ at $\bar{p}$, and produces $Q(p)$ when it charges p. The rival never rations its customers, so a firm that charges p sells $Q(p)$ when its rival charges more, which happens with probability $1 - F(p)$. It pays for its output in any case. Its expected profit is

$$\left[(1 - F(p))\, p - c\right] Q(p) = \left(\frac{c}{p}\, p - c\right) Q(p) = 0$$

at every price in the support, and prices below c lose money (Tirole, 1988, Exercise 5.9). Expected profit is zero, as in Bertrand, but the expected price exceeds c, as in Cournot. A firm cannot commit not to flood the market, and this competitive pressure drives profits down.

2.6.3 Bertrand or Cournot?

The choice between the two models is a choice about what firms commit to before they compete. Bertrand competition fits markets where capacity is ample or quickly adjusted and firms post prices that they cannot easily revise. Differentiated-goods markets are the main case, and most empirical work on them assumes Nash equilibrium in prices (Chapter 4). Cournot competition fits markets where output or capacity is committed before prices form, as in commodities produced in advance or capacity-constrained industries. Both models impose conduct rather than measuring it. Which description fits a given industry is an empirical question, and this motivates estimating conduct directly (Section 2.7 and Chapter 3).

Tirole (1988, sec. 5.6) draws the same lesson from cost structure. Firms almost always set prices, so the two models are not rival accounts of one market. They describe markets with different technologies. Bertrand is the better approximation when marginal cost is fairly flat. Cournot is the better approximation when marginal cost rises sharply, as it does at a capacity limit. Quantity competition is then best read as competition in scale: each firm's choice of scale fixes its cost function and so the conditions of later price competition. A capacity is one such choice, and other investments that shape the cost curve play the same role. Tirole also warns that the capacity justification must be checked model by model, for the reasons given in Section 2.6.2.

Remark 2.57 (Supply function equilibria). In some markets firms commit to entire supply schedules. In an electricity pool, for example, generators submit schedules before demand is known. Let firm i commit to a supply function $S_i(p)$, and let the price clear the market, $Q(p) = \sum_j S_j(p)$. Given its rivals' schedules, firm i faces residual demand $Q(p) - S_{-i}(p)$, with $S_{-i} = \sum_{j \neq i} S_j$. For each realization of demand it chooses the best point on this curve. The first-order condition is

$$q_i = \left(p - C_i'(q_i)\right) \left[S_{-i}'(p) - Q'(p)\right].$$

Rearranging, and writing $e_{-i} = S_{-i}'(p) \frac{p}{S_{-i}}$ for the elasticity of rivals' supply and $S_{-i} = (1 - s_i)Q$, gives

$$\frac{p - C_i'(q_i)}{p} = \frac{s_i}{\varepsilon + (1 - s_i)\, e_{-i}}.$$

Flat rival schedules ($e_{-i} = 0$) give the Cournot rule $\frac{s_i}{\varepsilon}$. Infinitely elastic schedules give price equal to marginal cost, as in Bertrand. The same formula describes a dominant firm facing a price-taking fringe, (2.10) in Example 2.7. Klemperer and Meyer (1989) show that, without uncertainty, many supply function equilibria exist, with outcomes between the competitive and Cournot outcomes. Demand uncertainty narrows the set, and with unbounded uncertainty the equilibrium is unique. Green and Newbery (1992) apply the model to the British electricity spot market, which Chapter 3 studies with the data of Wolfram (1999).

Price competition can also be studied dynamically. Consider a duopoly in which firms take turns setting prices and condition only on the rival's current price. A *Markov perfect equilibrium* is a subgame-perfect equilibrium in which each firm's price depends only on the payoff-relevant state, here the rival's current price. In this game such equilibria take two forms (Maskin and Tirole, 1988, pp. 571–572). In a *kinked demand curve* equilibrium the price settles at a focal level, because each firm expects a price cut to be matched and a price rise to go unmatched. In an *Edgeworth cycle* firms undercut each other in small steps until the price war becomes too costly. Then one firm raises its price, the other follows, and the undercutting starts again. In every such equilibrium profit stays bounded away from the Bertrand level. Such cycles appear in retail gasoline markets (Chapter 13).

2.7 Conduct: conjectural variations and the conduct parameter

Monopoly, Cournot and Bertrand each deliver one pricing rule. Empirical work needs a single equation that nests them, so that the data can speak about which one holds. This section develops that equation, the supply relation with a conduct parameter θ. It shows how firm behavior aggregates into an industry θ, lists the values that standard models imply, and discusses what an estimated θ can and cannot mean. Estimation and identification are the subject of Chapter 3.

2.7.1 The supply relation

Let $P(Q)$ be inverse market demand and MC industry marginal cost. The *supply relation* with *conduct parameter* $\theta \geq 0$ is

$$P = MC - \theta\, Q\, P'(Q). \tag{2.50}$$

Equivalently, $P + \theta Q P'(Q) = MC$: marginal cost equals a *perceived marginal revenue*. At $\theta = 0$ this is price taking, $P = MC$. At $\theta = 1$ it is the monopoly condition $MR = MC$. Since $P' < 0$, the term $-\theta Q P'(Q) \geq 0$ is the dollar markup. It equals θ times the monopoly markup $m = -\frac{Q(p)}{Q'(p)}$ of (2.5). Relation (2.50) is the industry form of Bresnahan's supply relation (2.15), which Section 2.2.4 stated at the level of firm i and observation t, with θ_{it} free to vary. Bresnahan calls it a supply relation because, outside perfect competition, firms have no supply curve that gives output as a function of price alone (Bresnahan, 1989, p. 1016, n. 6). As there, marginal cost is a function of unknown parameters that are estimated jointly with θ.

Dividing (2.50) by P and using $\varepsilon = -\frac{P}{QP'(Q)}$ gives the Lerner form:

$$\frac{P - MC}{P} = -\frac{\theta\, Q\, P'(Q)}{P} = \frac{\theta}{\varepsilon} \qquad \Longleftrightarrow \qquad \theta = \varepsilon\, \frac{P - MC}{P}. \tag{2.51}$$

The conduct parameter is the *elasticity-adjusted Lerner index*. For $\theta \in [0, 1]$ the Lerner index lies in $\left[0, \frac{1}{\varepsilon}\right]$, between price taking and the inverse-elasticity rule.

Remark 2.58 (Conduct between competition and monopoly). Under (2.50), $\theta \in [0, 1]$ if and only if

$$P + QP'(Q) \leq MC \leq P,$$

that is, marginal cost lies between monopoly marginal revenue and price. Indeed $MC = P + \theta QP'$ with $QP' < 0$. So $MC \leq P$ holds exactly when $\theta \geq 0$, and $MC \geq P + QP'$ holds exactly when $\theta \leq 1$. These inequalities yield bounds on marginal cost without fixing θ, and they hold observation by observation even when conduct varies. Rosen (2007) builds on this idea to bound marginal cost and markups by set identification, and Section 3.6.3 develops the approach.

Example 2.59 (The linear system)**.** Let demand and marginal cost be linear,

$$\begin{aligned} Q_t &= \alpha_0 + \alpha_1 P_t + \alpha_2 Y_t + e_t, \qquad \alpha_1 < 0, \\ MC_t &= \beta_0 + \beta_1 Q_t + \beta_2 W_t + u_t, \end{aligned}$$

where Y_t shifts demand, W_t shifts cost, and e_t and u_t are shocks. (In this example only, α and β denote the coefficients of the linear system.) The inverse demand slope is $P'(Q) = \frac{1}{\alpha_1}$. Substituting it and MC_t into (2.50) gives

$$\begin{aligned} P_t &= \beta_0 + \beta_1 Q_t + \beta_2 W_t + u_t - \frac{\theta}{\alpha_1} Q_t \\ &= \beta_0 + \left(\beta_1 - \frac{\theta}{\alpha_1}\right) Q_t + \beta_2 W_t + u_t. \end{aligned} \tag{2.52}$$

Conduct and the slope of marginal cost enter only through the composite slope $\beta_1 - \frac{\theta}{\alpha_1}$. Parallel demand shifts trace out the supply relation and reveal this composite slope. They cannot tell a competitive industry with rising marginal cost from a monopoly with flatter marginal cost. Chapter 3 shows how demand rotations (Bresnahan, 1982; Lau, 1982) break this observational equivalence.

2.7.2 Firm-level conduct and aggregation

The supply relation can be derived from firm behavior. Let firm i choose q_i in a homogeneous-good market with cost $C_i(q_i)$, and suppose it acts as if its rivals' total output responds to its own output with slope $r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$. The number r_i is firm i's *conjectural variation*, as in Proposition 1.17. The firm then perceives $\frac{\mathrm{d}Q}{\mathrm{d}q_i} = 1 + r_i$, and its perceived marginal revenue is

$$\frac{\mathrm{d}}{\mathrm{d}q_i}\left[P(Q)\, q_i\right] = P(Q) + q_i P'(Q)\frac{\mathrm{d}Q}{\mathrm{d}q_i} = P(Q) + (1 + r_i)\, q_i P'(Q).$$

Setting it equal to marginal cost gives the firm-level supply relation

$$P + \tilde{\theta}_i\, q_i P'(Q) = C_i'(q_i), \qquad \tilde{\theta}_i = 1 + r_i. \tag{2.53}$$

We call $\tilde{\theta}_i$ the *firm-level conduct parameter*. Cournot behavior is $r_i = 0$ and $\tilde{\theta}_i = 1$. Price taking is $r_i = -1$ and $\tilde{\theta}_i = 0$: the firm acts as if rivals offset any expansion one for one, so price does not move. This is the form of Bresnahan (1989, eqs. (12) and (14), pp. 1027–1028), whose symbol r_i we adopt. He writes θ_{it} for $1 + r_i$ and uses the two forms interchangeably. The literature often uses the same symbol for firm-level and industry-level conduct. We keep the tilde to separate them.

Proposition 2.60 (Aggregation of firm conduct)**.** *Let each of N firms satisfy (2.53), with shares $s_i = \frac{q_i}{Q}$ and market elasticity $\varepsilon = -\frac{P}{QP'(Q)}$. For any weights $\kappa_i \geq 0$ with $\sum_i \kappa_i = 1$, define industry marginal cost $MC = \sum_i \kappa_i C_i'(q_i)$. Then*

$$\frac{P - MC}{P} = \frac{\theta}{\varepsilon}, \qquad \text{with} \qquad \theta = \sum_{i=1}^{N} \kappa_i \, s_i \, \tilde{\theta}_i, \tag{2.54}$$

so the industry satisfies the supply relation (2.50) with this θ.

Proof. The proof takes five steps.

1. Rearrange (2.53): $P = C_i'(q_i) - \tilde{\theta}_i \, q_i P'(Q)$.
2. Use $-P'(Q) = \frac{P}{\varepsilon Q}$: $P = C_i'(q_i) + \tilde{\theta}_i \frac{q_i}{Q} \frac{P}{\varepsilon} = C_i'(q_i) + \tilde{\theta}_i \, s_i \frac{P}{\varepsilon}$.
3. Multiply by κ_i: $\kappa_i P = \kappa_i C_i'(q_i) + \kappa_i s_i \tilde{\theta}_i \frac{P}{\varepsilon}$.
4. Sum over i. Since $\sum_i \kappa_i = 1$, the left side is P, and $P = \sum_i \kappa_i C_i'(q_i) + \frac{P}{\varepsilon} \sum_i \kappa_i s_i \tilde{\theta}_i = MC + \frac{P}{\varepsilon} \, \theta$.
5. Subtract MC and divide by P to obtain (2.54). Multiplying $\frac{\theta P}{\varepsilon}$ by $1 = -\frac{\varepsilon Q P'}{P}$ gives $P = MC - \theta Q P'$, which is (2.50). □

The benchmarks follow at once. Under Cournot conduct ($\tilde{\theta}_i = 1$), $\theta = \sum_i \kappa_i s_i$. Equal weights and symmetric firms give $\theta = N \cdot \frac{1}{N} \cdot \frac{1}{N} = \frac{1}{N}$. Share weights $\kappa_i = s_i$ give $\theta = HHI$ and industry marginal cost $\bar{c} = \sum_i s_i c_i$, which is the Cowling-Waterson relation of Proposition 2.26. Joint profit maximization sets $P + QP'(Q) = C_i'(q_i)$ for every active firm. Comparing with (2.53) gives $\tilde{\theta}_i = \frac{Q}{q_i} = \frac{1}{s_i}$, hence $\theta = \sum_i \kappa_i = 1$. Price taking gives $\theta = 0$.

Two features of the aggregation deserve emphasis. First, when all firms share the same constant marginal cost c, step 2 of the proof shows that $\tilde{\theta}_i s_i = \varepsilon \frac{P - c}{P}$ is the same for every firm. The industry θ is then independent of the weights. Second, with heterogeneous costs the weights matter, because noncooperative firms with different costs have different margins (Proposition 2.26). A stable industry marginal cost curve need not exist, and an industry-level θ estimated from aggregate data is best read as average conduct (Bresnahan, 1989, p. 1030). Nothing in oligopoly theory forces all firms to share the same conduct. Bresnahan (1989, p. 1030) calls the contrary claim in the literature an error. This is the aggregation that Wolfram (1999) uses for electricity (Chapter 3).

2.7.3 The menu of conduct

Each standard oligopoly model implies values of r_i, $\tilde{\theta}_i$ and θ. Two models with leaders need a derivation.

Example 2.61 (Stackelberg leadership)**.** Let $P = a - bQ$ and let all firms have marginal cost c. Firm 1 leads, and firms $2, \ldots, N$ choose outputs after observing q_1 and play Cournot among themselves. Each follower's first-order condition is $a - bQ - bq_j = c$. By symmetry the followers produce

$$q_f = \frac{a - c - bq_1}{bN}, \qquad Q_{-1} = (N-1) \, q_f = \frac{(N-1)(a - c - bq_1)}{bN}.$$

The leader's conjecture is correct, $r_1 = \frac{\mathrm{d}Q_{-1}}{\mathrm{d}q_1} = -\frac{N-1}{N}$, so $\tilde{\theta}_1 = 1 + r_1 = \frac{1}{N}$. The leader's first-order condition is $a - bQ - \frac{b}{N} q_1 = c$, and total output satisfies $bQ = bq_1 + bQ_{-1} = \frac{(N-1)(a-c)}{N} + \frac{bq_1}{N}$.

Substituting,

$$a - c - \frac{(N-1)(a-c)}{N} - \frac{2bq_1}{N} = 0 \quad \Longrightarrow \quad q_1 = \frac{a-c}{2b}.$$

Then $q_f = \frac{a-c}{2bN}$, total output is $Q = \frac{(2N-1)(a-c)}{2bN}$, and $P - c = \frac{a-c}{2N}$. Industry conduct follows from (2.50) with $-QP' = bQ$:

$$\theta = \frac{P-c}{bQ} = \frac{\frac{a-c}{2N}}{\frac{(2N-1)(a-c)}{2N}} = \frac{1}{2N-1}.$$

A duopoly gives $\theta = \frac{1}{3}$, with $P - c = \frac{a-c}{4}$ and $Q = \frac{3(a-c)}{4b}$. Since $\frac{1}{2N-1} < \frac{1}{N}$ for $N \geq 2$, leadership is more competitive than Cournot. As a check on Proposition 2.60, the shares are $s_1 = \frac{N}{2N-1}$ and $s_f = \frac{1}{2N-1}$, so $\tilde{\theta}_1 s_1 = \tilde{\theta}_f s_f = \frac{1}{2N-1}$, as the common-cost case requires.

Bresnahan (1989, p. 1022) writes the leader's supply relation as (2.53) with $\tilde{\theta}_1 = 1 + \theta_S$, where θ_S is the derivative of the followers' total output with respect to the leader's. In the example $\theta_S = -\frac{N-1}{N}$.

Example 2.62 (Conduct of a dominant firm)**.** Return to the dominant firm d of Example 2.7, which faces a fringe of price takers with aggregate supply $S(P)$, $S' \geq 0$. Its residual demand is $q_d(P) = Q(P) - S(P)$, with slope $Q'(P) - S'(P)$. Its first-order condition is

$$P + \frac{q_d}{Q'(P) - S'(P)} = C_d'(q_d).$$

Writing this as (2.53) with $P'(Q) = \frac{1}{Q'(P)}$ gives

$$\tilde{\theta}_d = \frac{Q'(P)}{Q'(P) - S'(P)} = \frac{\varepsilon}{\varepsilon + \varepsilon_f(1 - s_d)}, \qquad v_d = \tilde{\theta}_d - 1 = -\frac{\varepsilon_f(1-s_d)}{\varepsilon + \varepsilon_f(1-s_d)},$$

where $\varepsilon_f = S'\frac{P}{S}$ is the fringe supply elasticity and s_d the dominant share. The second form uses $\frac{S'}{Q'} = -\frac{\varepsilon_f S}{\varepsilon Q} = -\frac{\varepsilon_f(1-s_d)}{\varepsilon}$. The dominant firm's Lerner index is $\frac{\tilde{\theta}_d s_d}{\varepsilon} = \frac{s_d}{\varepsilon + \varepsilon_f(1-s_d)}$, which is (2.10). Fringe firms have $\tilde{\theta} = 0$. In Bresnahan's notation, with $D_1 = P'(Q)$ and $S_1 = S'(P)$, the dominant firm has $\tilde{\theta}_d = 1 + S_D$ with $S_D = \frac{D_1 S_1}{1 - D_1 S_1} \in (-1, 0]$ (Bresnahan, 1989, eqs. (11) and (11′), p. 1023). Suslow (1986) estimates this model for Alcoa in the interwar aluminum market, with recycled aluminum as the fringe. She finds that Alcoa kept considerable monopoly power because S_D is small (Bresnahan, 1989, p. 1023).

Remark 2.63 (Recycling and durability create a fringe). A firm that sells a recyclable or durable good creates part of its own competition (Tirole, 1988, sec. 1.5). In the 1945 antitrust case against the Aluminum Company of America, Alcoa held about 90 percent of the primary aluminum market. Critics of the decision pointed to an approximately competitive industry that recycled the aluminum Alcoa had produced. Counting this secondary market, Alcoa's share was only about 64 percent (Tirole, 1988, sec. 1.5.1).

Tirole's model shows how far recycling disciplines the monopolist. Demand in each period is $q_t = Q(p_t)$, with inverse P. A competitive industry recycles the fraction $x(p_{t+1})$ of the previous period's consumption, where the recycling supply x rises with price, $x' > 0$, and stays below one. The symbol x is local to this remark. The monopolist supplies the rest at unit cost c, so its profit in period t is

$$\pi_t = \big[P(q_t) - c\big]\big(q_t - x(P(q_t))\, q_{t-1}\big),$$

and it maximizes $\sum_t \delta^t \pi_t$. Output q_t enters π_t and, through the recycled stock, π_{t+1}. In a stationary state with $q_t = q$, $p = P(q)$ and $x = x(p)$, the first-order condition for q_t is

$$P'(q)\,q\,(1-x) + (p-c)\big[1 - x'(p)P'(q)\,q\big] - \delta\,(p-c)\,x = 0.$$

Solving for the margin and dividing by p, with $-\frac{P'(q)q}{p} = \frac{1}{\varepsilon}$, gives

$$\frac{p-c}{p} = \frac{1}{\varepsilon} \cdot \frac{1-x}{1 - \delta x - x'(p)P'(q)\,q}.$$

This is Tirole's eq. (1.7) in Lerner form. The term $-x'P'q$ is positive and $\delta < 1$, so the denominator exceeds $1 - \delta x > 1 - x$. The margin is therefore positive but below the static monopoly margin $\frac{1}{\varepsilon}$. It approaches zero only when the recycled fraction x approaches one. Tirole judges that this was not the case for Alcoa, whose demand also grew fast, which keeps the recycled share low. Suslow (1986) estimates a model of this kind.

Durability has a starker effect. A monopolist that sells a durable good and cannot commit to its future prices competes with its own later sales, because buyers wait for price cuts. Coase (1972) conjectured that as price revisions become frequent, the monopolist's profit converges to zero and trade occurs at prices close to marginal cost. Later work proved the conjecture under suitable conditions (Tirole, 1988, secs. 1.1.3 and 1.5.2).

Table 2.4: The menu of conduct in a homogeneous-good market

Model	r_i	$\tilde{\theta}_i$	Industry θ	Source or derivation
Price taking	-1	0	0	(2.50) with $P = MC$
Bertrand, constant cost	-1	0	0 for any $N \geq 2$	Proposition 2.48
Cournot	0	1	$\frac{1}{N}$ if symmetric, HHI if $\kappa_i = s_i$	Proposition 2.60
Symmetric constant conjecture	r	$1 + r$	$\frac{1+r}{N}$	Iwata (1974)
Stackelberg leader, $N-1$ Cournot followers (linear)	$-\frac{N-1}{N}$	$\frac{1}{N}$	$\frac{1}{2N-1}$	Example 2.61
Stackelberg follower	0	1	same as leader row	Example 2.61
Dominant firm with price-taking fringe	$\frac{-\varepsilon_f(1-s_d)}{\varepsilon+\varepsilon_f(1-s_d)}$	$\frac{\varepsilon}{\varepsilon+\varepsilon_f(1-s_d)}$	$\kappa_d\, s_d\, \tilde{\theta}_d$	Example 2.62, Suslow (1986)
Joint monopoly or perfect collusion	$\frac{Q_{-i}}{q_i}$	$\frac{Q}{q_i}$	1	Proposition 2.60, with $r_i = N-1$ if symmetric
Repeated-game collusion	varies	varies	θ_t high when collusion holds, low in price wars	Green and Porter (1984), Porter (1983a)

Notes: $r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$ is the conjectural variation, $\tilde{\theta}_i = 1 + r_i$ the firm-level conduct parameter in (2.53), and industry $\theta = \sum_i \kappa_i s_i \tilde{\theta}_i$ (Proposition 2.60). The Bertrand entries are "as if" values, since price equals marginal cost. In the dominant-firm row, ε_f is the fringe supply elasticity and s_d the dominant share, and fringe firms have $\tilde{\theta} = 0$.

Table 2.4 collects the menu. The repeated-game row anticipates Section 2.10 and Chapter 12. In the theory of Green and Porter (1984), firms observe only the market price and cannot tell a

rival's secret output expansion from low demand. Collusive periods therefore alternate with price wars. Estimated conduct then varies over time. Porter (1983a) estimates such a regime-switching supply relation for a nineteenth-century railroad cartel (Chapter 13). Figure 2.8 shows the menu at work in the linear market. Each value of θ rotates perceived marginal revenue around the demand intercept and selects a different point on the demand curve.

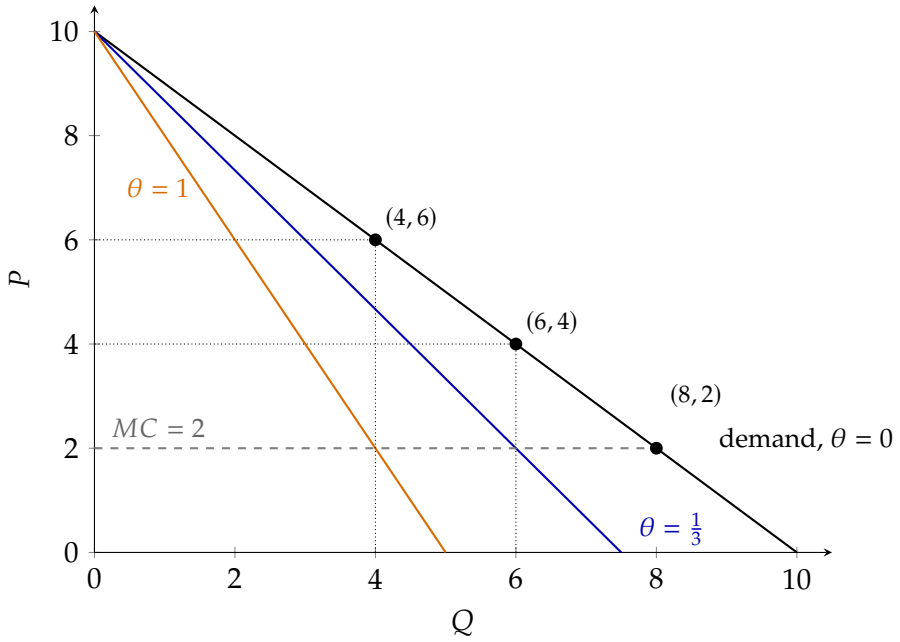

Figure 2.8: Perceived marginal revenue $10 - (1 + \theta)Q$ for demand $P = 10 - Q$ and $MC = 2$. Price taking ($\theta = 0$, perceived marginal revenue equal to demand) gives $Q = 8$ and $P = 2$. Conduct $\theta = \frac{1}{3}$, as in a Stackelberg duopoly or a symmetric Cournot triopoly, gives $Q = 6$ and $P = 4$. Monopoly ($\theta = 1$) gives $Q = 4$ and $P = 6$. In general $Q = \frac{8}{1+\theta}$.

2.7.4 Interpreting the conduct parameter

Bresnahan (1989, Sec. 2.2) distinguishes three ways in which empirical work has used θ.

The first takes θ from a single theory (Bresnahan, 1989, Sec. 2.2.1). Rosse (1970) estimates the supply relation of monopoly newspapers ($\theta = 1$). His marginal revenue includes the effect of circulation on advertising prices, and he infers marginal cost from $MR = MC$. Cournot models set $\tilde{\theta}_i = 1$ (Bresnahan, 1989, eq. (6)). Stackelberg and dominant-firm models give the leader the values derived above. Dynamic theories of collusion imply a θ that switches between regimes, as in Porter (1983a). In all these cases the theory fixes the value or the pattern of θ before the data are consulted.

The second approach estimates the supply relations of a few distinct theories and tests them against each other (Bresnahan, 1989, Sec. 2.2.2). Bresnahan (1987) compares joint-profit pricing with Bertrand pricing in the automobile industry of the mid-1950s. He finds collusive behavior in some years and Bertrand behavior in 1955 (Chapter 6). Bresnahan stresses that this approach differs from estimating a continuous θ only econometrically. A continuous θ leads to nested tests, while a few discrete theories lead to non-nested tests.

The third approach treats θ as a continuous parameter described as a "conjectural variation" (Bresnahan, 1989, Sec. 2.2.3). Iwata (1974) used it to locate the Japanese plate-glass industry

between competition and monopoly. Since $\tilde{\theta}_i - 1 = r_i$ is an identity, saying what the conjectural variation is and saying which oligopoly theory fits the data are the same statement (Bresnahan, 1989, p. 1027).

The critique of conjectural variations. Taken literally, a conjecture describes how a firm expects rivals to react to a change in its output. In a simultaneous-move game nobody can react, so any nonzero conjecture is inconsistent with the game being played. *Consistent conjectures*, which require each conjecture to equal the actual slope of rivals' responses, were one attempted repair (Bresnahan, 1981b). They keep the static framework and have not become standard. Bresnahan (1989, pp. 1028–1029) offers a different reading. Collusive conduct $\tilde{\theta}_i = N$ would literally mean that each firm expects rivals to match any output change one for one. In repeated-game models firms produce the collusive output for another reason. They expect a deviation to trigger a general breakdown of restraint. An estimated θ therefore describes what firms do. It does not reveal what they believe would happen after a deviation. If θ is stable and breakdowns are rare, it measures the average collusiveness of conduct. It tells us nothing about firms' expectations beyond the fact that they deter deviations (Bresnahan, 1989, n. 19).

A more basic problem is that an unrestricted θ explains everything.

Proposition 2.64 (Exact fit)**.** *Let (P_{it}, Q_{it}), with $Q_{it} > 0$, be data on prices and quantities. Take any demand system with slope $\frac{\partial Q_{it}}{\partial P_{it}} < 0$ at each observation and any marginal cost function, with implied values mc_{it}. Setting*

$$\theta_{it} = \frac{(P_{it} - mc_{it})\left|\frac{\partial Q_{it}}{\partial P_{it}}\right|}{Q_{it}}$$

makes the supply relation

$$P_{it} = mc_{it} + \theta_{it}\frac{Q_{it}}{\left|\frac{\partial Q_{it}}{\partial P_{it}}\right|}$$

hold exactly at every observation, with no error term. The implied θ_{it} is nonnegative whenever $mc_{it} \le P_{it}$.

Proof. Substituting the stated θ_{it} into the right side of the supply relation gives

$$mc_{it} + \frac{(P_{it} - mc_{it})\left|\frac{\partial Q_{it}}{\partial P_{it}}\right|}{Q_{it}} \cdot \frac{Q_{it}}{\left|\frac{\partial Q_{it}}{\partial P_{it}}\right|} = mc_{it} + (P_{it} - mc_{it}) = P_{it}. \qquad \square$$

The supply relation has empirical content only through restrictions on θ. The usual ones are that θ is constant across observations or groups, or that $\theta \in [0, 1]$. Others fix θ at the value implied by a specific game, or require deviations of θ to be uncorrelated with the instruments. Each restriction is an assumption, and each objection to a conduct study is an objection to one of them. Imposing a functional form on marginal cost does not help by itself, since the proposition holds for every cost function.

The conduct parameter as a specification test. Bresnahan (1989, p. 1031) credits Appelbaum (1979) with a useful observation. Setting $\theta = 0$ in (2.50) imposes price taking. Every approach to conduct is therefore a test of price taking against alternatives with market power. A cautious use of θ follows. We estimate it freely and test the hypotheses $\theta = 0$, $\theta = \frac{1}{N}$ and $\theta = 1$, without reading $\hat{\theta}$ as a deep behavioral parameter. Even this use requires care. If true conduct varies with demand, as in repeated-game models, an instrumental-variables estimate of a constant θ

measures how the markup responds to demand shifts. It need not equal average conduct, a point due to Corts (1999) and developed in Chapter 3.

Observed marginal cost. When marginal cost can be measured directly, (2.51) delivers conduct observation by observation, $\theta_t = \varepsilon_t \frac{P_t - MC_t}{P_t}$, once demand is known. A known cost structure serves a similar purpose. Fixed-proportions technology, for example, pins marginal cost down up to one or two parameters, which can be estimated jointly with θ. These are the strategies of Wolfram (1999) for electricity and Genesove and Mullin (1998) for sugar refining. Both compare the direct measure with the estimate a researcher would obtain without cost data (Chapter 3).

2.7.5 Forward contracts

Contracts signed before the spot market opens change the spot-market incentive to raise price. The case matters for electricity markets, where most output is often sold forward.

Example 2.65 (Cournot with forward sales)**.** Suppose firm i has sold x_i units forward at price p^f, before the spot market opens. Its spot-market profit is

$$P(Q)\left(q_i - x_i\right) + p^f x_i - C_i(q_i).$$

The forward revenue $p^f x_i$ is fixed, and only the uncontracted output $q_i - x_i$ earns the spot price. The Cournot first-order condition is

$$P(Q) + \left(q_i - x_i\right) P'(Q) = C_i'(q_i).$$

Using $-P' = \frac{P}{\varepsilon Q}$ and dividing by P,

$$\frac{P - C_i'(q_i)}{P} = \frac{q_i - x_i}{Q} \cdot \frac{1}{\varepsilon} = \frac{s_i}{\varepsilon}\left(1 - \frac{x_i}{q_i}\right). \tag{2.55}$$

In conduct terms, $\tilde{\theta}_i = 1 - \frac{x_i}{q_i}$. A firm with 80 percent of its output under contract has one fifth of the Cournot incentive to raise the spot price.

Allaz and Vila (1993) show that firms also have a strategic reason to sell forward. A forward sale commits a firm to a higher spot output. Since quantities are strategic substitutes, rivals respond by producing less. Every firm has this incentive, and together they end up in a prisoners' dilemma that lowers prices. In the linear duopoly with $P = a - bQ$ and cost c, suppose arbitrage makes the forward price equal the spot price. The spot stage gives $q_i = \frac{a - c + 2bx_i - bx_j}{3b}$ and $P - c = \frac{a - c - b(x_1 + x_2)}{3}$. Each firm then chooses x_i to maximize $(P - c)\, q_i$. The first-order condition is $a - c - 4bx_i - bx_j = 0$, so the symmetric solution is $x_i = \frac{a-c}{5b}$. Spot outputs are $q_i = \frac{2(a-c)}{5b}$, half of output is sold forward, and $P - c = \frac{a-c}{5}$. Without a forward market, Cournot gives $P - c = \frac{a-c}{3}$. As a check, (2.55) with $s_i = \frac{1}{2}$ and $\frac{x_i}{q_i} = \frac{1}{2}$ gives $P - c = \frac{1}{4}\, bQ = \frac{a-c}{5}$. Chapter 3 returns to contract cover in the British electricity market.

Remark 2.66 (Very inelastic demand). By Proposition 2.26, Cournot firm i has $L_i = \frac{s_i}{\varepsilon}$. With constant-elasticity demand, an interior equilibrium requires $L_i < 1$, that is, $s_i < \varepsilon$. When market demand is very inelastic, as in electricity, the static Cournot model predicts no interior equilibrium. Firms would withhold output until a capacity constraint binds. In such markets prices are held down by something outside the static model. Capacity limits, regulatory threats, forward contracts and the threat of entry are the usual candidates.

2.7.6 Pricing rules for the Bulow-Pfleiderer family

The supply relation yields closed-form pricing rules for the demand family $Q(p) = B(\bar{p} - p)^g$ of Example 2.12. With constant marginal cost c, the derivation has three steps.

First, compute $q\,P'(q)$. Since $P'(q) = \frac{1}{Q'(p)}$ and $Q'(p) = -gB(\bar{p} - p)^{g-1}$,

$$q\,P'(q) = \frac{Q(p)}{Q'(p)} = \frac{B(\bar{p} - p)^g}{-gB(\bar{p} - p)^{g-1}} = -\frac{\bar{p} - p}{g}.$$

Second, substitute into $p + \theta q P'(q) = c$:

$$p - \frac{\theta(\bar{p} - p)}{g} = c \quad \Longrightarrow \quad gp + \theta p = gc + \theta\bar{p}.$$

Third, solve for p:

$$P(c;\theta) = \frac{\theta\bar{p} + gc}{g + \theta}. \tag{2.56}$$

Monopoly ($\theta = 1$) gives $P(c;1) = \frac{\bar{p}+gc}{1+g}$, the rule of Example 2.12. Price taking gives $P(c;0) = c$. The rule nests the other families as limits.

- Linear demand ($g = 1$) gives $P = \frac{\theta\bar{p}+c}{1+\theta}$, and quadratic demand ($g = 2$) gives $P = \frac{\theta\bar{p}+2c}{2+\theta}$.
- Constant elasticity ($\bar{p} = 0$ and $g = -\varepsilon < 0$) gives $P = \frac{gc}{g+\theta} = \frac{\varepsilon}{\varepsilon-\theta}\,c$, which requires $\varepsilon > \theta$.
- In the exponential limit, g and $\bar{p}$ grow without bound with $\frac{g}{\bar{p}} = \lambda_s$ fixed. Demand tends to $Q \propto e^{-\lambda_s p}$, with constant semi-elasticity λ_s. Since $\frac{\bar{p}-p}{g} = \frac{1}{\lambda_s} - \frac{p}{g} \to \frac{1}{\lambda_s}$, the rule becomes $P = c + \frac{\theta}{\lambda_s}$, a constant dollar markup.

The cost slope of (2.56) is $\frac{\partial P}{\partial c} = \frac{g}{g+\theta}$, which depends on conduct and curvature together (Section 2.8). The intercept $\frac{\theta\bar{p}}{g+\theta}$ moves with the demand parameter $\bar{p}$. A season in which demand rotates, changing $\bar{p}$ or g, therefore shifts price by an amount that rises with θ and vanishes at $\theta = 0$. Genesove and Mullin (1998) estimate exactly these rules for sugar refining and use such a seasonal rotation to identify conduct (Chapter 3).

2.8 Pass-through

The previous sections characterized the level of the markup under each model of competition. Empirical work often learns more from how prices move than from where they sit. When marginal cost rises by one dollar, by how much does price rise? The answer, the pass-through rate, links much of the empirical work in this book. Tax incidence, tests of conduct, the price effects of mergers and the value of cost savings to consumers all depend on it. This section derives pass-through from the pricing first-order conditions of Sections 2.2, 2.4 and 2.7. Pass-through depends on three primitives: the curvature of demand, the slope of marginal cost and conduct. One pass-through number cannot separate them, and much of the section makes that statement precise.

2.8.1 Definition and uses

Definition 2.67 (Pass-through)**.** Let the equilibrium price p of a market depend on a cost parameter c that shifts marginal cost one for one. The *pass-through rate* is $\rho = \frac{\mathrm{d}p}{\mathrm{d}c}$. For a *specific tax* t, a fixed amount per unit sold, the pass-through rate is $\rho = \frac{\mathrm{d}p}{\mathrm{d}t}$. The *pass-through elasticity* is $\frac{\mathrm{d}p}{\mathrm{d}c}\frac{c}{p} = \rho\frac{c}{p}$. A cost shock is *industry-wide* when it raises the marginal cost of every firm by the same amount, and *firm-specific* when it raises the marginal cost of one firm only.

A specific tax collected from sellers raises their effective marginal cost by t. A tax collected from buyers is equivalent. If buyers pay the tax, demand at the seller price p_s is $Q(p_s + t)$. A monopolist that chooses p_s to maximize $Q(p_s + t)(p_s - c)$ is choosing the consumer price $p = p_s + t$ to maximize $Q(p)(p - c - t)$, which is the problem with a tax collected from sellers. The same change of variables works for every model of conduct in this chapter. The side of the market that legally pays the tax is therefore irrelevant. The pass-through of a specific tax equals the pass-through of an equal rise in marginal cost. We use c and t interchangeably when marginal cost is constant.

Pass-through enters applied work in four ways. First, it determines the *incidence* of a tax, the split of its burden between consumers and producers (Section 2.8.5). Second, it governs how shocks to input prices and exchange rates reach final prices. A pass-through elasticity of import prices below one with respect to the exchange rate is the "incomplete pass-through" of international economics. Third, the pass-through of an industry-wide cost shifter differs between competition and monopoly, so it can be used to test conduct. Sumner (1981) built such a test from state cigarette taxes, and Chapter 3 studies it in depth. Fourth, merger analysis needs pass-through twice. A merger's cost savings reach consumers only through the merged firm's pass-through. The upward pricing pressure of a merger is a shift in effective marginal cost, and pass-through converts it into a price change (Chapter 11).

2.8.2 Monopoly with constant marginal cost

We begin with a single price setter. The same results apply to any firm facing a residual demand curve with rivals' actions held fixed (Section 2.2.2).

Assumption 2.68 (Monopoly pass-through)**.** A monopolist faces demand $Q(p)$, twice continuously differentiable with $Q'(p) < 0$, and has constant marginal cost c. For every c in an open interval, profit $Q(p)(p - c)$ has an interior maximizer $p^m(c)$. The maximizer satisfies the first-order condition (2.3), $Q'(p)(p - c) + Q(p) = 0$, and the strict second-order condition $(p - c)Q''(p) + 2Q'(p) < 0$.

The strict second-order condition is the nonsingularity condition of the implicit function theorem (Appendix B). Hence $p^m(c)$ is continuously differentiable, and its derivative follows from differentiating the first-order condition. The sign of the derivative is known before we compute it. Lemma 2.6 shows by revealed preference that the monopoly price never falls when c rises, for any demand curve. Smoothness adds the rate.

Proposition 2.69 (Monopoly pass-through)**.** *Under Assumption 2.68, at* $p = p^m(c)$,

$$\rho = \frac{\mathrm{d}p^m}{\mathrm{d}c} = \frac{Q'(p)}{(p - c)Q''(p) + 2Q'(p)} > 0. \tag{2.57}$$

Proof. Write the first-order condition as an identity in c:

$$Q'\big(p(c)\big)\big(p(c)-c\big)+Q\big(p(c)\big)\equiv 0.$$

Differentiate each piece with respect to c, writing $\rho = p'(c)$:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}c}\,Q'\big(p(c)\big) &= Q''(p)\,\rho,\\ \frac{\mathrm{d}}{\mathrm{d}c}\,\big(p(c)-c\big) &= \rho-1,\\ \frac{\mathrm{d}}{\mathrm{d}c}\,Q\big(p(c)\big) &= Q'(p)\,\rho.\end{aligned}$$

The product rule applied to the first term of the identity gives $Q''\rho(p-c)+Q'(\rho-1)$. Adding the derivative of the second term,

$$(p-c)Q''\rho+Q'(\rho-1)+Q'\rho=0.$$

Collect the terms in ρ:

$$\rho\big[(p-c)Q''+2Q'\big]=Q'.$$

Dividing by the bracket gives (2.57). The numerator Q' is negative, and the bracket is negative by the second-order condition, so $\rho>0$. □

Formula (2.57) has three equivalent forms. Each one gives a different reading of what drives pass-through.

Log-curvature form. The first-order condition gives $p-c=-\frac{Q}{Q'}$. Substituting into the denominator of (2.57),

$$(p-c)Q''+2Q'=-\frac{QQ''}{Q'}+2Q'.$$

Dividing the numerator and the denominator of (2.57) by Q' gives

$$\rho=\frac{1}{2-\frac{Q(p)\,Q''(p)}{Q'(p)^2}}. \tag{2.58}$$

The ratio $\frac{QQ''}{(Q')^2}$ is a unit-free measure of the convexity of demand. It is zero for linear demand.

Markup-slope form. Let $m(p)=-\frac{Q(p)}{Q'(p)}$ be the dollar markup that the demand curve supports at price p, as in (2.5). The first-order condition reads $p-c=m(p)$. Differentiating with respect to c gives $\rho-1=m'(p)\rho$, so

$$\rho=\frac{1}{1-m'(p)}. \tag{2.59}$$

The quotient rule gives $m'(p)=-\frac{(Q')^2-QQ''}{(Q')^2}=-1+\frac{QQ''}{(Q')^2}$, so $1-m'(p)=2-\frac{QQ''}{(Q')^2}$, in agreement with (2.58). The reciprocal $\frac{1}{m}=-\frac{Q'}{Q}$ is the semi-elasticity of demand from Section 2.2.1. When the semi-elasticity rises with price, the supported markup falls ($m'<0$), and the monopolist absorbs part of any cost increase. When the semi-elasticity falls with price, the markup rises with price ($m'>0$), and the price rises by more than cost.

Quantity-space form. A monopolist choosing output q against inverse demand $P(q)$ sets marginal revenue equal to marginal cost, $P(q) + qP'(q) = c$. Recall from Remark 2.19 the curvature of inverse demand,

$$\chi(q) = -\frac{qP''(q)}{P'(q)}. \tag{2.60}$$

It is zero for linear inverse demand, positive when inverse demand is convex and negative when it is concave. Differentiating the marginal-revenue condition with respect to c,

$$\big[2P'(q) + qP''(q)\big]\frac{\mathrm{d}q}{\mathrm{d}c} = 1.$$

The price moves along the inverse demand curve, so

$$\rho = P'(q)\frac{\mathrm{d}q}{\mathrm{d}c} = \frac{P'}{2P' + qP''} = \frac{1}{2 + \frac{qP''}{P'}} = \frac{1}{2 - \chi(q)}. \tag{2.61}$$

The second-order condition in quantity space is $2P' + qP'' < 0$. Dividing by $P' < 0$ shows that it is equivalent to $\chi < 2$, which again makes ρ positive.

The log-curvature form and the quantity-space form agree because the two curvature measures coincide.

Lemma 2.70 (Curvature of direct and inverse demand)**.** *Let P be the inverse of a twice differentiable demand function Q with $Q' < 0$. At every point on the demand curve, $\chi = \frac{QQ''}{(Q')^2}$, and $\frac{\mathrm{d}^2 \ln Q(p)}{\mathrm{d}p^2} < 0$ if and only if $\chi < 1$.*

Proof. Differentiate the identity $P(Q(p)) = p$ once to get $P'Q' = 1$, so $P' = \frac{1}{Q'}$. Differentiate it again to get $P''(Q')^2 + P'Q'' = 0$, so $P'' = -\frac{P'Q''}{(Q')^2} = -\frac{Q''}{(Q')^3}$. Then

$$\chi = -\frac{Q\,P''}{P'} = -Q \cdot \left(-\frac{Q''}{(Q')^3}\right) \cdot Q' = \frac{QQ''}{(Q')^2}.$$

For the second claim, $\frac{\mathrm{d}^2 \ln Q}{\mathrm{d}p^2} = \frac{\mathrm{d}}{\mathrm{d}p}\frac{Q'}{Q} = \frac{QQ'' - (Q')^2}{Q^2}$. This is negative if and only if $QQ'' < (Q')^2$, that is, if and only if $\chi < 1$. □

Corollary 2.71 (Bulow and Pfleiderer, 1983)**.** *Under Assumption 2.68, monopoly pass-through at $p^m(c)$ satisfies $\rho < 1$ if demand is strictly log-concave there, $\rho = 1$ if $\ln Q$ is locally linear, and $\rho > 1$ if demand is strictly log-convex. Linear demand has $\rho = \frac{1}{2}$.*

Proof. By (2.61) and Lemma 2.70, $\rho = \frac{1}{2-\chi}$ with $2 - \chi > 0$. So $\rho < 1$ if and only if $2 - \chi > 1$, that is $\chi < 1$, which is strict log-concavity. The other two cases follow in the same way. Linear demand has $Q'' = 0$, so $\chi = 0$ and $\rho = \frac{1}{2}$. □

Log-concavity is the same property as a semi-elasticity that rises with price, since $\frac{\mathrm{d}^2 \ln Q}{\mathrm{d}p^2} = \frac{\mathrm{d}}{\mathrm{d}p}\frac{Q'}{Q}$. The corollary therefore restates the markup-slope form: a monopolist passes through less than the full cost increase exactly when higher prices make its customers more price sensitive at the margin.

Remark 2.72 (Pass-through and the distribution of willingness to pay). Suppose each of M consumers buys one unit if her willingness to pay v exceeds the price, with v drawn from a distribution G with density G'. Demand is $Q(p) = M[1 - G(p)]$, as in Section 2.2.1, and the supported markup is $m(p) = \frac{1-G(p)}{G'(p)} = \frac{1}{h(p)}$, where $h = \frac{G'}{1-G}$ is the hazard rate of G. The first-order condition reads $p - c = \frac{1}{h(p)}$. Since $m' = -\frac{h'}{h^2}$, (2.59) gives

$$\rho = \frac{1}{1 + \frac{h'(p)}{h(p)^2}}.$$

Pass-through is below one exactly when the hazard rate rises at p^m. A uniform distribution on $[0, \bar{v}]$ has $h = \frac{1}{\bar{v}-p}$ and $h' = h^2$, which gives linear demand and $\rho = \frac{1}{2}$. An exponential distribution has a constant hazard and $\rho = 1$. A Pareto distribution, $1 - G(v) = (\frac{v_0}{v})^{\varepsilon}$ for $v \geq v_0$, has $h = \frac{\varepsilon}{v}$ and $\frac{h'}{h^2} = -\frac{1}{\varepsilon}$. It gives constant-elasticity demand and $\rho = \frac{\varepsilon}{\varepsilon-1} > 1$. The normal and logistic distributions have increasing hazard rates. With standard normal willingness to pay and $c = 0$, for example, $p^m \approx 0.75$ and $\rho \approx 0.70$. Pass-through above one therefore requires a hazard rate that falls at the monopoly price, as in thick-tailed distributions such as the Pareto.

Example 2.73 (Five demand curves)**.** We compute the curvature χ and monopoly pass-through for five demand curves. Each case also gives pass-through under constant conduct θ with constant marginal cost, using the supply relation $P + \theta QP'(Q) = c$ of (2.50). Table 2.5 collects the results. Cases (ii), (iii) and (iv) are the three demand curves of Tirole (1988, Exercise 1.3). Case (i) is the linear member of case (ii). Tirole uses them to frame the critique by Bulow and Pfleiderer (1983) of the tax test of Sumner (1981).

(i) *Linear demand*, $P = a - bQ$ with $a > c$ and $b > 0$. Then $P' = -b$, $P'' = 0$ and $\chi = 0$, so $\rho = \frac{1}{2}$. Directly, $a - 2bQ = c$ gives $Q^m = \frac{a-c}{2b}$ and $p^m = \frac{a+c}{2}$. Under conduct θ, the supply relation is $a - bQ - \theta bQ = c$, so

$$Q = \frac{a-c}{b(1+\theta)}, \qquad P = a - \frac{a-c}{1+\theta} = \frac{\theta a + c}{1+\theta}, \qquad \rho = \frac{1}{1+\theta}.$$

(ii) *The power family*, $P = a - bQ^{\gamma}$ with $b\gamma > 0$ so that demand slopes down. Then $P' = -b\gamma Q^{\gamma-1}$ and $P'' = -b\gamma(\gamma-1)Q^{\gamma-2}$, so $\chi = -\frac{QP''}{P'} = 1 - \gamma$. The second-order condition $\chi < 2$ requires $\gamma > -1$. Monopoly pass-through is $\rho = \frac{1}{1+\gamma}$. Directly, marginal revenue is $a - (1+\gamma)bQ^{\gamma}$, and substituting $bQ^{\gamma} = a - P$ gives $MR = (1+\gamma)P - \gamma a$. Setting $MR = c$,

$$p^m = \frac{\gamma a + c}{1+\gamma}.$$

Under conduct θ, $\theta QP' = -\theta\gamma bQ^{\gamma} = -\theta\gamma(a - P)$, so the supply relation becomes $P(1 + \theta\gamma) = c + \theta\gamma a$, and

$$P = \frac{\theta\gamma a + c}{1+\theta\gamma}, \qquad \rho = \frac{1}{1+\theta\gamma}.$$

This is the family $Q = B(\bar{p} - p)^g$ of Example 2.12, with $a = \bar{p}$, $\gamma = \frac{1}{g}$ and $b = B^{-\frac{1}{g}}$. In that notation $\rho = \frac{g}{g+\theta}$, the slope of the pricing rule (2.56). Linear demand is $\gamma = 1$. Quadratic demand ($g = 2$) has $\gamma = \frac{1}{2}$, $\chi = \frac{1}{2}$ and monopoly pass-through $\frac{2}{3}$.

(iii) *Constant elasticity*, $Q = Ap^{-\varepsilon}$ with $\varepsilon > 1$, so $P = (\frac{Q}{A})^{-\frac{1}{\varepsilon}}$. This is the power family with $a = 0$, $\gamma = -\frac{1}{\varepsilon}$ and $b = -A^{\frac{1}{\varepsilon}}$. Hence $\chi = 1 + \frac{1}{\varepsilon}$ and $\rho = \frac{1}{1-\frac{1}{\varepsilon}} = \frac{\varepsilon}{\varepsilon-1}$. Directly, the Lerner rule gives

$p^m = \frac{\varepsilon}{\varepsilon-1}c$. Under conduct θ, the Lerner form (2.51) gives $P(1-\frac{\theta}{\varepsilon}) = c$, so

$$P = \frac{\varepsilon}{\varepsilon-\theta}\,c, \qquad \rho = \frac{\varepsilon}{\varepsilon-\theta} = \left(1-\frac{\theta}{\varepsilon}\right)^{-1}, \qquad \theta < \varepsilon.$$

The price is a fixed multiple of cost, so the pass-through elasticity equals one for every θ although $\rho > 1$.

(iv) *Exponential demand*, $Q = e^{\frac{a-p}{b}}$ with $b > 0$, so $P = a - b\ln Q$. Then $P' = -\frac{b}{Q}$, $P'' = \frac{b}{Q^2}$ and $\chi = 1$. The supply relation is $P - \theta b = c$, so $P = c + \theta b$ and $\rho = 1$ for every θ. The dollar markup θb does not depend on cost. A monopolist facing this demand curve passes through exactly one, as a competitive industry with flat marginal cost does. The case is the limit of the power family as $\gamma \to 0$. Take the member of the family with intercept $a_0 + \frac{b}{\gamma}$ and coefficient $\frac{b}{\gamma}$ on Q^γ. Its inverse demand is $a_0 - b\frac{Q^\gamma - 1}{\gamma}$, which converges to $a_0 - b\ln Q$ because $\frac{Q^\gamma-1}{\gamma} \to \ln Q$. Its pass-through $\frac{1}{1+\theta\gamma}$ converges to one.

(v) *Logit residual demand*. A single-product firm j with logit demand has market share

$$s_j(p_j) = \frac{e^{\delta_j - \alpha p_j}}{1 + \sum_{k\in\mathcal{J}} e^{\delta_k - \alpha p_k}}$$

(Chapter 7). Here δ_j is the part of product j's mean utility that does not depend on price, and $\alpha > 0$ is the price coefficient. The set of inside products is $\mathcal{J}$, and the outside good's utility is normalized to zero. Hold rivals' prices fixed and drop the subscript j. Differentiating, $s' = -\alpha s(1-s)$, and $s'' = -\alpha s'(1-2s) = \alpha^2 s(1-s)(1-2s)$. The first-order condition gives $p - c = -\frac{s}{s'} = \frac{1}{\alpha(1-s)}$. Market size cancels from (2.57). The two pieces of its denominator are

$$(p-c)s'' = \frac{\alpha^2 s(1-s)(1-2s)}{\alpha(1-s)} = \alpha s(1-2s), \qquad 2s' = -2\alpha s(1-s).$$

Their sum is $\alpha s(1-2s-2+2s) = -\alpha s$. Therefore

$$\rho = \frac{-\alpha s(1-s)}{-\alpha s} = 1 - s.$$

By Lemma 2.70, the curvature is $\chi = \frac{ss''}{(s')^2} = \frac{1-2s}{1-s} < 1$. Logit residual demand is log-concave, and a firm with a 30 percent share passes through 70 percent of an own-cost increase when rivals do not respond. The share falls as c rises, so pass-through rises with cost. Rivals' responses raise pass-through further (Chapters 4 and 11).

In four of the five rows pass-through does not vary with cost. This is no accident, as the next result shows.

Proposition 2.74 (Constant pass-through)**.** *Let a monopolist with constant marginal cost face inverse demand $P(Q)$ satisfying Assumption 2.68. If $P = a - bQ^\gamma$ with $b\gamma > 0$ and $\gamma > -1$, monopoly pass-through equals $\frac{1}{1+\gamma}$ at every cost. If $P = a - b\ln Q$ with $b > 0$, it equals one at every cost. Conversely, suppose pass-through equals a constant ρ for all c in an interval. Then on the corresponding interval of outputs inverse demand has one of these forms, with $\gamma = \frac{1}{\rho} - 1$ (Bulow and Pfleiderer, 1983).*

Proof. For the power family, example (ii) gives $\chi = 1 - \gamma$ at every output, so (2.61) gives $\rho = \frac{1}{2-(1-\gamma)} = \frac{1}{1+\gamma}$ whatever the cost. The condition $\gamma > -1$ is the second-order condition $\chi < 2$. For logarithmic inverse demand, example (iv) gives $\chi = 1$ and $\rho = 1$ at every output.

Table 2.5: Curvature and pass-through for common demand curves

Demand	Specification	Curvature χ	Monopoly ρ	ρ under conduct θ
Linear	$P = a - bQ$	0	$\frac{1}{2}$	$\frac{1}{1+\theta}$
Power family	$P = a - bQ^{\gamma}$, $b\gamma > 0$	$1 - \gamma$	$\frac{1}{1+\gamma}$	$\frac{1}{1+\theta\gamma} = \frac{g}{g+\theta}$
Constant elasticity	$Q = Ap^{-\varepsilon}$	$1 + \frac{1}{\varepsilon}$	$\frac{\varepsilon}{\varepsilon-1}$	$\frac{\varepsilon}{\varepsilon-\theta}$
Exponential	$P = a - b \ln Q$	1	1	1
Logit, rivals fixed	$s(p)$, share s	$\frac{1-2s}{1-s}$	$1 - s$	n.a.

Notes: Constant marginal cost. Curvature is $\chi = -\frac{QP''}{P'}$. Monopoly pass-through is $\frac{1}{2-\chi}$ by (2.61). The last column uses the supply relation $P + \theta QP' = c$ and equals $\frac{1}{1+\theta(1-\chi)}$ by (2.65). In the power family $g = \frac{1}{\gamma}$ is the exponent of $Q = B(\bar{p} - p)^g$. Constant elasticity is the power family with $a = 0$ and $\gamma = -\frac{1}{\varepsilon}$, and exponential demand is its limit as $\gamma \to 0$. The logit row is the residual demand of a single-product price setter with rivals' prices held fixed, for which an industry conduct parameter is not defined.

For the converse, monopoly output is continuous and strictly decreasing in c, because $\frac{\mathrm{d}q}{\mathrm{d}c} = \frac{1}{2P'+qP''} < 0$. A constant ρ on an interval of costs therefore means, by (2.61), that $\chi(Q) = 2 - \frac{1}{\rho}$ on an interval of outputs. That condition is the differential equation $QP''(Q) = -\left(2 - \frac{1}{\rho}\right)P'(Q)$. The equation is first-order and linear in $\ln|P'|$, and solving it is left as an exercise (Section 2.13). □

The constant-elasticity case sits inside the power family with $a = 0$ and $\gamma \in (-1, 0)$, and the logarithmic case is its limit as $\gamma \to 0$. Pass-through under constant conduct also depends on demand only through χ, as Section 2.8.3 shows. The power family therefore has constant pass-through under every constant conduct. Genesove and Mullin (1998) use it to estimate conduct in sugar refining (Chapter 3). Linear and log-linear demand impose restrictive monopoly pricing rules, and most variation in that industry comes from costs. The power family nests the linear, quadratic and log-linear forms, and the exponential form as a limit. It lets them check whether the choice of functional form drives the estimate of conduct. Outside this family pass-through varies with cost, and a linear regression of price on a cost shifter estimates an average of ρ over the sample.

Figure 2.9 draws the monopoly price as a function of marginal cost for three demand curves. The slopes are the constant pass-through rates of linear, constant-elasticity and exponential demand.

2.8.3 Conduct, curvature and rising marginal cost

We now allow imperfect competition of any degree and marginal cost that rises with output. The industry satisfies the supply relation (2.50) with conduct θ, and a specific tax t adds to marginal cost. Write the supply relation with the *marginal consumer surplus*

$$ms(Q) = -QP'(Q) \geq 0. \tag{2.62}$$

The name comes from consumer surplus $CS(Q) = \int_0^Q P(x)\,\mathrm{d}x - QP(Q)$, whose derivative is $P - P - QP' = ms(Q)$. It is the gain in consumer surplus from one more unit of output. The supply relation then reads $P(Q) - \theta\, ms(Q) = MC(Q) + t$: the markup equals conduct times the marginal consumer surplus. A monopolist ($\theta = 1$) keeps its markup equal to the surplus it would hand to inframarginal consumers by expanding.

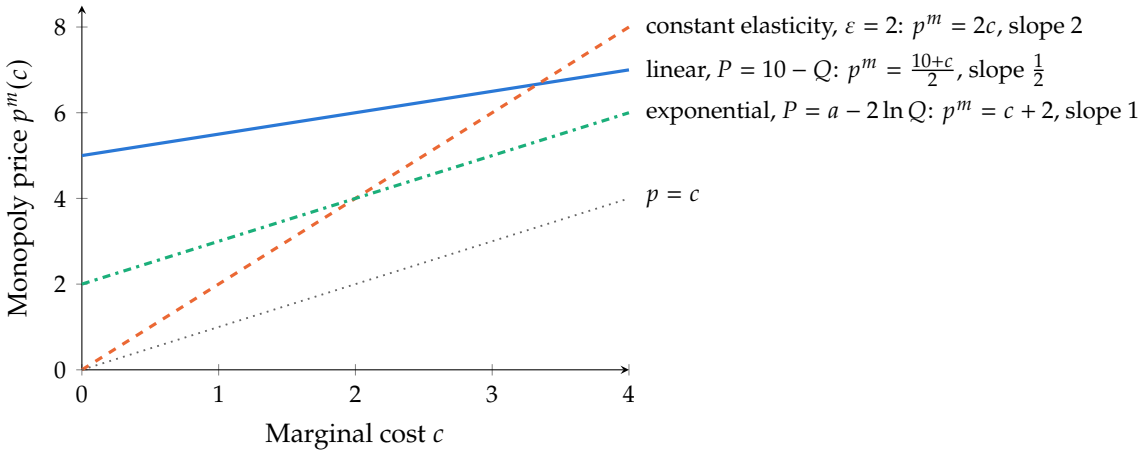

Figure 2.9: Monopoly price as a function of constant marginal cost for three demand curves. Linear demand ($a = 10$, $b = 1$) passes through one half of a cost change, exponential demand ($b = 2$) passes through all of it, and constant-elasticity demand ($\varepsilon = 2$) passes through twice the change. The dotted line is price equal to cost.

Assumption 2.75 (Pass-through under conduct)**.** Inverse demand $P(Q)$ is twice continuously differentiable with $P' < 0$. Industry marginal cost $MC(Q)$ is continuously differentiable with $MC' \geq 0$. Conduct $\theta \in [0, 1]$ does not vary with t. Equilibrium output $Q(t)$ is positive and satisfies

$$P(Q) + \theta Q P'(Q) = MC(Q) + t, \tag{2.63}$$

together with the stability condition $\Lambda(Q) \equiv P'(Q) - \theta\, ms'(Q) - MC'(Q) < 0$.

The stability condition says that perceived marginal revenue $P - \theta\, ms$ cuts effective marginal cost from above. It holds under monopoly by the second-order condition, and under symmetric Cournot competition by Assumption 2.18 (see the proof of Proposition 2.79). Three elasticities summarize the primitives at the equilibrium. The demand elasticity is $\varepsilon = -\frac{P}{QP'}$. The elasticity of the effective marginal-cost curve is $\varepsilon_S = \frac{MC+t}{Q\,MC'}$, which is infinite when marginal cost is flat. The elasticity of marginal consumer surplus is $\varepsilon_{ms} = \frac{ms}{Q\,ms'}$. Differentiating (2.62),

$$ms'(Q) = -P'(Q) - QP''(Q) = -P'(Q)\left(1 + \frac{QP''}{P'}\right) = -P'(Q)\,(1 - \chi),$$

so $\frac{1}{\varepsilon_{ms}} = \frac{Q\,ms'}{ms} = \frac{-QP'(1-\chi)}{-QP'} = 1 - \chi$. Exponential demand has $\chi = 1$, a constant marginal consumer surplus, and $\frac{1}{\varepsilon_{ms}} = 0$.

Proposition 2.76 (Pass-through under conduct, Weyl and Fabinger, 2013)**.** *Under Assumption 2.75,*

$$\rho = \frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{1 + \frac{\varepsilon - \theta}{\varepsilon_S} + \frac{\theta}{\varepsilon_{ms}}} = \frac{1}{1 + \theta(1 - \chi) + \frac{\varepsilon - \theta}{\varepsilon_S}}, \tag{2.64}$$

and the denominator is positive.

Proof. Step 1. Differentiate $P(Q) - \theta\, ms(Q) = MC(Q) + t$ with respect to t:

$$\left[P'(Q) - \theta\, ms'(Q)\right]\frac{\mathrm{d}Q}{\mathrm{d}t} = MC'(Q)\frac{\mathrm{d}Q}{\mathrm{d}t} + 1.$$

Collecting terms gives $\Lambda \frac{dQ}{dt} = 1$, so $\frac{dQ}{dt} = \frac{1}{\Lambda} < 0$.

Step 2. The price moves along the demand curve, so

$$\rho = P'(Q)\frac{dQ}{dt} = \frac{P'}{P' - \theta\, ms' - MC'} = \frac{1}{1 - \theta\frac{ms'}{P'} - \frac{MC'}{P'}}.$$

Step 3. The demand term is $-\frac{ms'}{P'} = 1 - \chi = \frac{1}{\varepsilon_{ms}}$ by the computation above.

Step 4. For the cost term, the definitions of the two elasticities give $MC' = \frac{MC+t}{Q\varepsilon_S}$ and $|P'| = \frac{P}{\varepsilon Q}$. Hence

$$-\frac{MC'}{P'} = \frac{MC'}{|P'|} = \frac{MC + t}{Q\varepsilon_S} \cdot \frac{\varepsilon Q}{P} = \frac{\varepsilon}{\varepsilon_S} \cdot \frac{MC + t}{P}.$$

Step 5. The Lerner form of (2.63) is $\frac{P-MC-t}{P} = \frac{\theta}{\varepsilon}$, as in (2.51), so $\frac{MC+t}{P} = \frac{\varepsilon-\theta}{\varepsilon}$. Substituting into Step 4 gives $-\frac{MC'}{P'} = \frac{\varepsilon-\theta}{\varepsilon_S}$.

Step 6. Steps 2 to 5 give (2.64). The denominator equals $\frac{\Lambda}{P'}$, a ratio of two negative numbers, so it is positive. □

Step 2 has a geometric reading. With flat marginal cost, pass-through is the slope of inverse demand divided by the slope of perceived marginal revenue, $\frac{P'}{P'(1+\theta(1-\chi))}$. A tax shifts the effective marginal cost line up by t. Output falls until perceived marginal revenue has risen by t, and price rises by the demand slope times the output change. When perceived marginal revenue is steep relative to demand, a small output cut absorbs the tax and price rises little. Under exponential demand, marginal consumer surplus is constant, so perceived marginal revenue is parallel to demand and price rises one for one. With rising marginal cost, effective marginal cost also falls as output contracts. A smaller output cut then restores the supply relation, and price rises less under every conduct.

Weyl and Fabinger (2013, eq. (2), p. 548) derive (2.64) for symmetric imperfect competition and extend it to conduct that varies with output. Their denominator adds the term $\frac{\theta}{\varepsilon_\theta}$, where $\varepsilon_\theta = \frac{\theta}{Q\,\theta'(Q)}$ is the elasticity of conduct with respect to output. The version here assumes constant θ, so this term vanishes.

Corollary 2.77 (Special cases)**.** *Under Assumption 2.75:*

(i) Price taking ($\theta = 0$) gives $\rho = \frac{\varepsilon_S}{\varepsilon_S+\varepsilon} \le 1$, with equality if and only if marginal cost is flat.

(ii) Flat marginal cost ($\varepsilon_S = \infty$) gives

$$\rho = \frac{1}{1 + \theta(1 - \chi)}. \tag{2.65}$$

(iii) Monopoly with flat marginal cost gives $\rho = \frac{1}{2-\chi}$, which is Proposition 2.69.

(iv) Symmetric Cournot competition among N firms with flat marginal cost gives $\rho = \frac{N}{N+1-\chi}$. Linear demand gives $\frac{N}{N+1}$, and constant elasticity gives $\frac{N\varepsilon}{N\varepsilon-1} > 1$.

(v) Monopoly with linear demand $P = a - bQ$ and linear marginal cost $MC = c_0 + kQ$ gives $\rho = \frac{b}{2b+k}$.

Proof. (i) Setting $\theta = 0$ in (2.64) gives $\rho = \frac{1}{1+\frac{\varepsilon}{\varepsilon_S}} = \frac{\varepsilon_S}{\varepsilon_S+\varepsilon}$. The same answer follows directly. A competitive industry with demand $Q(p)$ sets $p = MC(Q(p)) + t$. Differentiating, $\rho = MC'(Q)\,Q'(p)\,\rho + 1$, so

$$\rho = \frac{1}{1 + MC'\,|Q'|} = \frac{1}{1 + \frac{p}{Q\varepsilon_S}\cdot\frac{\varepsilon Q}{p}} = \frac{\varepsilon_S}{\varepsilon_S + \varepsilon},$$

where the middle step uses $p = MC + t$. The ratio is below one whenever $\varepsilon_S < \infty$.

(ii) The term $\frac{\varepsilon-\theta}{\varepsilon_S}$ vanishes when $\varepsilon_S = \infty$.

(iii) Set $\theta = 1$ in (2.65). By Lemma 2.70 this equals (2.58).

(iv) Each firm's first-order condition is $P + q_i P'(Q) = c + t$. Summing over the N firms and dividing by N gives $P + \frac{1}{N}QP'(Q) = c + t$, the supply relation with $\theta = \frac{1}{N}$. Then (2.65) gives

$$\rho = \frac{1}{1 + \frac{1-\chi}{N}} = \frac{N}{N + 1 - \chi}.$$

Linear demand has $\chi = 0$. Constant elasticity has $\chi = 1 + \frac{1}{\varepsilon}$, so $N + 1 - \chi = N - \frac{1}{\varepsilon}$ and $\rho = \frac{N\varepsilon}{N\varepsilon-1}$. An interior equilibrium requires $N\varepsilon > 1$.

(v) Here $\chi = 0$, and $\frac{\varepsilon-1}{\varepsilon_S} = \frac{MC'}{|P'|} = \frac{k}{b}$ by Steps 4 and 5 of the proof of Proposition 2.76. So $\rho = \frac{1}{2+\frac{k}{b}} = \frac{b}{2b+k}$. Directly, $a - 2bQ = c_0 + kQ + t$ gives $Q = \frac{a-c_0-t}{2b+k}$ and $\frac{\mathrm{d}P}{\mathrm{d}t} = -b\frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{b}{2b+k}$. □

Part (i) is the textbook incidence result for competitive markets. The side of the market with the smaller elasticity bears more of the tax. Part (iv) shows that Cournot pass-through approaches one as N grows, for any fixed curvature. With constant elasticity it approaches one from above, so a more competitive industry passes through less. Figure 2.10 plots (2.65) against curvature for four values of conduct.

The figure shows the identification problem at a glance. Under competition with flat marginal cost, pass-through is one for every demand curve. Market power rotates the line around the point $\chi = 1$. A pass-through above one can come from strong market power with mild convexity or from weak market power with strong convexity.

Corollary 2.78 (What pass-through reveals)**.** *Under Assumption 2.75:*

(i) Under price taking, $\rho \le 1$ for every demand curve and every nondecreasing marginal cost. A pass-through above one therefore rejects price taking.

(ii) With flat marginal cost, ρ identifies only the product

$$\theta(\chi - 1) = 1 - \frac{1}{\rho}. \tag{2.66}$$

Every $\theta \in (0, 1]$ is consistent with every observed $\rho > 0$ for a suitable curvature, and every θ is consistent with $\rho \le 1$.

(iii) With rising marginal cost, $\theta(\chi - 1) = 1 - \frac{1}{\rho} + \frac{\varepsilon-\theta}{\varepsilon_S} \ge 1 - \frac{1}{\rho}$. Rising marginal cost lowers pass-through for given conduct and curvature, so it strengthens the rejection in (i).

(iv) With constant-elasticity demand and flat marginal cost, $\theta = \varepsilon\left(1 - \frac{1}{\rho}\right)$. An estimate of the demand elasticity then converts pass-through into conduct.

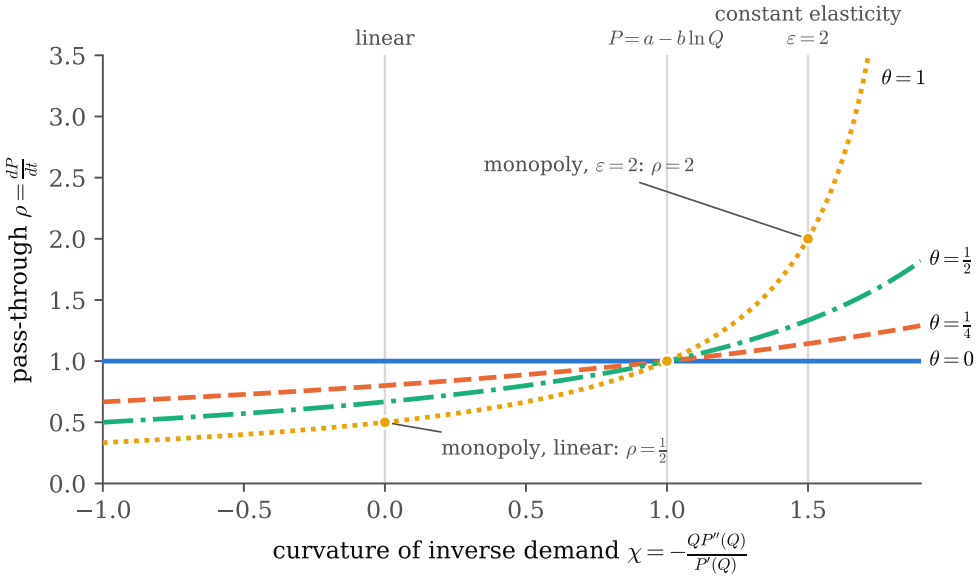

Figure 2.10: Pass-through with flat marginal cost, $\rho = \frac{1}{1+\theta(1-\chi)}$, against the curvature of inverse demand for four values of conduct. All curves cross at $\chi = 1$ (exponential demand), where $\rho = 1$ under every conduct. To the left of $\chi = 1$ market power lowers pass-through. To the right it raises pass-through. The dots mark monopoly with linear demand ($\rho = \frac{1}{2}$), exponential demand ($\rho = 1$) and constant elasticity $\varepsilon = 2$ ($\rho = 2$). The monopoly curve is cut at $\rho = 3.5$.

Proof. (i) is Corollary 2.77(i). (ii) Rearrange (2.65) as $\frac{1}{\rho} = 1-\theta(\chi-1)$. The data enter only through ρ, so only the product $\theta(\chi - 1)$ is identified. Given ρ and $\theta > 0$, the curvature $\chi = 1 + \frac{1}{\theta}\left(1 - \frac{1}{\rho}\right)$ reproduces ρ. This curvature satisfies the stability condition $1 + \theta(1 - \chi) = \frac{1}{\rho} > 0$, and under monopoly it satisfies $\chi < 2$. A value $\rho \leq 1$ is consistent with $\theta = 0$ and rising marginal cost, and with any $\theta > 0$ and $\chi \leq 1$. (iii) Rearrange (2.64). The added term is nonnegative because $\varepsilon \geq \theta$ whenever $P \geq MC + t$. (iv) Constant elasticity has $\chi - 1 = \frac{1}{\varepsilon}$. Substitute into (2.66). □

Part (i) is the robust content of a pass-through test. It needs no assumption on demand, and it needs only that marginal cost does not fall with output. Two caveats apply. The price must be a product price, since a price index can move for reasons of composition (Section 2.8.6). The shifter must also move cost alone, since a tax that shifts demand (for example through cross-border shopping) breaks the derivation. Part (ii) says that a single market-wide cost shock moves the equilibrium along one demand curve, and that this movement cannot separate conduct from curvature. Figure 2.11 draws the set of pairs (χ, θ) consistent with an illustrative pass-through of 1.07. Separating the two requires an assumption on curvature, as in part (iv), or variation that changes the slope of demand at a given price. Chapter 3 develops both routes and applies them to Sumner's cigarette data and to sugar refining.

2.8.4 Firm-specific versus industry-wide cost shocks in Cournot

So far a tax raised every firm's cost together. Many cost shocks hit one firm only: a local wage increase, a plant outage, a merger's cost savings, or an exchange-rate shock to one importer. In a homogeneous-good market all firms charge one price, and the question becomes how much

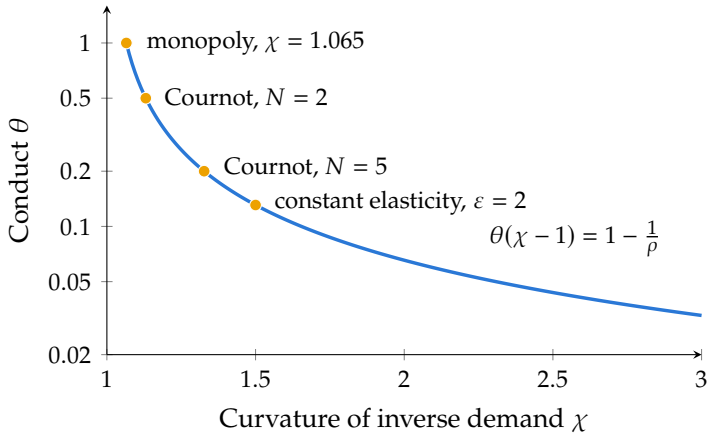

Figure 2.11: Pairs of demand curvature and conduct consistent with an illustrative pass-through $\rho = 1.07$ when marginal cost is flat. Every point on the curve satisfies $\theta(\chi - 1) = 1 - \frac{1}{1.07} \approx 0.065$. Symmetric Cournot with N firms ($\theta = \frac{1}{N}$) fits with $\chi = 1 + 0.065N$. A constant-elasticity demand with elasticity ε has $\chi = 1 + \frac{1}{\varepsilon}$ and fits with $\theta = 0.065\varepsilon$. The vertical axis is logarithmic.

that price responds to one firm's cost.

The linear Cournot model of Example 2.31 gives the answer in closed form. With $P = a - bQ$ and constant costs $c_1, \dots, c_N$,

$$P^* = \frac{a + \sum_j c_j}{N+1}, \qquad q_i^* = \frac{a - (N+1)c_i + \sum_j c_j}{b(N+1)}.$$

A rise in c_i alone and a common rise $\mathrm{d}c_j = \mathrm{d}c$ for all j give

$$\frac{\mathrm{d}P^*}{\mathrm{d}c_i} = \frac{1}{N+1}, \qquad \frac{\mathrm{d}q_i^*}{\mathrm{d}c_i} = -\frac{N}{b(N+1)}, \qquad \frac{\mathrm{d}q_j^*}{\mathrm{d}c_i} = \frac{1}{b(N+1)} \ (j \neq i), \qquad \frac{\mathrm{d}P^*}{\mathrm{d}c} = \frac{N}{N+1}.$$

Firm i's margin $P^* - c_i$ falls by $\frac{N}{N+1}$ per dollar of its own cost increase, so the firm absorbs most of a firm-specific shock. The next result extends these formulas to nonlinear demand.

Proposition 2.79 (Cournot pass-through)**.** *Let (C1) and (C3) of Assumption 2.18 hold with constant marginal costs $c_1, \dots, c_N$, let all N firms be active, and suppose $P'(Q) + q_j P''(Q) < 0$ at the equilibrium for every j (as (C2) guarantees). Let $s_i = \frac{q_i}{Q}$ and let χ be the curvature (2.60) at the equilibrium output. Then $N + 1 - \chi > 0$, and*

$$\frac{\mathrm{d}P}{\mathrm{d}c_i} = \frac{1}{N+1-\chi}, \qquad \frac{\mathrm{d}P}{\mathrm{d}c} = \frac{N}{N+1-\chi}, \qquad \frac{\mathrm{d}q_i}{\mathrm{d}c_i} = \frac{N - (1-s_i)\chi}{P'(Q)\,(N+1-\chi)} < 0, \tag{2.67}$$

where $\frac{\mathrm{d}P}{\mathrm{d}c}$ is the response to a common shock.

Proof. We use the replacement functions of Section 2.4. With constant costs, $\tilde{q}_i(Q)$ solves $P(Q) + qP'(Q) = c_i$, so $\tilde{q}_i(Q) = \frac{c_i - P(Q)}{P'(Q)}$ near the equilibrium. Differentiating $P(Q) + qP'(Q) = c_i$ in c_i at fixed Q gives $\frac{\partial \tilde{q}_i}{\partial c_i} = \frac{1}{P'}$. Differentiating it in Q gives $P' + \tilde{q}_i' P' + \tilde{q}_i P'' = 0$, so

$$\tilde{q}_j'(Q) = -\left(1 + \frac{q_j P''}{P'}\right) = -\left(1 + \frac{q_j}{Q} \cdot \frac{QP''}{P'}\right) = -(1 - s_j\chi).$$

By assumption $P' + q_j P'' < 0$ at the equilibrium. Dividing by $P' < 0$ gives $1 - s_j\chi > 0$ for every j. Summing over j and using $\sum_j s_j = 1$,

$$1 - \sum_j \tilde{q}_j'(Q) = 1 + \sum_j (1 - s_j\chi) = N + 1 - \chi > 0.$$

Industry output solves $\sum_j \tilde{q}_j(Q) = Q$. Since the derivative of $\sum_j \tilde{q}_j(Q) - Q$ in Q is nonzero, the implicit function theorem applies. Differentiating in c_i, as in the proof of Proposition 2.32, gives

$$\frac{\mathrm{d}Q}{\mathrm{d}c_i} = \frac{\frac{\partial \tilde{q}_i}{\partial c_i}}{1 - \sum_j \tilde{q}_j'(Q)}.$$

Hence $\frac{\mathrm{d}Q}{\mathrm{d}c_i} = \frac{1}{P'(N+1-\chi)}$ and $\frac{\mathrm{d}P}{\mathrm{d}c_i} = P'\frac{\mathrm{d}Q}{\mathrm{d}c_i} = \frac{1}{N+1-\chi}$. A common shock is the sum of N firm-specific shocks, so $\frac{\mathrm{d}P}{\mathrm{d}c} = \sum_i \frac{\mathrm{d}P}{\mathrm{d}c_i} = \frac{N}{N+1-\chi}$. For firm i's own output, $q_i = \tilde{q}_i(Q)$ in equilibrium, so

$$\frac{\mathrm{d}q_i}{\mathrm{d}c_i} = \frac{\partial \tilde{q}_i}{\partial c_i} + \tilde{q}_i'(Q)\frac{\mathrm{d}Q}{\mathrm{d}c_i} = \frac{1}{P'}\left[1 - \frac{1 - s_i\chi}{N + 1 - \chi}\right] = \frac{N - (1 - s_i)\chi}{P'(N + 1 - \chi)}.$$

The numerator equals $1 + \sum_{j\neq i}(1 - s_j\chi) > 0$, and $P' < 0$, so $\frac{\mathrm{d}q_i}{\mathrm{d}c_i} < 0$. □

Three features of (2.67) stand out. First, the price response to a firm-specific shock does not depend on the firm's share. A large firm and a small firm move the price by the same amount after equal cost increases. The direct effect on a firm's replacement output, $\frac{1}{P'}$, does not depend on its size, and rivals respond only to total output. Second, the common-shock pass-through equals Corollary 2.77(iv) even with asymmetric costs. Third, the ratio of the two is N for any demand curve. A firm-specific shock moves the market price by only a fraction $\frac{1}{N+1-\chi}$ of the shock, and the firm bears the rest through a lower margin.

The distinction matters for empirical work. A market-wide shifter, such as an excise tax, moves the industry along the market demand curve. Its pass-through speaks to industry conduct and market demand curvature, as in Section 2.8.3. A firm-specific shifter, such as a firm's own input price, moves the equilibrium along the firm's residual demand curve, which includes rivals' supply responses. Baker and Bresnahan (1988) use such shifters to estimate residual demand directly (Chapter 3). The distinction also matters for mergers. The cost savings of a merger are specific to the merged firm, so the relevant pass-through is the firm-specific one. Using an industry-wide rate would overstate how much of the savings reaches consumers (Chapter 11).

2.8.5 Incidence

Pass-through determines who bears a tax. Consumer surplus is $CS = \int_0^Q P(x)\,\mathrm{d}x - P(Q)Q$. Producer surplus is variable profit, $PS = P(Q)Q - C(Q) - tQ$, where C is industry variable cost with $C' = MC$ (as with symmetric firms). Tax revenue is $R = tQ$.

Proposition 2.80 (Incidence under conduct, Weyl and Fabinger, 2013, pp. 546–548)**.** *Under Assumption 2.75, a small change in the specific tax changes surplus by*

$$\frac{\mathrm{d}CS}{\mathrm{d}t} = -\rho Q, \qquad \frac{\mathrm{d}PS}{\mathrm{d}t} = -\big[1 - (1 - \theta)\rho\big]Q.$$

When the producer burden is nonzero, the incidence ratio, *consumer burden divided by producer burden, is*

$$I = \frac{\frac{\mathrm{d}CS}{\mathrm{d}t}}{\frac{\mathrm{d}PS}{\mathrm{d}t}} = \frac{\rho}{1-(1-\theta)\rho}. \tag{2.68}$$

Total surplus $W = CS + PS + R$ *satisfies* $\frac{\mathrm{d}W}{\mathrm{d}t} = -\theta\rho Q + t\frac{\mathrm{d}Q}{\mathrm{d}t}$.

Proof. Consumers. By Leibniz's rule,

$$\frac{\mathrm{d}CS}{\mathrm{d}t} = P(Q)\frac{\mathrm{d}Q}{\mathrm{d}t} - \Big[P'(Q)Q + P(Q)\Big]\frac{\mathrm{d}Q}{\mathrm{d}t} = -QP'(Q)\frac{\mathrm{d}Q}{\mathrm{d}t} = -Q\rho,$$

since $\rho = P'\frac{\mathrm{d}Q}{\mathrm{d}t}$.

Producers. Differentiating PS,

$$\frac{\mathrm{d}PS}{\mathrm{d}t} = P'Q\frac{\mathrm{d}Q}{\mathrm{d}t} + P\frac{\mathrm{d}Q}{\mathrm{d}t} - MC\frac{\mathrm{d}Q}{\mathrm{d}t} - Q - t\frac{\mathrm{d}Q}{\mathrm{d}t} = Q(\rho-1) + (P - MC - t)\frac{\mathrm{d}Q}{\mathrm{d}t}.$$

The supply relation (2.63) gives $P - MC - t = -\theta QP'$, and $\frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{\rho}{P'}$. Hence $(P - MC - t)\frac{\mathrm{d}Q}{\mathrm{d}t} = -\theta QP' \cdot \frac{\rho}{P'} = -\theta\rho Q$, and

$$\frac{\mathrm{d}PS}{\mathrm{d}t} = Q(\rho-1) - \theta\rho Q = -Q\big[1-(1-\theta)\rho\big].$$

Dividing the two derivatives gives (2.68).

Total surplus. Revenue changes by $\frac{\mathrm{d}R}{\mathrm{d}t} = Q + t\frac{\mathrm{d}Q}{\mathrm{d}t}$. Adding the three derivatives,

$$\frac{\mathrm{d}W}{\mathrm{d}t} = -\rho Q - Q + (1-\theta)\rho Q + Q + t\frac{\mathrm{d}Q}{\mathrm{d}t} = -\theta\rho Q + t\frac{\mathrm{d}Q}{\mathrm{d}t}. \qquad \square$$

Weyl and Fabinger (2013, p. 546) credit Atkin and Donaldson (2012) with first deriving the formula for $\frac{\mathrm{d}PS}{\mathrm{d}t}$, which extends the monopoly case to general conduct.

The special cases are instructive. Under price taking, $I = \frac{\rho}{1-\rho}$. With $\rho = \frac{\varepsilon_S}{\varepsilon_S+\varepsilon}$ from Corollary 2.77(i), this is $I = \frac{\varepsilon_S}{\varepsilon}$, the classic rule that the burden falls on the less elastic side. With flat marginal cost, competitive producers bear nothing. Under monopoly, $\frac{\mathrm{d}PS}{\mathrm{d}t} = -Q$ whatever the demand curve, which is the envelope theorem at work (Appendix B), and $I = \rho$. Consumers bear more than the monopolist exactly when $\rho > 1$. With linear demand, flat cost and conduct θ, $\rho = \frac{1}{1+\theta}$ and

$$I = \frac{\frac{1}{1+\theta}}{1-\frac{1-\theta}{1+\theta}} = \frac{\frac{1}{1+\theta}}{\frac{2\theta}{1+\theta}} = \frac{1}{2\theta}.$$

A linear monopoly ($\theta = 1$) puts one third of the private burden on consumers, and a symmetric Cournot duopoly ($\theta = \frac{1}{2}$) splits it equally.

Market power changes incidence in two ways that competitive analysis misses. First, consumers can bear more than the full tax ($\rho > 1$) while producers still lose. With constant elasticity $\varepsilon = 2$, a monopolist passes through $\rho = 2$, consumers lose $2Q$ per unit of tax and the monopolist loses Q. Second, producers can gain from a tax. The producer burden is negative when $\rho > \frac{1}{1-\theta}$. With flat marginal cost this condition reduces to $\theta(2-\chi) < 0$, that is $\chi > 2$ for $\theta > 0$. Monopoly rules this out through its second-order condition, but oligopoly with $\theta < 1$ allows $2 < \chi < 1 + \frac{1}{\theta}$. In symmetric Cournot with constant elasticity,

$$1 - \Big(1 - \frac{1}{N}\Big)\frac{N\varepsilon}{N\varepsilon - 1} = \frac{\varepsilon - 1}{N\varepsilon - 1},$$

which is negative when $\frac{1}{N} < \varepsilon < 1$. A common cost increase then raises industry profit. It pushes output toward the level that maximizes joint profit, which the firms could not reach on their own.

The total-surplus formula adds a third difference. Under competition the first tax dollar has no deadweight cost, because $\frac{\mathrm{d}W}{\mathrm{d}t} = 0$ at $t = 0$ when $\theta = 0$. Under market power the first dollar already costs $\theta\rho Q$, because output starts below its efficient level (Section 2.9). Linear monopoly loses $\frac{Q}{2}$ of surplus per unit of tax at $t = 0$, half of the revenue raised. Weyl and Fabinger (2013, pp. 537 and 546) state that this excess burden is ρ per unit of revenue under monopoly and positive whenever $\theta > 0$. We add the total-surplus formula itself, which also holds at $t > 0$.

Remark 2.81 (Ad valorem taxes). An *ad valorem tax* at rate t_a takes a fraction t_a of the price. Firms receive $(1 - t_a)P$, and the supply relation becomes $(1 - t_a)(P + \theta QP') = MC(Q)$, that is $P + \theta QP' = \frac{MC(Q)}{1-t_a}$. An ad valorem tax therefore scales effective marginal cost by $\frac{1}{1-t_a}$. At $t_a = 0$ a small rate $\mathrm{d}t_a$ raises effective marginal cost by $MC\,\mathrm{d}t_a$, so $\frac{\mathrm{d}P}{\mathrm{d}t_a} = \rho\,MC$. A specific tax $\mathrm{d}t = P\,\mathrm{d}t_a$ raises the same revenue to first order and raises price by $\rho P\,\mathrm{d}t_a$. At $t_a = 0$ the Lerner form gives $MC = (1 - \frac{\theta}{\varepsilon})P$, so the ad valorem tax raises price less per dollar of revenue whenever $\theta > 0$. Under competition the two taxes coincide to first order. The incidence formulas for ad valorem taxes are left to Section 2.13.

2.8.6 Measured prices and composition

Pass-through regressions often use a price index, an average across products, as the dependent variable. The index can move even when no product's price moves, because the mix of products bought changes.

Remark 2.82 (Composition bias). Let the observed price be the quantity-weighted average $\bar{p} = \sum_j w_j p_j$, with weights $w_j \geq 0$ summing to one. Differentiating with respect to the tax,

$$\frac{\mathrm{d}\bar{p}}{\mathrm{d}t} = \underbrace{\sum_j w_j \frac{\mathrm{d}p_j}{\mathrm{d}t}}_{\text{price effect}} + \underbrace{\sum_j p_j \frac{\mathrm{d}w_j}{\mathrm{d}t}}_{\text{composition effect}} . \tag{2.69}$$

The first term is the average of product-level pass-through. The second term is nonzero whenever the tax changes the mix of purchases. A regression of $\bar{p}$ on t estimates the sum.

A specific tax tends to make the composition effect positive. It raises every price by a similar dollar amount, which is a larger percentage of a cheap product's price. Suppose a cheap and an expensive product have prices $p_L < p_H$, and each price rises one for one with the tax. The relative price $\frac{p_H+t}{p_L+t}$ has derivative $\frac{p_L-p_H}{(p_L+t)^2} < 0$ in t, so the expensive product becomes relatively cheaper. If buyers respond to relative prices, the weight w_H rises, and the composition effect $(p_H - p_L)\frac{\mathrm{d}w_H}{\mathrm{d}t}$ is positive. A numerical illustration makes the size concrete. Let $p_L = 1$, $p_H = 2$ and $w_H = 0.5$, and let a tax of 0.10 raise both prices by 0.10 and w_H to 0.52. The index rises from 1.50 to $0.48 \times 1.10 + 0.52 \times 2.10 = 1.62$, so the measured pass-through is 1.2 although each product's pass-through is exactly one.

The bias pushes a test toward rejecting price taking, because it can create $\hat{\rho} > 1$ from product-level pass-through equal to one. The remedies are to estimate pass-through at the product level, or to use a fixed-weight index $\sum_j w_j^0 p_j$ that holds the weights at their pre-tax values. The same logic runs in the opposite direction when demand peaks. Nevo and

Hatzitaskos (2005) study canned tuna, whose average price falls during Lent although demand is high. They argue that a shift of purchases toward cheaper products explains much of the fall in the average price paid. In their supermarket data, the Lent coefficient is −1.78 cents per ounce for the quantity-weighted tuna price index and −0.51 for a fixed-weight index (Nevo and Hatzitaskos, 2005, p. 13 and Table 3). Chapter 3 returns to composition as one of the three standard critiques of Sumner's cigarette-tax test.

Pass-through thus carries information about market power, but only jointly with the curvature of demand and the slope of marginal cost. Pass-through above one is hard to reconcile with price taking. Beyond that, a pass-through estimate must be combined with an assumption or a second source of variation before it reveals conduct. The incidence of taxes, the consumer benefits of cost savings and the price effects of mergers all inherit this dependence on curvature.

2.9 Welfare and the deadweight loss of market power

The previous sections asked how far price exceeds marginal cost and why. This section asks what the gap costs society. A positive correlation between concentration and margins, or an estimated conduct parameter above zero, does not by itself tell us that the losses are large. To answer the normative question we need a measure of welfare, a way to compute it from demand and cost, and a sense of its likely size. We first set up the standard partial-equilibrium apparatus and derive closed forms for linear demand. We then present the Harberger approximation and the debate it started. The section closes with three qualifications: production inefficiency across firms, entry, and the trade-off between market power and cost savings in mergers.

2.9.1 Surplus measures

We work in a single market and use partial-equilibrium welfare analysis.

Assumption 2.83 (Partial-equilibrium welfare)**.**

(W1) Consumers have quasi-linear utility in the good and a numeraire, so market demand has no income effects. The area under the inverse demand curve then measures willingness to pay in units of the numeraire.

(W2) The industry produces output Q at the minimum total variable cost $C(Q)$, with C increasing and convex. Fixed costs are set aside until Section 2.9.5.

(W3) A dollar of consumer surplus and a dollar of profit carry equal social weight.

Assumption (W1) makes the Marshallian consumer surplus an exact money measure of welfare. Without it, the compensating and equivalent variations of Chapter 5 replace the area under the demand curve. Assumption (W3) is the *total-surplus standard*. Antitrust practice often uses a *consumer-surplus standard* instead, which counts only the first term. The distinction matters most for mergers (Chapter 11).

Definition 2.84 (Surplus and deadweight loss)**.** At industry output Q and price $P(Q)$, *consumer*

surplus, *producer surplus* and *total surplus* are

$$CS(Q) = \int_0^Q P(x)\,\mathrm{d}x - P(Q)\,Q, \tag{2.70}$$

$$PS(Q) = P(Q)\,Q - C(Q), \tag{2.71}$$

$$W(Q) = CS(Q) + PS(Q) = \int_0^Q P(x)\,\mathrm{d}x - C(Q). \tag{2.72}$$

Let Q^c maximize W. The *deadweight loss* at output Q is $DWL(Q) = W(Q^c) - W(Q)$.

The price drops out of total surplus because payments from consumers to producers are transfers. Differentiating (2.72) with respect to Q gives

$$W'(Q) = P(Q) - C'(Q), \qquad W''(Q) = P'(Q) - C''(Q) < 0.$$

Total surplus is therefore strictly concave, and it is maximized at the output where $P(Q^c) = C'(Q^c)$. This is the price-taking output, so the first-best benchmark is the competitive outcome. For any $Q < Q^c$, the fundamental theorem of calculus gives

$$DWL(Q) = W(Q^c) - W(Q) = \int_Q^{Q^c} \big[P(x) - C'(x)\big]\,\mathrm{d}x. \tag{2.73}$$

The integrand is the gap between willingness to pay and marginal cost on each unit that market power removes. With constant marginal cost c, the deadweight loss is the area between the demand curve and the horizontal line at c, from Q to Q^c. Producer surplus is then variable profit, $PS = (P - c)\,Q$.

Example 2.85 (The monopoly benchmark)**.** Take the market of Figure 2.1: $P(Q) = 10 - Q$ and $c = 2$. The competitive output solves $10 - Q = 2$, so $Q^c = 8$ and maximal surplus is $W(Q^c) = \tfrac{1}{2} \cdot 8 \cdot 8 = 32$. The monopolist sells $Q^m = 4$ at $p^m = 6$. Consumer surplus is $\tfrac{1}{2} \cdot 4 \cdot 4 = 8$, profit is $(6 - 2) \cdot 4 = 16$, and the deadweight loss is $\tfrac{1}{2}(6 - 2)(8 - 4) = 8$. Consumers keep one quarter of the potential surplus, the monopolist takes one half, and one quarter is destroyed.

Remark 2.86 (An output subsidy restores efficiency). A per-unit subsidy can remove the monopoly distortion (Tirole, 1988, sec. 1.1.1.3). Let consumers pay $p + t$ for each unit on which the firm receives p, so that $t < 0$ is a subsidy. The firm chooses p to maximize $pQ(p + t) - C\big(Q(p + t)\big)$, and its first-order condition is

$$Q(p + t) + Q'(p + t)\big[p - C'(Q)\big] = 0.$$

Write $p_b = p + t$ for the consumer price and substitute $p = p_b - t$:

$$\big[Q(p_b) - t\,Q'(p_b)\big] + Q'(p_b)\big[p_b - C'(Q)\big] = 0.$$

Efficiency requires the consumer price to equal marginal cost at the competitive price p^c. The second bracket then vanishes, so the first must vanish too:

$$t = \frac{Q(p^c)}{Q'(p^c)} < 0, \qquad \frac{t}{p^c} = -\frac{1}{\varepsilon(p^c)}.$$

The subsidy per unit, as a fraction of the competitive price, is the inverse elasticity of demand at that price. In Example 2.85, $p^c = 2$, $Q(p^c) = 8$ and $Q' = -1$, so $t = -8$. The firm receives 10

per unit, consumers pay 2 and buy the efficient 8 units, and total surplus reaches its maximum of 32. The firm's profit of 64 equals the subsidy bill of 64.

The subsidy has few advocates, and Tirole lists the objections. The total-surplus standard gives a dollar of profit the same weight as a dollar of consumer surplus, so it records no cost for the transfer to shareholders. The government must know the elasticity of demand and the firm's marginal cost. The firm gains from overstating the subsidy it needs, and it is reluctant to reveal its costs. Schemes that reward the firm for low prices lead into the theory of regulation, which this chapter does not pursue.

2.9.2 Linear demand with conduct

The conduct parameter of Section 2.7 indexes market power continuously, from price taking ($\theta = 0$) through symmetric Cournot ($\theta = \frac{1}{N}$) to monopoly ($\theta = 1$). With linear demand, every welfare quantity has a closed form in θ.

Proposition 2.87 (Welfare with linear demand and conduct θ)**.** *Let $P(Q) = a - bQ$ with $a > c \geq 0$ and $b > 0$, let marginal cost be constant at c, and let price satisfy the supply relation (2.50) with conduct $\theta \in [0, 1]$. Then*

(i) Equilibrium output and markup are $Q(\theta) = \frac{a-c}{b(1+\theta)}$ and $P(\theta) - c = \frac{\theta(a-c)}{1+\theta}$.

(ii) Maximal total surplus is $W^{\max} = \frac{(a-c)^2}{2b}$.

(iii) Consumer surplus, profit and deadweight loss are the shares $\frac{1}{(1+\theta)^2}$, $\frac{2\theta}{(1+\theta)^2}$ and $\frac{\theta^2}{(1+\theta)^2}$ of $W^{\max}$. In particular

$$DWL(\theta) = \frac{\theta^2 (a-c)^2}{2b(1+\theta)^2}. \tag{2.74}$$

Proof. (i) This repeats part (i) of Example 2.73. The supply relation is $P = c - \theta Q P'(Q)$, and here $P'(Q) = -b$. Substituting the demand curve,

$$\begin{aligned} a - bQ &= c + \theta b Q, \\ a - c &= b(1+\theta)\, Q, \\ Q(\theta) &= \frac{a-c}{b(1+\theta)}. \end{aligned}$$

The markup is $P - c = \theta b Q = \frac{\theta(a-c)}{1+\theta}$.

(ii) The competitive output solves $a - bQ = c$, so $Q^c = \frac{a-c}{b}$. Then

$$W^{\max} = \int_0^{Q^c} (a - bx - c)\, \mathrm{d}x = (a-c)\, Q^c - \frac{b}{2}(Q^c)^2 = \frac{(a-c)^2}{b} - \frac{(a-c)^2}{2b} = \frac{(a-c)^2}{2b}.$$

(iii) Consumer surplus is the triangle above the price,

$$CS = \int_0^{Q} (a - bx)\, \mathrm{d}x - (a - bQ)\, Q = aQ - \frac{b}{2}Q^2 - aQ + bQ^2 = \frac{b}{2}Q^2 = \frac{(a-c)^2}{2b(1+\theta)^2}.$$

Profit is the rectangle

$$\pi = (P - c)\, Q = \frac{\theta(a-c)}{1+\theta} \cdot \frac{a-c}{b(1+\theta)} = \frac{\theta(a-c)^2}{b(1+\theta)^2}.$$

The deadweight loss is the triangle with height $P - c$ and base $Q^c - Q = \frac{a-c}{b}\left(1 - \frac{1}{1+\theta}\right) = \frac{\theta(a-c)}{b(1+\theta)}$, so

$$DWL = \frac{1}{2} \cdot \frac{\theta(a-c)}{1+\theta} \cdot \frac{\theta(a-c)}{b(1+\theta)} = \frac{\theta^2(a-c)^2}{2b(1+\theta)^2}.$$

Dividing each expression by $W^{\max}$ gives the three shares. As a check, the three shares sum to

$$\frac{1 + 2\theta + \theta^2}{(1+\theta)^2} = 1. \qquad \square$$

Corollary 2.88 (Monopoly and Cournot)**.** *Under monopoly ($\theta = 1$) the shares are $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{1}{4}$. Under symmetric Cournot with N firms ($\theta = \frac{1}{N}$), multiplying numerator and denominator by N^2 gives*

$$\frac{CS}{W^{\max}} = \frac{N^2}{(N+1)^2}, \qquad \frac{\pi}{W^{\max}} = \frac{2N}{(N+1)^2}, \qquad \frac{DWL}{W^{\max}} = \frac{1}{(N+1)^2}. \tag{2.75}$$

For every $\theta > 0$ the ratio of deadweight loss to profit is $\frac{DWL}{\pi} = \frac{\theta}{2}$.

Table 2.6: Division of the maximal surplus under linear demand

Market	θ	Consumer surplus	Profit	Deadweight loss	$\frac{DWL}{\pi}$
Price taking	0	1	0	0	n.a.
Cournot, $N = 5$	$\frac{1}{5}$	$\frac{25}{36}$	$\frac{10}{36}$	$\frac{1}{36}$	0.10
Cournot, $N = 4$	$\frac{1}{4}$	$\frac{16}{25}$	$\frac{8}{25}$	$\frac{1}{25}$	0.125
Cournot, $N = 3$	$\frac{1}{3}$	$\frac{9}{16}$	$\frac{6}{16}$	$\frac{1}{16}$	0.17
Cournot, $N = 2$	$\frac{1}{2}$	$\frac{4}{9}$	$\frac{4}{9}$	$\frac{1}{9}$	0.25
Monopoly	1	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{4}$	0.50

Notes: Shares of $W^{\max} = \frac{(a-c)^2}{2b}$ from Proposition 2.87 and Corollary 2.88. The last column is $\frac{\theta}{2}$.

Table 2.6 carries two lessons. First, near competition the transfer to producers is first order in θ, while the deadweight loss is second order. For small θ the profit share is close to 2θ and the loss share is close to θ^2. Second, the deadweight loss falls quickly with the number of Cournot firms. It is $\frac{1}{9}$, or 11.1 percent of maximal surplus, under duopoly and $\frac{1}{36}$, or 2.8 percent, with five firms. With five firms the transfer to producers is ten times the deadweight loss. With linear demand, concern about market power in moderately concentrated markets is therefore largely a concern about distribution, unless market power also raises costs or wastes resources. The rest of this section examines those two channels.

2.9.3 The Harberger approximation

Closed forms need a demand curve. To estimate losses across many industries with little information, Harberger (1954) used a local approximation that needs only revenue, the Lerner index and the elasticity of demand. We derive it in general and then turn to its uses.

Fix an equilibrium with output Q, price $P = P(Q)$ and constant marginal cost $c < P$. Approximate inverse demand between Q and Q^c by its tangent at Q:

$$P(x) \approx P(Q) + P'(Q)(x - Q).$$

The competitive output then solves $P(Q) + P'(Q)(Q^c - Q) = c$, so

$$Q^c - Q \approx \frac{P(Q) - c}{-P'(Q)}.$$

Substituting the tangent into (2.73) and integrating,

$$\begin{aligned} DWL &\approx \int_Q^{Q^c} \left[P(Q) - c + P'(Q)(x - Q)\right] \mathrm{d}x \\ &= (P - c)(Q^c - Q) + \frac{1}{2}P'(Q)(Q^c - Q)^2 \\ &= \frac{(P - c)^2}{-P'(Q)} - \frac{1}{2} \cdot \frac{(P - c)^2}{-P'(Q)} = \frac{1}{2} \cdot \frac{(P - c)^2}{-P'(Q)}. \end{aligned}$$

The market elasticity is $\varepsilon = -\frac{1}{P'(Q)}\frac{P}{Q}$, so $-P'(Q) = \frac{P}{\varepsilon Q}$. With the Lerner index $L = \frac{P-c}{P}$ and revenue $R = PQ$, this gives the *Harberger approximation*

$$DWL \approx \frac{1}{2}(P - c)(Q^c - Q) \approx \frac{1}{2}\varepsilon L^2 R. \tag{2.76}$$

The loss is half the markup times the lost output, and the lost output is approximately εLQ. The loss is proportional to the square of the Lerner index, which is why small markups imply very small losses.

The approximation takes a simple form under any conduct. The supply relation in Lerner form, (2.51), gives $L = \frac{\theta}{\varepsilon}$. Substituting into (2.76) and using profit $\pi = (P - c)Q = LR$,

$$DWL \approx \frac{\theta^2}{2\varepsilon} R = \frac{\theta}{2} LR = \frac{\theta}{2}\pi. \tag{2.77}$$

Under monopoly, $\theta = 1$ and $L = \frac{1}{\varepsilon}$, so $DWL \approx \frac{R}{2\varepsilon} = \frac{1}{2}LR$: the triangle is about half the profit rectangle. For linear demand the tangent is the demand curve, so (2.76) and (2.77) hold exactly. They reproduce Proposition 2.87 and the ratio $\frac{DWL}{\pi} = \frac{\theta}{2}$ of Corollary 2.88.

Remark 2.89 (Accuracy with convex demand). The tangent understates the area under a convex demand curve, so (2.76) understates large losses. Take constant-elasticity demand $Q(p) = Ap^{-\varepsilon}$ with $\varepsilon > 1$ and monopoly pricing, $p^m = \frac{\varepsilon}{\varepsilon - 1}c$. The exact loss is the consumer surplus lost minus the profit gained,

$$DWL = \int_c^{p^m} Ap^{-\varepsilon}\,\mathrm{d}p - (p^m - c)A(p^m)^{-\varepsilon}.$$

Integrating, dividing by revenue $R = A(p^m)^{1-\varepsilon}$ and using $\frac{c}{p^m} = \frac{\varepsilon - 1}{\varepsilon}$,

$$\frac{DWL}{R} = \frac{1}{\varepsilon - 1}\left[\left(\frac{\varepsilon - 1}{\varepsilon}\right)^{1-\varepsilon} - 1\right] - \frac{1}{\varepsilon}.$$

The Harberger approximation gives $\frac{1}{2\varepsilon}$. For $\varepsilon = 2$ the exact loss is $\frac{1}{2}R$, twice the approximation of $\frac{1}{4}R$, and as large as the monopoly profit itself. Our computations give exact to approximate ratios of 2.39, 2.00, 1.75 and 1.60 for $\varepsilon = 1.5, 2, 3$ and 5. The approximation improves as the markup falls, as it should for a second-order expansion.

Remark 2.90 (The deadweight loss need not fall with the elasticity). The Lerner index $\frac{1}{\varepsilon}$ falls as demand becomes more elastic, but the deadweight loss need not (Tirole, 1988, sec. 1.1.1.2). Where demand is inelastic, a high price moves little output and mostly transfers money from consumers to the firm. Take $Q(p) = p^{-\varepsilon}$ with $\varepsilon > 1$ and constant marginal cost c (Tirole, 1988, Exercise 1.1). Maximal surplus is the consumer surplus at price c,

$$W^c = \int_c^\infty p^{-\varepsilon}\,\mathrm{d}p = \frac{c^{1-\varepsilon}}{\varepsilon - 1}.$$

At $p^m = \frac{\varepsilon}{\varepsilon-1}c$, consumer surplus is $\frac{(p^m)^{1-\varepsilon}}{\varepsilon-1}$ and profit is $(p^m - c)(p^m)^{-\varepsilon} = \frac{(p^m)^{1-\varepsilon}}{\varepsilon}$, since $p^m - c = \frac{p^m}{\varepsilon}$. Let $\kappa = \left(\frac{p^m}{c}\right)^{1-\varepsilon} = \left(\frac{\varepsilon-1}{\varepsilon}\right)^{\varepsilon-1}$, a symbol local to this remark. Dividing by W^c,

$$\frac{CS^m}{W^c} = \kappa, \qquad \frac{\pi^m}{W^c} = \frac{\varepsilon - 1}{\varepsilon}\,\kappa, \qquad \frac{DWL}{W^c} = 1 - \frac{2\varepsilon - 1}{\varepsilon}\,\kappa.$$

As $\varepsilon \to 1$, $\kappa \to 1$ and the relative loss tends to zero. As $\varepsilon \to \infty$, $\kappa \to e^{-1}$, so the relative loss tends to $1 - \frac{2}{e} \approx 0.264$ and the profit share to $\frac{1}{e} \approx 0.368$. For $\varepsilon = 1.5, 2, 3$ and 5 the relative loss is 0.230, 0.250, 0.259 and 0.263, and the profit share is 0.192, 0.250, 0.296 and 0.328. Both rise with ε, although the margin falls. The absolute loss also depends on the size of the market, W^c, which changes with ε. With $c = 1$ it falls steadily, from 0.460 at $\varepsilon = 1.5$ to 0.066 at $\varepsilon = 5$. With $c = 0.5$ it falls from 0.651 to 0.500 between $\varepsilon = 1.5$ and 2, and then rises to 1.051 at $\varepsilon = 5$. The loss is therefore not monotonic in the elasticity.

The other extreme shows what a deadweight loss requires (Tirole, 1988, Exercise 1.2). If all consumers have the same valuation $v > c$ for one unit, the monopolist charges v and every consumer buys. Output is efficient and the monopolist takes the whole surplus. A deadweight loss arises only when the monopoly price excludes consumers who value the good above its cost.

Harberger's estimate. Harberger (1954, pp. 79–82) applied (2.76) to each of 73 American manufacturing industries, using their average profit rates for 1924–28. He measured each industry's price distortion by its excess profit as a share of sales. Excess profit, positive or negative, is profit minus what the industry would earn at the average manufacturing rate of return on capital. He assumed a unit elasticity of demand in every industry. With $\varepsilon_k = 1$ and an excess-profit share of sales L_k, the loss in industry k is $\frac{1}{2}L_k^2 R_k$. The aggregate is therefore tiny. For example, an excess margin of 4 percent of sales implies a loss of $\frac{1}{2}(0.04)^2 = 0.0008$, or 0.08 percent of sales. Harberger concluded that the welfare loss from monopoly misallocation was "less than a tenth of a per cent of the national income" (Harberger, 1954, p. 86). The figure suggested that economists were wasting their time on monopoly pricing, and it set off a long controversy about both the data and the method (Tirole, 1988, sec. 1.1.1.2). Tirole notes one reason why it understates the problem. An average over the whole economy includes many fairly competitive industries, so it understates the typical distortion in industries that have market power.

Cowling and Mueller's revision. The unit elasticity is the weakest link. A profit-maximizing firm with positive marginal cost never prices where demand is inelastic (Proposition 2.4), and with a small markup it faces a large elasticity. If the firm behaves as a monopolist on its residual demand, the Lerner rule gives $\varepsilon_k = \frac{1}{L_k}$. Substituting into (2.76),

$$DWL_k \approx \frac{1}{2} \cdot \frac{1}{L_k} \cdot L_k^2 R_k = \frac{1}{2} L_k R_k = \frac{1}{2}\pi_k. \tag{2.78}$$

The ratio of (2.78) to Harberger's $\frac{1}{2}L_k^2 R_k$ is $\frac{1}{L_k}$. With a margin of 10 percent, the loss is ten times larger. Cowling and Mueller (1978) built their estimates on this logic. They set each firm's elasticity to the inverse of its price-cost margin, so each firm's loss is half its monopoly profit (Cowling and Mueller, 1978, eqs. (1) and (4), pp. 728–729). They also counted the costs of rent-seeking, which the next paragraphs discuss. Their estimates are shares of the gross corporate product originating in the firms in their samples. On their own method the loss ranges from 4 to 13 percent for the United States and from 3.9 to 7.2 percent for the United Kingdom (Cowling and Mueller, 1978, pp. 739 and 743). The low ends count only the welfare triangle, and the high ends add advertising and after-tax monopoly profit as rent-seeking costs (Cowling and Mueller, 1978, Table 1, p. 737). Jenny and Weber (1983) also report large losses once rent-seeking costs are counted, and Scherer (1980) is skeptical of these high estimates (Tirole, 1988, sec. 1.1.1.2). As (2.78) shows, the assumed elasticity alone can move the estimate by an order of magnitude, and the treatment of rent-seeking costs adds more.

Rent-seeking: Posner's rectangle. Posner (1975) argued that the profit rectangle can itself be a social cost. Firms spend resources to obtain or keep a monopoly position. Some outlays are strategic, such as research to win a patent, investment in capacity and the erection of barriers to entry. Others are administrative, such as lobbying, advertising aimed at the public and its elected representatives, and legal defense against antitrust charges (Tirole, 1988, sec. 1.3). Tirole derives Posner's conclusion from two axioms.

(i) *Rent dissipation.* Total outlays by the contenders equal the rent. This is the zero-profit condition of free entry into the contest. Entry, or extra spending, continues until each contender's probability of winning times the rent equals its outlay. For example, ten firms may each spend 1 for a 10 percent chance of a rent of 10, so that total outlays equal the rent.

(ii) *Socially wasteful dissipation.* The outlays have no socially valuable by-products.

Under both axioms the whole rectangle is lost, and the social cost of monopoly becomes $DWL + \pi$. In the linear monopoly of Example 2.85 that is $8 + 16 = 24$, three quarters of maximal surplus and three times the triangle. Under the monopoly version of the Harberger approximation it is $\frac{1}{2}LR + LR = \frac{3}{2}LR$.

Mankiw and Whinston (1986) give an equilibrium version of the same mechanism (their Example 2, p. 53). Firms that enter a linear market behave as a cartel, so total output equals the monopoly output for every number of firms. The social optimum has a single firm, which pays the set-up cost once. With free entry, firms enter until the collusive profits are fully dissipated into set-up costs. Mankiw and Whinston note the parallel with Posner. They report that the welfare loss approaches 50 percent of the area between demand and marginal cost as the set-up cost becomes small (their footnote 10). The arithmetic is simple. With $a - c = b = 1$, a single firm generates $W = \frac{3}{8} - F$, while free entry leaves only consumer surplus, $\frac{1}{8}$. The loss is $\frac{1}{4} - F$, which approaches one half of $W^{\max} = \frac{1}{2}$ as $F \to 0$. Rent dissipation also explains why profits can understate the social cost of market power. Where entry or rent-seeking has competed the rents away, accounting profits look normal and a Harberger calculation finds nothing.

Full dissipation is an upper bound, and each axiom can fail (Tirole, 1988, sec. 1.3). Axiom (i) fails for several reasons (Fisher, 1985). A monopoly may be won by luck, as with a fortuitous invention. Contenders may also start on unequal terms. A firm that already holds patents, mineral rights, better information or the advantages of incumbency faces rivals who are less willing to spend, so it keeps part of the rent. In bidding for a franchise, symmetric bidders bid away the whole rent, while the bidder with the highest potential rent keeps some surplus

when bidders differ. Even symmetric or nearly symmetric contenders need not dissipate the whole rent. Axiom (ii) fails when the outlays are transfers or buy something of value. If the government auctions the monopoly position, the payments go to the treasury and are not wasted. When airline fares and entry were regulated in the United States, airlines competed for passengers with lavish service. Passengers valued the service, although many would have traded some of it for lower fares. A rent shared with a union is a transfer from owners to workers. Then the recorded profit understates the rent, and the dissipation costs society nothing unless it changes labor supply. We add one point that is not in Tirole's list. Outlays that improve products or lower costs, such as research in a patent race, have social value. Tirole concludes that only a careful model of the particular rent-seeking game can say what fraction of profit to count as a social cost. The Posner rectangle marks the limit when rent-seeking is pure waste.

X-inefficiency. Leibenstein (1966) argued that firms sheltered from competition do not minimize costs, a shortfall he called *X-inefficiency*. If market power raises unit cost by x above the minimum, the loss includes the rectangle xQ on every unit produced. That rectangle is first order in x, while the Harberger triangle is second order in the markup. A modest amount of slack can therefore rival the allocative loss. Measuring productive efficiency directly requires cost or productivity data, which is one reason later chapters estimate costs from pricing conditions.

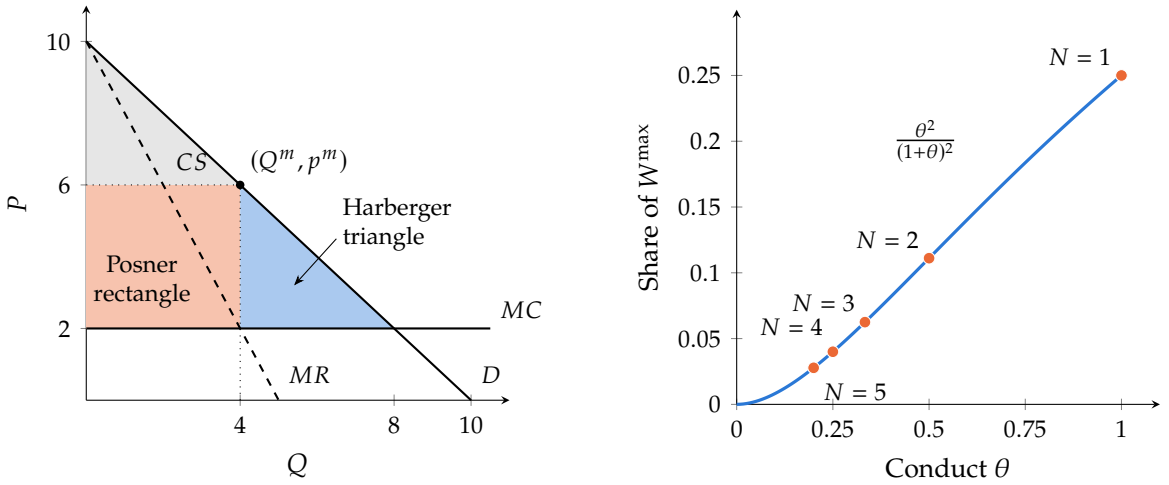
Why should market power in the product market raise the cost of producing a given output? Tirole (1988, sec. 1.2) locates the answer in the *delegation problem* inside the firm. Shareholders want maximal profit, but they cannot perfectly observe the technology or the behavior of managers and workers, who pursue other goals. Slack can therefore arise under any market structure. This undercuts the suggestion of Machlup (1967) that managerial slack can exist only when product markets are imperfectly competitive. What competition adds is a basis for comparison. Shareholders can judge their managers against firms that face similar supply or demand conditions. The excuse that times are hard is less credible when comparable firms do well. Such *yardstick* or tournament schemes do not require product-market competition, since two power plants in separate regions could be compared. Conditions are more correlated within a product market, however, as when Ford managers are rewarded on the performance of General Motors. Yardsticks are therefore more useful in industries with several competitors than in a monopoly.

Hicks (1935) wrote that "the best of all monopoly profits is a quiet life." Tirole calls the remark only half true. The managers of a monopoly may take more slack, but the slack is anticipated when their pay is set. If their participation constraint binds, lower effort is offset by lower rewards, and the managers gain little from the quiet life.

Figure 2.12 summarizes the section so far. The left panel shows the two areas that the debate is about. The right panel plots the deadweight-loss share of Proposition 2.87 against conduct and marks the Cournot values.

2.9.4 Production inefficiency under asymmetric Cournot

Market power distorts how output is divided across firms as well as how much is produced. Cost minimization for a given total Q requires equal marginal costs across active firms. In Cournot equilibrium the first-order condition (2.20) gives $C_i'(q_i) = P + q_i P'(Q)$. Marginal costs therefore differ whenever outputs differ, and larger firms have lower marginal costs. Efficient firms are larger, as Corollary 2.28 shows, but they are not large enough. Assumption (W2) then fails, and total surplus must be computed with the actual cost of the equilibrium allocation.



(a) Monopoly with $P = 10 - Q$ and $c = 2$

(b) Deadweight-loss share against conduct

Figure 2.12: The deadweight loss of market power. In panel (a), the shaded triangle is the Harberger deadweight loss, $\frac{1}{2}(6-2)(8-4) = 8$. The rectangle is monopoly profit, 16, which becomes a social cost under full rent dissipation. Consumer surplus is 8. Panel (b) shows the loss as a share of maximal surplus under linear demand, $\frac{\theta^2}{(1+\theta)^2}$, with the symmetric Cournot values $\theta = \frac{1}{N}$, which equal $\frac{1}{(N+1)^2}$.

The excess of that cost over the minimum $C(Q)$ is a second source of loss, separate from the output restriction in (2.73).

Remark 2.91 (Misallocation in the linear example). Take the market of Example 2.31: $P(Q) = 10 - Q$ and constant costs $c = (1, 2, 3)$. Cournot outputs are $q^* = (3, 2, 1)$, with $Q^* = 6$ and $P^* = 4$. The variable cost of this allocation is $1 \cdot 3 + 2 \cdot 2 + 3 \cdot 1 = 10$. Firm 1 alone could produce the same 6 units at cost 6, so the allocation wastes 4. Total surplus is $\int_0^6 (10 - x)\,\mathrm{d}x - 10 = 42 - 10 = 32$. The first best has firm 1 produce until $P = 1$, so $Q = 9$ and $W = \frac{1}{2} \cdot 9 \cdot 9 = 40.5$. The total loss of 8.5 splits into an output-restriction triangle, $\int_6^9 (9 - x)\,\mathrm{d}x = 4.5$, and the misallocation loss of 4. Production inefficiency is nearly as large as the allocative loss here.

The same example clarifies the efficiency critique of structure-conduct-performance regressions (Chapter 1). Lower firm 1's cost from 1 to 0, holding the rest fixed. Outputs become $(3.75, 1.75, 0.75)$ and the price falls from 4 to 3.75. The Herfindahl index rises from 0.389 to 0.453, and the share-weighted Lerner index rises from 0.583 to 0.755. Total surplus rises from 32 to 37.2, and consumer surplus from 18 to 19.5. Across markets that differ in cost dispersion, concentration and margins move together while welfare rises. A positive cross-section correlation between concentration and margins is therefore not evidence of a welfare loss.

2.9.5 Entry, mergers and the second best

With fixed costs, price equal to marginal cost cannot cover total cost, so the first best is not a feasible benchmark for a market economy. Section 2.5 studied the relevant second best, in which a planner chooses the number of firms but not their conduct after entry. Under business stealing, free entry delivers too many firms (Proposition 2.40). Each entrant counts its own profit, while the planner also subtracts the surplus lost when incumbents contract. In the linear Cournot example, three firms are optimal while seven enter, and the loss is 7.8 percent of

the maximal surplus (Table 2.2). Fixed costs thus change the welfare question. Markups are needed to pay for entry, and the policy issue becomes the number of firms and their conduct as well as the markup.

Market power can also come bundled with cost savings. Williamson (1968) framed this as a trade-off for merger policy. Suppose that before a merger the industry prices at unit cost, $p_0 = c_0$, and sells Q_0. The merger lowers unit cost to $c_1 < c_0$ and raises price to $p_1 > p_0$, so output falls to Q_1. The change in total surplus is the cost saving on the remaining output minus the deadweight triangle,

$$\Delta W = (c_0 - c_1)\,Q_1 - \int_{Q_1}^{Q_0} \big[P(x) - c_0\big]\,\mathrm{d}x \approx (c_0 - c_1)\,Q_1 - \frac{1}{2}(p_1 - p_0)(Q_0 - Q_1). \tag{2.79}$$

To see this, note that consumers lose $(p_1 - p_0)Q_1$ plus the triangle, while profit rises from zero to $(p_1 - c_1)Q_1 = (p_1 - p_0)Q_1 + (c_0 - c_1)Q_1$. The transfer cancels. Write $\Delta_p = \frac{p_1 - p_0}{p_0}$ and $\Delta_c = \frac{c_0 - c_1}{c_0}$. With linear demand of elasticity ε at the pre-merger point, $Q_0 - Q_1 = \varepsilon \Delta_p Q_0$ and $Q_1 = (1 - \varepsilon\Delta_p)Q_0$. Dividing (2.79) by $p_0 Q_0$, total surplus rises if and only if

$$\Delta_c \geq \frac{\varepsilon\,\Delta_p^2}{2(1 - \varepsilon\Delta_p)} \approx \frac{1}{2}\,\varepsilon\,\Delta_p^2. \tag{2.80}$$

The required saving is second order in the price increase. With $\varepsilon = 2$, a 10 percent price increase is offset by a cost saving of 1.25 percent, and a 20 percent increase by 6.7 percent. Williamson questioned the refusal of American courts to accept economies of scale as a defense in horizontal merger cases. He argued that, under reasonable assumptions about the elasticity of demand, a small cost reduction suffices to offset the deadweight loss of a merger's price increase (Tirole, 1988, sec. 1.4). Consumers lose whenever price rises, however, so a consumer-surplus standard rejects every such merger. Chapter 11 develops the trade-off for Cournot and differentiated-products mergers.

2.10 Toward collusion: Stigler's theory and repeated interaction

The conduct parameter summarizes how competitive an industry is, but it does not explain why firms that could earn more by acting together often fail to do so. This section takes up that question. We first show that collusion is not an equilibrium of the one-shot pricing game. We then give a substantive treatment of Stigler (1964), who located the obstacle to collusion in the detection of secret price cuts. The section ends with a preview of the repeated-game models that formalized his ideas, which Chapter 12 develops in full.

2.10.1 The static incentive to cheat

Proposition 2.92 (Collusion is not a static equilibrium)**.** *Let $N \geq 2$ firms with constant marginal cost c face inverse demand $P(Q)$ with $P' < 0$, and let Q^m be the joint-profit-maximizing output, with $P(Q^m) > c$.*

(i) In the Cournot game, at the symmetric collusive profile $q_i = \frac{Q^m}{N}$, each firm's marginal profit is

$$\frac{\partial \pi_i}{\partial q_i} = -\frac{N-1}{N}\,Q^m P'(Q^m) > 0. \tag{2.81}$$

With linear demand $P = a - bQ$ this equals $\frac{(N-1)(a-c)}{2N}$.

(ii) In the homogeneous Bertrand game, suppose all firms charge the monopoly price p^m. A firm that cuts its price to $p^m - \eta$, with $\eta > 0$, earns profit approaching π^m as $\eta \to 0$. This exceeds its collusive share $\frac{\pi^m}{N}$.

Proof. (i) Joint profit $\big(P(Q) - c\big)Q$ is maximized where $P(Q^m) + Q^m P'(Q^m) = c$. Firm i's marginal profit is $P(Q) + q_i P'(Q) - c$. At $q_i = \frac{Q^m}{N}$, substitute c from the joint first-order condition:

$$P(Q^m) + \frac{Q^m}{N} P'(Q^m) - P(Q^m) - Q^m P'(Q^m) = -\frac{N-1}{N} Q^m P'(Q^m) > 0.$$

With linear demand, $-P' = b$ and $Q^m = \frac{a-c}{2b}$, which gives $\frac{(N-1)(a-c)}{2N}$. (ii) The firm that undercuts serves the whole market and earns $(p^m - \eta - c)\, Q(p^m - \eta)$, which tends to π^m by continuity of demand. □

The marginal profit in (2.81) has a clear interpretation. Expanding output lowers the price on all units sold by the industry. The collusive optimum weighs that loss in full, while a single firm bears only the fraction $\frac{1}{N}$ of it. The neglected part, $-Q_{-i}P'(Q)$ with $Q_{-i} = Q - q_i$, is the external effect of one firm's output on its rivals' revenue. Stigler made the same point for secret price cuts. A cut offered to some buyers leaves the price to others unchanged. Marginal revenue on the extra sales is then only slightly below the price and hence above marginal cost (Stigler, 1964, footnote 3). Any theory of successful collusion must therefore explain what stops firms from acting on this incentive.

2.10.2 Stigler's theory of oligopoly

Stigler (1964) accepted the hypothesis that oligopolists wish to collude to maximize joint profits. He asked how that wish can be reconciled with two facts. Collusion is impossible for many firms, and it is much more effective in some circumstances than in others. His answer is that a collusive agreement must be policed, and that policing is a problem in the theory of information. The paper derives a long list of testable implications and offers some evidence. We follow its structure: price structure, methods of collusion, the detection problem, a statistical model of detection, a concentration measure, and the evidence. Later chapters on conduct and collusion refer to this treatment.

Stigler's notation clashes with ours, so we rename three symbols. In his Section II, p is the probability that a rival hears of one price cut, which we call h. In his Section III, p is the probability that an old buyer repeats his purchase with the same seller, which we call ϕ. His auxiliary ratio θ has nothing to do with conduct, and we call it τ. Table numbers are those of the original article.

Two-sided homogeneity and the collusive price structure

Stigler begins by questioning the usual notion of a homogeneous product. Homogeneity is defined by buyers' indifference between the products of different sellers. Yet transactions have two sides. Two purchase commitments are homogeneous to a seller only if he is indifferent between them at a common price. Buyers differ in the size of their purchases, which affects the cost of serving them, and in the urgency of purchase, which affects their demand elasticity. Full homogeneity therefore requires homogeneity of both products and buyers, and it rarely holds.

The heterogeneity of buyers matters for collusion because a profit-maximizing cartel needs a price structure, with prices tailored to classes of transactions. The colluding firms must agree

on how many price classes to recognize, weighing the gains from tailoring against the costs. A complex price structure is harder to agree on and harder to police.

Stigler's appendix shows the cost of ignoring buyer differences with a deliberately absurd example. A monopolist makes men's suits in one size only, so a buyer must pay an alteration cost ℓ to wear one. Let demand for suits that fit be linear, $Q(p) = A - Bp$, and let marginal cost be constant at c. A buyer facing price p pays $p + \ell$, so effective demand is $Q(p + \ell)$. The first-order condition for the price p received by the monopolist is

$$A - B(p + \ell) - B(p - c) = 0 \quad \Longrightarrow \quad p = \frac{1}{2}\left(\frac{A}{B} + c\right) - \frac{\ell}{2} = p^m - \frac{\ell}{2},$$

where p^m is the monopoly price for suits that fit. The alteration cost acts like an excise tax that the monopolist does not collect. The price received falls by $\frac{\ell}{2}$ and output falls by $\frac{B\ell}{2}$. For linear demand $q^m = B(p^m - c)$, so profit falls from $B(p^m - c)^2$ to $B\left(p^m - c - \frac{\ell}{2}\right)^2$. To first order, the relative decline is

$$\frac{\Delta\pi}{\pi} \approx \frac{\ell}{p^m - c} = \frac{\varepsilon\,\ell}{p^m},$$

using the Lerner rule $p^m - c = \frac{p^m}{\varepsilon}$. The loss is proportional to the alteration cost relative to price, multiplied by the elasticity. Stigler's illustration uses $\varepsilon = 5$ and $\frac{\ell}{p} = \frac{1}{40}$, which gives $\frac{5}{40} = 0.125$, a profit loss of about 12 percent. (The exact relative loss is $1 - (1 - 0.0625)^2 = 0.121$.) A monopolist or cartel that ignores the diversity of its buyers therefore leaves substantial profits on the table.

Methods of collusion and the policing problem

Collusion can take several forms. The most comprehensive is outright merger, which may be blocked by diseconomies of scale or by law. Next is a cartel with a joint sales agency, which is ill suited to custom work and costly to administer. Stigler assumes the remaining form: ostensibly independent firms jointly determine outputs and prices. He ignores the legal prohibition at first and brings it back when he ranks enforcement methods.

Once a price structure is agreed, any member who can violate it secretly earns more than by conforming. Stigler takes as an axiom that agreements whose violation would be profitable must be enforced. Enforcement consists of detecting significant deviations. Once detected, a deviation tends to disappear, because rivals will match it if it is not withdrawn. If detection is slow and incomplete, the conspiracy must either keep prices close to the competitive level, which weakens the incentive to cut, or restrict itself to markets where enforcement is efficient.

Stigler ranks the enforcement devices. Fixing market shares is probably the most efficient. If firm i is held to a fixed share s_i of industry output, its sales are $q_i = s_i Q(p)$. Its demand then has the same elasticity as industry demand at every price, so it gains nothing by cutting below the joint-profit-maximizing price (Stigler, 1964, footnote 4). With inspection of output and a formula that redistributes gains and losses from departures from quotas, the incentive to cut prices secretly disappears. Legal cartels use this method widely. Unfortunately for conspirators, it is easy to detect, since it may require side payments and leaves traces in output records.

Assigning each buyer to a single seller is almost as efficient. Short-run price cutting then has no purpose. Two problems remain. Long-run price cutting can still pay when buyers compete with each other and the seller supplies a major part of their costs. And the fortunes of sellers diverge as their assigned buyers grow or shrink at different rates. The resulting changes

in relative outputs violate the cost-minimizing condition of equal marginal costs (Stigler, 1964, footnote 5). With high buyer turnover the method is impracticable. Geographic division of markets is the common form of buyer assignment, and it is an obvious violation of the Sherman Act.

With these two devices excluded by antitrust law, policing requires an audit of transaction prices. Inspecting sellers' books gives only limited assurance. Ultimately, Stigler argues, there is no substitute for obtaining transaction prices from the buyers.

The arithmetic of detection. A seller will not offer secret cuts to buyers who are small relative to its total sales, because news of the cuts spreads. Suppose each buyer who receives a cut tells some rival with probability h, independently across buyers. The probability that rivals learn of at least one cut given to n buyers is

$$\mathbb{P}(\text{detection}) = 1 - (1 - h)^n. \tag{2.82}$$

Stigler's example takes $h = 0.01$. Then $(0.99)^{100} = 0.366$, so the detection probability is 0.634 for $n = 100$, and it is 0.99996 for $n = 1{,}000$. Inverting (2.82), a seller that wants to keep the detection probability below a level $\bar{d}$ can approach at most $\bar{n} = \frac{\ln(1-\bar{d})}{\ln(1-h)}$ buyers. With $h = 0.01$ and $\bar{d} = \frac{1}{2}$, this gives $\bar{n} \approx 68.97$, so at most 68 buyers. Panel (a) of Figure 2.13 plots (2.82). Secret cuts are therefore confined to buyers who are large relative to the seller.

This logic yields Stigler's *first prediction*: collusion is often effective against small buyers even where it fails against large ones. Sellers adhere to the agreed price for small retailers while cutting prices to chain stores and industrial buyers. Stigler then excludes small buyers from the analysis.

Detection is as hard as interested parties can make it. The price cutter protests his innocence or blames a subordinate. The cut may take the form of a change in some nonprice term of the sale. Buyers may report cuts in order to have them matched, and they may invent offers to test rivals. In Stigler's words, policing the collusion "sounds very much like the subtle and complex problem presented in a good detective story." The difference is that the murderer of the collusive price receives the bequest of patronage. The basic evidence of price cutting is that the cutter gains business he would otherwise not obtain. Stigler accordingly calls collusion perfect, in his sense, when no buyer changes sellers voluntarily.

Two further predictions follow. The *second prediction* is that collusion is more effective against buyers who report the prices offered to them correctly and fully. The leading example is a government purchasing through sealed bids that are opened publicly. The *third prediction* is that collusion is severely limited when the significant buyers constantly change identity. Construction is the leading case, since a plant or office building is a nonrepetitive purchase. Rivals then cannot tell whether a successful bidder cut prices, unless bidding is open and to specification. Most markets combine stable relationships with some turnover, and detection becomes a matter of statistical inference.

A statistical model of detection

Stigler's Section III formalizes the inference problem. The model rests on the following assumptions.

(S1) There are n_s sellers and n_o *old buyers*, all of equal size. Buyers who take less than about 0.33 percent of a seller's output are excluded, so the number of buyers per seller ranges from about 10 to 300.

(S2) In the absence of price cutting, each old buyer returns to his regular supplier with probability ϕ, independently of other buyers. A buyer who leaves chooses among the other $n_s - 1$ sellers with equal probability.

(S3) There are also $n_n = \lambda n_o$ *new buyers* per period, each equally likely to buy from any seller.

(S4) Each seller observes only its own sales. It infers price cutting by a rival when its sales pattern would be improbable under random switching alone.

A seller has three sources of evidence: losses of its own old customers, gains of old customers from rivals, and sales to new buyers. By symmetry, these are also the three groups to which a price cutter can direct secret cuts. Stigler derives one criterion for each.

Criterion I: poaching a rival's old customers. Seller i has $\frac{n_o}{n_s}$ old customers on average. The number who return is binomial with mean $\phi\frac{n_o}{n_s}$ and variance $\sigma_1^2 = \phi(1-\phi)\frac{n_o}{n_s}$. The number lost has mean $(1-\phi)\frac{n_o}{n_s}$ and the same variance. Seller i suspects price cutting when its losses exceed their mean by one standard deviation. The threshold loss is

$$(1-\phi)\frac{n_o}{n_s} + \sigma_1 = (1-\phi)\frac{n_o}{n_s}\left[1 + \frac{\sqrt{\phi(1-\phi)\frac{n_o}{n_s}}}{(1-\phi)\frac{n_o}{n_s}}\right] = (1-\phi)\frac{n_o}{n_s}(1+\tau), \qquad \tau \equiv \sqrt{\frac{\phi}{1-\phi}\cdot\frac{n_s}{n_o}}.$$

Each lost customer goes to a given rival with probability $\frac{1}{n_s-1}$. Given the threshold loss, the number a particular rival receives is binomial with mean and variance

$$m_2 = \frac{(1-\phi)\,n_o\,(1+\tau)}{n_s(n_s-1)}, \qquad \sigma_2^2 = \frac{n_s-2}{(n_s-1)^2}\cdot\frac{(1-\phi)\,n_o\,(1+\tau)}{n_s}.$$

The rival is suspected if it gains more than $m_2 + \sigma_2$ customers. Stigler puts the probability of a larger number at about 30 percent, and the joint probability of both one-standard-deviation events at about 10 percent. Without price cutting, the rival would receive $\frac{(1-\phi)\,n_o}{n_s(n_s-1)}$ of seller i's customers on average. The largest undetected gain is the excess of $m_2 + \sigma_2$ over this number:

$$m_2 + \sigma_2 - \frac{(1-\phi)\,n_o}{n_s(n_s-1)} = \frac{\tau(1-\phi)\,n_o}{n_s(n_s-1)} + \sigma_2.$$

Divide by the rival's average sales $\frac{n_o}{n_s}$. Since $\sigma_2\frac{n_s}{n_o} = \frac{1}{n_s-1}\sqrt{\frac{n_s(n_s-2)(1-\phi)(1+\tau)}{n_o}}$, we obtain Stigler's *Criterion I*,

$$G_{\mathrm{I}}(\phi, n_o, n_s) = \frac{1}{n_s-1}\left[\tau(1-\phi) + \sqrt{\frac{n_s(n_s-2)(1-\phi)(1+\tau)}{n_o}}\right]. \tag{2.83}$$

G_{I} is the largest share of its average sales that a price cutter can take from any one rival without being detected. Since the profit from secret cutting depends on the business it brings in, Stigler reads G_{I} as a measure of the incentive to cut prices.

Table 2.7 reproduces part of Stigler's Table 1, and panel (b) of Figure 2.13 plots one block of it. Stigler notes three features.

(a) The gain from any one rival is not very sensitive to the number of rivals, given the number of buyers and the repeat probability. With $\phi = 0.90$ and $n_o = 100$, it varies only between 5.4 and 6.0 percent for n_s from 3 to 20. The total incentive to cut prices is the sum over rivals, so it rises roughly in proportion to the number of rivals. With 10 sellers it is about $9 \times 5.4 = 48.6$ percent.

Table 2.7: Stigler's Criterion I: largest undetected gain from one rival (percent of average sales)

		Number of sellers n_s					
Repeat probability ϕ	Old buyers n_o	2	3	4	5	10	20
0.95	20	6.9	11.3	11.3	11.4	11.8	12.7
	50	4.4	6.6	6.5	6.4	6.5	6.8
	100	3.1	4.4	4.3	4.3	4.2	4.4
	400	1.5	2.1	2.0	1.9	1.8	1.8
0.90	20	9.5	14.8	14.7	14.6	14.8	15.7
	50	6.0	8.8	8.6	8.4	8.3	8.6
	100	4.2	6.0	5.8	5.6	5.4	5.5
	400	2.1	2.8	2.7	2.6	2.4	2.4
0.80	20	12.6	19.3	18.9	18.7	18.6	19.4
	50	8.0	11.6	11.2	11.0	10.6	10.8
	100	5.7	8.0	7.7	7.4	7.1	7.1
	400	2.8	3.8	3.6	3.5	3.2	3.2
0.70	20	14.5	22.3	21.8	21.5	21.2	21.9
	50	9.2	13.5	13.1	12.8	12.3	12.4
	100	6.5	9.3	9.0	8.7	8.2	8.2
	400	3.2	4.5	4.3	4.2	3.8	3.7

Notes: Selected rows of Stigler (1964), Table 1, which also reports $n_o = 30, 40, 200$. Entries are $100\, G_{\mathrm{I}}$ from (2.83), with n_o the total number of old buyers in the market. We recomputed all 168 printed cells of Table 1 from the formula. Every cell agrees with the printed value to within 0.06, which is rounding.

(b) The incentive falls as the number of buyers rises, roughly in inverse proportion to the square root of the number of buyers. In (2.83), $\tau \to 0$ as n_o grows with n_s fixed, and both terms are then proportional to $n_o^{-\frac{1}{2}}$. With $\phi = 0.95$ and five sellers, quadrupling n_o from 100 to 400 lowers the gain from 4.3 to 1.9 percent.

(c) The incentive rises as the repeat probability falls, at a decreasing rate. With $n_o = 50$ and five sellers, the gain is 6.4, 8.4, 11.0 and 12.8 percent for $\phi = 0.95, 0.90, 0.80$ and 0.70.

Feature (c) has an implication for buyers. Shifting patronage among sellers makes secret cuts harder to detect and so encourages them. Table 1 shows diminishing returns to such shifting. Stigler notes that a fuller model would let buyers choose ϕ by weighing this gain against the costs of switching. Large buyers have the most to gain, because their shifts are most likely to induce price cutting.

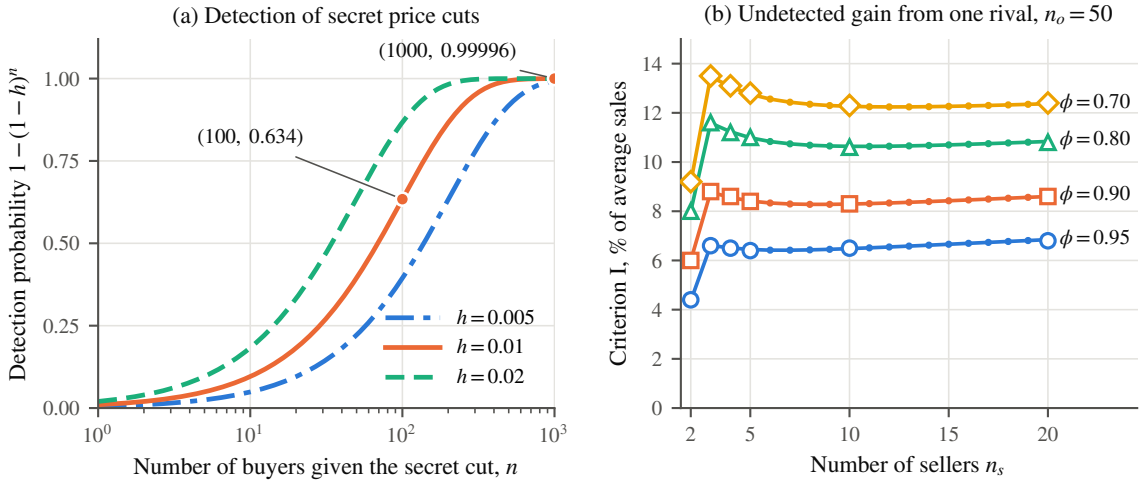


Figure 2.13: Detection of secret price cutting. Panel (a) plots the probability that rivals hear of at least one secret cut given to n buyers, $1-(1-h)^n$, where h is the probability that one cut is reported. The marked points are Stigler's examples for $h = 0.01$. Panel (b) plots Stigler's Criterion I, (2.83), for $n_o = 50$ old buyers and four repeat probabilities ϕ. Small dots are the formula at each integer n_s, and open markers are the printed entries of Stigler (1964), Table 1. They coincide up to rounding.

Criterion II: retaining one's own old customers. A price cutter can also use secret cuts to keep more of its own old customers than usual. Without price cutting, seller i loses on average $(1-\phi)\frac{n_o}{n_s}$ old customers, with variance σ_1^2. A single rival has little basis for judging whether it receives a fair share of these. Stigler therefore assumes that the rivals pool their information and suspect price cutting if seller i loses fewer than $(1-\phi)\frac{n_o}{n_s} - 2\sigma_1$ customers, a 5 percent probability level. The cutter can then retain at most $2\sigma_1$ extra old customers. As a share of its average sales, this is *Criterion II*,

$$G_{\text{II}}(\phi, n_o, n_s) = \frac{2\sigma_1}{\frac{n_o}{n_s}} = 2\sqrt{\phi(1-\phi)\,\frac{n_s}{n_o}}. \tag{2.84}$$

It depends on the market only through the number of old customers per seller. Panel A of Table 2.8 reproduces part of Stigler's Table 2.

Comparing the two criteria shows that a price cutter is easier to detect through its gains from any one rival than through an unusual rate of repeat sales. With $\phi = 0.95$ and 10 old customers per seller, Criterion II allows 13.8 percent. Table 1 gives the corresponding entries for one rival. They are 6.9 (2 sellers and 20 buyers), 8.9 (3 and 30), 7.4 (4 and 40), 6.4 (5 and 50) and 4.2 (10 and 100). Stigler adds two qualifications (Stigler, 1964, footnote 9). Multiplying the Table 1 entries by $n_s - 1$ gives the gain from all rivals together, which exceeds 13.8 percent beyond two sellers. And Table 1 uses a looser probability level, so strict comparability would lower the Table 2 entries by one fifth. Stigler concludes that Criterion II will seldom be useful.

Criterion III: new buyers. New buyers form a flow rather than a stock, and Stigler takes the annual flow relative to old buyers as the unit. Without price cutting, seller i expects to sell to $m_3 = \frac{\lambda n_o}{n_s}$ new buyers, with binomial variance $\sigma_3^2 = \left(1 - \frac{1}{n_s}\right)\frac{\lambda n_o}{n_s}$. Rivals cannot police this margin without pooling information. With pooling, the seller is deemed a price cutter if it wins more than $m_3 + 2\sigma_3$ new buyers, again a 5 percent level. Its total sales are $\frac{n_o(1+\lambda)}{n_s}$ on average, so the largest undetected gain as a share of sales is *Criterion III*,

$$G_{\text{III}}(\lambda, n_o, n_s) = \frac{2\sigma_3}{\frac{n_o(1+\lambda)}{n_s}} = \frac{2}{1+\lambda}\sqrt{\frac{(n_s - 1)\,\lambda}{n_o}}, \tag{2.85}$$

where the second equality uses $\sigma_3 \frac{n_s}{n_o} = \sqrt{\frac{(n_s-1)\lambda}{n_o}}$.

Panel B of Table 2.8 reproduces part of Stigler's Table 3. The incentive to cut prices to new buyers rises rapidly with the number of sellers, in proportion to $\sqrt{n_s - 1}$ for a given total of buyers. It rises slowly when buyers per seller are held fixed. With $\lambda = \frac{1}{10}$ and 10 buyers per seller, it is 12.9 percent with 2 sellers and 17.7 percent with 20. It also rises with the rate of entry of new buyers and falls with the absolute number of buyers. When new buyers arrive at 10 percent per year or more, secret cuts aimed at them allow larger undetected gains than poaching old customers from rivals. With $\phi = 0.90$, 100 old buyers and 10 sellers, Criterion I allows 5.4 percent from each rival, while Criterion III with $\lambda = \frac{1}{10}$ allows 17.2 percent in total. Markets with rapid entry of new buyers are therefore hard to cartelize.

Pooling of information and unequal firm sizes. With more than two sellers, firms can pool information and detect smaller deviations. The average number of old customers that one cutter can take from T rivals that pool information is at most $\frac{T(1-\phi)\,n_o}{n_s(n_s-T)}\left(1 + \frac{\tau}{\sqrt{T}}\right)$, with a correspondingly scaled variance. For $T = 1$ this is m_2. Both are smaller, relative to the customers lost by each pooling firm, than the corresponding expressions for one seller. Pooling has limits. It becomes expensive as the pool grows, and it produces less reliable information, because a member of the pool may itself be cutting prices.

Pooling by K firms is equivalent to a single firm K times as large as the others. Stigler's *Criterion IV* gives the gain of a small firm against such a large rival. It is measured as a percentage of the small firm's average number of old customers, with n_s counted in small-firm units:

$$G_{\text{IV}} = \frac{1}{n_s - K}\left[\tau(1-\phi)\sqrt{K} + \sqrt{\frac{n_s K(1-\phi)(n_s - K - 1)\left(1 + \frac{\tau}{\sqrt{K}}\right)}{n_o}}\right]. \tag{2.86}$$

For $K = 1$ it reduces to Criterion I. Compare Tables 1 and 4 for 100 customers, 10 firms and $\phi = 0.9$. A firm can take 5.4 percent of its sales from one rival, or about 50 percent from all nine. If the nine rivals combine, Table 4 caps its gain at 28.5 percent. In a second example with 20

Table 2.8: Stigler's Criteria II, III and IV (percent of average sales)

Panel A. Criterion II: old customers a price cutter can retain (Table 2)

	Old customers per seller $\frac{n_o}{n_s}$			
Repeat probability ϕ	10	20	50	100
0.95	13.8	9.7	6.2	4.4
0.90	19.0	13.4	8.5	6.0
0.80	25.3	17.9	11.3	8.0
0.70	29.0	20.5	13.0	9.2
0.50	31.6	22.4	14.1	10.0

Panel B. Criterion III: additional new customers obtainable (Table 3)

		Number of sellers n_s					
New-buyer rate λ	Old buyers n_o	2	3	4	5	10	20
$\frac{1}{100}$	20	4.4	6.3	7.7	8.9	13.3	19.3
	100	2.0	2.8	3.4	4.0	5.9	8.6
	400	1.0	1.4	1.7	2.0	3.0	4.3
$\frac{1}{10}$	20	12.9	18.2	22.3	25.7	38.6	56.0
	100	5.8	8.1	10.0	11.5	17.2	25.1
	400	2.9	4.1	5.0	5.8	8.6	12.5
$\frac{1}{4}$	20	17.9	25.3	31.0	35.8	53.7	78.0
	100	8.0	11.3	13.9	16.0	24.0	34.9
	400	4.0	5.7	6.9	8.0	12.0	17.4

Panel C. Criterion IV: gain of a small firm against a large one, $\phi = 0.9$ (Table 4)

		Size of large firm K			
Firms $n_s - K + 1$	Buyers per small seller	1	2	5	9
2	10	9.5	13.4	21.2	28.5
2	50	4.2	6.0	9.5	12.7
4	10	9.7	13.1	19.7	25.7
10	10	5.4	7.2	10.7	14.0
10	50	2.2	2.9	4.5	5.9

Notes: Selected cells of Stigler (1964), Tables 2 to 4. Panel A uses (2.84), Panel B uses (2.85) and Panel C uses (2.86). We recomputed every printed cell of the three tables. All agree to within 0.06 except one cell of Table 4 ($\phi = 0.9$, four firms, 50 buyers per small seller, $K = 1$). It is printed as 4.0, while the formula gives 3.93 and the matching Table 1 cell is 3.9. In Panel C, n_s counts sellers in units of the small firm, so a firm of size K counts as K sellers.

firms and 200 customers, the gain from nine rivals falls from about 30 percent to 14.0 percent when they merge. Pooling information thus substantially reduces the scope for secret price cutting. Stigler notes that Table 4 exaggerates the effect of size inequality. Only buyers above some size relative to the seller are worth secret cuts, and a small firm can profitably cut prices to buyers too small to interest a large seller.

Repetition over time. What may be chance in a single round cannot equally be chance if repeated. Over T rounds, the mean loss to a rival grows in proportion to T, while its standard deviation grows in proportion to $\sqrt{T}$. The threshold loss over T rounds is therefore $\frac{T(1-\phi)}{n_s-1} \cdot \frac{n_o}{n_s}\left(1 + \frac{\tau}{\sqrt{T}}\right)$. The tolerated excess, relative to the mean, falls only as $\frac{1}{\sqrt{T}}$. Stigler concludes that this source of information has minor efficacy unless buyers purchase, or sign contracts, frequently.

Concentration and the Herfindahl index

The model implies a measure of concentration suited to collusion. Suppose each new buyer picks firm i with probability equal to its output share s_i. Firm i's number of new customers is then binomial with variance $n_n s_i(1 - s_i)$. Summing over firms gives the total sampling noise against which price cutting must be detected,

$$\sum_i n_n s_i(1 - s_i) = n_n\left(\sum_i s_i - \sum_i s_i^2\right) = n_n(1 - HHI). \tag{2.87}$$

The noise falls as the Herfindahl index rises. A similar argument applies to old customers (Stigler, 1964, footnote 12). Firm j gains on average $(1 - \phi)n_o \frac{s_i s_j}{1-s_i}$ of the old customers lost by firm i, with variance $(1 - \phi)n_o \frac{s_i s_j}{1-s_i}\left(1 - \frac{s_j}{1-s_i}\right)$. Summing over $i \neq j$ gives approximately $(1-\phi)n_o s_j(1+HHI-2s_j)$. Summing over j gives $(1-\phi)n_o(1+HHI-2HHI) = (1-\phi)n_o(1-HHI)$. Stigler warns that the agreement of the two measures is superficial, because the first assumes pooling of information and the second does not.

This gives a second foundation for the Herfindahl index, alongside the Cournot identity $\bar{L} = \frac{HHI}{\varepsilon}$ of Proposition 2.26. The two arguments differ in kind. In Cournot, a higher *HHI* raises margins under fixed noncooperative conduct. In Stigler's model, a higher *HHI* makes collusion easier to police, so conduct itself changes. Both make the Herfindahl index more informative than a four-firm ratio.

The analysis extends to nonprice competition with two modifications. There must be a definite joint profit-maximizing policy to agree on, which is clearer for some variables than others. And nonprice moves differ in detectability. Advertising, product quality and servicing leave visible traces, while reciprocal purchasing and patent licensing do not. Collusion should suppress competition in the visible dimensions and leave it alive in the hidden ones. The common belief that nonprice competition is more prevalent than price competition is therefore only partly consistent with the theory.

The model's predictions can be collected. Collusion is easier to sustain when there are fewer sellers and when buyers are fewer and larger relative to sellers. It is easier when buyers are loyal (ϕ high) and new buyers arrive slowly (λ low). It is also easier when sellers are unequal in size or pool information, when buyers report prices, and when transactions are homogeneous enough for a simple price structure.

Evidence

Stigler's Section IV offers what he calls fragments of evidence. Two studies of the effect of the number of sellers on price come first. He notes that, as far as he knows, no systematic analysis of this effect had been made before.

Newspapers and radio. The first study concerns newspaper advertising rates in 53 cities in 1939. The rate per line per million circulation, called the milline rate R, falls with circulation z. Stigler therefore first regresses

$$\log R = 5.194 - \underset{(0.620)}{1.688}\,\log z + \underset{(0.063)}{0.139}\,(\log z)^2$$

He then tabulates the residuals by the number of evening papers in the city (Panel A of Table 2.9). The mean residual is 0.0211 in one-paper cities and −0.0213 in two-paper cities. Stigler reads this as rates about 5 percent above average in one-paper towns and 5 percent below in two-paper towns. That reading matches base-10 logarithms, since $10^{0.0211} = 1.050$, while $e^{0.0211} = 1.021$. Stigler adds that one-paper cities with an independent morning paper fall nearly midway between the two groups, although their tabulated mean residual (−0.0174) lies close to the two-paper mean. Few cities had more than two evening papers, so larger numbers of firms could not be studied. The subgroup means are internally consistent: $\frac{10(-0.0174)+13(0.0507)}{23} = 0.0211$.

The second study regresses the logarithm of AM radio spot rates on station characteristics for 345 stations in Ohio, Indiana, Michigan and Illinois in 1961 (Panel B of Table 2.9). The elasticity of the rate with respect to the number of stations in the county is −0.074, with a standard error of 0.046. The number of stations ranges from 1 to 13 and is highly correlated with county population ($r^2 = 0.796$ in logarithms), which the regression controls for. Both studies suggest that prices respond little to the number of rivals. Stigler finds this consistent with his model, in which the number of buyers, the share of new buyers and the relative sizes of firms matter as much as the number of sellers.

Profitability and concentration. The direct test of the theory relates profitability to concentration across industries. Stigler restricts the sample to 17 industries in which the sampled firms account for at least 35 percent of industry sales and earn at least half of their revenue in the industry. Large steel and chemical firms, for example, operate in many markets and are excluded. Table 2.10 reproduces his Table 7. Concentration in 1954 is measured by the four-firm share and by the Herfindahl index. Profitability over 1953–57 is measured by the rate of return on all assets, the rate of return on net worth, and the ratio of market to book value of common stock.

All six rank correlations are positive. The Herfindahl index correlates more strongly with each profitability measure than the four-firm share does, as the variance argument of (2.87) suggests. Stigler reads the data as showing no relation between profitability and concentration when *HHI* is below 0.250 or the four-firm share is below about 80 percent. Our computations from Table 7 agree. Among the ten industries with $HHI < 0.250$, the Spearman correlations of *HHI* with the three profitability measures are −0.03, 0.18 and 0.11. The seven industries above the threshold earn on average 11.8 percent on assets, against 7.3 percent below it. Stigler is careful about what this shows. The data, like those on advertising rates, "confirm our theory only in the sense that they support theories which assert that competition increases with number of firms."

Price cutting in steel. The last piece of evidence uses prices paid by buyers of steel products in the second quarter of 1939, measured relative to quoted prices. Table 2.11 reproduces Stigler's

Table 2.9: Number of sellers and prices in Stigler (1964)

Panel A. Residuals from the regression of newspaper advertising rates on circulation, 1939 (Table 5)

Evening papers in city	Cities	Mean residual	Standard deviation of mean
One	23	0.0211	0.0210
With morning paper	10	−0.0174	0.0324
Without morning paper	13	0.0507	0.0233
Two	30	−0.0213	0.0135

Panel B. Regression of log AM spot commercial rates, 1961, $n = 345$ (Table 6)

Regressor	Coefficient	Standard error
Log population of county, 1960	0.238	0.026
Log kilowatt power of station	0.206	0.015
Broadcast period: sunrise to sunset	−0.114	0.025
Broadcast period: longer, under 18 hours	−0.086	0.027
Broadcast period: 18 to 21 hours	−0.053	0.028
Log number of stations in county	−0.074	0.046
R^2	0.743	

Notes: From Stigler (1964), Tables 5 and 6. Panel A: residuals, in logarithms, from $\log R = 5.194 - 1.688 \log z + 0.139(\log z)^2$, where R is the milline rate and z is circulation. The standard errors of the slope coefficients are 0.620 and 0.063. Stigler's data come from the American Association of Advertising Agencies. Panel B: the dependent variable is the logarithm of the average rate for 26 spots on May 1, 1961. The broadcast-period variables are dummies. Table 6 does not state the omitted category. Stigler's data come from the Standard Rate and Data Service.

Table 9. The entry of 8.3 for hot-rolled sheets, for example, is an average reduction of 8.3 percent from quoted prices, with a standard deviation of 7.3 percent of quoted prices. The average discount is almost perfectly correlated with the dispersion of transaction prices. Our correlation across the eight products is 0.91. Stigler interprets this as expected: the less perfect the market knowledge, the more extensive the price cutting.

The data show larger discounts in the less concentrated product classes. Cold-rolled strip has the lowest index, 0.0549, and the largest discount, 8.8 percent. Structural shapes have the highest index, 0.3280, and a discount of 3.2 percent. This is the ordering the theory predicts, since secret cuts are harder to police when sellers are numerous and small. Stigler's summary sentence states the relation with the opposite sign. His remarks on individual products fit the data. He notes that structural shapes and hot-rolled strip sold somewhat below the average relationship, while cold-finished bars sold above it. In our fitted line, the first two have discounts 1.7 and 3.0 points above the line and cold-finished bars 4.8 points below. He adds that the deviations are not explained by demand, measured by 1939 output relative to 1937. Our residuals are indeed uncorrelated with that measure. The survey also excluded some very large buyers in the automobile and container industries. Since very large buyers obtained the largest concessions, Stigler infers that the table understates price cutting.

Stigler judged these fragments "fairly favorable to the theory," while granting that they do not constitute strong support. He expected more powerful tests from the electrical equipment conspiracy cases then in the courts. The theory predicts that prices on public bids will be higher and less dispersed than in privately negotiated sales. It also predicts that price cutting increases as the number of buyers diminishes (Stigler, 1964, footnote 16). He saw the large number of testable hypotheses as the main merit of the theory.

Table 2.10: Profitability and concentration in 17 industries (Stigler 1964)

	Concentration, 1954		Average return, 1953–57		Market to book
Industry (firms)	Top-4 share	*HHI*	All assets	Net worth	value, 1953–57
Panel A. Industry data (Table 7)					
Sulfur mining (4)	98	0.407	19.03	23.85	3.02
Automobiles (3)	98	0.369	11.71	20.26	2.30
Flat glass (3)	90	0.296	11.79	16.17	2.22
Gypsum products (2)	90	0.280	12.16	20.26	1.83
Primary aluminum (4)	98	0.277	6.87	13.46	2.48
Metal cans (4)	80	0.260	7.27	13.90	1.60
Chewing gum (2)	86	0.254	13.50	17.06	2.46
Hard-surface floor coverings (3)	87	0.233	6.56	7.59	0.98
Cigarettes (5)	83	0.213	7.23	11.18	1.29
Industrial gases (3)	84	0.202	8.25	11.53	1.33
Corn wet milling (3)	75	0.201	9.17	11.55	1.48
Typewriters (3)	83	0.198	3.55	5.39	0.84
Domestic laundry equipment (2)	68	0.174	9.97	17.76	1.66
Rubber tires (9)	79	0.171	7.86	14.02	1.70
Rayon fiber (4)	76	0.169	5.64	6.62	0.84
Carbon black (2)	73	0.152	8.29	9.97	1.40
Distilled liquors (6)	64	0.118	6.94	7.55	0.77
Panel B. Rank correlations with profitability (Table 8)					
Top-4 share			0.322	0.507	0.642
Herfindahl index			0.524	0.692	0.730

Notes: From Stigler (1964), Tables 7 and 8. The number of sampled firms is in parentheses. Returns are in percent. In Panel B, each entry is the rank correlation between the concentration measure in the row and the profitability measure in the column. Stigler reports a rank correlation of 0.903 between the two concentration measures (his footnote 14). Our Spearman correlations computed from Panel A are 0.320, 0.499 and 0.652 for the top-4 share. For *HHI* they are 0.525, 0.692 and 0.737, and between the two measures 0.903. The small differences presumably reflect the treatment of ties.

Table 2.11: Prices of steel products and industry structure (Stigler 1964)

	Prices, 2nd quarter 1939 (percent)			
Product class	Average discount from list price	Standard deviation	Herfindahl index	Output 1939 relative to 1937
Hot-rolled sheets	8.3	7.3	0.0902	1.14
Merchant bars	1.2	4.5	0.1517	0.84
Hot-rolled strip	8.5	8.3	0.1069	0.56
Plates	2.6	4.8	0.1740	0.85
Structural shapes	3.2	4.3	0.3280	0.92
Cold-rolled strip	8.8	9.8	0.0549	0.88
Cold-rolled sheets	5.8	5.0	0.0963	1.14
Cold-finished bars	0.9	3.4	0.0964	0.83

Notes: From Stigler (1964), Table 9, in his row order. The Herfindahl index uses 1938 capacity. Transaction prices come from a Bureau of Labor Statistics survey reported in *Iron Age* (1946). Capacity data come from the *Directory of Iron and Steel Works of the United States and Canada*, and output data from the American Iron and Steel Institute. In our computations across the eight rows, the correlation of the discount with its standard deviation is 0.91. The correlation of the discount with *HHI* is −0.46 (Spearman −0.55), and the least-squares line is discount = 7.40 − 18.09 *HHI*.

Assessment

Stigler's paper made collusion an information problem. It gave the first systematic account of why cartels hold in some markets and fail in others, and it tied cartel stability to observable features of markets. These include the number and size distribution of sellers, the size and loyalty of buyers and the rate of arrival of new buyers. They also include the transparency of transaction prices and the complexity of the price structure. Several of these ideas now organize antitrust thinking about coordinated effects, from the role of large buyers to the danger of price transparency (Chapter 13).

The model has clear limits. It contains no equilibrium. Punishment after detection is asserted, as the matching of detected cuts, and never derived. The price cutter does not choose how much to cut by weighing gains against the risk of detection. The detection rules use fixed probability thresholds, such as one standard deviation, without a decision-theoretic basis. The collusive price level is not determined, and the criteria measure the incentive to cut by undetected sales alone, ignoring the margin on those sales. The evidence is cross-sectional and inherits the endogeneity of market structure discussed in Chapter 1.

Green and Porter (1984) read Stigler differently from the cross-industry tradition he inspired (pp. 87–88). In their reading, Stigler justified cross-industry regressions by relating concentration informally to a cartel's ability to deter cheating, and by assuming that profitability reflects cartel success. They recast his cartel as the solution to a design problem: an institution that achieves an efficient outcome subject to the constraint that members act noncooperatively. That shift leads directly to the repeated-game models of the next subsection.

2.10.3 Repeated interaction: a preview

Repeated interaction gives Stigler's enforcement a formal foundation. A deviation today can be punished tomorrow, so collusive prices can be an equilibrium even though each firm gains by deviating in the short run. As in Section 2.2.3 and Chapter 12, $\delta \in (0,1)$ denotes the discount factor. The stage game is played in periods $t = 0, 1, 2, \ldots$, and each firm maximizes $\sum_{t \geq 0} \delta^t \pi_{it}$. We use *grim-trigger strategies*: firms play the collusive action as long as no one has deviated, and revert forever to the static Nash equilibrium after any deviation (Friedman, 1971). Static Nash play forever is itself a subgame-perfect equilibrium, so the threat is credible. The one-shot deviation principle, the folk theorem and optimal punishments are developed in Chapter 12.

The horizon must be infinite (Tirole, 1988, sec. 11.3.2). A repeated game has almost perfect information (Section 2.3.3), so it can be solved by backward induction when it ends at a known date. If the stage game has a unique Nash equilibrium, the stage equilibrium is then played in every period, and collusion unravels from the end (Proposition 12.11). The Bertrand game has several equilibrium profiles, but all of them give zero profit, so the same argument applies. With an infinite horizon there is no last period from which to start. Repeating the stage equilibrium forever remains a subgame-perfect equilibrium, because no current action changes future play. Other equilibria now exist, and they are sustained by the threat of reverting to the stage equilibrium after a deviation. Propositions 2.93 and 2.95 state when this threat suffices. We give the intuition here and prove both results in Section 12.3.

Proposition 2.93 (Collusion in the Bertrand supergame)**.** *Let N identical firms with constant marginal cost c play the homogeneous Bertrand game of Section 2.6 in every period, with observed prices. Grim-trigger strategies with collusive price p^m and Bertrand reversion form a subgame-perfect*

equilibrium if and only if

$$\delta \geq 1 - \frac{1}{N}. \tag{2.88}$$

Proposition 12.14 gives the proof. On the collusive path, conforming yields $\frac{\pi^m}{N}$ in every period, worth $\frac{\pi^m}{N(1-\delta)}$. The best deviation undercuts p^m slightly, earns almost π^m once, and earns zero after the reversion to Bertrand pricing. Collusion is sustainable when $\frac{\pi^m}{N(1-\delta)} \geq \pi^m$, which is (2.88).

The threshold rises with N. Each firm's collusive share $\frac{\pi^m}{N}$ shrinks while the one-period gain from deviation stays at about π^m. This is the formal version of Stigler's observation that collusion is impossible for many firms. Tirole (1988, sec. 6.3.2.1) uses it to give Bain's link between concentration and tacit collusion a precise sense.

Example 2.94 (Detection lags)**.** Stigler's insight is that deviations are detected with delay. Suppose rivals learn of a secret price cut only with probability $\mu \in (0, 1]$ in each period, for instance because random switching of buyers masks the lost sales. Until detection, the cutter serves the market at a price just below p^m. Its deviation payoff becomes

$$\pi^m \sum_{t \geq 0} \big[\delta(1-\mu)\big]^t = \frac{\pi^m}{1 - \delta(1-\mu)}.$$

Conforming is optimal if and only if

$$\frac{\pi^m}{N(1-\delta)} \geq \frac{\pi^m}{1 - \delta + \delta\mu} \iff \delta\mu \geq (N-1)(1-\delta) \iff \delta \geq \frac{N-1}{N-1+\mu}.$$

With $\mu = 1$ this is (2.88). As $\mu \to 0$ the threshold tends to 1, and collusion becomes impossible. If a cut reaches 100 buyers who each report it with probability $h = 0.01$, then $\mu = 1 - (0.99)^{100} = 0.634$ from (2.82). The threshold rises from 0.50 to 0.61 for two firms and from 0.80 to 0.86 for five.

Proposition 2.95 (Collusion in the linear Cournot supergame)**.** *Let N identical firms with constant marginal cost c play the Cournot game with $P(Q) = a - bQ$ in every period. Grim-trigger strategies with collusive output $\frac{Q^m}{N}$ each and reversion to the Cournot equilibrium form a subgame-perfect equilibrium if and only if*

$$\delta \geq \delta^*(N) = \frac{(N+1)^2}{N^2 + 6N + 1}. \tag{2.89}$$

Proposition 12.18 gives the proof. Let π_c, π_d and π_n be the per-period collusive, best one-shot deviation and Cournot profits. A firm conforms if collusion forever is worth at least one period of deviation profit followed by Cournot profit forever:

$$\frac{\pi_c}{1-\delta} \geq \pi_d + \frac{\delta\,\pi_n}{1-\delta} \iff \delta \geq \frac{\pi_d - \pi_c}{\pi_d - \pi_n}.$$

With linear demand the three profits are proportional to $\frac{(a-c)^2}{b}$, so the ratio depends only on N. It simplifies to (2.89).

The threshold is $\delta^*(2) = \frac{9}{17} = 0.529$, and it rises to 0.571, 0.643 and 0.752 for $N = 3, 5$ and 10. Its derivative is $\frac{4(N-1)(N+1)}{(N^2+6N+1)^2} > 0$, and $\delta^*(N) \to 1$ as $N \to \infty$. The comparison with Bertrand is instructive. For $N = 2$ the Cournot threshold is higher than the Bertrand value of 0.5. For

$N \geq 3$ it is lower: 0.571 against 0.667 at $N = 3$, and 0.752 against 0.900 at $N = 10$. Two forces work in opposite directions. Cournot reversion is a milder punishment than Bertrand reversion. But a Cournot deviator cannot capture the whole market, because rivals' outputs stay fixed. With three or more firms the second force dominates.

Conduct as a reduced form of dynamic play. In these models the static conduct parameter of Section 2.7 summarizes the outcome of dynamic play. It is close to 1 in collusive phases and close to its Cournot or Bertrand value in punishment phases. Bresnahan (1989) draws the empirical implication directly from Stigler (pp. 1023–1025). If self-interest alone holds a collusive arrangement together, uncertainty about rivals' behavior will sometimes trigger price wars even without actual cheating. Data on a collusive industry should then show periods of cooperation and periods of competition. "Empirically, of course, this will show up as time-varying θ." Two models formalize the idea with different predictions about when the price wars occur.

Green and Porter: price wars after bad news. Green and Porter (1984) study cartel self-enforcement under demand uncertainty. In their model firms choose outputs, and the market price depends on total output and an unobserved demand shock. Firms observe the price, but neither rivals' outputs nor the shock. A low price may therefore signal either cheating or bad demand. The cartel uses a trigger price. Firms produce collusive outputs while the price stays above the trigger and revert to Cournot output for a fixed number of periods after it falls below. In equilibrium no firm cheats, yet low demand realizations set off price wars. The wars are necessary, because without them cheating could not be deterred. Green and Porter emphasize that earlier formulations make incentives so perfect that the deterrent mechanism is never observed. With imperfect information, recurrent price wars are part of successful collusion. They need not indicate a sequence of failed attempts to form a cartel (pp. 87–88).

A simple price-setting version conveys the logic. Two firms face demand $Q(p)$ with probability $1 - \zeta$ and zero demand with probability ζ, independently each period. A firm with zero sales cannot tell low demand from a rival's secret cut. The strategy is to price at p^m until a period of zero sales and then price at c forever. The value of collusion is $V = \frac{(1-\zeta)\frac{\pi^m}{2}}{1-\delta(1-\zeta)}$. A deviator earns $(1 - \zeta)\pi^m$ once and nothing afterwards. Conforming is optimal if and only if

$$\frac{(1-\zeta)\frac{\pi^m}{2}}{1-\delta(1-\zeta)} \geq (1-\zeta)\,\pi^m \iff \delta(1-\zeta) \geq \frac{1}{2}.$$

More noise (ζ higher) makes collusion harder, and price wars start after unexpectedly low demand. Chapter 12 treats finite punishments and the optimal trigger, including the refinements of Abreu et al. (1986).

Rotemberg and Saloner: price wars during booms. Rotemberg and Saloner (1986) study implicitly colluding oligopolists facing fluctuating demand that they observe. Their key finding is that the temptation to deviate from the collusive outcome is often greater when demand is high. To moderate the temptation, the oligopoly lowers its prices in booms. Suppose demand states are independent over time, and let $\pi_s(p)$ be industry profit at price p in state s. With collusive prices p_s and Bertrand reversion, the incentive constraint in state s is

$$\left(1 - \frac{1}{N}\right)\pi_s(p_s) \leq \frac{\delta}{1-\delta} \cdot \frac{1}{N}\,\mathbb{E}\big[\pi_{s'}(p_{s'})\big].$$

The left side is the gain from deviating in the current state, and it rises with current demand. The right side is the expected future loss, which does not depend on the current state. In high-demand states the constraint binds first, and the cartel must cap profits below the monopoly

level by cutting price. The abstract of the 1984 working-paper version cites supporting evidence from the railroads in the 1880s and the automobile industry in the 1950s. It also cites the cyclical behavior of cement prices and price-cost margins.

Implications for measurement. Both models imply that conduct varies over time, but they disagree about the pattern. In Green and Porter, conduct switches to the competitive value after unanticipated low demand and returns after a fixed lag. In Rotemberg and Saloner, conduct varies within the collusive regime with the level of demand. Porter (1983a) estimated a supply relation with two regimes for a nineteenth-century railroad cartel (Chapter 13). Bresnahan notes that the existence of regimes is easier to establish than their causes. Asking whether there are price wars uses all periods of data, while asking what starts and stops them has as many observations as there are wars. Time variation in conduct also complicates the interpretation of a constant estimated θ, which is the critique of Corts (1999) developed in Chapter 3.

2.11 From homogeneous to differentiated products

The theory so far assumed a homogeneous good. Few markets fit that description. Products differ in physical characteristics, location, brand and service, even in markets that look homogeneous, such as pharmaceuticals with chemically identical generics or retail gasoline. Electricity and refined sugar, the settings of two case studies in Chapter 3, come close to homogeneity. Most empirical questions in industrial organization need a model of demand for differentiated products. Measuring market power, evaluating mergers, assessing taxes and tariffs, analyzing product introductions and valuing new goods all depend on substitution patterns. With differentiated products there is also no natural boundary for the market, so an estimated demand system can stand in for market definition. This section shows how the pricing logic of this chapter carries over and points to where it is developed.

A single-product firm j that sets its price, taking rivals' prices as given, is a monopolist on its residual demand $q_j(p)$, as in Section 2.2.2. The first-order condition $q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} = 0$ gives the dollar markup and Lerner rules (2.5) and (2.6), with the own-price derivative of residual demand in place of the market derivative:

$$p_j - mc_j = -\frac{q_j}{\frac{\partial q_j}{\partial p_j}}, \qquad \frac{p_j - mc_j}{p_j} = \frac{1}{|\varepsilon_{jj}|}. \tag{2.90}$$

For example, with logit demand and price coefficient α, $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$, so the markup is $\frac{1}{\alpha(1-s_j)}$. Pass-through follows the formulas of Section 2.8, and for the logit it equals $1 - s_j$ when rivals' prices are held fixed (Example 2.73).

A firm that owns several products adds a new term. Let firm f own the set $\mathcal{J}_f$ and maximize $\sum_{k\in\mathcal{J}_f}(p_k - mc_k)\, q_k(p)$ over its own prices. The first-order condition for p_j, $j \in \mathcal{J}_f$, is

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + \sum_{k\in\mathcal{J}_f\setminus\{j\}}(p_k - mc_k)\frac{\partial q_k}{\partial p_j} = 0.$$

Divide by $\frac{\partial q_j}{\partial p_j} < 0$, solve for p_j, and define the *diversion ratio* $D_{jk} = -\frac{\partial q_k}{\partial p_j}\left(\frac{\partial q_j}{\partial p_j}\right)^{-1}$, the fraction of

the sales lost by product j that product k recaptures when p_j rises. Then

$$p_j = mc_j - \frac{q_j}{\frac{\partial q_j}{\partial p_j}} + \sum_{k \in \mathcal{J}_f \setminus \{j\}} (p_k - mc_k)\, D_{jk}. \tag{2.91}$$

Price equals marginal cost, plus the single-product markup, plus the margins the firm earns on sales recaptured by its other products. The last term is an opportunity cost of selling product j, since each sale partly cannibalizes the firm's other products. Joint ownership of substitutes therefore raises prices. A merger adds the acquired products to $\mathcal{J}_f$ and the corresponding terms to (2.91). This is the logic of upward pricing pressure in Chapter 11. The homogeneous-goods analogue is the gap between Cournot conduct, in which each firm ignores its effect on rivals, and collusion, in which it internalizes all of it (Proposition 2.92).

When one firm owns every product, this first-order condition is the condition (2.12) of the multiproduct monopolist in Section 2.2.3. The diversion-ratio form is the same condition divided by the own-price derivative. To see the link with the Lerner form, substitute $\frac{\partial q_k}{\partial p_j} = \varepsilon_{kj} \frac{q_k}{p_j}$ and $\frac{\partial q_j}{\partial p_j} = -|\varepsilon_{jj}| \frac{q_j}{p_j}$ into the definition of the diversion ratio:

$$D_{jk} = \frac{\varepsilon_{kj}\, q_k}{|\varepsilon_{jj}|\, q_j}.$$

The single-product markup is $-q_j \left(\frac{\partial q_j}{\partial p_j}\right)^{-1} = \frac{p_j}{|\varepsilon_{jj}|}$. Dividing (2.91) by p_j and writing $R_j = p_j q_j$ then gives

$$\frac{p_j - mc_j}{p_j} = \frac{1}{|\varepsilon_{jj}|} + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \frac{(p_k - mc_k)\, q_k\, \varepsilon_{kj}}{R_j\, |\varepsilon_{jj}|},$$

which is (2.13) with the sum restricted to the firm's own products. Positive diversion corresponds to substitutes in that formula, and it raises the Lerner index above the inverse own elasticity.

Stacking (2.91) over products gives the matrix form $p = mc - (\Omega \odot \Delta^\top)^{-1} q$, with ownership matrix Ω ($\Omega_{jk} = 1$ if j and k have the same owner) and demand Jacobian Δ, whose (j,k) element is $\frac{\partial q_j}{\partial p_k}$. Chapter 4 develops this system, the existence and uniqueness of equilibrium, the recovery of marginal costs from estimated demand, and the demand models that supply the derivatives. Theory in this area mostly studies prices and products given a demand system. Empirical work does the reverse: it models demand richly and supply simply, usually as static Bertrand-Nash pricing. Richer demand models add assumptions and computation, so they should be judged by what they add for the question at hand and the data available.

2.12 Bibliographic notes

Tirole (1988) remains the standard textbook treatment of the theory in this chapter. The electronic edition we used has no printed page numbers, so we cite it by chapter, section, equation and exercise. Its chapter 1 (secs. 1.1 to 1.5) covers single-product and multiproduct monopoly, the deadweight loss and the output subsidy (Sections 2.2 and 2.9). It also treats cost distortions, rent seeking and the limits that recycling and durability place on monopoly power. Chapter 5 covers Bertrand competition, rationing and capacity constraints in secs. 5.1 to 5.3 (Section 2.6). Its secs. 5.4 and 5.5 treat Cournot competition and concentration indices, and sec. 5.7 treats existence, convergence and the capacity-price game (Sections 2.1 and 2.4).

Section 6.3 treats the supergames previewed in Section 2.10.3. Chapter 11 is a user's manual for the game theory of Section 2.3, and Fudenberg and Tirole (1991) give a complete treatment. Shapiro (1989) surveys static and dynamic oligopoly theory, and Vives (1999) develops existence, uniqueness and comparative statics with the tools of aggregative and supermodular games.

The aggregative proof of Proposition 2.23 goes back to Szidarovszky and Yakowitz (1977) and Novshek (1985). The effects of entry on Cournot outcomes go back to Seade (1980), and the margin-concentration identity to Cowling and Waterson (1976). Encaoua and Jacquemin (1980) give the axioms for concentration indices. Demsetz (1973) gives the efficiency explanation of the link between concentration and profit. Dansby and Willig (1979) give the welfare interpretation of the Herfindahl index. Bulow et al. (1985) introduced the language of strategic substitutes and complements. Edgeworth (1925), first published in 1897, showed that capacity limits undo the Bertrand outcome. Beckmann (1967) and Levitan and Shubik (1972) solved the capacity-constrained price game. Kreps and Scheinkman (1983) and Davidson and Deneckere (1986) are the key papers on capacity commitment and price competition, and Gertner (1985) studies the game in which capacities are not observed. Klemperer and Meyer (1989) develop supply function equilibria.

The conduct parameter and its interpretation are best read in Bresnahan (1989), which also gives the menu of conduct for leaders, fringes and collusive regimes. Corts (1999) shows why a constant estimated θ need not measure average conduct, a point that Chapter 3 develops. The theory of pass-through starts with Bulow and Pfleiderer (1983), and Weyl and Fabinger (2013) unify pass-through and incidence under imperfect competition. Sumner (1981) and Genesove and Mullin (1998) use pass-through and the Bulow-Pfleiderer demand family to measure conduct.

The welfare analysis of free entry follows Mankiw and Whinston (1986), who build on Spence (1976) and Dixit and Stiglitz (1977) for the case of product diversity. Berry and Waldfogel (1999) measure the inefficiency of free entry in radio broadcasting, an empirical test of the excess-entry theorem. The 1996 working-paper version (NBER Working Paper 5528), which we cite here, uses data on advertising prices, numbers of stations and listening in 135 US metropolitan markets. Relative to the social optimum, the welfare loss of free entry is 40 percent of industry revenue, counting market participants other than listeners. Free entry would be optimal if the marginal value of programming to listeners exceeded three times the value of marginal listeners to advertisers, who pay 4.5 cents per hour. Chapter 4 returns to this paper.

The deadweight loss of monopoly was first estimated by Harberger (1954). Posner (1975) added the costs of rent-seeking, and Fisher (1985) questioned the conditions under which rents are fully dissipated. Cowling and Mueller (1978, pp. 739 and 743) found losses of up to 13 percent of gross corporate product in the United States and 7.2 percent in the United Kingdom once rent-seeking costs are counted. Jenny and Weber (1983) also found large losses, and Scherer (1980) doubts these high estimates (Tirole, 1988, sec. 1.1.1.2). Leibenstein (1966) named X-inefficiency, and Coase (1972) posed the problem of the durable-good monopolist. Williamson (1968) framed the trade-off between market power and cost savings that merger policy still uses.

Stigler (1964) founded the information-based theory of collusion. Friedman (1971) gave the first repeated-game model of collusion with trigger strategies, and Green and Porter (1984) and Rotemberg and Saloner (1986) showed how imperfect monitoring and demand fluctuations generate price wars. Abreu et al. (1986) characterized optimal cartel equilibria under imperfect monitoring. Chapter 12 develops these models and Chapter 13 confronts them with data.

2.13 Exercises

1. *Cournot competition with constant-elasticity demand.* Inverse demand is $P(Q) = \left(\frac{Q}{A}\right)^{-\frac{1}{\varepsilon}}$ with $A > 0$ and $\varepsilon > 0$, and N firms have the same constant marginal cost $c > 0$.

   (a) Derive the symmetric Cournot equilibrium price and the Lerner index. Show that an interior equilibrium requires $N\varepsilon > 1$, and check the second-order condition at the equilibrium.

   (b) Show that the firm-level inequality $P'(Q) + q_i P''(Q) < 0$ of Remark 2.19, evaluated at the symmetric equilibrium, holds if and only if $N\varepsilon > 1 + \varepsilon$. Give an example with $N = 2$ in which an interior equilibrium exists although this inequality fails at the equilibrium. Are quantities strategic substitutes or complements there?

   (c) Assume $N\varepsilon > 1 + \varepsilon$. Use Proposition 2.79 to compute the pass-through of a common cost shock and of a shock to one firm's cost. Compare the two with the monopoly rate $\frac{\varepsilon}{\varepsilon - 1}$ and explain why a more competitive industry passes through less.

2. *Consistent conjectures.* Two firms face $P(Q) = a - bQ$ and have the cost function $C(q) = cq + \frac{k}{2}q^2$ with $k \geq 0$. Each firm holds the constant conjecture $r = \frac{\mathrm{d}q_j}{\mathrm{d}q_i}$, the conjectural variation of Section 2.7.2 with one rival.

   (a) Derive firm i's first-order condition and its reaction function. Show that the reaction function has slope $-\frac{b}{(2+r)b+k}$.

   (b) A conjecture is *consistent* if it equals the slope of the rival's reaction function. Show that with $k = 0$ the only consistent conjecture is $r = -1$, and that it yields price equal to marginal cost.

   (c) Show that with $k > 0$ the consistent conjecture lies in $(-1, 0)$. Compute the implied industry conduct parameter.

   (d) Explain why consistency does not answer the critique of conjectural variations in Section 2.7.4.

3. *Constant pass-through.* Complete the proof of Proposition 2.74.

   (a) Suppose monopoly pass-through equals a constant $\rho > 0$ on an interval of costs. Show that $\frac{QP''(Q)}{P'(Q)} = \frac{1}{\rho} - 2$ on the corresponding interval of outputs.

   (b) Solve this differential equation for P', and then for P. Show that $P(Q) = a - bQ^{\gamma}$ with $\gamma = \frac{1}{\rho} - 1$ when $\rho \neq 1$, and $P(Q) = a - b \ln Q$ when $\rho = 1$.

   (c) Identify the members of the family with linear, quadratic and constant-elasticity demand, and state the restrictions on (a, b, γ) that make demand downward sloping and satisfy the second-order condition.

   (d) Show that pass-through is also constant under any constant conduct θ, and find its value.

4. *Specific and ad valorem taxes under monopoly.* A monopolist with constant marginal cost c faces $Q(p) = Ap^{-\varepsilon}$ with $\varepsilon > 1$.

   (a) Derive the price under a specific tax t and under an ad valorem tax at rate t_a (Remark 2.81). Compute $\frac{\mathrm{d}p}{\mathrm{d}t}$ and $\frac{\mathrm{d}p}{\mathrm{d}t_a}$ at zero taxes.

(b) Use Proposition 2.80 and the envelope theorem to compute the consumer burden, the producer burden and the tax revenue of each tax at the margin, starting from zero taxes.

(c) Normalize both taxes to raise one dollar of revenue at the margin. Which tax imposes the smaller burden on consumers, and which the smaller loss of total surplus? Explain the answer in terms of the effect of each tax on the firm's markup.

5. *Excess entry.* Use the linear Cournot market of Example 2.42 with $a - c = 8$ and $b = 1$.

(a) Find the set-up cost F for which the second-best number of firms is $N^o = 4$.

(b) Compute the free-entry number of firms with N treated as continuous and as an integer.

(c) Compute total surplus at N^o and at the integer N^e, and express the loss as a percentage of the maximal surplus $\frac{(a-c)^2}{2b}$.

(d) Show that, with N continuous, the loss as a share of the maximal surplus depends on the primitives only through N^o. Explain why the loss shrinks as N^o grows although $N^e - N^o$ grows.

6. *Partial collusion in a Cournot duopoly.* Two firms with constant marginal cost c face $P(Q) = a - bQ$ in every period, discount the future by δ and use grim-trigger strategies with Cournot reversion. They agree on a symmetric output q per firm, between the collusive output $\frac{a-c}{4b}$ and the Cournot output $\frac{a-c}{3b}$.

(a) Compute the per-period profit from conforming, the profit from the best one-period deviation, and the Cournot profit, as functions of q.

(b) Show that the incentive constraint holds if and only if $q \geq \frac{(a-c)(9-5\delta)}{b(27-3\delta)}$.

(c) Conclude that firms with $\delta < \frac{9}{17}$ can still sustain prices above the Cournot level. Plot the implied conduct parameter $\theta(\delta)$ against $\delta \in [0, 1)$ and relate the result to the time-varying conduct of Section 2.10.3.

7. *Stigler's model of detection.*

(a) Use (2.83) to compute Criterion I for $\phi = 0.9$, $n_o = 100$ and $n_s = 5$, and check your answer against Table 2.7.

(b) Show that, as $n_o \to \infty$ with n_s and ϕ fixed,

$$\sqrt{n_o}\, G_{\mathrm{I}} \to \frac{1}{n_s - 1}\left[\sqrt{\phi(1-\phi)n_s} + \sqrt{n_s(n_s-2)(1-\phi)}\right].$$

Interpret the result in terms of the number of buyers per seller.

(c) Derive (2.87). Construct two markets with the same four-firm concentration ratio and different Herfindahl indices, and say in which one Stigler's theory predicts more effective collusion.

(d) List two features of a modern repeated-game model of collusion that Stigler's model lacks, and explain how each changes the predictions in (b) and (c).

8. *Interpreting a pass-through estimate.* A regression of the retail price of a product on a specific excise tax, across regions and years, gives $\hat{\rho} = 1.07$ with a small standard error.

(a) Use Corollary 2.78 to state what this estimate rules out. List the maintained assumptions behind the conclusion.

(b) Describe the set of pairs (χ, θ) consistent with the estimate when marginal cost is flat. Which value of θ does it imply if demand has constant elasticity $\varepsilon = 1.5$? If demand is linear?

(c) The price variable is an average over brands. Explain how the composition effect of Remark 2.82 could produce $\hat{\rho} > 1$ in a competitive industry, and describe a test.

(d) Suppose instead that the tax applied to one of N Cournot firms only. What would an estimate of 1.07 then imply about the curvature of demand, by Proposition 2.79?

Chapter 3

Measuring Market Power in Homogeneous-Goods Industries

How far above marginal cost do firms set their prices, and why? Chapter 2 answers the question in theory. Given demand, cost and a model of competition, it derives the margin. This chapter turns the question around. We observe prices and quantities, and we want to learn how much market power firms have and how they compete. The first difficulty is that marginal cost is almost never observed. Accounting margins rest on average costs and on accounting valuations of capital, which is why the cross-industry studies of Chapter 1 could not settle the question. Concentration does not settle it either, because the same market structure is compatible with very different conduct.

The New Empirical Industrial Organization (NEIO) responds in three ways (Section 1.6). It studies one industry at a time. It infers marginal cost from pricing behavior instead of reading it from accounts. And it treats conduct as a parameter to be estimated. The central device is the pricing condition. If demand $Q(P)$ has been estimated and conduct θ is known, the first-order condition can be inverted for marginal cost,

$$\widehat{mc} = P + \theta \frac{Q(P)}{\hat{Q}'(P)} = P - \theta \frac{Q(P)}{|\hat{Q}'(P)|}.$$

The catch is that θ is rarely known. Data on prices and quantities must then identify demand, marginal cost and conduct together. This chapter asks when they can, and what the resulting estimates mean.

The chapter has four movements. Section 3.1 sets up the supply relation that all methods share. It shows that an unrestricted conduct parameter fits any data, and it uses Stigler (1964) to explain why structure does not pin down conduct. Sections 3.2 to 3.4 study designs that move cost. They cover tax pass-through (Sumner, 1981) and tests that need no functional forms (Sullivan, 1985; Ashenfelter and Sullivan, 1987; Panzar and Rosse, 1987). They also cover residual demand with firm-specific cost shifters (Baker and Bresnahan, 1988). These designs deliver tests and bounds. Sections 3.5 and 3.6 turn to demand. Rotations of demand identify conduct (Bresnahan, 1982; Lau, 1982). When conduct varies, however, an estimated constant θ measures the slope of the supply relation, which can differ greatly from its level (Corts, 1999). Sections 3.7 and 3.8 study sugar refining and British electricity, two industries in which marginal cost can be measured almost directly (Genesove and Mullin, 1998; Wolfram, 1999). There we can compare the estimates with the truth. The electricity section also reviews later

studies of restructured markets in the United States and Spain, several of which use firms' bids or forward positions (Kellogg and Reguant, 2021). Section 3.9 draws the lessons together.

The chapter builds on the pricing rules, conjectural variations and pass-through theory of Chapter 2, and it develops in full the identification argument previewed in Section 1.7. Its ideas recur throughout the book. The supply relation with an ownership matrix is the differentiated-products version of the conduct parameter (Chapters 4 and 8). Merger simulation recovers marginal cost by inverting a pricing condition, exactly as above (Chapter 11). Dynamic models of collusion explain why conduct varies over time (Chapters 12 and 13). The campus coffee shop of Chapter 1 returns in the first exercise, which asks which of the chapter's methods its data could support.

3.1 The measurement problem and the supply relation

Every method in this chapter infers market power from the way prices and quantities respond to observable shifts in demand and cost. This section sets up the framework they share. It defines the objects we want to measure and writes the supply relation that all later methods use. It then shows that an unrestricted conduct parameter fits any data, explains with Stigler (1964) why market structure alone cannot settle the question, and closes with a map of the approaches.

3.1.1 What we want to measure

Our main object is the *Lerner index* $L = \frac{P-MC}{P}$, the gap between price and marginal cost as a share of price (Definition 1.8). A closely related object is the *markup rate* $\frac{P-MC}{MC}$, the gap as a share of marginal cost. The two carry the same information. A price 25 percent above marginal cost has a markup rate of 0.25 and a Lerner index of $\frac{0.25}{1.25} = 0.2$. Both measure margins at the margin. They are not measures of profit. Consider a firm with constant marginal cost c and fixed cost F that just breaks even under free entry. It sets $P = c + \frac{F}{q}$, so its markup rate is $\frac{F}{cq} > 0$ although it earns no rents (Section 1.2.4). A positive Lerner index measures the ability to price above marginal cost. Whether that ability yields excess profits depends on fixed and sunk costs, which the methods of this chapter do not measure. The same distinction runs through the recent debate on rising markups (De Loecker et al., 2020), which Section 1.5.4 reviews.

Two pricing rules from Chapter 2 serve as benchmarks, the Lerner rule (2.6) and Proposition 2.26. A monopolist with constant marginal cost c facing demand $Q(P)$ with elasticity $\varepsilon = -Q'(P)\frac{P}{Q(P)} > 0$ sets

$$P - c = -\frac{Q(P)}{Q'(P)}, \qquad \frac{P-c}{P} = \frac{1}{\varepsilon}.$$

With N Cournot firms, constant marginal costs c_i and output shares $s_i = \frac{q_i}{Q}$, each firm satisfies

$$\frac{P-c_i}{P} = \frac{s_i}{\varepsilon}, \qquad \sum_{i=1}^{N} s_i \frac{P-c_i}{P} = \frac{HHI}{\varepsilon},$$

where $HHI = \sum_i s_i^2$ is the Herfindahl index. Both rules are special cases of a single equation.

Definition 3.1 (Supply relation and conduct parameter)**.** Let $P(Q, Y)$ be inverse market demand, with demand shifters Y and slope $P'(Q, Y) \equiv \frac{\partial P(Q,Y)}{\partial Q} < 0$. Let $MC(Q, W)$ be industry marginal

cost, with cost shifters W. The *supply relation* is

$$P = MC(Q, W) - \theta\, Q\, P'(Q, Y), \tag{3.1}$$

and the number $\theta \geq 0$ is the *conduct parameter*.

Equation (3.1) says that marginal cost equals a *perceived marginal revenue* $P + \theta QP'$. We call it a supply relation because, outside perfect competition, firms do not have supply curves that give output as a function of price alone (Bresnahan, 1989, p. 1016). Dividing (3.1) by P and using $\varepsilon = -\frac{P}{QP'}$ gives the Lerner form

$$\frac{P - MC}{P} = -\frac{\theta\, Q\, P'}{P} = \frac{\theta}{\varepsilon} \qquad \Longleftrightarrow \qquad \theta = \varepsilon\, \frac{P - MC}{P} \equiv L_\varepsilon. \tag{3.2}$$

The conduct parameter is the *elasticity-adjusted Lerner index* L_ε. It equals 0 under price taking, $\frac{1}{N}$ under symmetric Cournot competition, and 1 under monopoly or joint profit maximization. Bertrand competition with a homogeneous good and constant marginal cost gives $\theta = 0$ for any $N \geq 2$. It is also convenient to name the *markup term*

$$m \equiv \frac{Q}{\left|\frac{\partial Q}{\partial P}\right|} = -Q\, P'(Q, Y) = \frac{P}{\varepsilon},$$

so that (3.1) reads $P = MC + \theta m$. At $\theta = 1$, m is the dollar markup of a monopolist.

Industry data rarely come with firm-level costs and quantities. The next result shows what an industry-level θ means when firms differ in costs and in conduct. It restates Proposition 2.60 with market subscripts and generalizes Proposition 1.33, which uses output shares as weights and constant conjectures.

Proposition 3.2 (Aggregation of firm supply relations)**.** *Let N firms produce a homogeneous good, with outputs q_{it}, industry output $Q_t = \sum_i q_{it}$, shares $s_{it} = \frac{q_{it}}{Q_t}$ and market elasticity $\varepsilon_t = -\frac{P_t}{Q_t P'(Q_t)}$. Suppose each firm satisfies the firm supply relation*

$$P_t = MC_{it} - \tilde{\theta}_{it}\, q_{it}\, P'(Q_t),$$

with firm-level conduct parameter $\tilde{\theta}_{it} \geq 0$. Then for any weights $\varphi_{it} \geq 0$ with $\sum_i \varphi_{it} = 1$,

$$P_t = \sum_{i=1}^{N} \varphi_{it}\, MC_{it} + \frac{P_t}{\varepsilon_t} \sum_{i=1}^{N} \varphi_{it}\, s_{it}\, \tilde{\theta}_{it}. \tag{3.3}$$

The industry therefore satisfies (3.1) with industry marginal cost $MC_t = \sum_i \varphi_{it} MC_{it}$ and industry conduct $\theta_t = \sum_i \varphi_{it}\, s_{it}\, \tilde{\theta}_{it}$.

Proof. Multiply firm i's supply relation by φ_{it} and sum over firms. The left side becomes $\sum_i \varphi_{it} P_t = P_t$ because the weights sum to one. The right side becomes

$$\begin{aligned} \sum_i \varphi_{it} MC_{it} - P'(Q_t) \sum_i \varphi_{it}\, \tilde{\theta}_{it}\, q_{it} &= \sum_i \varphi_{it} MC_{it} - Q_t P'(Q_t) \sum_i \varphi_{it}\, \tilde{\theta}_{it}\, s_{it} \\ &= \sum_i \varphi_{it} MC_{it} + \frac{P_t}{\varepsilon_t} \sum_i \varphi_{it}\, \tilde{\theta}_{it}\, s_{it}, \end{aligned}$$

using $q_{it} = s_{it} Q_t$ in the first line and $-Q_t P'(Q_t) = \frac{P_t}{\varepsilon_t}$ in the second. Since $\frac{P_t}{\varepsilon_t} = -Q_t P'(Q_t)$, equation (3.3) is (3.1) with the stated MC_t and θ_t. □

Corollary 3.3 (Benchmarks for industry conduct)**.** *Under the assumptions of Proposition 3.2, the following hold.*

(i) Cournot conduct ($\tilde{\theta}_{it} = 1$) gives $\theta_t = \sum_i \varphi_{it} s_{it}$. This equals $\frac{1}{N}$ for symmetric firms and HHI_t when $\varphi_{it} = s_{it}$.

(ii) Joint profit maximization gives $\tilde{\theta}_{it} = \frac{Q_t}{q_{it}} = \frac{1}{s_{it}}$ and hence $\theta_t = 1$ for any weights.

(iii) Price taking ($\tilde{\theta}_{it} = 0$) gives $\theta_t = 0$.

(iv) A constant conjectural variation $r_i = \frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$ gives $\tilde{\theta}_{it} = 1 + r_i$.

Proof. Parts (i), (iii) and (iv) follow by substitution in $\theta_t = \sum_i \varphi_{it} s_{it} \tilde{\theta}_{it}$, with $\sum_i s_{it}^2 = HHI_t$ and, for (iv), the first-order condition $P + q_i P'(Q)(1 + r_i) = MC_i$ of Proposition 1.33. For (ii), joint profit $P(Q)Q - \sum_j C_j(q_j)$ has derivative $P + QP'(Q) - MC_i$ with respect to q_i. Setting it to zero and writing $QP' = \frac{Q}{q_i} q_i P'$ gives the firm supply relation with $\tilde{\theta}_{it} = \frac{Q_t}{q_{it}}$. Then $\varphi_{it} s_{it} \tilde{\theta}_{it} = \varphi_{it}$, and the weights sum to one. □

Remark 3.4 (Industry conduct is average conduct). Proposition 3.2 says that an industry supply relation estimated on aggregate data measures a weighted average of firms' marginal costs and a weighted average of their conduct. The weights are a choice of the analyst. With $\varphi_{it} = s_{it}$ we recover the share-weighted margins of Cowling and Waterson (1976). Firms with different costs have different margins under most oligopoly models, so a stable industry marginal cost curve need not exist. Bresnahan (1989, p. 1030) therefore reads the aggregate θ_t as industry average conduct. He rejects the claim that oligopoly theory forces all firms to share the same conduct parameter. The electricity study in Section 3.8 uses weights built from plant-level marginal costs and relies on this proposition.

Remark 3.5 (The language of conjectures). Much of the empirical literature writes $\tilde{\theta}_{it} = 1 + r_i$ and calls r_i a *conjectural variation*, the response of rivals' output that firm i "expects". The two parameterizations are identical as a matter of logic (Bresnahan, 1989, p. 1027). The expectations reading is misleading near collusion. In repeated-game models of tacit collusion, firms produce their collusive quotas because they expect a deviation to trigger a breakdown of restraint (Chapter 12). Matching of a deviation is never observed in equilibrium. An estimated "conjecture" therefore measures how close behavior is to the collusive outcome. It says nothing about what rivals would do after a deviation (Bresnahan, 1989, pp. 1028–1029). Section 1.6.4 develops the point.

3.1.2 An unrestricted conduct parameter has no content

The supply relation becomes a model only once we restrict how conduct varies. To see why, index markets or firms by i and periods by t, and allow conduct to vary freely:

$$P_{it} = mc_{it} + \theta_{it} \frac{Q_{it}}{\left| \frac{\partial Q_{it}}{\partial P_{it}} \right|}. \tag{3.4}$$

The absolute value matters. The demand slope is negative, so dividing Q_{it} by the slope itself would turn the markup term into a markdown.

Proposition 3.6 (Exact fit)**.** *Take any data* $\{(P_{it}, Q_{it})\}$*, any demand slopes* $\frac{\partial Q_{it}}{\partial P_{it}} < 0$ *and any marginal cost function* $mc_{it} = c(q_{it}, W_{it}; \beta)$ *with any parameter* β*. Then*

$$\theta_{it} = \frac{(P_{it} - mc_{it}) \left| \frac{\partial Q_{it}}{\partial P_{it}} \right|}{Q_{it}}$$

satisfies (3.4) *exactly at every observation.*

This is Proposition 2.64, restated because every method below responds to it. The proposition has a sharp implication. With as many conduct parameters as observations, the model needs no error term and rejects nothing, whatever functional form we impose on cost. The θ_{it} absorb every residual. Empirical content comes only from restrictions on conduct. Four kinds appear in this chapter.

(a) Conduct is constant, or constant within a small number of regimes such as collusion and price wars.

(b) Conduct lies in $[0, 1]$, which bounds marginal cost between $P_{it} + Q_{it}P'(Q_{it})$ and P_{it}.

(c) Conduct is uncorrelated with the instruments used to estimate it.

(d) Conduct takes the value implied by a specific game, such as Cournot or joint profit maximization.

Every method below combines one or more of these restrictions with restrictions on demand and cost. Restriction (b) alone yields bounds (Section 3.6.3). Section 3.6.2 shows what an estimated constant θ measures when restriction (a) fails (Corts, 1999).

3.1.3 Why structure does not pin down conduct: Stigler (1964)

The structure-conduct-performance tradition took conduct to follow from structure. Stigler (1964) gave the first systematic argument for why it need not. Section 2.10.2 develops his model, his four detection criteria and his evidence in full, with the original tables. Here we keep the part of the argument that bears on measurement.

The policing problem. Stigler started from the premise that oligopolists wish to collude to maximize joint profits. He asked why collusion succeeds in some markets and fails in others. His answer is that a collusive agreement must be policed. Any member who can cut prices secretly earns more than by conforming. The basic evidence of a secret cut is that the cutter wins customers it would otherwise not obtain. Policing is therefore a problem of statistical inference from sales.

In his model, n_s sellers of equal size share n_o old buyers. Each old buyer returns to his supplier with probability ϕ, as in Section 2.10.2, and otherwise moves to one of the other sellers at random. A seller observes only its own sales. It suspects a rival of price cutting when its own losses of old customers and the rival's gains are both improbably large. Stigler's Criterion I (2.83) gives the largest share of average sales that a price cutter can take from one rival without detection. It falls with the number of buyers and with the repeat probability, and it barely depends on the number of sellers (Table 2.7). With 100 old buyers, 10 sellers and $\phi = 0.9$, a firm can take 5.4 percent of average sales from each rival. That is about 50 percent from all nine together. If the nine rivals merge or pool their information, the gain falls to 28.5 percent (Panel C of Table 2.8).

The model also yields a concentration measure. If each new buyer chooses a seller with probability equal to its market share, the sampling noise that masks secret cuts is proportional to $1 - HHI$ (2.87). The Herfindahl index thus emerges from the detection problem itself. Collusion is harder to sustain with more sellers, more and smaller buyers, more turnover among buyers and more new buyers. It is easier with unequal sellers and against buyers who reveal the prices they pay. Green and Porter (1984) later formalized secret price cutting as a repeated game with imperfect monitoring, in which price wars occur on the equilibrium path (Chapter 12).

Evidence. Stigler's own evidence is fragmentary. Newspaper advertising rates in 1939 and radio spot rates in 1961 respond little to the number of rival sellers (Table 2.9). Across 17 industries, all six rank correlations between profitability and concentration are positive (Table 2.10). The Herfindahl index correlates more strongly with profitability than the four-firm share does. Stigler nonetheless finds no relation when HHI is below 0.25 or the four-firm share below about 80 percent. Among steel products in 1939, discounts from list prices are larger where the Herfindahl index is smaller, with a rank correlation of -0.55 (Table 2.11). Stigler called this evidence "fairly favorable to the theory" and added that it did not constitute strong support.

Lessons for measurement. In Stigler's model the map from structure to conduct depends on what sellers can observe. It also depends on the number, size and turnover of buyers, and on the dynamics of detection and punishment. None of these is captured by a concentration ratio. Two markets with the same Herfindahl index can therefore support very different conduct. This is the deepest reason why the methods of this chapter measure conduct industry by industry.

Cross-sections of prices and concentration face further problems of interpretation (Bresnahan, 1989, pp. 1042–1044). Concentration is endogenous. Under free entry, larger markets hold more firms, and price equals average cost everywhere, so a price-concentration relation need not reflect conduct. With heterogeneous costs, markets with more firms offer more draws on a low-cost firm (Proposition 1.29). In the aggregate supply relation of Proposition 3.2, a lower price in unconcentrated markets may reflect lower average marginal cost, lower average conduct, or both. Section 1.5.2 treats these studies in detail.

3.1.4 A taxonomy of approaches

Table 3.1 organizes the approaches of this chapter by the data they need, the assumptions they maintain and what they deliver. Some deliver tests of a single hypothesis, some deliver bounds, and some deliver point estimates of θ. Table 1.6 gives a complementary classification by identification argument.

Approach (e) gets no section of its own, so we describe it here. Let $w = (w_1, \ldots, w_K)$ be the vector of factor prices, as in Section 3.3.3. The approach estimates marginal cost from a flexible cost function $C(Q, w)$ and its factor demands $X_k = \frac{\partial C}{\partial w_k}$ (Shephard's lemma, Appendix B). It estimates them jointly with demand and the supply relation (Bresnahan, 1989, Section 3.3). Its identifying idea is homogeneity (Bresnahan, 1989, p. 1034). Total cost is homogeneous of degree one in factor prices, so marginal cost is too, and Euler's theorem gives

$$MC(Q, w) = \sum_k w_k \frac{\partial MC(Q, w)}{\partial w_k}.$$

Every term of marginal cost therefore scales with factor prices, while the markup term θm in $P = MC + \theta m$ does not. Scaling all factor prices by a common factor moves marginal cost

Table 3.1: Approaches to measuring market power in homogeneous-goods industries

Approach	Data needed	Maintained assumptions	What is identified	Section
(a) Market-wide cost shifters	Prices and an observed, exogenous cost component (taxes). Quantities or revenue for some tests	Shape of demand and of marginal cost. Long-run equilibrium for the revenue test	Test of competition. Bounds on θ. Sign of the revenue statistic	3.2, 3.3
(b) Firm-specific cost shifters	One firm's price and quantity, its own cost shifters and rivals' cost shifters	Own cost shifters excluded from rivals' supply. Special conduct for a markup reading	Slope of the firm's residual demand	3.4
(c) Demand rotations	Industry price and quantity, a demand shifter, a demand rotator and cost shifters	Functional forms of demand and marginal cost. Constant θ	Point estimate of θ and of the slope of marginal cost	3.5
(d) Observed marginal cost	Prices, quantities and engineering or accounting cost data	Correct measurement of marginal cost. Estimated demand elasticity	$\theta_t = \varepsilon_t L_t$ observation by observation. Validation of (c)	3.7, 3.8
(e) Cost and factor-demand functions	Prices, output, factor prices, input quantities	Flexible cost function homogeneous of degree one in factor prices. Correct price of capital	Marginal cost from factor demands, then θ	3.1.4
(f) Regime switching	Long time series of price and quantity	Two or more conduct regimes. No other unobserved shifts of the supply relation	Size and frequency of shifts in conduct	Chapter 13

Notes: Our construction. Approach (a) covers Sumner (1981), Sullivan (1985), Ashenfelter and Sullivan (1987) and Panzar and Rosse (1987). Approach (b) is Baker and Bresnahan (1988), and (c) is Bresnahan (1982) and Lau (1982). Approach (d) covers Genesove and Mullin (1998) and Wolfram (1999). Approach (e) covers Gollop and Roberts (1979), Appelbaum (1979, 1982) and Hall (1988), and (f) is Porter (1983a).

proportionally and leaves the markup term unchanged. Any part of the supply relation that does not scale with factor prices is attributed to market power. Section 1.7.2 gives a worked example. The approach leans hard on the functional form of cost and on observing the true marginal price of every input. Valuing capital services is the familiar weak point, and it revives the accounting critiques of the cross-industry literature (Bresnahan, 1989, p. 1040).

3.2 Testing with cost pass-through: Sumner (1981)

Suppose one component of marginal cost is observed and varies for reasons unrelated to demand. Then the response of price to that component reveals the pricing rule, without any measurement of the rest of cost. Excise taxes are such a component. Sumner (1981) used state cigarette taxes to test whether the US cigarette industry behaved competitively, collusively, or in between. This section first develops the theory of pass-through under general conduct. It then presents Sumner's design and results, the critiques his test invites, and a replication that clarifies what the data can and cannot reveal.

3.2.1 Pass-through under conduct

Assumption 3.7 (Pass-through environment)**.** A homogeneous good has twice differentiable inverse demand $P(Q)$ with $P'(Q) < 0$. Industry marginal cost $MC(Q)$ is differentiable with $MC'(Q) \geq 0$. A specific (per-unit) tax t is collected from sellers, so effective marginal cost is $MC(Q) + t$. Conduct $\theta \geq 0$ does not vary with t, and the equilibrium is interior and satisfies the supply relation

$$P(Q) + \theta\, Q\, P'(Q) = MC(Q) + t. \tag{3.5}$$

Three local features of the primitives govern pass-through. The *curvature* of inverse demand is $\chi \equiv -\frac{QP''(Q)}{P'(Q)}$. It is zero for linear demand and positive when inverse demand is convex. The price elasticity of demand is $\varepsilon = -\frac{P}{QP'(Q)}$. The elasticity of the effective marginal cost curve is $\varepsilon_S \equiv \frac{MC+t}{Q\,MC'(Q)}$, which is infinite when marginal cost is flat. *Pass-through* is $\rho \equiv \frac{\mathrm{d}P}{\mathrm{d}t}$, the change in the equilibrium price per unit change in the tax.

Proposition 3.8 (Pass-through under conduct)**.** *Under Assumption 3.7, let $J \equiv P'(1+\theta) + \theta Q P'' - MC'$ and suppose the stability condition $J < 0$ holds. Proposition 2.76 then gives*

$$\rho = \frac{1}{1 + \theta(1-\chi) + \frac{MC'(Q)}{|P'(Q)|}} = \frac{1}{1 + \frac{\theta}{\varepsilon_{ms}} + \frac{\varepsilon - \theta}{\varepsilon_S}}, \qquad \varepsilon_{ms} \equiv \frac{1}{1-\chi}, \tag{3.6}$$

and both denominators are positive.

The stability condition $J < 0$ is the condition $\Lambda < 0$ of Assumption 2.75, written out with $ms' = -P'(1-\chi)$. It says that perceived marginal revenue cuts effective marginal cost from above. Differentiating (3.5) in t gives $\frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{1}{J} < 0$, so output falls when the tax rises. The price moves along the demand curve, so $\rho = \frac{P'}{J}$, and dividing by P' gives the first form. Steps 4 and 5 of the proof of Proposition 2.76 show that $\frac{MC'}{|P'|} = \frac{\varepsilon - \theta}{\varepsilon_S}$, which links the two forms.

The second form in (3.6) is the formula of Weyl and Fabinger (2013, eq. (2), p. 548) for constant conduct. They call $\varepsilon_{ms} = \frac{ms}{Q\,ms'}$, with $ms(Q) = -QP'(Q)$, the elasticity of the inverse marginal surplus function (Weyl and Fabinger, 2013, p. 538). Their formula adds the term $\frac{\theta}{\varepsilon_\theta}$ to the denominator, where $\varepsilon_\theta = \frac{\theta}{Q\,\theta'(Q)}$ is the elasticity of conduct with respect to output (Section 2.8.3). The term vanishes here because θ is constant.

Corollary 3.9 (Special cases)**.** *Corollary 2.77, Corollary 2.71 and Example 2.73 give the following special cases of Proposition 3.8.*

(i) Competition with rising marginal cost ($\theta = 0$) gives $\rho = \frac{1}{1+\frac{\varepsilon}{\varepsilon_S}} = \frac{\varepsilon_S}{\varepsilon_S + \varepsilon} \leq 1$, with equality only when marginal cost is flat (Corollary 2.77(i)).

(ii) Monopoly with flat marginal cost gives $\rho = \frac{1}{2-\chi}$. In terms of direct demand $D(P)$, $\chi = \frac{D(P)D''(P)}{D'(P)^2}$, so $\rho < 1$ if and only if D is log-concave (Lemma 2.70 and Corollary 2.71).

(iii) Linear demand ($\chi = 0$) with flat marginal cost gives $\rho = \frac{1}{1+\theta}$ (Example 2.73(i)).

(iv) Constant-elasticity demand $P = AQ^{-\frac{1}{\varepsilon}}$ has $\chi = 1 + \frac{1}{\varepsilon}$, and with flat marginal cost $\rho = \frac{\varepsilon}{\varepsilon - \theta}$ (Example 2.73(iii)).

(v) The Bulow-Pfleiderer family $P = a - bQ^\gamma$, with $b, \gamma > 0$, has $\chi = 1 - \gamma$, and with flat marginal cost $\rho = \frac{1}{1+\theta\gamma}$ (Example 2.73(ii)).

(vi) Log demand $P = a - b \ln Q$, with $b > 0$, has $\chi = 1$, and with flat marginal cost $\rho = 1$ for every θ. The markup is the constant θb (Example 2.73(iv)).

The symbols A, a, b and γ are local to this corollary.

Part (v) is the family of Example 2.12 in inverse form, with $\gamma = \frac{1}{g}$. Section 3.7 writes it in direct form, as Genesove and Mullin (1998) do, so the exponent there is the reciprocal of the γ used here. The log demand of part (vi) is the inverse of exponential direct demand $Q = e^{\frac{a-P}{b}}$.

Figure 3.1 plots pass-through against conduct for four demand curves with flat marginal cost. Under competition every curve passes through $\rho = 1$. As conduct rises, the curves fan out in a direction set by curvature alone. Pass-through exceeds one only for demand more convex than log demand.

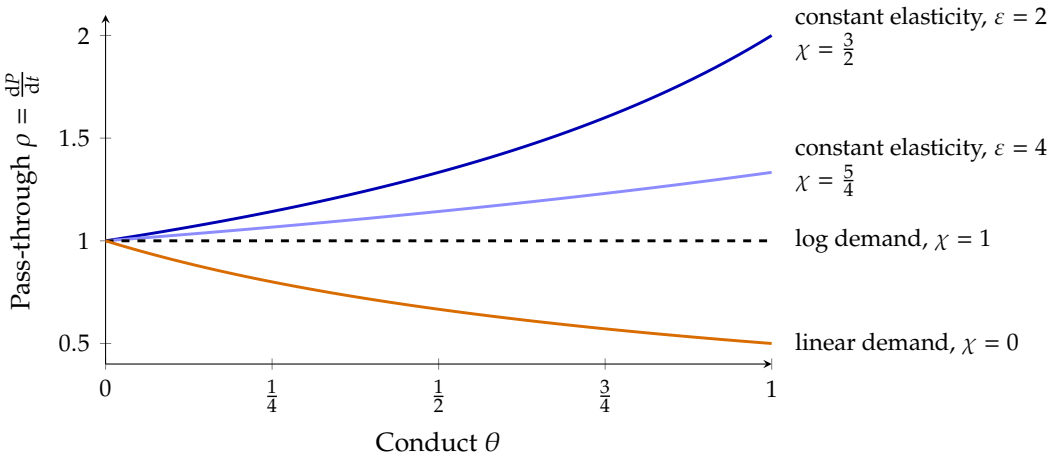

Figure 3.1: Pass-through of a specific tax as a function of conduct for four demand curves, with flat marginal cost. From Corollary 3.9, $\rho = \frac{1}{1+\theta(1-\chi)}$. Linear demand gives $\frac{1}{1+\theta}$, log demand gives 1 for every θ, and constant elasticity gives $\frac{\varepsilon}{\varepsilon-\theta}$. The dashed line is also the competitive benchmark.

Proposition 3.10 (What pass-through identifies)**.** *Corollary 2.78 gives the following. Under Assumption 3.7 with flat marginal cost, pass-through identifies only the composite*

$$\kappa \equiv \theta(\chi - 1) = 1 - \frac{1}{\rho}. \tag{3.7}$$

Consequently, the following hold.

(i) $\rho > 1$ rejects $\theta = 0$ for every demand curve. Rising marginal cost only strengthens the rejection.

(ii) Any ρ in $(0, \infty)$ is consistent with every conduct $\theta \in (0, 1]$, for a suitable curvature. Pass-through alone never rejects monopoly.

(iii) Under constant-elasticity demand with elasticity ε, $\theta = \varepsilon\kappa$.

Equation (3.7) is (2.66). Part (i) combines parts (i) and (iii) of Corollary 2.78. Parts (ii) and (iii) are parts (ii) and (iv) of that corollary. Given ρ and conduct $\theta > 0$, the curvature $\chi = 1 + \frac{\kappa}{\theta}$ reproduces the observed pass-through.

The proposition is the key to reading every cost pass-through study. A market-wide cost shock moves the equilibrium along a single demand curve. What it reveals is the slope of perceived marginal revenue relative to the slope of demand, and that slope mixes conduct with curvature. Separating them needs either an assumption on curvature, as in Sumner's constant elasticity, or variation that changes the slope of demand at a given point (Section 3.5).

3.2.2 Sumner's design and results

The question. Is the US cigarette industry competitive, collusive, or in between? The industry was a textbook example of oligopoly. In the Tobacco Case of 1946 the major manufacturers were convicted of operating an illegal cartel, and the consensus was that their behavior did not change after the verdict (Sumner, 1981, p. 1010). Earlier work had measured market power by the ratio of price to marginal cost, which requires cost data that are rarely reliable. Sumner proposed a scheme that avoids measuring cost: "The coefficient of the tax rate term in a price equation identifies the ratio of price to marginal cost" (Sumner, 1981, p. 1010).

The setting. Cigarettes carry a federal excise tax and state excise taxes, both specific taxes per pack. The federal tax was 8 cents per pack for more than 25 years. The median state tax rose from 3 cents in 1954 to 12 cents in 1978. Combined taxes nonetheless fell in real terms, from 48.7 percent of the retail price in 1954 to 35.5 percent in 1978. In 1978 state taxes ranged from 2 cents in North Carolina to 21 cents in Florida, Connecticut and Massachusetts. The three states with a large stake in tobacco growing and cigarette manufacturing (North Carolina, Virginia and Kentucky) all had low taxes. Tobacco interests cannot explain the variation among the other states (Sumner, 1981, n. 8).

Two features of the distribution system matter for the test. First, the institutions limit arbitrage across states. The federal tax is paid by manufacturers, with the stamp affixed at the factory. Distributors must hold a license in the state where they operate and must pay the state tax and affix its stamp within a few days of receiving a shipment. Reselling out of state requires a special permit. Manufacturers therefore know the final state of sale and could, in principle, set prices that depend on the state tax. Sumner argues that differentials of several cents per pack could persist before arbitrage became profitable. Second, he assumes that wholesale and retail distribution are competitive, citing the large numbers of retailers and distributors in each market.

The data. The panel covers 47 states and the District of Columbia annually from 1954 to 1978, 1,200 state-years. Alaska, Hawaii and New Hampshire are excluded for lack of data and peculiar tax laws. Prices are the Tobacco Tax Council's "weighted-average price per package" for each state and year. The Council asks wholesalers for average retail prices by type of cigarette (regular, king, 100 mm) and type of sale (carton, single pack, machine). It aggregates them with national weights, so the most obvious quality differences are held fixed across states.

The model. Sumner starts from the markup rule of a firm j facing a demand curve with elasticity $\eta_j < 0$ (his sign convention),

$$P_j = \frac{\eta_j}{\eta_j + 1} M_j \qquad \text{(his eq. 1)},$$

where M_j is marginal cost. In our notation, with $\varepsilon_j = -\eta_j > 0$, this is $P_j = \frac{\varepsilon_j}{\varepsilon_j - 1} M_j$. Under monopoly ε_j is the market elasticity, and under perfect competition it is infinite. Marginal cost is expanded as $M_j = X_j\beta + e_j + R$ (his eq. 2), with observed cost factors X_j, unobserved factors e_j and the tax R, which does not vary by firm.

Only state-average prices are observed, so Sumner aggregates. Let S_j be firm j's market share, $\omega_j \equiv \frac{P_j}{M_j}$ its price-to-cost ratio, and $P = \sum_j S_j P_j$, $M = \sum_j S_j M_j$ and $\bar{\omega} = \sum_j S_j \omega_j$ the share-weighted averages. Then

$$P = \sum_j S_j\, \omega_j M_j = \bar{\omega} M + \sum_j S_j (\omega_j - \bar{\omega})(M_j - M) \qquad \text{(his eq. 3)}.$$

To verify the identity, expand the last sum. It equals $\sum_j S_j \omega_j M_j - \bar{\omega} M - \bar{\omega} M + \bar{\omega} M$, because $\sum_j S_j = 1$. Sumner also identifies $\bar{\omega}$ with $\frac{\bar{\eta}}{\bar{\eta}+1}$ for the share-weighted elasticity $\bar{\eta}$, which holds only approximately because the map is nonlinear. The covariance term vanishes if price-cost ratios or marginal costs vary little across firms, or are unrelated. Sumner argues that retail prices vary little across brands within a market and that costs are similar, since cigarettes are made in one region with a standard technology. Dropping the covariance term gives $P = \bar{\omega} M$, and substituting the cost equation gives the linear price equation

$$P_{it} = X_{it}\psi + \bar{\omega} R_{it} + U_{it} \qquad \text{(his eq. 4)},$$

with states i, years t, $\psi = \bar{\omega}\beta$ and $U_{it} = \bar{\omega} e_{it}$. Sumner calls the tax coefficient θ. Under constant $\bar{\omega}$ it equals the pass-through $\frac{dP}{dR}$, so we write it as ρ.

The link to conduct is direct. With constant-elasticity market demand, flat marginal cost and conduct θ, Corollary 3.9(iv) gives $P = \frac{\varepsilon}{\varepsilon - \theta}(k + t)$, with non-tax marginal cost k and tax t. Comparing with his eq. 1, Sumner's firm-level elasticity is

$$\varepsilon_j = \frac{\varepsilon}{\theta},$$

the market elasticity divided by conduct. It is the elasticity that firms behave as if they face.

The estimating equation and the estimator. With states indexed by s and years by y, the most complete specification is

$$p_{sy} = \mu_s + \tau_y + \rho\, t_{sy} + e_{sy}. \tag{3.8}$$

Here p_{sy} is the price per pack and t_{sy} the combined state and federal tax. The terms μ_s and τ_y are state and year fixed effects. The state effects absorb $\frac{\varepsilon}{\varepsilon - \theta} k_{sy}$ to the extent that it is constant within a state, and the year effects absorb national cost and price-level changes. Equation (3.8) is a two-way fixed-effects, or difference-in-differences, regression (Appendix A). Sumner estimates it by OLS. He also reports a specification that replaces the year effects by the national consumer price index and drops the state effects. He estimates it by OLS and by a variance-components (random-effects) generalized least squares (GLS) estimator with random state and year effects (Fuller and Battese, 1974).

The hypotheses are sharp. Competition with flat marginal cost implies $\rho = 1$. Monopoly with constant-elasticity demand implies $\rho = \frac{\varepsilon}{\varepsilon - 1} > 1$, and conduct θ implies $\rho = \frac{\varepsilon}{\varepsilon - \theta}$. An estimate of ρ can be inverted for the firm-level elasticity, $\varepsilon_j = \frac{\rho}{\rho - 1}$.

Identification. Tax variation is treated as exogenous: the residual e_{sy} is assumed uncorrelated with t_{sy} given the fixed effects. The state effects absorb stable differences in tax levels, such as the low taxes of producing states. What identifies ρ is therefore the timing of tax changes within states relative to other states. The assumption fails if states raise taxes when local costs or demand change, or if taxes shift the demand for legal sales through cross-border shopping and smuggling. The tax shifts the marginal cost of every seller in a state by the same amount, so the test concerns market demand and industry conduct. A cost shifter specific to one firm would instead trace out that firm's residual demand (Section 3.4).

Results. Table 3.2 reproduces Sumner's Table 1. With state and year effects, $\hat{\rho} = 1.074$ with a standard error of 0.013. A 10-cent difference in taxes thus raises the price by 10.74 cents. The t-statistic for $\rho = 1$ is $\frac{1.074 - 1}{0.013} = 5.7$. The other two specifications give 1.029 and 1.069, with t-statistics of 2.6 and 5.3. All three reject competition at conventional levels. The last column of the table reports our replication on a reconstructed panel (Section 3.2.4), which reproduces all three estimates to within 0.001.

Table 3.2: Effect of the excise tax on the retail price of cigarettes

	Sumner (1981), Table 1				Implications		Replication
	$\hat{\rho}$	Elasticity	Controls	Method	t for $\rho = 1$	$\frac{\hat{\rho}}{\hat{\rho}-1}$	$\hat{\rho}$
(1)	1.074 (0.013)	−13.5	DY_t, DS_i	OLS	5.7	14.5	1.075 (0.013)
(2)	1.029 (0.011)	−34.5	NCPI	OLS	2.6	35.5	1.029 (0.011)
(3)	1.069 (0.013)	−14.5	NCPI	VC	5.3	15.5	1.069 (0.013)

Notes: The dependent variable is the retail price per pack in cents. The sample has 1,200 state-years (48 states including DC, 1954–78). Standard errors are in parentheses. "Elasticity" is Sumner's implied price elasticity, with his negative sign. DY_t are year dummies (1978 excluded) and DS_i state dummies (Wyoming excluded). NCPI is the national consumer price index, and row (2) has no state dummies. VC is a variance-components (random-effects) GLS estimator with a random effect for each state and each year. Sumner reports R^2 of about 0.99 with dummies and about 0.95 without. Our replication gives 0.994 and 0.985. The column $\frac{\hat{\rho}}{\hat{\rho}-1}$ inverts his eq. 1 exactly, in absolute value. The replication uses OLS for rows (1) and (2) and two-way random-effects GLS for row (3), with conventional standard errors, as in the paper.

The implied elasticities in the table deserve a check. Sumner's reported values equal $\frac{1}{1-\hat{\rho}}$ exactly, for example $\frac{1}{1-1.074} = -13.5$. Inverting his eq. 1 exactly instead gives $\eta_j = -\frac{\hat{\rho}}{\hat{\rho}-1}$, which is −14.5, −35.5 and −15.5. The reported values thus treat $\hat{\rho} - 1$ as the markup over cost, $\frac{P-M}{M} = -\frac{1}{\eta_j}$, in place of the Lerner condition $\frac{P-M}{P} = -\frac{1}{\eta_j}$. The two agree to first order in $\frac{1}{|\eta_j|}$, so the difference is immaterial for his conclusions. His text uses the same approximation: "Taking $\theta = 1.05$, a 1 percent rise in the price of a firm's product would cause a 20 percent fall in the quantity sold" (Sumner, 1981, p. 1019).

Robustness. Sumner reports four checks. First, he estimates nonlinear versions of eq. 4 that let the price-to-cost ratio vary with price, $\bar{\omega}(P) = \gamma P^{1-\lambda}$. Substituting in $P = \bar{\omega}(P)M$ gives $P^{\lambda} = \gamma M$, which he estimates by nonlinear least squares with additive and multiplicative errors (his eqs. 4′ and 4″). The hypothesis $\lambda = 1$, under which the ratio is constant and equal to γ, is not rejected. The estimates are $\hat{\lambda} = 0.972$ (0.027) and 0.981 (0.026), with $\hat{\gamma} = 1.029$ and 1.062 (Sumner, 1981, n. 9). Second, the pooled equation estimated separately for each year gives estimates in the range of Table 1, with no trend. Third, a squared tax term added to the yearly equations is insignificant in most years. Smuggling would make price a concave function of the tax, so this check speaks against a large role for smuggling. Fourth, adding New Hampshire leaves the results essentially unchanged.

Interpretation. Sumner draws two conclusions. Pass-through significantly above one rejects atomistic competition. The implied firm-level elasticities, between 13.5 and 34.5 in absolute value, are far above estimates of the industry elasticity of demand, which "are generally between −0.3 and −0.8" (Sumner, 1981, p. 1017). His own estimate of the industry elasticity is about −0.40 (n. 10). A cartel acting as a monopolist would face the industry elasticity, so the estimates are inconsistent with an effective cartel. A monopolist would never price on the inelastic part of demand, so with an industry elasticity below one it would raise prices far above the observed level. Sumner concludes that monopoly power is small relative to tax and

other cost differences. Taking $\rho = 1.05$, it adds about 3 cents to the average price of a pack.

In conduct-parameter language, the constant-elasticity model gives $\theta = \varepsilon\kappa$ with $\kappa = 1 - \frac{1}{\rho}$ (Proposition 3.10). With $\hat{\rho} = 1.074$, $\hat{\kappa} = 0.069$. An industry elasticity of 0.4 then gives $\theta \approx 0.028$, and the range from 0.3 to 0.8 gives θ between 0.021 and 0.055. These values are close to competition. They correspond to the conduct of a symmetric Cournot industry with 18 to 48 firms, in an industry with only six major manufacturers (Ashenfelter and Sullivan, 1987, p. 488). Sumner's alternative explanation is Barzel's (1976) quality effect, which we discuss with the other critiques below.

3.2.3 Curvature, cost, composition, and further critiques

Sumner's rejection of competition needs only flat marginal cost. His rejection of collusion also needs constant-elasticity demand. Three critiques address these assumptions and the price measure.

Demand curvature. Proposition 3.10 shows that a pass-through test identifies conduct only conditional on curvature. A monopolist facing log demand passes through exactly one, the competitive value (Corollary 3.9(vi)). A monopolist facing concave or linear inverse demand passes through less than one. A pass-through below one would then wrongly "accept" competition, or even suggest that firms absorb taxes. Sumner's nonlinear check tests whether pass-through varies with the price level. Constant pass-through is consistent with constant elasticity, but also with any other pair (θ, χ) whose product $\theta(\chi - 1)$ stays constant. It cannot pin down curvature on its own.

Cost curvature. With rising marginal cost, competitive pass-through is $\frac{\varepsilon_S}{\varepsilon_S + \varepsilon} < 1$ (Corollary 3.9(i)). A pass-through near one is then consistent with several combinations: competition with flat marginal cost, monopoly with log demand, or monopoly with log-convex demand and rising marginal cost. The slope of marginal cost and conduct both enter the slope of the supply relation. This is the identification problem of Section 3.5 in another guise. Rising marginal cost pushes competitive pass-through below one, so it leaves the rejection of competition intact.

Composition. Sumner's price is an average over brands and package types. Suppose the measured price is $\bar{p} = \sum_j w_j p_j$, with quantity weights w_j. Then

$$\frac{\mathrm{d}\bar{p}}{\mathrm{d}t} = \sum_j w_j \frac{\mathrm{d}p_j}{\mathrm{d}t} + \sum_j p_j \frac{\mathrm{d}w_j}{\mathrm{d}t}.$$

The first term is the average pass-through of individual prices. The second is a composition effect. A specific tax raises the prices of cheap varieties proportionally more than those of expensive ones, so consumers may trade up. The second term is then positive, and the regression overstates product-level pass-through. The test is biased toward rejecting competition. The Tobacco Tax Council's fixed national weights remove composition effects across package types and types of sale, but not across brands within a type. Sumner's observation that retail prices vary little across brands limits this channel. Nevo and Hatzitaskos (2005, p. 13) make a related point in another setting. Much of the fall in the average price of tuna during Lent, a period of high demand, comes from a shift of purchases toward cheaper products.

A close relative of the composition effect is the quality response emphasized by Barzel (1976). A per-unit tax lowers the relative price of quality, so higher taxes should induce higher quality per unit. Measured price per pack then rises by more than the tax even under competition. Sumner replies that the price data hold the obvious quality dimensions fixed and

that centralized manufacturing leaves little room for quality variation across states. He also notes that a Barzel effect would bias the estimate upward, which strengthens the case against an effective cartel (Sumner, 1981, p. 1018).

Further critiques. Four further issues apply to any tax pass-through study. First, taxes shift demand as well as cost. Consumers in high-tax states buy across borders or from smugglers, so legal sales respond to the tax beyond the movement along demand. Sumner's own footnote 6 notes that smuggling can lower measured prices net of tax at both extremes. In very low-tax states, bulk sales for export carry low transaction costs. In very high-tax states, legal sellers compete with the illegal market. Second, timing matters. Prices are observed once a year, and announced tax increases can trigger stockpiling and anticipatory price changes, so annual data may mix short-run and long-run pass-through. Third, the test measures the conduct of the whole vertical chain. Market power among wholesalers or retailers, or retailers who apply percentage markups, would also produce $\rho > 1$ with competitive manufacturers. Fourth, the regression errors are serially correlated within states, so conventional standard errors overstate precision (Bertrand et al., 2004). Section 3.2.4 shows that clustering by state matters here. Specific and ad valorem taxes also pass through differently. An ad valorem tax at rate τ on the consumer price scales effective marginal cost by $\frac{1}{1-\tau}$. Its pass-through therefore depends on the level of cost as well as on curvature.

3.2.4 A replication and what it adds

We re-estimate Sumner's regressions on a reconstructed panel with the same coverage: 47 states and the District of Columbia, 1954 to 1978, 1,200 state-years. Prices and taxes come from Tobacco Institute (1983, Table 13), the historical compilation of *The Tax Burden on Tobacco*. They are nominal cents per pack on November 1 of each year. The tax is the state tax plus the federal tax of 8 cents, and municipal taxes are excluded. We deflate by the consumer price index for all urban consumers (CPI-U) where needed. The average price rises from 22.5 cents in 1954 to 56.6 cents in 1978. The median state tax rises from 3 to 12 cents, as in Sumner's footnote 8. The same footnote gives a stronger check. In the reconstructed panel the median combined tax is 48.7 percent of the median price in 1954 and 35.3 percent in 1978, against Sumner's 48.7 and 35.5 percent. Of the 1,152 year-to-year transitions within states, 191 involve a tax change. Only 6 are decreases, and the average change is 2.4 cents. The tax accounts for 46.7 percent of the retail price on average.

Table 3.2 shows that the reconstructed data reproduce all three of Sumner's estimates. Table 3.3 reports three extensions, and Appendix C develops the exercise in full.

Clustering. Sumner's conventional standard error of 0.013 ignores serial correlation of the errors within states. Clustering by state raises it to 0.034. Pass-through remains significantly above one, with a 95 percent interval of $[1.006, 1.143]$ and $p = 0.033$. The rejection of competition survives, but its margin is much thinner than a t-statistic of 5.7 suggests. In real terms (M1) the estimate is 1.107 with a clustered standard error of 0.026.

Constant pass-through. If conduct and curvature are constant, pass-through does not vary with the tax. Specification M2 lets it vary through a quadratic in the real tax. Estimated pass-through is 1.097 at the 10th percentile of the tax and 1.113 at the 90th, and the test of $b_2 = 0$ gives $p = 0.76$. The test has little power, however. The 95 percent interval for the difference between the two percentiles is wider than $\hat{\rho} - 1$ itself.

The identified set. By Proposition 3.10, the data identify $\hat{\kappa} = 0.069$, with 95 percent interval $[0.006, 0.125]$. Every pair (χ, θ) on the hyperbola $\theta(\chi - 1) = \hat{\kappa}$ fits the estimate equally well.

Table 3.3: Replication and extensions of the pass-through regression

Specification	Statistic	Estimate	S.e.
M0: nominal cents, state and year effects	$\hat{\rho}$	1.075	0.013
	$\hat{\rho}$, state-clustered s.e.	1.075	0.034
	95% confidence interval	[1.006, 1.143]	
	p-value for $\rho = 1$ (clustered)	0.033	
M1: real cents, state and year effects	$\hat{\rho}$	1.107	0.026
M2: quadratic in the real tax	$\hat{\rho}$ at 10th percentile of tax	1.097	0.039
	$\hat{\rho}$ at 90th percentile of tax	1.113	0.034
	p-value for $b_2 = 0$	0.76	
	95% interval for $\rho(p_{90}) - \rho(p_{10})$	[−0.090, 0.122]	
Composite from M0	$\hat{\kappa} = 1 - \frac{1}{\hat{\rho}}$	0.069	
	95% interval for κ	[0.006, 0.125]	

Notes: 1,200 state-years. All specifications include state and year fixed effects. Standard errors are clustered by state (48 clusters) except in the first row. M1 deflates price and tax by the CPI-U. M2 regresses the real price on $b_1(T_{sy} - \bar{T}) + b_2(T_{sy} - \bar{T})^2$, so that $\rho(T) = b_1 + 2b_2(T - \bar{T})$. The interval for κ maps the endpoints of the clustered interval for ρ. $\hat{\kappa}$ uses the unrounded estimate $\hat{\rho} = 1.0746$.

Figure 3.2 plots this set. Monopoly fits with $\chi = 1.069$, a demand curve slightly more convex than log demand. Symmetric Cournot with six firms fits with $\chi = 1.42$. Constant elasticity with an industry elasticity of 0.4 has $\chi = 3.5$ and gives $\theta = 0.028$, with interval $[0.002, 0.050]$. The data alone cannot choose among these. Sumner's rejection of collusion rests on the constant-elasticity assumption combined with outside estimates of the industry elasticity.

A bound that does not depend on curvature. Outside information on the industry elasticity can rule out monopoly without any assumption on curvature. With flat marginal cost $c \geq 0$ and tax t, the Lerner form of (3.5) is $\frac{P-t-c}{P} = \frac{\theta}{\varepsilon}$, where ε is the elasticity at the observed equilibrium. Since $c \geq 0$,

$$\theta = \varepsilon\left(1 - \frac{t}{P} - \frac{c}{P}\right) \leq \varepsilon\left(1 - \frac{t}{P}\right). \tag{3.9}$$

The tax is a large share of the cigarette price. At the sample mean share of 0.467 and $\varepsilon = 0.4$, the bound gives $\theta \leq 0.213$. At the lowest share in the sample (0.229) it gives $\theta \leq 0.308$. Both rule out monopoly. Equivalently, monopoly at the mean tax share requires an elasticity of at least $\frac{1}{1-0.467} = 1.88$ at the observed price. The bound uses the level of prices and taxes, and pass-through does not enter it. Sullivan's bound in Section 3.3.1 develops the same idea with an elasticity estimated from the tax variation itself.

Remark 3.11 (Pass-through as a tool). Proposition 3.8 turns pass-through into a measurement device. Given estimates of ρ, ε and the slope of marginal cost, it pins down conduct for any assumed curvature. Conversely, given conduct, it predicts the incidence of taxes and cost shocks. Weyl and Fabinger (2013) develop this program in general. Recent applications combine first-order conditions of this kind with credible sources of variation. Miller et al. (2017a) study the US portland cement industry from 1980 to 2010. Their estimated pass-through of fuel costs ranges from 1.03 to 1.65 across specifications (Table 4, p. 84). They combine it with conduct estimates from earlier work to measure the incidence of a price on carbon emissions. Bergquist and Dinerstein (2020) use the first-order-condition approach to estimate the effect of coordination among intermediaries in the Kenyan maize market. Their field experiment supplies the instruments (Asker and Nocke, 2021, p. 214, n. 86). Identification of conduct still

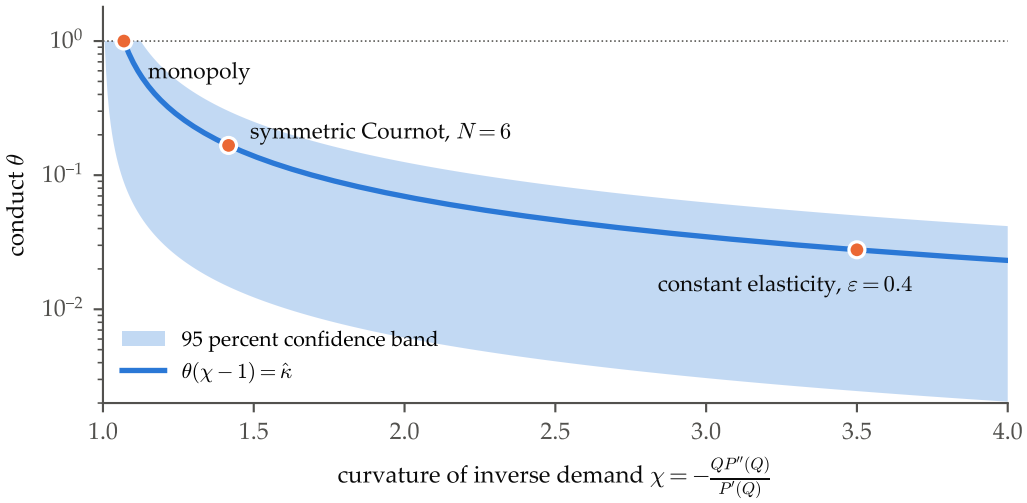

Figure 3.2: Pairs of demand curvature χ and conduct θ consistent with the estimated cigarette tax pass-through $\hat{\rho} = 1.0746$. The curve is $\theta(\chi - 1) = \hat{\kappa}$ with $\hat{\kappa} = 0.069$, and the band maps the 95 percent state-clustered confidence interval for ρ. The marked points are monopoly ($\chi = 1.069$), symmetric Cournot with six firms ($\chi = 1.42$, $\theta = \frac{1}{6}$) and constant-elasticity demand with $\varepsilon = 0.4$ ($\chi = 3.5$, $\theta = 0.028$). The vertical axis is logarithmic.

requires curvature, which must come from demand estimated over a range of prices or from assumption.

Contribution. Sumner's paper introduced a design that is now standard. It uses an observed, exogenous component of marginal cost and a fixed-effects panel to learn about the pricing rule without measuring cost. Its rejection of competition holds for any demand curve and any non-decreasing marginal cost, although clustering weakens it. Its rejection of collusion holds only given curvature, or given an industry elasticity and the curvature-free bound (3.9). The lesson extends beyond cigarettes. A market-wide cost shifter traces out demand and reveals the slope of perceived marginal revenue, which mixes conduct with curvature. Cost shifters therefore deliver tests and bounds on conduct. Point identification requires variation that rotates demand (Section 3.5), cost shifters specific to one firm (Section 3.4), or direct measures of cost (Sections 3.7 and 3.8).

3.3 Comparative statics in cost without functional forms

Sumner's test in Section 3.2 turns a cost shock into a statement about conduct. It does so by assuming a demand curve with constant elasticity and a flat marginal cost. This section studies three tests that drop those functional forms. Each test asks what profit maximization alone implies about the response of an equilibrium to a change in cost. The answers are inequalities. They can reject monopoly or bound conduct from above, but they rarely deliver a point estimate.

We proceed in three steps. We first derive the bound of Sullivan (1985) and explain why cost shifters can only produce inequalities. We then prove the revealed-preference test of Ashenfelter and Sullivan (1987) and report its evidence from the cigarette industry. Finally we

develop the revenue test of Panzar and Rosse (1987), which needs data on revenue and factor prices only.

3.3.1 Sullivan's bound and why cost shifters give only inequalities

Consider N firms selling a homogeneous good. Inverse demand $P(Q)$ is stable and decreasing, $P' < 0$. Firm i has cost $C_i(q_i) + tq_i$, where t is a specific tax paid by sellers and C_i is increasing. Its marginal cost is therefore $MC_i = C_i'(q_i) + t \geq t$. Following Bresnahan (1989, eq. 24), we write the first-order condition of firm i in conjectural-variations form,

$$P(Q) + (1 + r_i)\, q_i P'(Q) = MC_i, \qquad i = 1, \ldots, N, \tag{3.10}$$

where r_i is the conjectural variation $\frac{\mathrm{d}Q_{-i}}{\mathrm{d}q_i}$ of Section 3.1.1. Cournot behavior is $r_i = 0$, joint profit maximization by N identical firms is $1 + r_i = N$, and price taking is the limit $1 + r_i \to 0$. As in Section 3.1.1, r_i describes how close output is to the competitive and collusive levels. It makes no claim about what firms believe.

Definition 3.12 (Numbers equivalent)**.** Suppose $1 + r_i > 0$ for every i. The *numbers equivalent* of the industry is

$$N_e = \sum_{i=1}^{N} \frac{1}{1 + r_i}.$$

In a Cournot industry $N_e = N$, so N_e counts the Cournot firms that would produce the same conduct. A cartel of N identical firms has $N_e = N \cdot \frac{1}{N} = 1$, and price taking corresponds to $N_e \to \infty$. The next lemma connects N_e to the industry conduct parameter of (3.1).

Lemma 3.13. *If all firms have the same marginal cost c, the conditions* (3.10) *aggregate to the supply relation $P + \theta Q P'(Q) = c$ with $\theta = \frac{1}{N_e}$.*

Proof. Rearrange (3.10) as $P - c = -(1 + r_i) q_i P'$ and divide by $1 + r_i$:

$$\frac{P - c}{1 + r_i} = -q_i P'.$$

Summing over i gives $(P - c)N_e = -QP'$. Dividing by N_e gives $P + \frac{1}{N_e} QP' = c$. □

The lemma is a special case of Proposition 3.2. With a common marginal cost, each firm's condition reads $s_i(1 + r_i) = \varepsilon \frac{P - c}{P}$, so every firm has the same value of $s_i \tilde{\theta}_i$. The industry conduct $\sum_i \varphi_i s_i \tilde{\theta}_i$ is then the same for all weights, and the lemma shows that it equals $\frac{1}{N_e}$.

Now let $z_c > 0$ be any variable that shifts marginal cost and is excluded from demand. The tax is the leading example, and a factor price is another. Write the equilibrium price and output as $P^*(z_c)$ and $Q^*(z_c)$. The *reduced-form elasticities* of price and quantity with respect to the cost shifter are

$$E_P = \frac{\mathrm{d} \ln P^*}{\mathrm{d} \ln z_c}, \qquad E_Q = \frac{\mathrm{d} \ln Q^*}{\mathrm{d} \ln z_c}. \tag{3.11}$$

Bresnahan (1989) writes them H_P and H_Q. Both can be estimated from regressions of log price and log output on the cost shifter. The first result says what they reveal.

Lemma 3.14 (Cost shifters trace out demand)**.** *If z_c does not enter demand and $E_P \neq 0$, the demand elasticity at the observed equilibrium is $\varepsilon = -\frac{E_Q}{E_P}$, whatever the conduct, the slope of marginal cost and the curvature of demand.*

Proof. Every equilibrium lies on the same demand curve, so $P^*(z_c) = P(Q^*(z_c))$ for all z_c. Differentiating in z_c gives $\frac{dP^*}{dz_c} = P'(Q^*)\frac{dQ^*}{dz_c}$. Multiply both sides by $\frac{z_c}{P^*}$ and insert $\frac{Q^*}{Q^*}$:

$$E_P = \frac{Q^* P'(Q^*)}{P^*} \cdot \frac{z_c}{Q^*} \frac{dQ^*}{dz_c} = -\frac{1}{\varepsilon} E_Q.$$

Solving for ε completes the proof. □

Proposition 3.15 (Sullivan's bound)**.** *Suppose $1 + r_i > 0$ and $MC_i \geq t$ for every firm, and let z_c satisfy Lemma 3.14. Then*

$$N_e \;\geq\; \frac{1}{\varepsilon\left(1 - \frac{t}{P}\right)} \;=\; -\frac{E_P}{E_Q} \cdot \frac{P}{P - t}. \tag{3.12}$$

If, in addition, all firms share the marginal cost c, conduct satisfies

$$\theta = \varepsilon L = -L\,\frac{E_Q}{E_P} \;\leq\; -\frac{E_Q}{E_P}\left(1 - \frac{t}{P}\right). \tag{3.13}$$

Proof. By (3.10), $P - MC_i = -(1 + r_i) q_i P' > 0$, so $P > MC_i \geq t$. Divide by $1 + r_i > 0$ and use $MC_i \geq t$:

$$\frac{P - t}{1 + r_i} \;\geq\; \frac{P - MC_i}{1 + r_i} \;=\; -q_i P'.$$

Sum over i and use $-QP' = \frac{P}{\varepsilon}$:

$$(P - t)\, N_e \;\geq\; -QP' \;=\; \frac{P}{\varepsilon}.$$

Divide by $P - t > 0$ to get $N_e \geq \frac{P}{\varepsilon(P - t)}$, which is the first expression in (3.12). Substituting $\varepsilon = -\frac{E_Q}{E_P}$ from Lemma 3.14 gives the second. Under a common marginal cost, Lemma 3.13 gives $\theta = \frac{1}{N_e}$ and (3.2) gives $\theta = \varepsilon L$. Finally $c \geq t$ implies $L \leq 1 - \frac{t}{P}$. □

Three features of the bound matter for what follows. First, it uses two reduced-form elasticities and the tax share of the price. Nothing depends on the curvature of demand, the slope of marginal cost or the functional form of either. Second, it is one-sided. A large value of the right side of (3.12) rejects collusive conduct, but no value can reject competition, because $N_e = \infty$ satisfies every lower bound. Third, it is the Lerner bound (3.9) of Section 3.2.4 with the demand elasticity estimated from the cost shock itself.

Bresnahan (1989, eq. 25) states the bound in the form

$$\sum_i (1 + r_i)^{-1} \;\geq\; -\frac{H_P}{H_Q L} \;\geq\; -\frac{H_P}{H_Q},$$

with H_P and H_Q our E_P and E_Q and L the common Lerner index. The first relation holds with equality under a common marginal cost, by Lemma 3.13. The second uses only $L \leq 1$, that is $MC \geq 0$, and coincides with (3.12) at $t = 0$. Using the tax as a floor on marginal cost tightens the bound, and this is the refinement that Sullivan uses (Bresnahan, 1989, p. 1038). For a cartel ($N_e = 1$) the bound says that $\varepsilon(1 - \frac{t}{P}) \geq 1$. A monopolist never prices on the inelastic part of demand, and the tax sharpens that rule. Its Lerner index $\frac{1}{\varepsilon}$ cannot exceed the share of the price left after tax.

Example 3.16 (An illustrative calculation)**.** Suppose a 10 percent tax increase raises the price by 4 percent and lowers sales by 1.6 percent. Suppose also that the tax is 40 percent of the price. These numbers are illustrative only. Then $E_P = 0.4$, $E_Q = -0.16$ and $\varepsilon = \frac{0.16}{0.4} = 0.4$. The bound is

$$N_e \;\geq\; \frac{1}{0.4 \times (1 - 0.4)} = \frac{1}{0.24} \approx 4.2, \qquad \theta \;\leq\; 0.24.$$

Monopoly and Cournot conduct with up to four firms are rejected. Cournot conduct with five or more firms is not.

Sullivan (1985) applies the bound to a panel of U.S. states and years in the cigarette industry. State excise taxes are the cost shifter, and an analysis-of-variance procedure absorbs the other exogenous variables. He rejects the hypothesis that cigarette prices are set as if by a cartel (Bresnahan, 1989, p. 1038). Ashenfelter and Sullivan (1987, p. 496) summarize his finding as industry behavior inconsistent with a numbers equivalent below two or three.

Why cost shifters give only inequalities. The proof of Lemma 3.14 shows what a cost shifter does. Demand does not move, so every observed equilibrium lies on one demand curve, and variation in z_c traces that curve out. A cost shifter therefore identifies the demand elasticity at each observed point. Conduct, however, sits in the supply relation, which in Lerner form reads $P - MC = \theta \frac{P}{\varepsilon}$. Once ε is known, θ is pinned down only if the level of marginal cost is known. The data restrict it only to $t \leq MC \leq P$. Mapping these two bounds through the supply relation gives the identified set

$$0 \;\leq\; \theta \;\leq\; \varepsilon \left(1 - \frac{t}{P}\right). \tag{3.14}$$

A demand shifter works the other way round. It moves equilibria along the supply relation and so traces out the equation that contains θ. Bresnahan (1989, p. 1039) draws this contrast, and Section 3.5 shows when demand shifters identify conduct. Pass-through is a partial exception. The slope of price in cost does involve θ, but Proposition 3.10 shows that it confounds conduct with the curvature of demand and the slope of marginal cost.

3.3.2 Ashenfelter and Sullivan (1987): a revealed-preference test

Question. Parametric tests of monopoly fit equations of a chosen functional form and then test restrictions on them. Ashenfelter and Sullivan (1987) point out that such a procedure always tests a joint hypothesis. They quote Varian (1983, p. 99): such a procedure tests "whatever one wants to test plus the maintained hypothesis of functional form." They therefore adapt the nonparametric revealed-preference approach of Afriat (1967) and Varian (1982) to monopoly. Excise taxes are well suited to it. Large tax changes give the test power, and every tax change yields a separate prediction. The researcher can therefore report the percentage of correct predictions, which separates a model that fails as a rule from one that fails occasionally (p. 484).

The test. An industry acts as a single decision maker, a monopoly or a perfect cartel. It faces a decreasing inverse demand $P(q)$ and a cost $C(q) = C_0(q) + tq$, where C_0 is increasing and t is the excise tax per unit. Let $t_0 < t_1$ be two tax rates with the same P and C_0. Let q_0 and q_1 be the profit-maximizing outputs and $p_0 = P(q_0)$, $p_1 = P(q_1)$ the prices.

Proposition 3.17 (Ashenfelter and Sullivan)**.** *Under these assumptions:*

(i) Output does not rise and price does not fall, $q_1 \leq q_0$ and $p_1 \geq p_0$.

(ii) Revenue falls by at least the old tax times the fall in output,

$$p_1 q_1 - p_0 q_0 \;\le\; t_0\,(q_1 - q_0). \tag{3.15}$$

(iii) If $p_1 > p_0$, the arc elasticity of demand satisfies

$$\frac{(q_0 - q_1)\,p_0}{(p_1 - p_0)\,q_0} \;\ge\; \frac{p_0}{p_1 - t_0}. \tag{3.16}$$

Proof. Output q_0 is optimal at tax t_0, so it earns at least as much as q_1 would:

$$p_0 q_0 - C_0(q_0) - t_0 q_0 \;\ge\; p_1 q_1 - C_0(q_1) - t_0 q_1. \tag{3.17}$$

Output q_1 is optimal at tax t_1:

$$p_1 q_1 - C_0(q_1) - t_1 q_1 \;\ge\; p_0 q_0 - C_0(q_0) - t_1 q_0. \tag{3.18}$$

Add the two inequalities. Revenues and the C_0 terms cancel, which leaves

$$-t_0 q_0 - t_1 q_1 \;\ge\; -t_0 q_1 - t_1 q_0 \quad\Longleftrightarrow\quad (t_1 - t_0)(q_0 - q_1) \;\ge\; 0.$$

Since $t_1 > t_0$, $q_1 \le q_0$. Demand slopes down, so $p_1 \ge p_0$. This proves (i). Rearrange (3.17):

$$p_1 q_1 - p_0 q_0 \;\le\; \big[C_0(q_1) - C_0(q_0)\big] + t_0(q_1 - q_0).$$

The bracket is not positive because $q_1 \le q_0$ and C_0 is increasing. This proves (ii). For (iii), write $p_1 q_1 - p_0 q_0 = p_1(q_1 - q_0) + q_0(p_1 - p_0)$ and substitute into (3.15):

$$q_0(p_1 - p_0) \;\le\; (p_1 - t_0)(q_0 - q_1).$$

A monopolist prices above marginal cost, so $p_1 > t_1 > t_0$. Multiply both sides by the positive number $\frac{p_0}{q_0(p_1 - p_0)(p_1 - t_0)}$ to obtain (3.16). □

Inequality (3.15) has a direct reading. Moving from q_0 to q_1 saves $t_0(q_0 - q_1)$ in taxes at the old rate. The revenue lost by the move must exceed this saving. Otherwise the monopolist would have chosen q_1 when the tax was still t_0. Inequality (3.16) extends the rule that a monopolist never produces on the inelastic part of demand. The arc elasticity must exceed $\frac{p_0}{p_1 - t_0}$, which is above one whenever the price rises by less than the old tax. The test uses two observed points, no functional form, no derivatives and no convexity of cost. It is local because it compares points close in time, where demand and cost are plausibly the same. Figure 3.3 draws the logic in the plane of output and revenue.

A conduct index. The test extends to intermediate conduct. Following Ashenfelter and Sullivan (1987, eq. 12), who call the index β, say that the industry has *conduct index* $\theta \in [0, 1]$ if, at its chosen output q,

$$\Delta q\, P(q + \Delta q) + \theta\, q\big[P(q + \Delta q) - P(q)\big] \;\le\; C(q + \Delta q) - C(q) \quad \text{for all } \Delta q. \tag{3.19}$$

With $\theta = 1$ the left side equals $(q + \Delta q)P(q + \Delta q) - qP(q)$, so (3.19) is the monopoly optimality condition. With $\theta = 0$ it is the revealed-preference form of price equal to marginal cost. Dividing (3.19) by $\Delta q > 0$ and letting $\Delta q \to 0$ gives $P + \theta q P' \le C'$. Dividing by $\Delta q < 0$ reverses

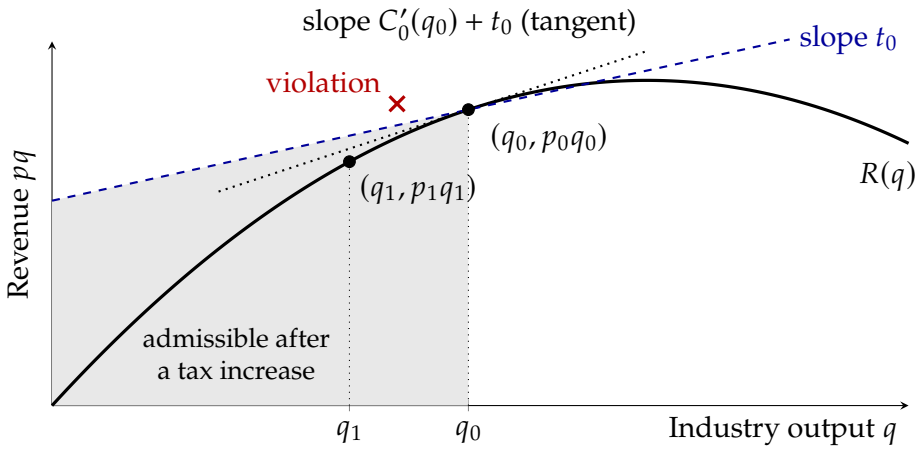

Figure 3.3: The revealed-preference logic of Proposition 3.17. After the tax rises from t_0 to t_1, the new point (q_1, p_1q_1) must lie left of q_0 and below the line through (q_0, p_0q_0) with slope t_0 (shaded region). The tangent of the revenue curve at q_0 has slope equal to marginal revenue, $C_0'(q_0) + t_0$, which is at least t_0. A point above the dashed line, such as the cross, rejects monopoly with stable demand and cost. The curve is drawn for $R(q) = 10q - q^2$, $C_0' = 1$, $t_0 = 2$ and $t_1 = 4$.

the inequality. Together they give $P + \theta qP' = C'$, which is the supply relation (3.1). The index is therefore a finite-difference version of the conduct parameter.

Apply (3.19) at $q = q_0$ under tax t_0 with $\Delta q = q_1 - q_0$. Then drop the term $C_0(q_1) - C_0(q_0) \le 0$. For $\theta \in (0, 1)$ the signs $q_1 \le q_0$ and $p_1 \ge p_0$ can no longer be proved, so the test assumes them (p. 487). Under these signs,

$$p_1(q_1 - q_0) + \theta\, q_0(p_1 - p_0) \;\le\; t_0(q_1 - q_0).$$

Solving for θ and inverting gives the two forms of the bound

$$\theta \;\le\; \frac{(p_1 - t_0)(q_0 - q_1)}{(p_1 - p_0)\, q_0}, \qquad N_e = \frac{1}{\theta} \;\ge\; \frac{q_0(p_1 - p_0)}{(q_0 - q_1)(p_1 - t_0)}. \tag{3.20}$$

The second form is the arc version of (3.12).[1] To see this, evaluate the elasticities at some price p between p_0 and p_1. Then $-\frac{E_P}{E_Q}$ becomes the ratio of the percentage price rise to the percentage output fall, $\frac{q_0(p_1-p_0)}{p\,(q_0-q_1)}$. The factor $\frac{P}{P-t}$ becomes $\frac{p}{p_1-t_0}$, because $p_1 - t_0$ bounds the per-unit margin from above along the path. Multiplying the two gives the right side of (3.20). Like Sullivan's bound, (3.20) can only reject less competitive conduct in favor of more competitive conduct (their n. 6).

Data. The data are those of Sullivan (1985), from the Tobacco Tax Council's *The Tax Burden on Tobacco*. They cover 45 states from 1955 to 1982 and contain three variables. The tax is the sum of the state and federal excise rates, averaged by time in force in years when the rate changed. Per capita consumption is inferred from state tax receipts. The average retail price per pack comes from a survey taken each November. Both dollar variables are deflated by the national consumer price index. The industry is highly concentrated. It has six major firms, and the two

[1] Ashenfelter and Sullivan (1987, eq. 18) derive the bound on N_e separately, by integrating the firms' first-order conditions over the tax change. Their printed equation has $q_1 - q_0$ in the denominator. We reverse that factor so that the bound is positive, as their equation (14) and their text require.

and four largest firms produce 66 and 90 percent of output. The major firms kept virtually identical list prices for thirty years and were twice convicted of antitrust violations (p. 488).

Design. Demand and cost may differ across states and drift over time. The test is therefore applied only to pairs of observations from the same state at most two years apart. Each pair is ordered so that t_0 is the lower real tax rate. The authors consider all consecutive-year pairs and several subsets. They also use *skip-year* pairs, separated by one year, which avoid the time-averaged tax in years of change. The cleanest subset is *flat-jump-flat*: the statutory rate is constant in both years of the pair and rises in the year between them. For each pair they check the output and price predictions of Proposition 3.17(i) and the revenue inequality (3.15).

Table 3.4: Ashenfelter and Sullivan (1987): percentage of monopoly predictions that hold

		Percentage of pairs for which the prediction holds				
Pairs of observations	Cases	$\Delta q \le 0$	$\Delta p \ge 0$	Both	Revenue	All three
Panel A: Table I						
Consecutive years	1178	70.8	75.3	54.6	36.7	14.9
real tax increases	216	74.1	83.8	68.1	17.1	6.0
real tax decreases	962	70.1	73.4	51.6	41.1	16.8
statutory changes	288	69.8	81.9	62.5	22.9	9.7
no statutory change	890	71.1	73.2	52.0	41.1	16.5
Skip-year changes	1133	71.8	85.0	62.0	27.4	15.1
flat-jump-flat	199	68.8	94.0	66.8	13.6	10.6
Panel B: Table II, skip-year changes by size of the tax change						
$\Delta t < 1$ cent	467	69.2	76.9	53.5	42.0	23.1
$1 < \Delta t < 2$ cents	444	69.1	86.9	61.0	23.0	11.9
$\Delta t > 2$ cents	222	82.9	98.2	81.5	5.9	4.5

Notes: Reproduced from Ashenfelter and Sullivan (1987, Tables I and II). "Revenue" is inequality (3.15). "Both" requires output to fall and price to rise. "All three" adds the revenue inequality. In each pair the lower real tax rate defines t_0. Tax changes in Panel B are in 1967 cents. The paper's Table II labels the last row $\Delta t < 2$, but its text (pp. 491–492) identifies the row as changes above 2 cents, and the three rows sum to the 1133 skip-year cases. Its first column header reads $\Delta q \ge 0$, while its note defines the prediction as a decline in quantity.

Results. Table 3.4 reproduces the main results. The revenue inequality, the distinctive prediction of monopoly, holds in only 432 of 1178 consecutive-year pairs, or 36.7 percent. It fares worse where measurement is cleanest. It holds in 13.6 percent of the flat-jump-flat pairs and in only 5.9 percent of the skip-year pairs with tax changes above 2 cents. The output and price predictions also fail often. They hold jointly in 54.6 percent of all consecutive-year pairs. They improve with the size of the tax change, to 81.5 percent for changes above 2 cents. The pattern is the one the authors stress (p. 492). Large tax increases usually raise prices and lower sales, yet they rarely lower revenue by as much as monopoly requires.

Figure 3.4 asks which oligopoly conduct the data can rationalize. It applies the bound (3.20) to the pairs in which output fell and price rose. These are 702 skip-year pairs and 133 flat-jump-flat pairs. Only 24.4 and 15.8 percent of them are consistent with $N_e = 1$. A numbers equivalent of 5 rationalizes 75.1 and 76.7 percent. Even $N_e = 9$ leaves 13.5 and 12.0 percent unexplained. The authors conclude that simple conjectural-variations models can be rejected "unless they embody at least a moderate amount of competition" (p. 492).

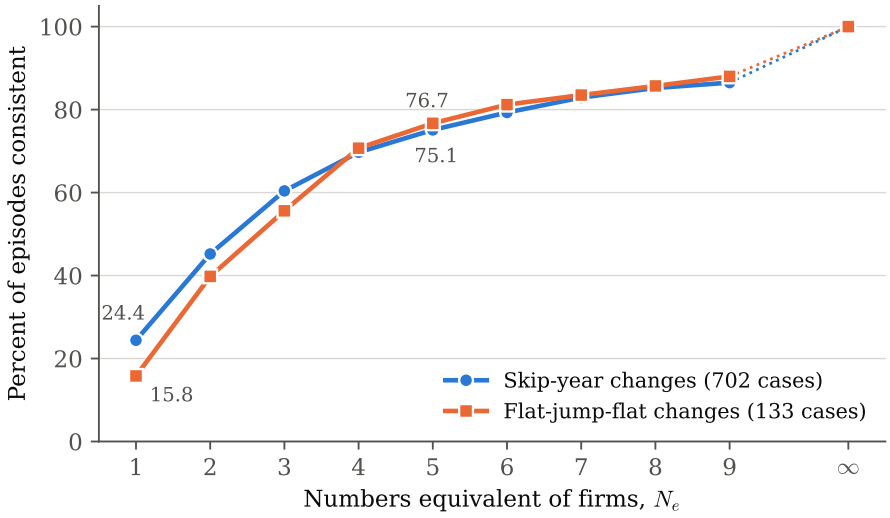

Figure 3.4: Share of tax-increase episodes consistent with a numbers equivalent N_e, from the bound (3.20). Only pairs with $\Delta q \leq 0$ and $\Delta p \geq 0$ enter. At $N_e = \infty$ every episode is consistent. The paper's table heads the second column "Jump-Flat-Jump", and its text calls the sample flat-jump-flat. Redrawn from the numbers in Ashenfelter and Sullivan (1987, Table III).

Robustness. The authors probe the failures in four ways. First, 371 of the 1133 skip-year pairs show price and quantity moving in the same direction, which signals a demand shift. Dropping them raises both the output and the price predictions to 92 percent, while the revenue inequality holds in only 26 percent (p. 493). Second, they allow for trends with a comparison group. In a simple version, the predicted change without a tax change is the mean change in states that kept their statutory rate that year. In a two-way version, it is the fit of a model with state and year effects to the state-years without a statutory change. The tests then ask whether quantity fell below, and price rose above, these predictions. Their Table IV reports the results. With the simple fit, the quantity and price predictions hold in 68.4 and 80.9 percent of the 288 consecutive-year statutory changes, and jointly in 60.1 percent. On the 199 flat-jump-flat pairs they hold in 68.8 and 92.0 percent, and jointly in 65.3 percent. The two-way fit does better. On the statutory changes the shares are 77.8, 79.2 and 68.4 percent. On flat-jump-flat pairs both predictions hold in 83.9 percent of cases, with 85.9 and 97.0 percent separately. The authors note the analogy with program evaluation, where untreated units serve as controls (Ashenfelter, 1978). In modern terms this is a difference-in-differences adjustment (Appendix A). Third, in nominal terms the price rises in 196 of the 199 flat-jump-flat pairs, though rising consumer prices make that success partly mechanical. Fourth, they test whether tax increases follow particular movements in prices and quantities. Their sign-based contingency tables condition on whether the tax rose in the previous year. The Pearson statistic is 3.9 when it did not and 34.9 when it did, each with 3 degrees of freedom. The overall statistic is 38.8 with 6 degrees of freedom. The second and the overall statistic rest on cells with very small expected counts, so the χ^2 approximation may be poor. Almost all of the 34.9 comes from the two cells in which price and quantity both fell. The authors conclude that endogenous tax timing does not explain the failures (Table V, pp. 495–496).

Assessment. The test shows how far pure revealed preference can go, and it rejects monopoly decisively. Its limits are instructive. The approach has no stochastic framework, a drawback

the authors acknowledge (n. 3). The percentages are therefore descriptive, and a single mismeasured pair can violate (3.15). Quantities inferred from tax receipts are suspect in exactly the years the test uses, because consumers and retailers can stock up before a tax increase or buy across state lines. The maintained hypothesis of stable demand and cost over one or two years is strong, as the frequent failures of the output and price predictions show. Once a comparison group corrects for demand shifts, the test is no longer nonparametric, as the authors concede (p. 494). Finally, a rejection of monopoly says little about which oligopoly model holds, beyond the lower bound on N_e. The paper's lasting contribution is the idea of bounding conduct with inequalities implied by optimization, which returns in Section 3.6.3.

3.3.3 Panzar and Rosse (1987): the revenue test

Panzar and Rosse (1987) propose two ideas (Bresnahan, 1989, pp. 1034–1035). The first is to estimate a reduced form and focus on the coefficients of factor prices. The second is to use revenue as the dependent variable. Revenue is often observable when price and quantity are not. It also needs no quality correction, whereas a price per unit can overstate the true price where the product is better. Section 1.7.2 previewed the test. This section proves its properties.

Setup. Firm i produces output q at cost $C(q, w, z)$, where $w = (w_1, \dots, w_K)$ is the vector of factor prices and z collects other cost shifters. Its revenue function is $R(q, y)$, with y a vector of demand shifters. Solving the equilibrium for the firm's revenue gives the *reduced-form revenue* $R^*(w, z, y)$. The *Panzar-Rosse statistic* is the sum of the factor-price elasticities of reduced-form revenue,

$$\psi = \sum_{k=1}^{K} \frac{\partial R^*}{\partial w_k} \frac{w_k}{R^*} = \left. \frac{\mathrm{d} \ln R^*(\lambda w, z, y)}{\mathrm{d}\lambda} \right|_{\lambda=1}, \tag{3.21}$$

where the second equality follows from the chain rule. In words, ψ is the percentage change in equilibrium revenue after a 1 percent increase in all factor prices. Bresnahan (1989) writes it H_R. With a log-linear specification,

$$\ln R_i = a + \sum_{k=1}^{K} \beta_k \ln w_{ki} + \gamma^\top x_i + e_i, \qquad \hat{\psi} = \sum_{k=1}^{K} \hat{\beta}_k, \tag{3.22}$$

where x_i contains the other cost and demand shifters. Early applications either use such a specification, which makes ψ constant, or report ψ near the center of the sample (Bresnahan, 1989, n. 27).

Lemma 3.18 (Homogeneity of cost)**.** *For a cost-minimizing firm and every $\lambda > 0$, $C(q, \lambda w, z) = \lambda C(q, w, z)$. Marginal cost C_q is also homogeneous of degree one in w, and $\sum_k w_k \frac{\partial C_q}{\partial w_k} = C_q$.*

Proof. Scaling all factor prices by λ leaves relative prices, and hence the cost-minimizing input bundle, unchanged. Cost is therefore multiplied by λ. Differentiating $C(q, \lambda w, z) = \lambda C(q, w, z)$ in q gives $C_q(q, \lambda w, z) = \lambda C_q(q, w, z)$. Euler's theorem for functions homogeneous of degree one gives the last statement. □

Proposition 3.19 (Panzar and Rosse)**.**

(i) Monopoly. *If the firm is a monopolist, $\psi \leq 0$. This holds also when it chooses a vector of outputs, qualities or advertising levels.*

(ii) Long-run competition. *Suppose free entry drives every active firm to the minimum of a U-shaped average cost curve. Then $\psi = 1$, and firm revenue does not depend on the demand shifters y.*

(iii) Chamberlinian competition. *Consider a symmetric free-entry equilibrium in which each firm maximizes profit against a downward-sloping demand. Suppose entry shifts that demand down and does not make it less elastic at a given output. Then $\psi \le 1$.*

Proof. (i), first proof: revealed preference. Let x be the vector of choices, with revenue $R(x)$ and cost $C(x, w)$ homogeneous of degree one in w. Fix w^0 and $w^1 = \lambda w^0$ with $\lambda > 1$, and let x^0 and x^1 be the optimal choices. Optimality of x^0 at w^0 gives

$$R(x^0) - C(x^0, w^0) \ge R(x^1) - C(x^1, w^0) \quad \Longrightarrow \quad C(x^1, w^0) - C(x^0, w^0) \ge R(x^1) - R(x^0).$$

Optimality of x^1 at w^1, with $C(x, w^1) = \lambda C(x, w^0)$, gives

$$R(x^1) - R(x^0) \;\ge\; \lambda\big[C(x^1, w^0) - C(x^0, w^0)\big] \;\ge\; \lambda\big[R(x^1) - R(x^0)\big],$$

where the second step uses the first display. Hence $(1 - \lambda)[R(x^1) - R(x^0)] \ge 0$. Since $\lambda > 1$, $R(x^1) \le R(x^0)$. Equilibrium revenue cannot rise when all factor prices rise in proportion, so $R^*(\lambda w^0) \le R^*(w^0)$ for $\lambda > 1$, and (3.21) gives $\psi \le 0$.

(i), second proof: comparative statics. With a single output, the monopolist's first-order condition is $R_q(q^*, y) = C_q(q^*, w, z)$, and the second-order condition is $R_{qq} - C_{qq} < 0$. Differentiating the first-order condition in w_k gives

$$R_{qq}\frac{\partial q^*}{\partial w_k} = C_{qq}\frac{\partial q^*}{\partial w_k} + C_{qw_k} \quad \Longrightarrow \quad \frac{\partial q^*}{\partial w_k} = \frac{C_{qw_k}}{R_{qq} - C_{qq}}.$$

Equilibrium revenue is $R^* = R(q^*(w), y)$, so $\frac{\partial R^*}{\partial w_k} = R_q \frac{\partial q^*}{\partial w_k}$. Multiply by w_k, sum over k, and apply Lemma 3.18 and then the first-order condition:

$$\sum_k w_k \frac{\partial R^*}{\partial w_k} = \frac{R_q \sum_k w_k C_{qw_k}}{R_{qq} - C_{qq}} = \frac{R_q\, C_q}{R_{qq} - C_{qq}} = \frac{(R_q)^2}{R_{qq} - C_{qq}}.$$

Dividing by R^* yields

$$\psi = \frac{(R_q)^2}{(R_{qq} - C_{qq})\, R^*} \;\le\; 0, \tag{3.23}$$

which is equation (23) of Bresnahan (1989). The inequality is strict when marginal cost is positive, because then $R_q > 0$.

(ii) Write average cost as $AC(q, w, z) = \frac{C(q,w,z)}{q}$. Each active firm produces at the output $q^m(w, z)$ that minimizes it, and free entry sets the price equal to minimum average cost $MAC(w, z)$. By Lemma 3.18, $AC(q, \lambda w, z) = \lambda AC(q, w, z)$. Scaling by λ does not move the minimizer, so q^m is homogeneous of degree zero in w, and MAC is homogeneous of degree one. Firm revenue $R^* = MAC(w, z)\, q^m(w, z)$ is then homogeneous of degree one in w, and Euler's theorem gives $\sum_k w_k \frac{\partial R^*}{\partial w_k} = R^*$, that is, $\psi = 1$. Neither factor of R^* involves y. A demand shift changes the number of firms and leaves the revenue of each unchanged.

(iii) Treat the number of firms n as continuous. Each firm's revenue is $R(q, n)$ with $R_n < 0$, since more rivals lower the price at which a given output sells. A symmetric equilibrium

satisfies $R_q(q,n) = C_q(q,w)$ and zero profit, $R(q,n) = C(q,w)$. Scale w by λ and differentiate both conditions at $\lambda = 1$, using $C(q,\lambda w) = \lambda C(q,w)$:

$$R_q\,\mathrm{d}q + R_n\,\mathrm{d}n = C_q\,\mathrm{d}q + C\,\mathrm{d}\lambda,$$
$$R_{qq}\,\mathrm{d}q + R_{qn}\,\mathrm{d}n = C_{qq}\,\mathrm{d}q + C_q\,\mathrm{d}\lambda.$$

Since $R_q = C_q$, the first line gives $R_n\,\mathrm{d}n = C\,\mathrm{d}\lambda$. The change in revenue is $\mathrm{d}R^* = R_q\,\mathrm{d}q + R_n\,\mathrm{d}n = C_q\,\mathrm{d}q + C\,\mathrm{d}\lambda$. Dividing by $R^* = C$ gives

$$\psi = 1 + \frac{C_q}{C}\frac{\mathrm{d}q}{\mathrm{d}\lambda},$$

so $\psi \le 1$ exactly when firm output does not rise. Substituting $\frac{\mathrm{d}n}{\mathrm{d}\lambda} = \frac{C}{R_n}$ into the second line gives

$$\frac{\mathrm{d}q}{\mathrm{d}\lambda} = \frac{C_q - \frac{R_{qn}}{R_n}C}{R_{qq} - C_{qq}}.$$

The denominator is negative by the second-order condition. So $\frac{\mathrm{d}q}{\mathrm{d}\lambda} \le 0$ if and only if $C_q \ge \frac{R_{qn}}{R_n}C$. Use $C = R$ and $C_q = R_q$, divide by $R > 0$, and multiply by $\frac{R_n}{R_q} < 0$. The condition becomes $\frac{R_n}{R} \le \frac{R_{qn}}{R_q}$, that is, $\frac{\partial}{\partial n}\ln\frac{R_q}{R} \ge 0$. At a fixed q, $\frac{qR_q}{R} = 1 - \frac{1}{\varepsilon_f}$, where ε_f is the elasticity of the firm's demand. The condition therefore says that entry does not lower ε_f. □

Part (iii) is Proposition 1 of Panzar and Rosse (1987, p. 451). They assume that each firm's inverse demand falls with its own output and with the number of rivals. Their Assumption 1 adds that the elasticity of each firm's perceived demand is nondecreasing in the number of symmetric rivals (p. 450). The derivation above is ours. Like theirs, it shows that the result rests on how entry changes the elasticity of each firm's demand. When entry leaves ε_f unchanged, firm output is fixed and $\psi = 1$, as in the long-run competitive case. Panzar and Rosse also show that monopolistic competition, long-run competition and conjectural-variation oligopoly are each consistent with $\psi > 0$ (p. 447). In their oligopoly model, ψ has the sign opposite to that of industry marginal revenue. It is positive when industry output lies on the inelastic part of market demand (pp. 454–455).

Example 3.20 (Values of ψ in standard models)**.** Let marginal cost be a constant $c(w)$, homogeneous of degree one in w, so that $\frac{\mathrm{d}\ln c}{\mathrm{d}\ln\lambda} = 1$.

(a) Monopoly with demand $Q = AP^{-\varepsilon}$, $\varepsilon > 1$. The price is $P = \frac{\varepsilon}{\varepsilon-1}c$ and revenue is $R^* = AP^{1-\varepsilon}$, so $\psi = 1 - \varepsilon < 0$.

(b) Monopoly with demand $P = a - bQ$. Then $Q = \frac{a-c}{2b}$, $P = \frac{a+c}{2}$ and $R^* = \frac{a^2-c^2}{4b}$, so $\psi = -\frac{2c^2}{a^2-c^2} < 0$.

(c) Long-run competition with $C(q,w) = g(w)(f + q^2)$ and g homogeneous of degree one. Average cost $g(w)(\frac{f}{q} + q)$ is minimized at $q^m = \sqrt{f}$, so $MAC = 2g(w)\sqrt{f}$, $R^* = 2g(w)f$ and $\psi = 1$.

(d) Short-run competition with n fixed firms and rising marginal cost. Firm revenue is $\frac{P\,D(P)}{n}$, so $\psi = (1-\varepsilon)\frac{\mathrm{d}\ln P}{\mathrm{d}\ln\lambda}$. Its sign is the sign of $1 - \varepsilon$.

(e) Cournot with n fixed firms and demand $Q = AP^{-\varepsilon}$, $n\varepsilon > 1$. The Lerner index is $\frac{1}{n\varepsilon}$, so $P = \frac{n\varepsilon}{n\varepsilon-1}c$. Firm revenue is $\frac{AP^{1-\varepsilon}}{n}$, so $\psi = 1 - \varepsilon$, as under monopoly.

Cases (d) and (e) show what the statistic cannot do. Short-run competition and oligopoly do not sign ψ, and $\psi < 0$ arises without monopoly whenever demand is elastic. A negative $\hat{\psi}$ is therefore no proof of monopoly, a "false finding of monopoly" in the words of Bresnahan (1989, p. 1036). The usable conclusions are one-sided. An estimate $\hat{\psi} > 0$ rejects monopoly. An estimate $\hat{\psi} < 1$ rejects long-run competition, provided the markets are in long-run equilibrium. An estimate between zero and one rejects both.

The specification matters as much as the sign. When the hypothesis is monopoly, R^* depends on demand shifters, and the revenue equation is misspecified if they are left out (Bresnahan, 1989, n. 28). When the hypothesis is long-run competition, demand shifters should have zero coefficients. This gives a second testable restriction (p. 1037 and n. 30). Every factor price must be measured, and each must vary exogenously. If a factor is omitted, $\hat{\psi}$ measures the response to only part of a proportional cost increase. The long-run interpretation also requires that a cross-section of local markets reflects differences in long-run equilibria. Rosse (1970) addresses this with a "permanent plant" hypothesis, and markets with rising demand should be treated separately from markets with falling demand (Bresnahan, 1989, p. 1037).

Applications. The first applications use cross-sections of similar local markets, which suits the long-run reading of the statistic. In a newspaper study, Rosse and Panzar (1977) take each newspaper as an observation, with its revenue, mostly from advertising, as the dependent variable. They reject monopoly ($\hat{\psi} > 0$) even for newspapers that are the only paper in their town. Bresnahan (1989, p. 1037) reads this as evidence of competition from other media. In all but one specification the study also rejects $\psi = 1$, and no specification rejects the Chamberlinian bound $\psi \leq 1$. Panzar and Rosse (1987, p. 453, n. 4) call these results suggestive rather than conclusive. Shaffer (1982) applies the test to a cross-section of banks in New York State in 1979. He rejects both monopoly and long-run competition (p. 1037). The test also bears on market definition. A rejection of monopoly for a firm or a group of firms means they cannot be treated as acting in isolation (Bresnahan, 1989, p. 1050).

Assessment. The revenue test asks little of the data on endogenous variables and makes no assumption about functional forms. Its demands lie elsewhere. It needs the full vector of factor prices with exogenous variation in each, and its sharpest prediction ($\psi = 1$) requires long-run equilibrium with free entry. Like the two tests before it, it delivers inequalities. All three reject monopoly or cartel pricing in their applications, and none of them says how much market power remains.

3.4 Residual demand: Baker and Bresnahan (1988)

3.4.1 The question and the idea

The tests so far treat the product as homogeneous and ask about industry conduct. Most industries sell differentiated products, and then a firm's market power depends on substitution as well as on behavior. A firm with a unique product can have substantial power, while a firm whose rival sells a near-identical product may have almost none. Measuring this with a full demand system is costly. Even with constant elasticities and symmetry, N products require N own-price elasticities, N income elasticities and $\frac{N(N-1)}{2}$ cross-price elasticities (Bresnahan, 1989, p. 1045). With 100 products that is more than 5,000 parameters.

Baker and Bresnahan (1988) estimate one equation per firm instead. The *residual demand curve* of a firm is the relation between its own price and quantity after accounting for the supply response of all other firms (p. 284). A firm in a perfectly competitive industry faces a flat residual demand curve. A monopolist's residual demand is the industry demand. A firm selling a differentiated product lies in between. Figure 3.5 draws the construction for a homogeneous good. The slope of residual demand summarizes market power without identifying its source.

3.4.2 Deriving the residual demand curve

Firm 1 is the firm of interest and sells a single product. Let $\mathbf{Q} = (Q_2, \ldots, Q_N)$ be the quantities of all other relevant products, including products of firms in other "industries". No market is defined in advance. Let Y be demand shifters, W industry-wide cost shifters, and W^i cost shifters specific to firm i. The model has four blocks (Baker and Bresnahan, 1988, pp. 286–289). Firm 1's inverse demand is

$$P_1 = P^1(Q_1, \mathbf{Q}, Y). \tag{3.24}$$

When all products are identical it reduces to $P_1 = P^1(Q_1 + \sum_{i \neq 1} Q_i, Y)$, and only then are market definition and demand estimation straightforward. The rivals' inverse demands are

$$P_i = P^i(\mathbf{Q}, Q_1, Y), \qquad i \neq 1. \tag{3.25}$$

Each rival's supply relation sets marginal cost equal to perceived marginal revenue,

$$MC^i(Q_i, W, W^i) = P^i(\cdot) + Q_i \sum_j \frac{\partial P^i}{\partial Q_j} \frac{\partial Q_j}{\partial Q_i}, \qquad i \neq 1, \tag{3.26}$$

where the conjectures $\frac{\partial Q_j}{\partial Q_i}$ are indexed by conduct parameters θ^i, as in Section 3.1. The firm-specific shifters W^i do not appear in W. They may be local input prices or the shadow rental value of an asset the firm does not trade.

Solve the $2(N-1)$ equations (3.25) and (3.26) for the rivals' prices and quantities, holding Q_1 fixed. Write W^I for the collection of the rivals' shifters W^i. The solution for quantities is the *partial reduced form*

$$\mathbf{Q} = E^I(Q_1, Y, W, W^I), \tag{3.27}$$

in which Q_1 is the only endogenous variable on the right. Let $e_{i1} = \frac{\partial \ln E^i}{\partial \ln Q_1}$ be the elasticity of rival i's equilibrium quantity with respect to Q_1. Substituting (3.27) into (3.24) gives the residual inverse demand of firm 1,

$$P_1 = P^1\big(Q_1, E^I(Q_1, Y, W, W^I), Y\big) \equiv R(Q_1, Y, W, W^I). \tag{3.28}$$

Its observable arguments are own quantity, demand shifters and the cost shifters of other firms. Its parameters mix demand, cost and conduct parameters, and they cannot in general be recovered from it.

The elasticity of an inverse demand function is called a *flexibility*. Let $\eta_{1j} = \frac{\partial \ln P^1}{\partial \ln Q_j}$ be the flexibilities of firm 1's structural inverse demand. Differentiate the log of (3.28) in $\ln Q_1$ by the chain rule:

$$\eta_1^R \equiv \frac{\partial \ln R}{\partial \ln Q_1} = \frac{\partial \ln P^1}{\partial \ln Q_1} + \sum_{i \neq 1} \frac{\partial \ln P^1}{\partial \ln Q_i} \frac{\partial \ln E^i}{\partial \ln Q_1} = \eta_{11} + \sum_{i \neq 1} \eta_{1i}\, e_{i1}. \tag{3.29}$$

This is equation (7) of the paper.[2] The *inverse residual demand elasticity* η_1^R is the parameter to be estimated, and $\frac{1}{\eta_1^R}$ is the elasticity of residual demand. The first term is the own flexibility. The second adds the price effect of the rivals' responses. With homogeneous products and rivals that expand when firm 1 contracts, the second term partly offsets the first. In the competitive limit the two cancel.

Firm 1's own supply relation closes the model:

$$P_1 - MC^1(Q_1, W, W^1) = M^1(\mathbf{Q}, Q_1, Y, \theta^1) = MK^1(Q_1, Y, W, W^I, \theta), \tag{3.30}$$

where M^1 is the gap between price and perceived marginal revenue. The second equality substitutes (3.27) for $\mathbf{Q}$, and Baker and Bresnahan (1988) call MK^1 the *residual markup*. The intersection of (3.28) and (3.30) determines P_1 and Q_1.

Identification. Equations (3.28) and (3.30) form a two-equation simultaneous system in (P_1, Q_1). The shifters Y, W and W^I enter both equations. Firm 1's own cost shifter W^1 enters only the supply relation. It is therefore the excluded instrument for Q_1 in the residual demand curve (p. 289). The order condition requires at least one firm-specific cost shifter. The rank condition requires that firm 1's costs move independently of the costs of all other firms (Bresnahan, 1989, n. 43). Bresnahan suggests exchange rates as a natural experiment for producers in a single country, since they move real costs across countries. Industry-wide cost shifters cannot serve, because they shift the residual demand curve itself.

This is the central contrast with Section 3.2 and Section 3.3.1. A tax moves every firm's marginal cost together. It therefore traces out market demand and speaks to industry conduct. A cost shifter specific to one firm moves that firm's supply relation alone. It traces out the firm's residual demand and speaks to the firm's market power.

Example 3.21 (Dominant firm with a price-taking fringe)**.** Let products be homogeneous and let the rivals be price takers with supply $S(P, W, W^I)$. Firm 1's residual demand is $Q_1 = D(P, Y) - S(P, W, W^I)$. Write ε for the market demand elasticity, ε_S for the fringe supply elasticity and $s_1 = \frac{Q_1}{D}$ for firm 1's share. Differentiating gives the residual demand elasticity

$$\varepsilon^R = -\frac{\partial Q_1}{\partial P}\frac{P}{Q_1} = \frac{\varepsilon D + \varepsilon_S S}{Q_1} = \frac{\varepsilon}{s_1} + \varepsilon_S \frac{1 - s_1}{s_1},$$

the familiar formula of Landes and Posner (1981). Here $\eta_1^R = -\frac{1}{\varepsilon^R}$. With no fringe, $s_1 = 1$ and $\varepsilon^R = \varepsilon$. With a fringe whose marginal cost is flat, $\varepsilon_S = \infty$ and residual demand is flat at the fringe's cost (Bresnahan, 1989, p. 1049).

A linear case verifies the markup property proved below. Let $D = a - bP$, $S = dP$ and let firm 1 have constant marginal cost c. Residual demand is $Q_1 = a - (b + d)P$, or $P = \frac{a - Q_1}{b + d}$. The dominant firm's optimum is $Q_1 = \frac{a - (b+d)c}{2}$, which gives $P - c = \frac{Q_1}{b+d}$. Hence

$$\frac{P - c}{P} = \frac{Q_1}{a - Q_1} = -\frac{\partial \ln P}{\partial \ln Q_1} = -\eta_1^R.$$

[2] The printed equation (7) writes the reaction elasticity with the indices in the order $1i$. The definition two lines above it, which we follow, is $\frac{\partial \ln E^i}{\partial \ln Q_1}$.

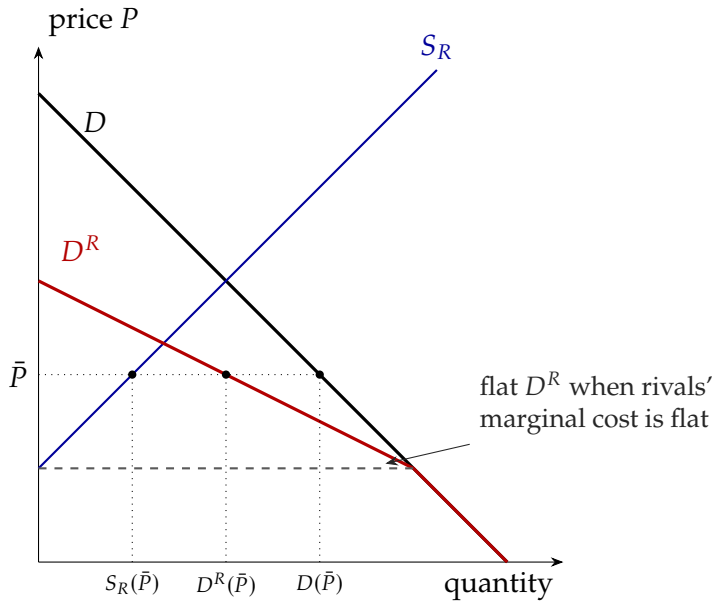

Figure 3.5: Residual demand. At each price $\bar{P}$ the residual demand of firm 1 is market demand minus the quantity rivals supply, $D^R(\bar{P}) = D(\bar{P}) - S_R(\bar{P})$. A monopolist faces D itself. If rivals can expand at a flat marginal cost, residual demand is flat at that cost (dashed). Upward-sloping rival supply produces an intermediate slope. Drawn for D: $P = 10 - Q$ and S_R: $P = 2 + Q$, which give D^R: $P = 6 - \frac{Q_1}{2}$ above the price 2.

3.4.3 When the residual demand slope measures the markup

A firm with a flat residual demand curve cannot raise its price, so $\eta_1^R < 0$ implies $P_1 > MC_1$ (p. 289). The exact relation between η_1^R and the Lerner index depends on conduct.

Proposition 3.22 (Baker and Bresnahan)**.** *Firm 1's Lerner index equals the negative of its inverse residual demand elasticity,*

$$\frac{P_1 - MC_1}{P_1} = -\eta_1^R, \tag{3.31}$$

in each of the following cases. (a) Firm 1 is a Stackelberg leader relative to its environment, so that it chooses Q_1 knowing that rivals respond along E^I. A dominant firm facing a price-taking fringe is the leading example. (b) Firms are in a consistent-conjectures equilibrium (Bresnahan, 1981b), in which firm 1's conjectured reaction elasticities equal the true ones. (c) The industry is perfectly competitive.

Proof. (a) Firm 1 maximizes $R(Q_1, Y, W, W^I)\,Q_1 - C_1(Q_1)$. The first-order condition is $R + Q_1 \frac{\partial R}{\partial Q_1} = MC_1$. Divide by $P_1 = R$:

$$1 + \eta_1^R = \frac{MC_1}{P_1} \quad \Longleftrightarrow \quad \frac{P_1 - MC_1}{P_1} = -\eta_1^R.$$

(b) Let $\hat{e}_{i1}$ be firm 1's conjectured elasticity of Q_i with respect to Q_1. Its perceived marginal revenue is

$$\frac{\mathrm{d}(P^1 Q_1)}{\mathrm{d}Q_1} = P^1 + Q_1\Big[\frac{\partial P^1}{\partial Q_1} + \sum_{i \neq 1} \frac{\partial P^1}{\partial Q_i}\frac{\mathrm{d}Q_i}{\mathrm{d}Q_1}\Big] = P^1\Big[1 + \eta_{11} + \sum_{i \neq 1} \eta_{1i}\,\hat{e}_{i1}\Big].$$

Equating it to MC_1 gives $\frac{P_1 - MC_1}{P_1} = -(\eta_{11} + \sum_{i \neq 1} \eta_{1i} \hat{e}_{i1})$, which is equation (11) of the paper. Consistency means $\hat{e}_{i1} = e_{i1}$, and then the right side equals $-\eta_1^R$ by (3.29). (c) Under perfect competition rivals absorb any change in Q_1 at an unchanged price, so $\eta_1^R = 0$, and price equals marginal cost. □

Product differentiation gives an approximate version. When products are poor substitutes, the cross flexibilities η_{1i} are small. Then $\eta_1^R \approx \eta_{11}$, and the markup under any conjecture is close to $-\eta_{11}$. Questions about strategic variables disappear in this limit (Sonnenschein, 1968). Baker and Bresnahan (1988, p. 290) conclude that a large $-\eta_1^R$ will generally indicate substantial market power for firms selling differentiated products. Outside these cases the equality can fail, as the next example shows.

Example 3.23 (Cournot competition: residual demand understates the markup)**.** Let $P = a - Q$ and let N identical Cournot firms have marginal cost c. Rival j's best response is $q_j = \frac{a - c - Q_{-j}}{2}$. Given Q_1, symmetric rivals each produce q with $2q = a - c - Q_1 - (N-2)q$, so $q = \frac{a - c - Q_1}{N}$. Substituting into demand gives the residual inverse demand

$$P = a - Q_1 - (N-1)\frac{a - c - Q_1}{N} = \frac{a + (N-1)c}{N} - \frac{Q_1}{N}.$$

At the Cournot equilibrium $Q_1 = \frac{a-c}{N+1}$ and $P = \frac{a+Nc}{N+1}$, a point on this curve. The Lerner index is $L = \frac{a-c}{a+Nc}$. The inverse residual demand elasticity is

$$-\eta_1^R = \frac{1}{N} \cdot \frac{Q_1}{P} = \frac{a - c}{N(a + Nc)} = \frac{L}{N}.$$

A Cournot firm takes rivals' outputs as given, while its residual demand incorporates their responses. With strategic substitutes the rivals' contraction absorbs part of the price effect, so $-\eta_1^R$ understates the markup by the factor N.

3.4.4 The brewing application

Setting. Baker and Bresnahan (1988) estimate the residual demand curves of Anheuser-Busch (A-B), Pabst and Coors over 1962–1982. The industry has substantial product differentiation, and no satisfactory estimates of its demand and cross elasticities existed. Antitrust enforcers suspected market power and blocked several proposed mergers (p. 285). A-B was the largest brewer throughout. Its share of national unit sales rose from under 10 percent to over 30 percent, overwhelmingly through internal growth. Pabst held 7.5 to 11.5 percent of national sales over the last decade of the sample. Its regional share was much higher, about a quarter of dollar sales in the East North Central states during the 1970s. Coors was slightly smaller than Pabst nationally. It had the largest share in each of ten western states, averaging about 40 percent in the mountain states and nearly 30 percent in the Pacific states (pp. 290–291). Coors brewed in a single plant in Golden, Colorado, the largest in the industry, while A-B had ten plants. Miller's national marketing of light beer from 1975 changed product differentiation in the industry and possibly the nature of competition.

Data. The data are annual for 1962–1982, so each equation has 21 observations. Price p_j is the log of real average revenue, beer revenue divided by gallons sold, with revenue taken from firm annual reports. Quantity q_j is the log of per capita barrels, using the U.S. population over

18. Monetary values are deflated by the GNP deflator. As a robustness check, the authors use the price of each firm's flagship brand in northern California (Budweiser, Coors and Pabst Blue Ribbon). Average revenue could understate market power if brand composition changes. The flagship prices are highly correlated with firm average revenue, at 0.96, 0.94 and 0.99 for the three firms. Correlations of average revenue across firms are lower, 0.82 for A-B and Coors, 0.93 for A-B and Pabst, and 0.65 for Coors and Pabst (Table 1).

Estimating equation. The authors estimate (3.28) in double-log form for each firm j, so that coefficients are elasticities. With lower-case letters for logs, their equation (6'') is

$$p_j = \eta_j^R \, q_j + \delta_j^\top (w, w_I) + \gamma_j^\top y + u_j, \tag{3.32}$$

where δ_j and γ_j are local symbols for coefficient vectors and u_j is the error. Industry costs w consist of the log of real short-run average variable cost (*sravc*), average industry plant size (*APS*) and the log of the real user cost of capital (*pk*). Short-run average variable cost summarizes all non-capital factor prices. The rivals' firm-specific costs w_I are summarized by their excess capacity $EKTI_j$. The demand shifters y are log real per capita disposable income (*pcdi*), a time trend (*TIME*) and a dummy for 1975 and later (*LITE*). Advertising and two demographic variables were tested and dropped. In the A-B equation the slope is $\eta_j^R + \eta^{LITE} \cdot LITE$, so the interaction coefficient measures the change in slope after 1975. To save degrees of freedom, the three equations share one index of rivals' marginal cost. This is the cross-equation restriction (12),

$$\delta_{1j}\, sravc + \delta_{2j} APS + \delta_{3j}\, pk + \delta_{4j} EKTI = \delta_j \big(sravc + \beta_{APS} APS + \beta_{PK}\, pk + \beta_{EKTI} EKTI \big) \equiv \delta_j \, MC, \tag{3.33}$$

with β_{APS}, β_{PK} and β_{EKTI} common to all firms (again local symbols). It assumes that the other firms use inputs in the same proportions. Tests do not reject it, though they have little power (n. 21).

Instruments. Two variables on the right of (3.32) are endogenous. Short-run average variable cost is endogenous if short-run marginal cost rises with output. It is instrumented by exogenous factor prices, namely the brewing wage and the materials and advertising price indices (*pl*, *pm*, *pa*). Own quantity is endogenous because of the supply relation (3.30). All its instruments proxy for firm-specific factor prices W^1 (p. 293). The first is the firm's per capita capacity K_j. Brewing capacity is altered infrequently and in large increments. A-B, with a quarter to a third of national sales, typically added capacity in steps of about 20 percent of its annual production. Short-run marginal cost is therefore lowest just after an expansion and highest just before the next one. Excess capacity would track this cycle too, but it is endogenous even in the short run and is not used. The second instrument is the firm's average plant size APS_j for the multiplant firms A-B and Pabst, which tracks plant-level scale economies. For Coors it is the log real Colorado manufacturing wage (*cw*). The national brewing wage is already among the industry cost variables, so independent movements in Colorado wages shift Coors's costs alone (p. 294).

Estimator. The three equations are estimated jointly by three-stage least squares. Stack them as $y = Xb + u$ and let $P_Z = Z(Z^\top Z)^{-1} Z^\top$ project on the instruments. Let $\hat{\Sigma}$ be the 3×3 covariance matrix of first-round two-stage least squares residuals. Without restrictions the estimator is

$$\hat{b}_{3SLS} = \left[X^\top (\hat{\Sigma}^{-1} \otimes P_Z) X \right]^{-1} X^\top (\hat{\Sigma}^{-1} \otimes P_Z)\, y.$$

Restriction (3.33) makes the coefficients products of parameters, such as $\delta_j \beta_{APS}$. The estimator then minimizes $u(b)^\top (\hat{\Sigma}^{-1} \otimes P_Z) u(b)$ over the restricted parameters (Appendix A). Joint

estimation uses the correlation of errors across equations, and single-equation two-stage least squares gives similar elasticities with little loss of efficiency (n. 20). The reported specification drops demand variables whose coefficients are smaller than their standard errors. This removes the demographic variables, keeps *LITE* only for A-B, and keeps *TIME* only for Pabst and Coors. Cost variables are kept even when insignificant, for a reason the next proposition makes clear.

What ordinary least squares would do. Suppose no firm-specific cost shifter were available. The authors argue that ordinary least squares would then be biased toward finding no market power (p. 298). A linear version of the system shows why and when.

Proposition 3.24 (Bias of least squares in residual demand)**.** *Let residual demand be $p = \eta q + u$ with $\eta \le 0$, and let the supply relation be $p = \lambda q + \gamma w_1 + v$, with $\lambda > \eta$ and $\gamma \neq 0$. Let w_1 be uncorrelated with (u, v), and write σ_u^2, σ_v^2, σ_{uv} and σ_w^2 for the variances and the covariance. Then*

$$\operatorname{plim} \hat{\eta}_{OLS} = \eta + (\lambda - \eta) \frac{\sigma_u^2 - \sigma_{uv}}{\sigma_u^2 + \sigma_v^2 - 2\sigma_{uv} + \gamma^2 \sigma_w^2}, \tag{3.34}$$

while instrumental variables with instrument w_1 is consistent for η. If $\sigma_{uv} = 0$, the least squares limit is the weighted average $(1 - \omega)\eta + \omega\lambda$ with $\omega = \frac{\sigma_u^2}{\sigma_u^2 + \sigma_v^2 + \gamma^2 \sigma_w^2} \in [0, 1)$.

Proof. Equate the two equations and solve for the equilibrium quantity:

$$q = \frac{u - v - \gamma w_1}{\lambda - \eta}.$$

Hence $\operatorname{Cov}(q, u) = \frac{\sigma_u^2 - \sigma_{uv}}{\lambda - \eta}$ and $\operatorname{Var}(q) = \frac{\sigma_u^2 + \sigma_v^2 - 2\sigma_{uv} + \gamma^2 \sigma_w^2}{(\lambda - \eta)^2}$. Least squares converges to $\eta + \frac{\operatorname{Cov}(q,u)}{\operatorname{Var}(q)}$, which is (3.34). For the instrumental variables estimator, $\operatorname{Cov}(w_1, q) = -\frac{\gamma \sigma_w^2}{\lambda - \eta} \neq 0$ and $\operatorname{Cov}(w_1, p) = \eta \operatorname{Cov}(w_1, q)$, so their ratio is η. Setting $\sigma_{uv} = 0$ in (3.34) gives the weighted average. □

With uncorrelated shocks, least squares lands between the residual demand slope and the supply slope. If the supply relation is flat or rising, $\lambda \ge 0$, the estimate is pulled toward a flat residual demand. That direction is conservative, since it understates market power. The proposition also shows when the argument fails. A covariance σ_{uv} above σ_u^2 reverses the sign of the bias. Omitted industry cost variables create such a positive covariance, because they enter both equations. This is why the authors keep all cost variables (n. 23).

3.4.5 Results

Table 3.5 reproduces the paper's Table 3. The coefficient on log quantity is η_j^R.

Under the markup reading of Proposition 3.22, the estimates sort the three firms sharply. Coors's coefficient of -0.745 has a t-statistic of $\frac{0.745}{0.054} \approx 13.8$. The authors read it as a 74 percent markup over marginal cost (p. 295). Strictly, $-\eta_1^R$ is a Lerner index, a margin as a share of price. A Lerner index of 0.745 means $\frac{P}{MC} = \frac{1}{1 - 0.745} \approx 3.9$, a markup over cost of about 290 percent (Section 3.1.1). A-B's coefficient before 1975 is -0.312, with $t \approx 4.9$ and $\frac{P}{MC} \approx 1.45$.

After 1975 A-B's coefficient is $-0.312 + 0.282 = -0.030$. The paper does not report the covariance of the two estimates, so the standard error of the sum is unknown. It can still be bounded. For any correlation the variance of a sum is at least $(0.064 - 0.040)^2$, so the standard error is at least 0.024. The t-statistic for a flat residual demand after 1975 is therefore at most

Table 3.5: Baker and Bresnahan (1988): residual demand estimates, three-stage least squares

	Anheuser-Busch		Pabst		Coors	
Variable	Coef.	(s.e.)	Coef.	(s.e.)	Coef.	(s.e.)
Constant	2.113	(0.505)	3.979	(0.362)	−1.638	(0.805)
Own log quantity q_j	−0.312	(0.064)	−0.058	(0.031)	−0.745	(0.054)
$LITE \times q_{AB}$	0.282	(0.040)				
LITE	0.591	(0.068)

MC index	0.278	(0.019)	0.107	(0.089)	0.266	(0.226)
TIME			−0.017	(0.004)	0.032	(0.010)
Common parameters of the MC index						
APS	−0.194 (0.291)					
PK	0.042 (0.115)					
EKTI	−0.033 (0.022)					
Durbin-Watson	2.13		1.95		1.70	
Observations	21		21		21	

Notes: Reproduced from Baker and Bresnahan (1988, Table 3). Dependent variable: log real average revenue of the firm, 1962–1982. Estimates impose restriction (3.33). The *MC* row reports δ_j and the common parameters report β_{APS}, β_{PK} and β_{EKTI}. Treating quantity as exogenous gives own-quantity coefficients of −0.312 (A-B), −0.053 (Pabst) and −0.738 (Coors) (n. 26).

$\frac{0.030}{0.024} = 1.25$. Competition cannot be rejected for A-B after 1975 at conventional levels, whatever the covariance.

Pabst's coefficient is −0.058 with $t \approx 1.87$, which the authors call insignificant. They report a 95 percent confidence interval for the markup of 1 to 11 percent (p. 296). The reported standard error implies a two-sided 95 percent interval of $-0.058 \pm 1.96 \times 0.031$, or about −0.3 to 11.9 percent. The interval of 1 to 11 percent corresponds to ±1.645 standard errors, a two-sided 90 percent interval. A two-sided test at 5 percent therefore does not reject a flat residual demand for Pabst. With 21 observations, using a t distribution in place of the normal would make a rejection even less likely.

The other coefficients have no clean structural reading, since each mixes direct demand effects with the indirect effects of rivals' adjustments (Baker and Bresnahan, 1988, p. 297). The positive income coefficient for Coors means that a rise in income shifts sales toward Coors after all rivals adjust. The authors label Coors a normal good and Pabst an inferior good in residual demand. Real prices trend down by 1.7 percent a year for Pabst and up by 3.2 percent a year for Coors, holding the other variables fixed. The Durbin-Watson statistics of 1.70 to 2.13 show no strong first-order serial correlation in the double-log specification.

The least squares estimates in the note to Table 3.5 confirm the sign of Proposition 3.24. They are slightly closer to zero than the instrumental variables estimates for Coors and Pabst and identical for A-B. The bias is small, and the authors note that treating quantity as endogenous matters little in their data (n. 19).

3.4.6 Robustness, interpretation and critiques

Robustness. Using flagship-brand prices and quantities leaves the elasticity estimates unchanged (p. 293). A linear specification evaluated at sample means gives the same qualitative pattern. It shows somewhat less market power for A-B early in the sample and for Coors overall, and the two sets of elasticities are not statistically different under an assumption of independence. The authors prefer the double-log form because the linear errors are strongly serially correlated (pp. 296–297). Demand elasticity results are robust to imposing restriction (3.33) (n. 21).

Interpretation. The authors draw four inferences (p. 297). First, product differentiation is important, and the steep residual demands of Coors and A-B probably come from products distinct in image and geography. Second, regional market share is a poor guide to market power, since Pabst had high regional shares and almost no power. Third, rising concentration and differentiation after 1975 reflect competition. A-B lost most of its market power after Miller's light beer, although the new product apparently raised the demand for all beer. Fourth, tacit collusion is unlikely. Under collusion every firm's residual demand would slope down and prices would move closely together. Pabst shows neither. The authors concede that they cannot reject the unlikely case in which all firms except Pabst collude to raise prices to the level of Pabst, the high-cost producer (n. 25).

Critiques. The markup reading requires one of the special cases of Proposition 3.22. In Cournot-like competition Example 3.23 shows that $-\eta_1^R$ understates the markup, by a factor of N in the linear case. The authors themselves call the exact quantitative reading possibly too strong (p. 297). The instruments raise their own questions. Capacity is added in anticipation of growth (p. 293), so it may correlate with expected demand. The Colorado wage could move with western incomes and hence with demand for Coors. The sample has 21 annual observations, and the specification was chosen by dropping variables with $|t| < 1$, so reported standard errors ignore the search. National average revenue also aggregates regional markets in which the three firms held very different positions. The light-beer dummy is collinear with a surge in industry advertising in the mid-1970s, so its meaning is uncertain (n. 16). Finally, the evidence against collusion leans on Pabst. Its price correlates at only 0.65 with Coors's, yet at 0.93 with A-B's (Table 1).

Contribution. The paper made firm-level market power measurable with one equation and modest data. It separated two kinds of cost variation. Market-wide shifters identify market demand and industry conduct, while firm-specific shifters identify a firm's residual demand. In Bresnahan's words, the residual demand elasticity "summarizes the market power of the firm" but is "insufficient to determine the sources of that market power" (Bresnahan, 1989, p. 1049).

3.4.7 Residual demand, market definition and mergers

Residual demand applies equally to a group of firms (Baker and Bresnahan, 1988, n. 7). This matters for antitrust. A hypothetical cartel price increase of 5 percent is part of the algorithm that defines a market under the 1984 Merger Guidelines of the U.S. Department of Justice. The residual demand of a candidate group of firms speaks to that question directly. Scheffman and Spiller (1987) extend the method in this way to define geographic markets. The question of a group's market power is well posed even where defining a relevant market and computing shares in it would be senseless (Bresnahan, 1989, n. 44). Baker and Bresnahan (1985) use the

same tools to estimate the gains from merger in differentiated industries. They ask how much steeper the residual demand of two firms would be after a merger (Bresnahan, 1989, p. 1050). If the two products are close substitutes and few others are similar, each provides much of the competitive brake on the other. The steepening of the joint residual demand measures the loss of that brake. These ideas return in Chapter 11, and residual demand with a full system of differentiated products is the subject of Chapter 4.

The studies in this section and the last share a pattern. Sullivan rejects cartel pricing in cigarettes, and Ashenfelter and Sullivan find that only conduct with a moderate amount of competition fits the data. Panzar and Rosse reject monopoly for newspapers, and Shaffer rejects both monopoly and long-run competition for banks. Baker and Bresnahan place three brewers between price taking and substantial power. Most estimates of this generation fall between competition and monopoly, and inequalities or special conduct cases cannot say where. Interpreting such results requires more structure on demand, cost and conduct. Section 3.5 asks what that structure must provide for conduct to be identified.

3.5 The identification of conduct

The tests of Sections 3.2 and 3.3 move cost and watch prices. Cost shifters trace out the demand curve, so they speak to the supply relation only indirectly, and they deliver tests or bounds. This section asks the reverse question. What do movements in demand reveal about conduct? The answer, due to Bresnahan (1982) and Lau (1982), has two halves. When the slope of marginal cost is unknown, demand shifts that move the demand curve in parallel reveal nothing about conduct. Shifts that change the slope of demand identify it. Section 1.7 previews the argument. Here we develop the full theory. We cover the linear model and its observational equivalence, the rotation argument and its estimation, a general version of Lau's theorem with proof, and the other routes used in practice.

3.5.1 The linear model and observational equivalence

We start from the simplest model in which the question can be posed. It is the model of Bresnahan (1982), which Bresnahan (1989, Section 3.1) uses to explain how the data identify market power. Markets are indexed by $t = 1, \dots, T$, which may be periods, locations or both.

Assumption 3.25 (Linear market)**.**

(i) Market demand is $Q_t = a_0 + a_1 P_t + a_2 Y_t + u_t^d$ with $a_1 < 0$ and $a_2 \neq 0$. The variable Y_t is an observed *demand shifter*.

(ii) Industry marginal cost is $MC_t = b_0 + b_1 Q_t + b_2 W_t + u_t^s$ with $b_2 \neq 0$. The variable W_t is an observed *cost shifter*.

(iii) Conduct is a constant $\theta \geq 0$. Perceived marginal revenue $P_t + \theta Q_t \frac{\partial P_t}{\partial Q_t}$ equals marginal cost.

(iv) The errors satisfy $\mathbb{E}[u_t^d \mid Y_t, W_t] = \mathbb{E}[u_t^s \mid Y_t, W_t] = 0$, and the vector $(1, Y_t, W_t)$ has a nonsingular second-moment matrix.

Part (iii) is the supply relation (3.1) with a linear demand curve. The slope of inverse demand is $\frac{\partial P_t}{\partial Q_t} = \frac{1}{a_1}$, so perceived marginal revenue is $P_t + \theta \frac{Q_t}{a_1}$. Setting it equal to marginal

cost and solving for price gives

$$P_t = MC_t - \theta \frac{Q_t}{a_1} = b_0 + b_1 Q_t + \theta \left(-\frac{Q_t}{a_1} \right) + b_2 W_t + u_t^s.$$

The term $-\theta \frac{Q_t}{a_1} = \theta \frac{Q_t}{|a_1|} \geq 0$ is the markup. Collecting the two terms in Q_t, the model consists of three equations:

$$\begin{aligned} \text{demand:} \quad & Q_t = a_0 + a_1 P_t + a_2 Y_t + u_t^d, \\ \text{marginal cost:} \quad & MC_t = b_0 + b_1 Q_t + b_2 W_t + u_t^s, \\ \text{supply relation:} \quad & P_t = b_0 + \lambda Q_t + b_2 W_t + u_t^s, \qquad \lambda \equiv b_1 - \frac{\theta}{a_1}. \end{aligned} \tag{3.35}$$

The *composite slope* λ adds the slope of marginal cost, b_1, to the conduct-weighted magnitude of the slope of inverse demand, $\frac{\theta}{|a_1|}$. Only demand and the supply relation involve observed endogenous variables, so the estimation problem has two equations.

The reduced form. Substituting the supply relation into demand gives

$$\begin{aligned} Q_t &= a_0 + a_1 \left(b_0 + \lambda Q_t + b_2 W_t + u_t^s \right) + a_2 Y_t + u_t^d, \\ (1 - a_1 \lambda) Q_t &= a_0 + a_1 b_0 + a_2 Y_t + a_1 b_2 W_t + u_t^d + a_1 u_t^s. \end{aligned}$$

Let $\Delta \equiv 1 - a_1 \lambda = 1 + \theta - a_1 b_1$. It is positive whenever $b_1 \geq 0$, because $a_1 < 0$, and we assume $\Delta > 0$ throughout. Dividing by Δ and substituting back into the supply relation yields the reduced form

$$Q_t = \frac{a_0 + a_1 b_0 + a_2 Y_t + a_1 b_2 W_t + u_t^d + a_1 u_t^s}{\Delta}, \qquad P_t = \frac{b_0 + \lambda a_0 + \lambda a_2 Y_t + b_2 W_t + \lambda u_t^d + u_t^s}{\Delta}. \tag{3.36}$$

The reduced-form coefficients on the shifters are $\pi_{QY} = \frac{a_2}{\Delta}$, $\pi_{PY} = \frac{\lambda a_2}{\Delta}$, $\pi_{QW} = \frac{a_1 b_2}{\Delta}$ and $\pi_{PW} = \frac{b_2}{\Delta}$. Regressions of P_t and Q_t on $(1, Y_t, W_t)$ identify all four. Two ratios then deliver the slopes:

$$a_1 = \frac{\pi_{QW}}{\pi_{PW}}, \qquad \lambda = \frac{\pi_{PY}}{\pi_{QY}}.$$

A cost shift moves the equilibrium along the demand curve, so the ratio of the quantity response to the price response is the slope of demand. A demand shift moves the equilibrium along the supply relation, so the ratio of the price response to the quantity response is the slope of the supply relation. With $\Delta = 1 - a_1 \lambda$ in hand, $a_2 = \Delta \pi_{QY}$ and $b_2 = \Delta \pi_{PW}$, and the intercepts follow. Each equation is exactly identified, so this indirect least squares solution coincides with two-stage least squares (2SLS). Demand is estimated by 2SLS of Q_t on $(1, P_t, Y_t)$ with instruments $(1, Y_t, W_t)$. The supply relation is estimated by 2SLS of P_t on $(1, Q_t, W_t)$ with the same instruments (Appendix A).

Proposition 3.26 (Observational equivalence)**.** *Let the structure $(a_0, a_1, a_2, b_0, b_1, b_2, \theta)$ and the distribution of (u_t^d, u_t^s) satisfy Assumption 3.25 with $\Delta > 0$. For any $\theta' \geq 0$, replace (b_1, θ) by (b_1', θ') with*

$$b_1' = b_1 + \frac{\theta' - \theta}{a_1},$$

and keep everything else. The new structure generates the same conditional distribution of (P_t, Q_t) given (Y_t, W_t). Hence θ and b_1 are not separately identified.

Proof. The composite slope of the new structure is

$$\lambda' = b_1' - \frac{\theta'}{a_1} = b_1 + \frac{\theta' - \theta}{a_1} - \frac{\theta'}{a_1} = b_1 - \frac{\theta}{a_1} = \lambda,$$

and therefore $\Delta' = 1 - a_1\lambda' = \Delta > 0$. The reduced form (3.36) depends on the structure only through $(a_0, a_1, a_2, b_0, \lambda, b_2)$ and the errors, and none of these has changed. The two structures map every value of (Y_t, W_t, u_t^d, u_t^s) into the same (P_t, Q_t), so the conditional distributions coincide. □

The set of structures that fit the data is the line $b_1 = \lambda + \frac{\theta}{a_1}$ in the (θ, b_1) plane. It slopes down because $a_1 < 0$. More market power must be offset by flatter marginal cost. A sign restriction on the slope of marginal cost turns this line into an interval for conduct.

Corollary 3.27 (An interval for conduct)**.** *Under Assumption 3.25, suppose $\lambda > 0$ and marginal cost does not fall with output, $b_1 \geq 0$. Then the values of conduct consistent with the data form the interval $\theta \in [0, |a_1|\lambda]$. Constant marginal cost ($b_1 = 0$) selects the upper endpoint, and price taking selects the lower endpoint. If $|a_1|\lambda < 1$, the data reject monopoly with nondecreasing marginal cost.*

Proof. By Proposition 3.26, every pair $(\theta, \lambda + \frac{\theta}{a_1})$ with $\theta \geq 0$ fits the data. The restriction $b_1 \geq 0$ reads $\lambda + \frac{\theta}{a_1} \geq 0$. Multiplying by $a_1 < 0$ reverses the inequality and gives $a_1\lambda + \theta \leq 0$, that is, $\theta \leq -a_1\lambda = |a_1|\lambda$. Together with $\theta \geq 0$ this is the interval. Monopoly, $\theta = 1$, lies in it exactly when $1 \leq |a_1|\lambda$. □

The interval is the demand-side counterpart of the cost-side bounds of Section 3.3.1. It also shows what the assumption of constant marginal cost buys. It picks the largest conduct consistent with the data, because it attributes the entire slope of the supply relation to market power.

A graphical version. Figure 3.6 redraws Figure 1 of Bresnahan (1982), a schematic, with illustrative numbers of our own. Inverse demand shifts from $D_1 : P = 10 - Q$ to $D_2 : P = 12 - Q$, so $a_1 = -1$ in both markets. The competitive model has marginal cost $MC^c = 2 + 1.1Q$ and $\theta = 0$. The monopoly model has $MC^m = 2 + 0.1Q$ and $\theta = 1$. Both have composite slope $\lambda = 1.1$. Under competition the first equilibrium solves $10 - Q = 2 + 1.1Q$, so $Q = \frac{8}{2.1} = 3.81$ and $P = 6.19$. Under monopoly, marginal revenue $MR_1 = 10 - 2Q$ equals MC^m where $10 - 2Q = 2 + 0.1Q$. This gives the same quantity $\frac{8}{2.1}$ and, reading price off demand, the same price. After the shift both models predict $Q = \frac{10}{2.1} = 4.76$ and $P = 7.24$. The two models produce the equilibria E_1 and E_2 exactly.

The two readings of the same data differ greatly in what they say about welfare. In the competitive reading the Lerner index at E_1 is zero. In the monopoly reading marginal cost at E_1 is $2 + 0.1 \times 3.81 = 2.38$, so the Lerner index is $\frac{6.19 - 2.38}{6.19} = 0.62$. The economics behind the equivalence is simple. When demand shifts out, price rises in both models. Under competition it rises because marginal cost rises steeply with output. Under monopoly it rises because marginal revenue shifts out while marginal cost barely moves. A parallel shift raises price either because marginal cost rises with output or because of market power, and the ratio $\frac{\Delta P}{\Delta Q} = \lambda$ is the same in both cases.

3.5.2 Rotations of demand identify conduct

Bresnahan (1982) breaks the equivalence by letting an exogenous variable change the slope of demand. Let Z_t be an observed *demand rotator*, and write demand as

$$Q_t = a_0 + a_1 P_t + a_2 Y_t + a_3 P_t Z_t + a_4 Z_t + u_t^d, \tag{3.37}$$

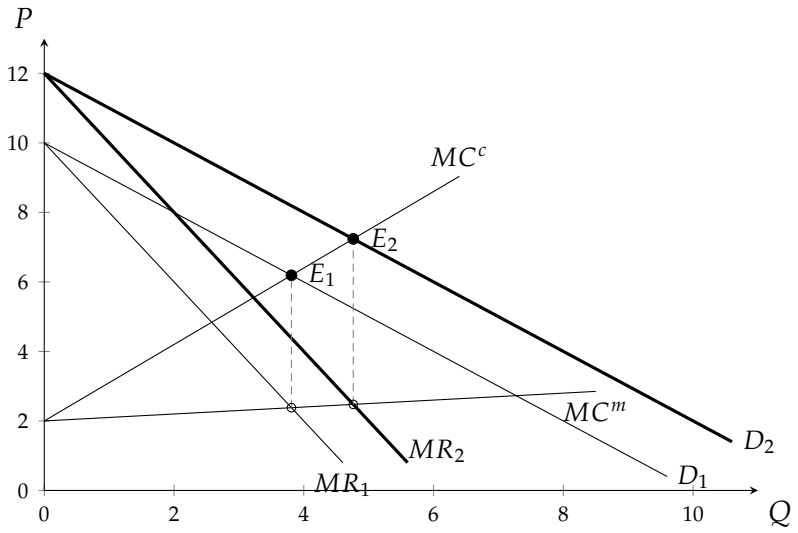

Figure 3.6: Observational equivalence under a parallel demand shift. Demand shifts from $D_1 : P = 10 - Q$ to $D_2 : P = 12 - Q$. Competitive firms with $MC^c = 2 + 1.1Q$ and a monopolist with $MC^m = 2 + 0.1Q$ both produce $E_1 = (3.81, 6.19)$ and $E_2 = (4.76, 7.24)$. Under monopoly, output is set where MR_i crosses MC^m (open circles) and price is read off demand (dashed lines). Drawn after Figure 1 of Bresnahan (1982), with illustrative numbers chosen here.

with $a_1 + a_3 Z_t < 0$ on the support of Z_t. The slope of demand is $\frac{\partial Q_t}{\partial P_t} = a_1 + a_3 Z_t$, which varies with Z_t when $a_3 \neq 0$. We let Z_t also shift the level of demand through a_4. Nothing below requires $a_4 = 0$. Perceived marginal revenue is now $P_t + \theta \frac{Q_t}{a_1 + a_3 Z_t}$, and the supply relation becomes

$$P_t = b_0 + b_1 Q_t + \theta Q_t^* + b_2 W_t + u_t^s, \qquad Q_t^* \equiv -\frac{Q_t}{a_1 + a_3 Z_t} = \frac{Q_t}{|a_1 + a_3 Z_t|}. \tag{3.38}$$

The variable Q_t^* is the *markup term* $m_t \equiv \frac{Q_t}{\left|\frac{\partial Q_t}{\partial P_t}\right|} = \frac{P_t}{\varepsilon_t}$. It is the dollar markup a monopolist would charge, so θQ_t^* is the markup. With $a_3 = 0$ the markup term is proportional to Q_t, and (3.38) collapses to the supply relation of (3.35). With $a_3 \neq 0$, the markup term moves with Z_t at a given quantity, while the cost term $b_1 Q_t$ does not.

Proposition 3.28 (Rotations identify conduct)**.** *Let demand be* (3.37) *with known parameters, and let the supply relation be* (3.38)*. Let $X_t = (Y_t, Z_t, W_t)$, assume $\mathbb{E}[u_t^s \mid X_t] = 0$, and assume Z_t does not enter marginal cost. Suppose $\mu(X_t) \equiv \mathbb{E}[Q_t \mid X_t]$ is strictly monotone in Y_t for each (Z_t, W_t), $a_3 \neq 0$, Z_t takes at least two values, and W_t is not degenerate. Then (b_0, b_1, b_2, θ) are identified.*

Proof. Write $Q_t^* = g(Z_t) Q_t$ with $g(Z) \equiv -\frac{1}{a_1 + a_3 Z}$, a known function. Taking expectations of (3.38) conditional on X_t gives

$$\mathbb{E}[P_t \mid X_t] = b_0 + b_1 \, \mu(X_t) + \theta \, g(Z_t) \, \mu(X_t) + b_2 W_t.$$

The left side and $\mu(X_t)$ are features of the distribution of the data. Suppose a second vector $(b_0', b_1', b_2', \theta')$ satisfies the same equation. Subtracting, the differences $c = (b_0 - b_0', b_1 - b_1', b_2 - b_2', \theta - \theta')$ satisfy

$$0 = c_0 + c_1 \, \mu(X) + c_3 \, g(Z) \, \mu(X) + c_2 W \quad \text{for all } X.$$

Fix (Z, W) and vary Y. Since μ changes with Y, the coefficient on μ must vanish: $c_1 + c_3 g(Z) = 0$ for every Z. Because $a_3 \neq 0$, the function g takes different values at two values of Z, so $c_1 = c_3 = 0$. The remaining condition $c_0 + c_2 W = 0$ for all W gives $c_0 = c_2 = 0$. □

The proof has a transparent deterministic core. Suppose two markets share the same W and the same quantity Q but have different rotators $Z_1 \neq Z_2$. The demand shifter Y can always be chosen to make this happen. Marginal cost is then the same in both markets, and the price difference isolates the markup:

$$P_1 - P_2 = \theta\, Q \left[g(Z_1) - g(Z_2) \right].$$

The bracket is nonzero when $a_3 \neq 0$, so the price difference reveals θ. Once θ is known, two markets with the same Z and different Q reveal b_1.

Estimation. The natural estimator has two steps. In the first step we estimate demand (3.37) by 2SLS. The regressors P_t and $P_t Z_t$ are endogenous, $(1, Y_t, Z_t)$ are included exogenous variables, and W_t and $W_t Z_t$ are the excluded instruments. In the second step we construct

$$\hat{Q}_t^* = -\frac{Q_t}{\hat{a}_1 + \hat{a}_3 Z_t}$$

and estimate the supply relation $P_t = b_0 + b_1 Q_t + \theta \hat{Q}_t^* + b_2 W_t + e_t$ by 2SLS. Here Q_t and $\hat{Q}_t^*$ are endogenous, $(1, W_t)$ are included exogenous variables, and $(Y_t, Z_t, Y_t Z_t)$ are the excluded instruments. Three instruments for two endogenous regressors leave one overidentifying restriction to test. Because $\hat{Q}_t^*$ is a generated regressor, conventional second-step standard errors are too small. Bresnahan (1989, p. 1033, fn. 23) calls this explicit two-step procedure "so ugly that no one would ever undertake it", while noting that it shows why more powerful techniques identify θ.

The better procedure estimates both equations jointly by the generalized method of moments (GMM). Stack the parameters in $\Theta = (a_0, \ldots, a_4, b_0, b_1, b_2, \theta)$ and define the residuals

$$\begin{aligned} u_t^d(\Theta) &= Q_t - a_0 - a_1 P_t - a_2 Y_t - a_3 P_t Z_t - a_4 Z_t, \\ u_t^s(\Theta) &= P_t - b_0 - b_1 Q_t + \theta \frac{Q_t}{a_1 + a_3 Z_t} - b_2 W_t. \end{aligned} \tag{3.39}$$

With instrument vectors $h_t^d = (1, Y_t, Z_t, W_t, W_t Z_t)^\top$ and $h_t^s = (1, W_t, Y_t, Z_t, Y_t Z_t)^\top$, the moment conditions are $\mathbb{E}[h_t^d u_t^d(\Theta)] = 0$ and $\mathbb{E}[h_t^s u_t^s(\Theta)] = 0$. GMM minimizes a quadratic form in the sample analogues of the ten moments. The system is nonlinear in Θ because θ multiplies a ratio that involves (a_1, a_3). Joint estimation imposes the cross-equation restriction that the slope inside the markup term equals the slope of demand, and its standard errors account for the estimation of demand automatically (Appendix A).

A graphical version. Figure 3.7 redraws Figure 2 of Bresnahan (1982) in the same way. We keep D_1, MC^c, MC^m and $E_1 = (3.81, 6.19)$ from Figure 3.6. Demand rotates around E_1 to the flatter curve $D_3 \colon P = 7.714 - 0.4Q$, which passes through E_1 because $6.19 + 0.4 \times 3.81 = 7.714$. The competitive equilibrium solves $7.714 - 0.4Q = 2 + 1.1Q$, so $Q = \frac{5.714}{1.5} = 3.81$. Competition stays at E_1. The monopolist sets $MR_3 = 7.714 - 0.8Q$ equal to $2 + 0.1Q$, so $Q = \frac{5.714}{0.9} = 6.35$ and $P = 7.714 - 0.4 \times 6.35 = 5.17$. Monopoly moves to $E_3 = (6.35, 5.17)$. At E_1 the elasticity of demand rises from $\frac{6.19}{3.81} = 1.62$ to $\frac{6.19}{0.4 \times 3.81} = 4.06$, and the monopolist cuts its markup.

The rotation does more than separate two polar models. The size of the response measures conduct. Write the magnitudes of the inverse-demand slopes before and after the rotation

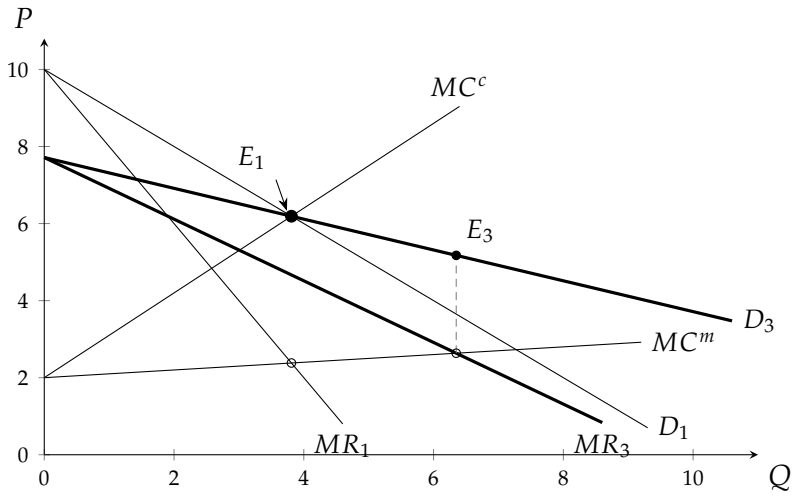

Figure 3.7: A demand rotation separates competition from monopoly. Demand rotates around $E_1 = (3.81, 6.19)$ from $D_1 : P = 10 - Q$ to $D_3 : P = 7.714 - 0.4Q$. Competitive firms with $MC^c = 2 + 1.1Q$ stay at E_1. A monopolist with $MC^m = 2 + 0.1Q$ sets $MR_3 = MC^m$ (open circle) and moves to $E_3 = (6.35, 5.17)$. Drawn after Figure 2 of Bresnahan (1982), with illustrative numbers chosen here.

as $g_1 = g(Z_1)$ and $g_3 = g(Z_3)$, with the function $g(Z) = -\frac{1}{a_1 + a_3 Z} = \frac{1}{|a_1 + a_3 Z|}$ from the proof of Proposition 3.28. Every structure consistent with the original market has marginal cost slope $b_1(\theta) = \lambda_1 - \theta g_1$, where λ_1 is the composite slope estimated before the rotation. After the rotation the supply relation has slope $b_1(\theta) + \theta g_3 = \lambda_1 - \theta(g_1 - g_3)$. Since the original supply relation passed through (Q_1, P_1), the new one is

$$P = P_1 + \left[\lambda_1 - \theta(g_1 - g_3)\right](Q - Q_1) - \theta(g_1 - g_3)Q_1.$$

The rotated demand curve is $P = P_1 - g_3(Q - Q_1)$. Equating the two and solving,

$$\begin{aligned}(Q - Q_1)\left[g_3 + \lambda_1 - \theta(g_1 - g_3)\right] &= \theta(g_1 - g_3)Q_1, \\ Q_3 - Q_1 &= \frac{\theta(g_1 - g_3)Q_1}{g_3 + \lambda_1 - \theta(g_1 - g_3)}.\end{aligned}$$

Rearranging the first line at $Q = Q_3$ expresses conduct in terms of observables:

$$\theta = \frac{(g_3 + \lambda_1)(Q_3 - Q_1)}{(g_1 - g_3)\,Q_3}. \tag{3.40}$$

In the example $g_1 = 1$, $g_3 = 0.4$ and $\lambda_1 = 1.1$. The response is zero under competition, 2.54 under monopoly, and 0.95 when $\theta = 0.5$. Plugging the monopoly outcome into (3.40) gives $\frac{1.5 \times 2.54}{0.6 \times 6.35} = 1.00$. When demand becomes more elastic, a firm with market power cuts its markup, and its output response rises with its conduct. At the original quantity the supply relation shifts down by $\theta(g_1 - g_3)Q_1$, an amount proportional to conduct.

Rotators in practice. Applications need a natural experiment that changes the slope of demand (Bresnahan, 1989, pp. 1033–1034). One shifter might measure the size of the economy, such as national income, while a second measures the price of a substitute. In Just and Chern (1980) the market power lies on the buying side. Tomato processors buy from many farmers, and the adoption of a mechanical harvester changed the elasticity of supply they faced. In Bresnahan

(1981a, 1987) demand elasticities depend on how crowded the product space is, which changes with the set of models offered (Chapter 6). In sugar refining the canning season changes the composition of buyers and makes demand less elastic (Section 3.7). The method stands or falls with the estimated demand elasticities. Critics offered other readings of the tomato harvester, and the automobile results depend on how products are ordered in quality space (Bresnahan, 1989, p. 1034).

Two caveats follow from the theory. First, the rotator must be excluded from marginal cost. If the canning season also changes the slope of marginal cost, through overtime for example, then a term $b_3 Z_t Q_t$ in marginal cost competes with $\theta g(Z_t) Q_t$. The two differ only through the curvature of g, a thin reed for identification. Second, the linear model can identify θ even without a separate shifter Y_t, using Z_t and Z_t^2 as instruments. That identification comes entirely from the linearity of marginal cost in quantity, as the next theorem shows.

3.5.3 Lau's theorem: identification without functional forms

The rotation argument does not depend on linearity. Lau (1982) shows that it holds for general demand and cost functions. Bresnahan (1989, p. 1033) summarizes his sufficient condition for identification. The inverse demand function must not be writable with the demand shifters separable from quantity, which requires at least two shifters. We state and prove a version of this result.

Let inverse demand be $P = f(Q, Y)$ with a vector of demand shifters $Y \in \mathbb{R}^k$ and $f_Q < 0$, and let industry marginal cost be an unknown function $c(Q, W)$. The supply relation is

$$P = c(Q, W) - \theta \, Q \, f_Q(Q, Y). \tag{3.41}$$

Following Lau, we work without econometric errors. The data are the equilibrium map $(Y, W) \mapsto (P, Q)$. Berry and Haile (2014, p. 1776) describe the class Lau studied as deterministic conjectural-variations models with homogeneous goods and symmetric firms. We make three assumptions. The demand function f is known, because the cost shifters W are excluded from demand and trace it out. The true structure has a unique equilibrium with $Q > 0$ for every (Y, W). The function f is twice continuously differentiable.

Definition 3.29 (Single-index demand)**.** Inverse demand has a *single index* if $f(Q, Y) = \tilde{g}(Q, r(Y))$ for a scalar function r and some function $\tilde{g}$.

Theorem 3.30 (Lau)**.**

(i) Suppose demand has a single index, and for each W the equilibrium quantity $Q^e(r, W)$ is strictly monotone in the index r. Then for every $\theta' \geq 0$ there is a marginal cost function $c'(Q, W)$ such that every observed equilibrium satisfies the demand and supply relations of the structure (f, c', θ'). The supply relation cannot distinguish θ' from θ, so conduct is not identified from it.

(ii) Suppose that at some observed equilibrium (Q_0, Y_0, W_0) the $2 \times k$ Jacobian of $\big(f(Q_0, Y),\ f_Q(Q_0, Y)\big)$ with respect to Y has rank two at Y_0. Suppose also that the equilibrium map is observed for all Y in a neighborhood of Y_0 with $W = W_0$. Then θ is identified.

Proof. (i) Fix W. Because $Q^e(\cdot, W)$ is strictly monotone, it has an inverse $r = H(Q, W)$ on its range. Define

$$c'(Q, W) \equiv \tilde{g}\left(Q, H(Q, W)\right) + \theta' \, Q \, \tilde{g}_Q\left(Q, H(Q, W)\right),$$

which depends on (Q, W) only. Take any observed equilibrium (P, Q) at (Y, W) and let $r = r(Y)$. Then $Q = Q^e(r, W)$, so $H(Q, W) = r$ and $P = \tilde{g}(Q, r)$. Substituting,

$$c'(Q, W) = P + \theta' \, Q \, \tilde{g}_Q(Q, r) = P + \theta' \, Q \, f_Q(Q, Y).$$

Rearranging gives $P = c'(Q, W) - \theta' Q f_Q(Q, Y)$, which is the supply relation of the alternative structure. Demand is unchanged. The observed point therefore solves the equilibrium conditions of (f, c', θ').

The construction does not make the observed point the only solution for the alternative structure. Take $f(Q, r) = 2 + r^2(r - Q)$ with $r \in (0, 1)$, $c = 2$ and $\theta = 0$, so the equilibrium is $Q = r$. Matching every observation with $\theta' = 1$ forces $c'(Q) = 2 - Q^3$, and the alternative supply relation becomes $Q^3 - 2r^2Q + r^3 = (Q - r)(Q^2 + rQ - r^2) = 0$. It has a second positive root, $Q = \frac{\sqrt{5}-1}{2} r$, and at $Q = r$ the alternative firm's first-order condition picks a profit minimum. Part (i) is therefore a statement about the supply relation. If the alternative structure must also have a unique profit-maximizing equilibrium, the argument needs further conditions on f and c'.

(ii) Fix W_0 and define $\Phi(Q, Y) \equiv f(Q, Y) + \theta Q f_Q(Q, Y) - c(Q, W_0)$, so equilibria satisfy $\Phi = 0$. Consider the set $\Gamma = \{Y : \Phi(Q_0, Y) = 0\}$ of shifter values that produce the equilibrium quantity Q_0. Its gradient at Y_0 is $\nabla f + \theta Q_0 \nabla f_Q$, where gradients are taken with respect to Y. This gradient is nonzero, because ∇f and ∇f_Q are linearly independent. By the implicit function theorem, Γ is locally a manifold of dimension $k - 1$ through Y_0, with tangent space $T = \{v : (\nabla f + \theta Q_0 \nabla f_Q) \cdot v = 0\}$. Suppose $f_Q(Q_0, \cdot)$ were constant on Γ near Y_0. Then $\nabla f_Q \cdot v = 0$ for all $v \in T$, so $\nabla f_Q = \ell(\nabla f + \theta Q_0 \nabla f_Q)$ for some scalar ℓ. If $\ell \neq 0$, this makes ∇f and ∇f_Q linearly dependent. If $\ell = 0$, it makes $\nabla f_Q = 0$. Both contradict rank two. Hence some $Y_1 \in \Gamma$ has $f_Q(Q_0, Y_1) \neq f_Q(Q_0, Y_0)$. The two equilibria share Q_0 and W_0, hence the same marginal cost $c(Q_0, W_0)$. Subtracting their supply relations,

$$P_1 - P_0 = -\theta \, Q_0 \left[f_Q(Q_0, Y_1) - f_Q(Q_0, Y_0) \right], \qquad \theta = -\frac{P_1 - P_0}{Q_0 \left[f_Q(Q_0, Y_1) - f_Q(Q_0, Y_0) \right]}. \quad (3.42)$$

Every term on the right is observed or known, so θ is identified. □

The two parts fit together. Under a single index, f and f_Q depend on Y only through r. Their Jacobian is $\left(\tilde{g}_r \nabla r, \tilde{g}_{Qr} \nabla r\right)$, which has rank at most one. Part (ii) is therefore the local failure of the single-index structure. In words, θ is identified when the demand shifters can move the slope of demand at a given quantity independently of its level. In the data, every observation with the same W lies on a single curve $P = \phi(Q, W)$ when demand has a single index. Any conduct value can then be rationalized by a suitable marginal cost, as part (i) constructs.

Three examples make the condition concrete. Constant-elasticity demand with a scale shifter, $Q = YP^{-\varepsilon}$, has inverse demand $P = (\frac{Q}{Y})^{-\frac{1}{\varepsilon}}$, a single index. Conduct is not identified without restrictions on cost. Letting a second shifter move the elasticity, $Q = Y_1 P^{-\varepsilon(Y_2)}$, breaks the single index. In the linear rotation model (3.37), inverse demand is $f = \frac{Q - a_0 - a_2 Y - a_4 Z}{a_1 + a_3 Z}$ with $f_Q = \frac{1}{a_1 + a_3 Z}$. The Jacobian with respect to (Y, Z) has determinant

$$\frac{\partial f}{\partial Y}\frac{\partial f_Q}{\partial Z} - \frac{\partial f}{\partial Z}\frac{\partial f_Q}{\partial Y} = \left(-\frac{a_2}{a_1 + a_3 Z}\right)\left(-\frac{a_3}{(a_1 + a_3 Z)^2}\right) - 0 = \frac{a_2 a_3}{(a_1 + a_3 Z)^3},$$

which is nonzero exactly when both $a_2 \neq 0$ and $a_3 \neq 0$. A pure rotator without a shifter ($a_2 = 0$) leaves a single index $r = Z$, so the identification in the linear model with $a_2 = 0$ rests on

the functional form of cost. This matches an observation of Berry and Haile (2014, p. 1754). Lau's results require exogenous variation that alters both the level and the slope of aggregate demand, a point they credit to Nevo (1998). Nothing in the proof uses linearity, which is the sense in which the rotation argument is nonparametric.

3.5.4 Other routes to identification

Demand rotations are one of several ways to separate conduct from the slope of marginal cost. Each replaces the rotator with a restriction or with extra data, and each restriction has a cost.

Constant marginal cost makes a single demand shifter enough. With $b_1 = 0$ the composite slope is $\lambda = -\frac{\theta}{a_1}$, so $\theta = -a_1\lambda$, the upper endpoint in Corollary 3.27. Equivalently, pass-through reveals conduct. With linear demand and constant marginal cost, $\rho = \frac{1}{1+\theta}$ by Corollary 3.9(iii), which is the logic of the pass-through tests of Section 3.2.1. The weakness is that any slope of marginal cost is read as market power, so the method overstates θ when $b_1 > 0$.

Observed marginal cost removes the problem. Once demand is estimated, $\theta_t = \varepsilon_t L_t$ can be computed observation by observation from (3.2). This is the strategy of the two validation studies of this chapter. In British electricity, marginal cost comes from fuel prices and plant efficiencies (Section 3.8). In insurance markets, claims data can play the same role, because the cost of serving a customer is the expected claim. A related route assumes that cost is known up to a few parameters. In sugar refining the fixed-proportions technology gives $MC = c_0 + kP^{raw}$, and c_0 and k can be estimated jointly with θ or set from engineering evidence (Section 3.7).

Homogeneity of marginal cost in factor prices gives another restriction. Any term of the supply relation that does not scale with factor prices must belong to the markup, the route of Appelbaum (1982) described in Section 3.1.4. Firm-specific cost shifters identify a single firm's residual demand, an object different from industry conduct (Section 3.4).

Changes in market structure or regulation can shift conduct while leaving cost unchanged. Spiller and Favaro (1984) study Uruguayan banking across a change in the regulation of entry. They find that freer entry shifts the supply relation downward (Bresnahan, 1989, fn. 36). The identifying assumption is that the regulatory change moved conduct and left marginal cost alone.

Supply shocks identify regimes of conduct. Porter (1983a) lets the supply relation switch between a price-war regime with low conduct and a collusive regime with high conduct. Bresnahan (1989, Section 3.4) explains what identifies the switch. Holding the exogenous variables fixed, the joint distribution of price and quantity has two modes, one per regime, and switching-regression methods detect them. The risk is that an unobserved cost shock also shifts the supply relation. In the railroad data the regime changes move price and quantity by about 50 percent, which, together with contemporary discussion of cartel adherence, makes the conduct reading plausible (Bresnahan, 1989, p. 1042). We study this work in Chapter 13.

The modern literature recasts identification of conduct as testing among a finite menu of models, such as Bertrand pricing, joint profit maximization or pricing that internalizes common ownership. Bresnahan (1987) compares collusive and competitive models of the 1955 automobile market (Chapter 6). Nevo (2001) compares the margins implied by alternative conduct models with accounting margins in breakfast cereal (Chapter 8). Berry and Haile (2014, Section 6) give nonparametric conditions under which cross-market and cross-product variation discriminates between conduct models. Their argument generalizes the rotation logic beyond rotations. Backus et al. (2021a) and Duarte et al. (2024) turn it into practical tests built on the model-selection test of Rivers and Vuong (2002). Their instruments must move markups but be excluded from marginal cost. Backus et al. (2021a, Section 2.2) show that the test gains

power when the instrument predicts the difference between the markups of the two models. Duarte et al. (2024, Section 5) show that weak instruments distort the size and lower the power of the test, and they give a diagnostic for instrument strength.

3.6 Interpreting the conduct parameter

Suppose the identification problem is solved and we have an estimate $\hat{\theta}$ strictly between zero and one. What have we learned? This section asks where the conduct parameter comes from. It shows that a constant-θ estimate can mismeasure market power badly when conduct varies, presents a bounds alternative, and reviews the record of estimates.

3.6.1 Where the conduct parameter comes from

The literature reads θ in three ways. The first treats it as shorthand for a specific game. Homogeneous-good Bertrand pricing gives $\theta = 0$, symmetric Cournot gives $\theta = \frac{1}{N}$, and joint profit maximization gives $\theta = 1$ (Chapter 2). Dynamic games can make conduct vary over time. In Green and Porter (1984), firms cannot observe demand shocks or rivals' outputs, low prices trigger reversion to a punishment phase, and conduct alternates between collusion and price wars (Chapter 12). Studies in this tradition impose a lot of structure on θ in the econometric specification.

The second reading treats θ as a continuous *conjectural variation*, the firm-level parameter $\tilde{\theta}_i = 1 + r_i$ of Corollary 3.3. Conjectures of this kind go back to Bowley (1924). Three criticisms followed. The first is that the approach lacks a consistent theory. In a static game firms move simultaneously, so a nonzero response has no foundation. The attempt to discipline conjectures by requiring them to be consistent ended with Daughety (1985) and Lindh (1992). Without peculiar informational assumptions, Cournot conjectures are the only consistent ones (Corts, 1999, p. 230). The second is that the parameter is hard to interpret as a belief. As Remark 3.5 explains, it describes what firms do and says nothing about what they expect rivals to do. The third is the identification problem of Section 3.5.

The third reading uses $\hat{\theta}$ only as a specification test. We estimate θ freely and test $\theta = 0$, $\theta = \frac{1}{N}$ or $\theta = 1$ without giving $\hat{\theta}$ a structural meaning. Every specification nests price taking, so every estimate tests it (Section 1.6.4).

Two normalizations coexist, and we must keep them apart. Corts writes a firm-level supply relation in which conduct equals 0 under competition, 1 under Cournot and N under joint monopoly. When all firms share the same conduct, the industry parameter of (3.1) is the firm-level parameter divided by N (Corts, 1999, fn. 1). We use the industry normalization throughout and say so whenever we quote a firm-level number.

The *as-if* reading interprets an estimate in $(0, 1)$ through (3.2). Whatever game firms play, we can compute the conduct value that would rationalize the observed margin, $\theta_t = \varepsilon_t L_t$, the *elasticity-adjusted Lerner index*. It separates industries with high margins because demand is inelastic from industries with high margins because conduct is less competitive (Corts, 1999, p. 231). Bresnahan (1989, p. 1029) states the conditions for this reading. If the estimated "conjectures" are constant over time and breakdowns of collusion are infrequent, "we can safely interpret the parameters as measuring the average collusiveness of conduct." The exact-fit result of Proposition 3.6 shows why some such condition is needed. A conduct parameter free to vary by observation fits any data, and a constant θ is the restriction that gives the model

content. What does a constant-θ estimate measure when conduct does vary? That is the question of Corts (1999).

3.6.2 The Corts critique

The question

Corts (1999) asks whether what he calls the *conduct parameter method* recovers the as-if conduct parameter when behavior is generated by a game other than a conjectural-variations equilibrium. The question matters because the method was popular when Corts wrote, and it remains in use. Its data requirements are modest and its output is a single, easily interpreted number. Corts lists more than a dozen applications, among them Iwata (1974), Appelbaum (1982), Porter (1983a), Roberts (1984), Spiller and Favaro (1984) and Ellison (1994).

Corts separates the method into two steps (Corts, 1999, p. 229). The first estimates the slope of the supply relation, which he calls *equilibrium variation*: how equilibrium behavior responds to perturbations of demand. The second maps this slope into the *equilibrium value* of the elasticity-adjusted margin. The literature has handled the first step with care, through constant marginal cost (Iwata, 1974), demand rotators (Bresnahan, 1982; Lau, 1982), or supply shocks and regimes (Porter, 1983a). Corts attacks the second step. He makes the first step trivial by assuming constant marginal cost, linear demand and a symmetric equilibrium.

What the conduct parameter method estimates

We first state the result in a general form. Let the true markup satisfy

$$P_t = c_0 + c_W^{\top} W_t + \theta_t m_t, \qquad m_t \equiv \frac{Q_t}{\left|\frac{\partial Q_t}{\partial P_t}\right|} = \frac{P_t}{\varepsilon_t}, \tag{3.43}$$

so that $\theta_t = \varepsilon_t L_t$ is the as-if conduct in market t. Marginal cost $c_0 + c_W^{\top} W_t$ is constant in output, its level is unknown, and it shifts with observed cost shifters W_t. Demand is known, so m_t is observed. This is the most favorable case for the method. If marginal cost were known, θ_t could be computed directly and nothing would need to be estimated. The researcher assumes constant conduct and estimates $P_t = c_0 + c_W^{\top} W_t + \theta m_t + v_t$ by instrumental variables, using a demand shifter or rotator Z_t as the instrument for m_t.

Proposition 3.31 (What a constant conduct parameter estimates)**.** *Let $\tilde{Z}_t$ be the residual from the linear projection of Z_t on $(1, W_t)$, and assume $\operatorname{Cov}(\tilde{Z}_t, m_t) \neq 0$.*

(i) The instrumental-variables estimator converges to

$$\operatorname{plim} \hat{\theta} = \frac{\operatorname{Cov}(\tilde{Z}_t, \theta_t m_t)}{\operatorname{Cov}(\tilde{Z}_t, m_t)} = \mathbb{E}[\theta_t] + \frac{\operatorname{Cov}\left(\tilde{Z}_t, (\theta_t - \mathbb{E}[\theta_t])\, m_t\right)}{\operatorname{Cov}(\tilde{Z}_t, m_t)}. \tag{3.44}$$

It equals average conduct if conduct is constant, or if θ_t is independent of (Z_t, W_t, m_t). In general the second term is not zero and can have either sign.

(ii) Suppose there are no cost shifters, Z_t is continuous with support bounded below, $m_t = \mu(Z_t)$ for a differentiable increasing function μ, and the markup is a differentiable function of the markup term, $\theta_t m_t = \mathcal{M}(m_t)$. Then

$$\operatorname{plim} \hat{\theta} = \int \mathcal{M}'\left(\mu(z)\right) \omega(z)\, \mathrm{d}z, \qquad \omega(z) = \frac{\mu'(z)\, v(z)}{\int \mu'(s)\, v(s)\, \mathrm{d}s} \geq 0,$$

where $v(z) = \mathbb{E}\left[(Z_t - \mathbb{E}Z_t)\mathbf{1}\{Z_t \geq z\}\right]$. *The estimate is a weighted average of the local slopes* $\mathcal{M}'$ *of the supply relation.*

Proof. (i) By the Frisch-Waugh logic for instrumental variables, the coefficient on m_t in a just-identified regression with exogenous controls $(1, W_t)$ is $\frac{\mathrm{Cov}(\tilde{Z}_t, P_t)}{\mathrm{Cov}(\tilde{Z}_t, m_t)}$ in the limit. Substitute (3.43) for P_t. The term $c_0 + c_W^\top W_t$ is a linear function of $(1, W_t)$, so its covariance with $\tilde{Z}_t$ is zero, which leaves the first expression. For the second, write $\theta_t m_t = \mathbb{E}[\theta_t]m_t + (\theta_t - \mathbb{E}[\theta_t])m_t$ and divide. If θ_t is independent of (Z_t, W_t, m_t), then $\mathrm{Cov}(\tilde{Z}_t, (\theta_t - \mathbb{E}\theta_t)m_t) = \mathbb{E}[\theta_t - \mathbb{E}\theta_t]\,\mathbb{E}[\tilde{Z}_t m_t] = 0$, because $\tilde{Z}_t$ is a function of (Z_t, W_t) and has mean zero.

(ii) Let $\underline{z}$ be the lower end of the support. For any differentiable h, $h(Z) = h(\underline{z}) + \int \mathbf{1}\{Z \geq z\}h'(z)\,\mathrm{d}z$, so $\mathrm{Cov}(Z, h(Z)) = \int h'(z)\,\mathrm{Cov}(Z, \mathbf{1}\{Z \geq z\})\,\mathrm{d}z = \int h'(z)v(z)\,\mathrm{d}z$. The weight $v(z)$ is nonnegative. For $z \geq \mathbb{E}Z$ it is the expectation of a nonnegative variable. For $z < \mathbb{E}Z$ it equals $-\mathbb{E}[(Z - \mathbb{E}Z)\mathbf{1}\{Z < z\}]$, minus the expectation of a nonpositive variable. Apply the identity to $h = \mathcal{M} \circ \mu$, with $h' = \mathcal{M}'(\mu)\mu'$, and to $h = \mu$, then take the ratio. □

Part (ii) connects the critique to the interpretation of instrumental variables in simultaneous equations as weighted averages of derivatives, a link Corts draws in his footnote 5. He cites the 1995 NBER working paper that later appeared as Angrist et al. (2000). The level of conduct at markup term m is $\frac{\mathcal{M}(m)}{m}$, the slope of the ray from the origin. The estimate averages the slope of the supply relation itself. A small-dispersion version makes the gap explicit. If $\theta_t = \theta(m_t)$ and m_t varies little around $\bar{m}$, then $\mathcal{M}(m) \approx \mathcal{M}(\bar{m}) + \mathcal{M}'(\bar{m})(m - \bar{m})$ and

$$\operatorname{plim} \hat{\theta} \approx \mathcal{M}'(\bar{m}) = \theta(\bar{m}) + \bar{m}\,\theta'(\bar{m}) = \theta(\bar{m})\left(1 + \eta_\theta\right), \qquad \eta_\theta \equiv \frac{\mathrm{d}\ln\theta}{\mathrm{d}\ln m}. \tag{3.45}$$

The estimate equals the level of conduct only when conduct does not vary with demand conditions. If collusion weakens when demand is high ($\eta_\theta < 0$), the estimate understates conduct. If $\eta_\theta < -1$, it is negative.

Example 3.32 (Conduct linear in the markup term)**.** Let $\theta_t = \vartheta_0 - \vartheta_1 m_t$ with $\vartheta_1 > 0$, so collusion is harder when demand is strong, as in Rotemberg and Saloner (1986). Then $\theta_t m_t = \vartheta_0 m_t - \vartheta_1 m_t^2$. With no cost shifters, and writing $m_t = \bar{m} + d_t$ with $\bar{m} = \mathbb{E}[m_t]$,

$$\mathrm{Cov}(Z_t, m_t^2) = 2\bar{m}\ \mathrm{Cov}(Z_t, m_t) + \mathbb{E}\left[(Z_t - \mathbb{E}Z_t)\,d_t^2\right].$$

If (Z_t, m_t) is jointly symmetric about its mean, the last term is zero, and (3.44) gives

$$\operatorname{plim} \hat{\theta} = \vartheta_0 - \vartheta_1 \frac{\mathrm{Cov}(Z_t, m_t^2)}{\mathrm{Cov}(Z_t, m_t)} = \vartheta_0 - 2\vartheta_1\bar{m}, \qquad \mathbb{E}[\theta_t] = \vartheta_0 - \vartheta_1\bar{m}.$$

The estimate understates average conduct by $\vartheta_1\bar{m}$, and it is negative whenever $\vartheta_0 < 2\vartheta_1\bar{m}$. With $\vartheta_0 = 1$ and $\vartheta_1\bar{m} = 0.6$, average conduct is 0.4 while the estimate is -0.2.

Corts derives the special case of linear demand. Let inverse demand be $P_t = A(x_t) - BQ_t + e_t$, where $A(x) = A_0 + A_1 x$ with $A_1 > 0$ and x_t is a demand shifter, and let marginal cost be constant in output. Each of N symmetric firms produces $q_t = \frac{Q_t}{N}$. The firm-level supply relation is $P_t = c(w_t) + \theta_i B q_t$. Two-stage least squares with instrument x_t gives a coefficient on q_t equal to $\frac{A_1}{\gamma_q} - NB$ in the limit (Corts, 1999, eqs. 7–8). Here γ_q is the first-stage coefficient of q_t on x_t after partialling out w_t. The firm-level conduct estimate is this coefficient divided by B:

$$\operatorname{plim} \hat{\theta}_i = \frac{A_1}{B\gamma_q} - N \qquad \text{(Corts, 1999, eq. 9).}$$

It depends only on demand parameters and on how equilibrium quantity responds to the demand shifter. When the optimal quantity rule $q^*(x)$ is linear, $\gamma_q = \frac{\mathrm{d}q^*}{\mathrm{d}x}$ and the estimate is the slope of the margin with respect to demand-driven quantity, $\hat{\theta}_i = \frac{1}{B}\left(\frac{\mathrm{d}(P-c)}{\mathrm{d}x}\right)\left(\frac{\mathrm{d}q^*}{\mathrm{d}x}\right)^{-1}$ (Corts, 1999, eq. 10). The as-if parameter is $\tilde{\theta}_i = \frac{P-c}{Bq^*}$. Corts's Proposition 1 follows. The method measures market power correctly if and only if

$$\frac{P-c}{q^*} = \left(\frac{\mathrm{d}(P-c)}{\mathrm{d}x}\right)\left(\frac{\mathrm{d}q^*}{\mathrm{d}x}\right)^{-1},$$

that is, if and only if the average relation between margin and output equals the marginal relation.

Figure 3.8 illustrates the point in the spirit of Corts's Figure 1. In a conjectural-variations model the supply relation is a ray from the marginal cost intercept, so its slope and its level coincide. Another game can generate a flatter supply relation through points with the same average markup. The method then infers lower conduct and assigns the rest of the margin to a higher marginal cost intercept.

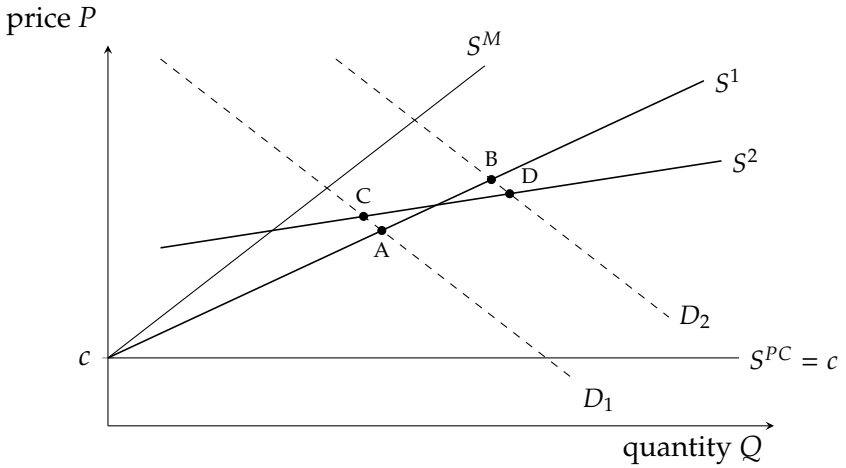

Figure 3.8: Slope versus level of the supply relation. Inverse demand shifts from $D_1\colon P = 6 - Q$ to $D_2\colon P = 8 - Q$, and marginal cost is $c = 1$. Industry 1 follows the conjectural-variations supply relation $S^1\colon P = 1 + 0.6Q$ (points A and B). Industry 2 follows $S^2\colon P = 2.5 + 0.2Q$ (points C and D). Both industries have average markup 2.25 at average quantity 3.75, an m-weighted average conduct of 0.6. The conduct parameter method estimates 0.6 for industry 1 and 0.2 for industry 2, and attributes the rest of industry 2's margin to a marginal cost of 2.5. S^{PC} and S^M are the competitive and monopoly supply relations. Drawn in the spirit of Figure 1 of Corts (1999).

The numbers in Figure 3.8 are easy to check. On S^1, point A solves $6 - Q = 1 + 0.6Q$, so $Q = 3.125$ and the markup is 1.875. Point B solves $8 - Q = 1 + 0.6Q$, so $Q = 4.375$ and the markup is 2.625. On S^2, point C solves $6 - Q = 2.5 + 0.2Q$, so $Q = 2.917$ and the markup is 2.083. Point D gives $Q = 4.583$ and markup 2.417. Both pairs average a markup of 2.25 at quantity 3.75. The ratio $\frac{2.25}{3.75} = 0.6$ is the m-weighted average conduct $\frac{\mathbb{E}[\theta_t m_t]}{\mathbb{E}[m_t]}$, since $m_t = Q_t$ when the slope of demand is -1.

Corts's supergame model

To show that the gap can be large in a coherent model, Corts studies efficient tacit collusion supported by repeated interaction (Corts, 1999, Section 3). The model is closely related to Rotemberg and Saloner (1986) when demand is independent over time and to Kandori (1991) when it is serially correlated (Corts, 1999, fn. 2). We use δ for the discount factor in the rest of this subsection. N symmetric firms choose quantities every period. Inverse demand is $P_t = A(x_t) - BQ_t$ and marginal cost is $c(w_t)$, where the demand state x_t and the cost state w_t are observed by all firms before they choose. A deviation is punished by reversion to the one-shot Cournot equilibrium forever. An *efficient* supergame equilibrium chooses, in each state, the quantity that maximizes joint profit subject to the incentive constraint. Let $y_t = A(x_t) - c(w_t)$ be the demand margin and q the output of each firm.

The incentive constraint takes a simple form. A firm's collusive profit is $\pi(q) = q(y_t - BNq)$. Against rivals who produce $(N-1)q$, the best deviation produces $\frac{y_t - B(N-1)q}{2B}$ and earns $\pi^b(q) = \frac{(y_t - B(N-1)q)^2}{4B}$. The one-period gain from deviating is

$$\begin{aligned}\pi^b(q) - \pi(q) &= \frac{(y_t - B(N-1)q)^2 - 4Bq(y_t - BNq)}{4B} \\ &= \frac{y_t^2 - 2B(N+1)\,q\,y_t + B^2\left[(N-1)^2 + 4N\right]q^2}{4B} \\ &= \frac{\left(y_t - B(N+1)q\right)^2}{4B}.\end{aligned}$$

Let $\Lambda(x_t)$ be the expected discounted profit lost by entering the punishment phase (Corts, 1999, eq. 15). It sums, over future periods $i \geq 1$, δ^i times the expected excess of collusive over Cournot profit. The incentive constraint is $\frac{(y_t - B(N+1)q)^2}{4B} \leq \Lambda(x_t)$. Collusive output lies below the Cournot output $q^c = \frac{y_t}{B(N+1)}$, so the constraint reads $y_t - B(N+1)q \leq 2\sqrt{B\Lambda(x_t)}$. The smallest sustainable output is

$$\tilde{q}_t = \frac{y_t}{B(N+1)} - \frac{2\sqrt{B\Lambda(x_t)}}{B(N+1)} \qquad \text{(Corts, 1999, eq. 14).} \tag{3.46}$$

The efficient output is the joint-monopoly output $q_t^m = \frac{y_t}{2BN}$ when it is sustainable, and $\tilde{q}_t$ otherwise. In industry units, conduct in state t is $\theta_t = \frac{P_t - c_t}{BQ_t}$, which equals 1 at q_t^m and $\frac{1}{N}$ at q^c.

Equation (3.46) shows why persistence matters. A higher demand state raises the gain from deviating, which pushes output up toward Cournot. If demand is persistent, a higher state also raises expected future collusive profits and so the cost of punishment $\Lambda(x_t)$, which pushes output down. When shocks are independent over time, only the first effect operates. Then Λ does not depend on x_t, and $\frac{\mathrm{d}\tilde{q}_t}{\mathrm{d}x_t} = \frac{A_1}{B(N+1)}$, the Cournot response.

Simulation design and results. Corts simulates a symmetric duopoly with linear demand and constant marginal cost. The demand and cost states each take ten evenly spaced values. The cost state is independent over time, and its role is to identify demand. The demand state follows a Markov chain that stays in the same state with probability ϖ and moves to each other state with probability $\frac{1-\varpi}{9}$ (Corts calls this probability λ). Firms' quantities are computed by iterating on $\Lambda(x_t)$ until convergence, and the conduct parameter method is applied to a sample from the resulting process.

Figure 3.9 reproduces Corts's results for positively correlated demand, in his firm-level normalization (1 is Cournot and 2 is joint monopoly). He draws five lessons (Corts, 1999, pp. 237–240). (a) For high discount factors the method measures market power accurately whatever the demand process. (b) For low discount factors it detects no market power when demand is independent over time. (c) It is accurate when demand is fully persistent. (d) It becomes more accurate as demand becomes more persistent. (e) When demand states are negatively correlated, higher values of the estimate go with lower values of the as-if parameter. The magnitudes are large. An estimate of 1.2 is consistent with an as-if parameter of 1.3 when $\varpi = 0.9$ and of 1.9 when $\varpi = 0.5$ (Corts, 1999, p. 238). Two industries with similar estimates can thus differ greatly in collusiveness, and an industry whose demand becomes more or less persistent can appear to change its conduct when it has not.

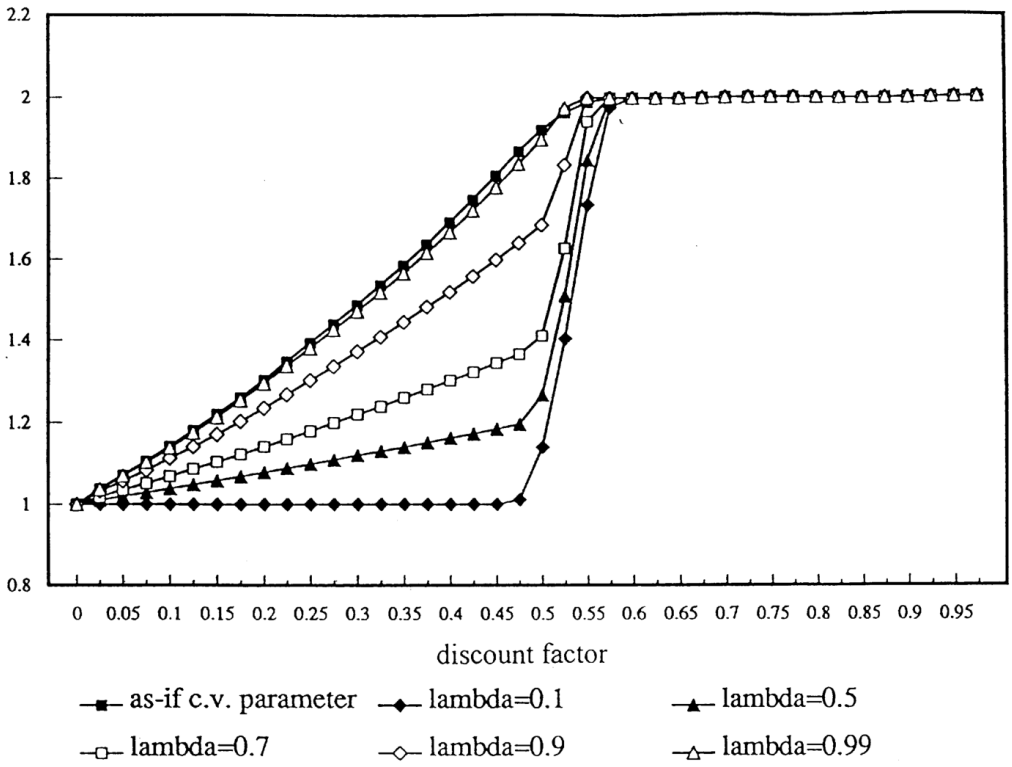

Figure 3.9: Conduct estimates in Corts's supergame simulations with positively correlated demand, symmetric duopoly. The vertical axis is firm-level conduct (1 is Cournot, 2 is joint monopoly). The top curve is the as-if conduct parameter. The other curves are conduct parameter estimates for demand persistence ϖ ("lambda" in the original) of 0.1, 0.5, 0.7, 0.9 and 0.99. With ten states, $\varpi = 0.1$ makes demand independent over time. Source: Corts (1999), Figure 2.

Corts proves the main patterns (Corts, 1999, Section 3.2). If joint monopoly is sustained in every state, the estimate equals the as-if parameter (his Proposition 2). The monopoly supply relation is itself a conjectural-variations relation, so it does not matter how monopoly is sustained. If demand is independent over time and monopoly is sustained in no state, the estimate equals the Cournot value for every such discount factor (Proposition 3). Prices and profits rise with δ over this range, yet the method detects none of the collusion. The proof is the one given above, since $\frac{\mathrm{d}\tilde{q}_t}{\mathrm{d}x_t}$ equals the Cournot response. If demand is fully persistent, the estimate converges to the as-if parameter (Proposition 4), because $\tilde{q}_t$ becomes proportional to the demand margin. If a higher demand state shifts the distribution of future states to the

right, the estimate exceeds the Cournot value whenever monopoly is sustained in no state (Proposition 5). The method then detects some collusion but understates it. With negatively correlated demand, which resembles seasonal variation, the estimate can fall below the Cournot value even though prices are above it. Corts warns that seasonal dummies used as demand shifters may then fail to detect collusion, or produce estimates negatively correlated with true conduct (Corts, 1999, p. 240).

A worked example: Bertrand collusion with demand shocks

The following model is our own illustration, in the spirit of Rotemberg and Saloner (1986) and of Corts. It replaces Cournot reversion with Bertrand reversion and delivers closed forms. N symmetric firms sell a homogeneous good at constant marginal cost c and set prices every period. Demand is $Q_t = A_t - P_t$. The demand state A_t is independent and identically distributed over time with a continuous distribution on $[\underline{A}, \bar{A}]$, $\underline{A} > c$, and firms observe it before pricing. Firms collude with grim-trigger strategies. Any deviation is followed by pricing at marginal cost forever, which yields zero profit. Let $\Pi(p, A) = (p - c)(A - p)$ be industry profit and $\pi^m(A) = \frac{(A-c)^2}{4}$ monopoly profit.

The incentive constraint. Suppose firms charge $p \le p^m(A) = \frac{A+c}{2}$ and share the market equally. A deviator undercuts slightly, takes the whole market and earns almost $\Pi(p, A)$ today and nothing afterward. Colluding yields $\frac{\Pi(p,A)}{N}$ today plus $\frac{\delta}{1-\delta}\frac{V}{N}$, where $V = \mathbb{E}[\Pi(p(A'), A')]$ is expected industry profit per period on the collusive path. The incentive constraint is

$$\Pi(p, A) - \frac{\Pi(p, A)}{N} \le \frac{\delta}{1-\delta}\frac{V}{N} \quad \Longleftrightarrow \quad \Pi(p, A) \le K \equiv \frac{\delta V}{(1-\delta)(N-1)}.$$

Collusion thus caps industry profit at K in every state. A price above $p^m(A)$ is never better. A deviator could then undercut to $p^m(A)$ and earn $\pi^m(A)$, so the constraint would require $\pi^m(A) \le \frac{\Pi(p,A)+(N-1)K}{N}$, which fails whenever $\pi^m(A) > K$. The most profitable sustainable price is therefore

$$p(A) = \begin{cases} \frac{A+c}{2} & \text{if } \pi^m(A) \le K, \\ \frac{A+c}{2} - \sqrt{\pi^m(A) - K} & \text{if } \pi^m(A) > K, \end{cases} \tag{3.47}$$

where the second line is the lower root of $(p - c)(A - p) = K$. The cap binds in high-demand states, $A > A^* \equiv c + 2\sqrt{K}$. There the price falls as demand rises. Differentiating the second line, $\frac{\mathrm{d}p}{\mathrm{d}A} = \frac{1}{2} - \frac{A-c}{4\sqrt{\pi^m(A)-K}} < 0$, because $\sqrt{\pi^m(A) - K} < \frac{A-c}{2}$. These are the price wars during booms of Rotemberg and Saloner (1986).

The equilibrium cap. Expected industry profit is $V = \mathbb{E}[\min\{\pi^m(A), K\}]$, so the cap solves the fixed-point equation

$$K = \nu\, \mathbb{E}\left[\min\{\pi^m(A), K\}\right] \equiv T(K), \qquad \nu \equiv \frac{\delta}{(1-\delta)(N-1)}. \tag{3.48}$$

Lemma 3.33 (The most collusive equilibrium)**.** *(i) If $\delta < 1 - \frac{1}{N}$, the only solution of (3.48) is $K = 0$, and firms price at cost. (ii) If $\delta > 1 - \frac{1}{N}$, there is exactly one positive solution K^*. It is the largest fixed point, and the iteration $K_{n+1} = T(K_n)$ started at any $K_0 \ge \nu\mathbb{E}[\pi^m(A)]$ decreases to K^*. (iii) Monopoly pricing in every state is sustainable if and only if $\nu\, \mathbb{E}[\pi^m(A)] \ge \pi^m(\bar{A})$.*

Proof. The map T is increasing and concave, because $\min\{\pi^m(A), K\}$ is increasing and concave in K for every A. It satisfies $T(0) = 0$, its right derivative at zero is ν (since $\pi^m(A) > 0$), and it is bounded by $\nu\mathbb{E}[\pi^m(A)]$. The condition $\nu < 1$ is equivalent to $\delta < (1-\delta)(N-1)$, that is, to $\delta < 1 - \frac{1}{N}$. (i) If $\nu < 1$, then $T(K) \le \nu K < K$ for every $K > 0$. (ii) If $\nu > 1$, the function $T(K) - K$ is positive for small $K > 0$ and negative for large K, so it has a positive root. It is concave and equals zero at $K = 0$ with positive slope there. A second positive root would force a concave function to be zero at two points while positive between zero and the first, which is impossible. Starting at $K_0 \ge \nu\mathbb{E}[\pi^m(A)] \ge K^*$, the sequence satisfies $K^* = T(K^*) \le T(K_n) \le K_n$, so it decreases and converges to a fixed point no smaller than K^*, which must be K^*. (iii) If $K \ge \pi^m(\bar{A})$, then $T(K) = \nu\mathbb{E}[\pi^m(A)]$, and the fixed point satisfies $K \ge \pi^m(\bar{A})$ exactly when $\nu\mathbb{E}[\pi^m(A)] \ge \pi^m(\bar{A})$. □

Collusion above cost requires $\delta > 1 - \frac{1}{N}$, the familiar condition for Bertrand collusion with constant demand. It plays the role of condition (i) in Rotemberg and Saloner (1986), which requires that the number of firms not be too large relative to the discount factor. They also select the greatest fixed point. For any δ above it, the cap exceeds $\pi^m(\underline{A})$. If $K \le \pi^m(\underline{A})$, then $T(K) = \nu K > K$, so no fixed point lies there. The lowest demand states are therefore always priced at the monopoly level.

Conduct and the conduct parameter estimate. The markup term is $m_t = Q_t$, because $|\frac{\partial Q}{\partial P}| = 1$. Conduct in state A is $\theta(A) = \frac{p(A)-c}{Q}$. In unconstrained states $p - c = Q = \frac{A-c}{2}$, so $\theta = 1$. In constrained states $(p-c)Q = K$, so

$$\theta(A) = \frac{K}{Q^2}, \qquad P - c = \frac{K}{Q}.$$

Conduct falls as demand rises, and the supply relation in the constrained region is a rectangular hyperbola. Its local slope is $-\frac{K}{Q^2} = -\theta(A)$. Part (ii) of Proposition 3.31 applies with $Z_t = A_t$, since $m_t = A_t - p(A_t)$ is increasing in A_t. The estimate is a weighted average of the local slope $+1$ in unconstrained states and $-\theta(A)$ in constrained states, so it can be negative while every $\theta(A)$ lies in $(0, 1]$.

Table 3.6 and Figure 3.10 report the numbers for $N = 2$, $c = 0$ and A_t uniform on $[6, 10]$. Population moments are computed by quadrature, and a regression on 200,000 simulated periods reproduces them to within 0.002. Collusion requires $\delta > 0.5$. Monopoly in every state requires $\nu\mathbb{E}[\pi^m(A)] \ge \pi^m(10)$, that is, $\nu \ge \frac{25}{16.33}$, which holds for $\delta \ge 0.6048$. In between, the cap binds in the high-demand states. At $\delta = 0.51$, conduct ranges from 0.17 in the highest state to 1 in the lowest, and its mean is 0.51. The m-weighted average conduct is $\frac{\mathbb{E}[P_t - c]}{\mathbb{E}[Q_t]} = \frac{2.34}{5.66} = 0.41$. The instrumental-variables estimate is -0.36. A researcher would conclude that prices lie below the competitive level in an industry whose average elasticity-adjusted Lerner index is about one half. The estimate turns positive only near $\delta = 0.56$ and catches up with average conduct when monopoly is sustained everywhere. With $N = 3$ the pattern is the same: at $\delta = 0.677$ mean conduct is 0.53 and the estimate is -0.36.

The example and Corts's model reach the same conclusion by different routes. With Cournot reversion and independent shocks, the estimate sticks at the Cournot value. With Bertrand reversion the static benchmark is price taking, and the constant profit cap makes the constrained supply relation slope downward, so the estimate falls below zero. In both cases the estimate reflects how the incentive constraint varies with demand, and it carries no direct information on the level of conduct.

Table 3.6: Mean conduct and the conduct parameter estimate in the Bertrand supergame

Discount factor δ	Profit cap K	Cutoff state A^*	Share of states constrained	Mean conduct $\mathbb{E}[\theta_t]$	IV estimate $\hat{\theta}$
0.5001	9.30	6.10	0.98	0.28	−0.27
0.505	11.37	6.74	0.81	0.44	−0.35
0.51	12.54	7.08	0.73	0.51	−0.36
0.52	14.38	7.58	0.61	0.62	−0.33
0.53	15.94	7.99	0.50	0.71	−0.28
0.55	18.69	8.65	0.34	0.83	−0.10
0.57	21.15	9.20	0.20	0.92	0.21
0.6048	25.00	10.00	0.00	1.00	1.00

Notes: $N = 2$ Bertrand firms, marginal cost $c = 0$, demand $Q_t = A_t - P_t$ with A_t independent and uniform on $[6, 10]$, grim-trigger punishment at marginal cost. K is the largest solution of (3.48), and the cap binds for $A_t > A^* = 2\sqrt{K}$. Conduct is $\theta_t = \frac{P_t - c}{Q_t}$, the elasticity-adjusted Lerner index. The estimate is $\frac{\mathrm{Cov}(A_t, P_t - c)}{\mathrm{Cov}(A_t, Q_t)}$, the limit of the instrumental-variables estimator with a constant and the demand state as instrument. For $\delta < 0.5$ prices equal cost and both measures are zero. Population moments computed by quadrature.

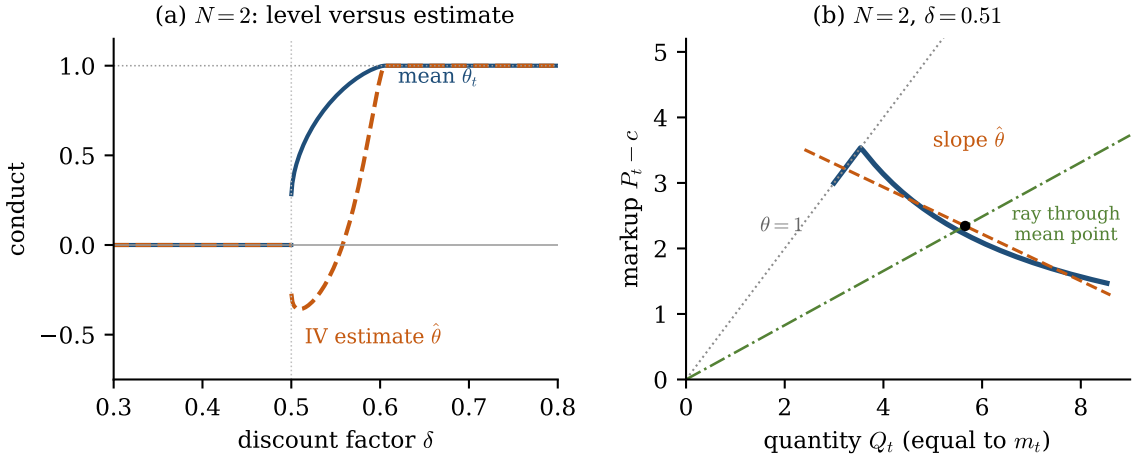

Figure 3.10: Level of conduct versus its estimate in a Bertrand supergame with independent demand shocks ($N = 2$, $c = 0$, A_t uniform on $[6, 10]$). Panel (a): mean conduct $\mathbb{E}[\theta_t]$ and the instrumental-variables estimate $\hat{\theta}$ against the discount factor. Panel (b): the locus of equilibrium markups and quantities at $\delta = 0.51$. It follows the monopoly ray $\theta = 1$ in low-demand states and the hyperbola $P - c = \frac{K}{Q}$ in high-demand states. The dashed line through the mean point has slope $\hat{\theta} = -0.36$, and the dash-dotted ray through the mean point has slope 0.41, the m-weighted average conduct.

Assessment

The critique changes how we read a conduct estimate. A constant-θ estimate measures the slope of the supply relation, a weighted average of marginal responses of the markup to demand. Reading it as the level of conduct requires the marginal and average relations to coincide. This holds in conjectural-variations models, under monopoly in every state, and in the limit of fully persistent demand. Corts concludes that, when behavior results from efficient supergame collusion, the method understates market power if demand shocks are not fully permanent. It may detect no market power at all when shocks are transitory, even with average margins near the monopoly level (Corts, 1999, pp. 244–245).

Three further points follow. First, the specification-test reading does not escape the critique. The estimate can equal the Cournot value over a wide range of collusive equilibria. A failure to reject Cournot then carries little information, and tests of the nested static models may lack power. Second, Corts argues that "not even the positive correlation" of the estimate with the as-if parameter can be maintained across models (Corts, 1999, p. 245). Comparisons of conduct across industries or over time are therefore suspect. Third, the evidence available to Corts points the same way. In the electricity study of Wolfram (1999) and the sugar study of Genesove and Mullin (1998), the estimates obtained without cost data fall below the direct measures. Both studies were available to Corts as working papers. Corts notes that equality of the two can be rejected in both cases (Corts, 1999, p. 245). Sections 3.7 and 3.8 examine both studies.

Genesove and Mullin frame the point in the same terms. The conduct parameter "measures the marginal response of price, and hence the markup, to changes in exogenous variables" (Genesove and Mullin, 1995, p. 2). It therefore "infers market power from the marginal behavior of the markup, not from the level of the markup." They add an example (Genesove and Mullin, 1995, p. 3). Supergame models such as Rotemberg and Saloner (1986) may make the marginal response of price to demand shifters independent of the discount rate. It is then also independent of the price level at a baseline state of demand.

The critique has limits. Corts's models are stylized, with linear demand, constant cost, perfect monitoring and an efficient equilibrium, and the simulations are not calibrated to any industry. They show that the mismeasurement can be severe, and they leave its size in a given application open. The direction of the bias depends on the persistence of demand, which the researcher can sometimes measure.

The contribution is lasting. Berry and Haile (2014, fn. 7) cite Corts (1999) and Reiss and Wolak (2007) for the fundamental problems of the conduct parameter approach. Corts calls for explicit structural models of conduct. The field responded in three ways. It estimates dynamic models of collusion directly, as in the work on the railroad cartel of Porter (1983a) and Ellison (1994) (Chapter 13). It tests a finite menu of conduct models within richer demand systems (Section 3.5.4). And it validates the method where marginal cost is observed (Sections 3.7 and 3.8).

3.6.3 Bounds instead of point estimates

If conduct varies and a constant θ misleads, we can give up point identification. Rosen (2007, Section 2.2) replaces the equilibrium assumption with known bounds on each firm's conduct in each period. The widest bounds are price taking and monopoly. Conduct may vary freely within them, so the parameters of marginal cost are in general only set identified. We present the idea in the homogeneous-good setting of this chapter.

Suppose only that industry conduct lies between price taking and joint monopoly, $\theta_t \in [0, 1]$,

with no restriction on how it varies across observations. The supply relation gives $P_t - mc_t = -\theta_t Q_t P'(Q_t)$. Since $-Q_t P'(Q_t) \geq 0$, the bounds on θ_t imply $0 \leq P_t - mc_t \leq -Q_t P'(Q_t)$, that is,

$$P_t + Q_t P'(Q_t) \;\leq\; mc_t \;\leq\; P_t. \tag{3.49}$$

Marginal cost lies between monopoly marginal revenue and price, observation by observation. With a parametric marginal cost $mc_t = c(Q_t, W_t; \beta) + u_t^s$ and $\mathbb{E}[u_t^s \mid X_t] = 0$ for instruments X_t, the inequalities become conditional moment inequalities:

$$\mathbb{E}\left[P_t - c(Q_t, W_t; \beta) \mid X_t\right] \geq 0, \qquad \mathbb{E}\left[c(Q_t, W_t; \beta) - P_t - Q_t P'(Q_t) \mid X_t\right] \geq 0.$$

The *identified set* is the set of β that satisfy both for almost every X_t. Since $P'(Q_t)$ comes from an estimated demand curve, estimation has two steps. Bounds on β imply bounds on marginal cost, on markups and on each θ_t, without assuming that conduct is constant.

A deterministic example shows the geometry. Let $mc = b_0 + b_1 Q$ with true values $(b_0, b_1) = (2, 0.5)$, and let inverse demand in market t be $P = A_t - Q$. Four markets have $A_t = 8, 10, 12, 14$ and conduct $\theta_t = 0.2, 0.9, 0.5, 0.1$. The equilibrium solves $A_t - Q - (2 + 0.5Q) = \theta_t Q$, so $Q_t = \frac{A_t - 2}{1.5 + \theta_t}$. Each market contributes the two half-planes $P_t - Q_t \leq b_0 + b_1 Q_t \leq P_t$ in the (b_1, b_0) plane, and we add the restrictions $b_0 \geq 0$ and $b_1 \geq 0$. Figure 3.11 shows the intersection. It is a quadrilateral with $b_1 \in [0, 0.76]$ and $b_0 \in [0.80, 4.47]$. Without the sign restrictions the slope could range from -1.38 to 0.76. The implied bounds on conduct are informative in some markets. Conduct lies in $[0.66, 1]$ in the second market (true value 0.9) and in $[0.36, 0.73]$ in the third (true value 0.5). In the first and fourth markets only the upper bound moves, to 0.32 and 0.42 (true values 0.2 and 0.1).

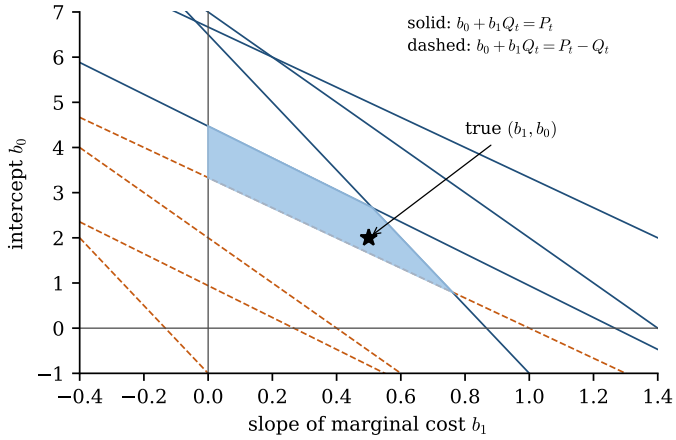

Figure 3.11: Identified set for a linear marginal cost $mc = b_0 + b_1 Q$ when conduct varies freely in $[0, 1]$. Each of four markets with inverse demand $P = A_t - Q$ restricts (b_1, b_0) to the band between a solid line (marginal cost equals price) and a dashed line (marginal cost equals monopoly marginal revenue). The shaded region is the intersection with $b_0, b_1 \geq 0$. The star marks the true values $(0.5, 2)$.

The set shrinks quickly when some markets sit near the extremes of conduct. Consider six markets with $A_t = 6, 8, \ldots, 16$ and $\theta_t = 0.1, 0.8, 0.3, 1, 0, 0.6$, one of them competitive and one fully collusive. The identified set is then a small triangle with $b_1 \in [0.33, 0.50]$ and $b_0 \in [2.00, 2.67]$. Every market's conduct is bounded within an interval of width at most 0.1. The approach trades precision for robustness. It needs no assumption on how conduct varies,

and it states plainly what the data cannot reveal. Its bounds can be wide, and inference requires methods for moment inequalities. The Lerner bound (3.9) and Sullivan's bound in Section 3.3.1 use the same logic in reverse. A lower bound on marginal cost, the tax, bounds conduct from above.

3.6.4 The record of conduct estimates

Almost all estimates of conduct fall strictly between zero and one. The finding is unsurprising, yet it is useful against extreme claims that an industry is perfectly competitive or fully cartelized. Table 1.7 reproduces the estimated Lerner indices that Bresnahan (1989, Table 17.1) collected from early studies. Section 1.7.4 discusses the three conclusions he draws from them (Bresnahan, 1989, pp. 1052–1053). He concludes that some concentrated industries have high margins and that anticompetitive conduct is one cause. He also finds that the studies reveal little about how market power relates to industry structure.

The entries of that table are margins, and they differ from conduct parameters by the factor ε. Bresnahan left out studies whose estimates could not be converted into a Lerner index. These include the Panzar-Rosse and Sullivan methods, which yield tests or bounds, and the residual demand method, whose elasticities equal the Lerner index only in special cases (Bresnahan, 1989, fn. 47). Two lessons of this section qualify the record further. A conduct estimate is a slope, so estimates in $(0, 1)$ are compatible with conduct that swings between collusion and price wars (Section 3.6.2). The most direct test of the methods compares them with observed costs, which is the task of Sections 3.7 and 3.8.

3.7 Sugar refining, 1890–1914: Genesove and Mullin (1998)

The methods of Sections 3.2 and 3.5 infer market power without observing marginal cost. Their answers are only as good as the maintained assumptions on demand, cost and conduct. Whether those assumptions deliver the right answer in a real industry is an empirical question. Genesove and Mullin (1998) answer it for American cane sugar refining between 1890 and 1914, an industry in which marginal cost can be measured almost directly. They compute conduct twice. The first computation uses the cost information and serves as a benchmark. The second treats cost as unknown and applies the standard estimator of the New Empirical Industrial Organization (NEIO). Together with the electricity study of Section 3.8, this comparison is the closest the literature comes to a controlled test of the conduct-parameter method.[3]

3.7.1 The question and why sugar

Genesove and Mullin start from the supply relation (3.1) with a constant marginal cost c,

$$P + \theta\, Q\, P'(Q) = c, \tag{3.50}$$

and from its Lerner form (3.2), $\theta = \varepsilon(P)\frac{P-c}{P} \equiv L_\varepsilon$. With complete cost information and an estimated demand elasticity, the elasticity-adjusted Lerner index delivers θ period by

[3]We work from two versions. The article (Genesove and Mullin, 1998) is cited by its table numbers ("Table 2") and its published page numbers. The working paper (Genesove and Mullin, 1995) contains a longer history, the cost evidence and several tables that the article omits. We cite those as "WP Table 9" and give its printed page numbers. Published Tables 2, 3 and 4 correspond to WP Tables 4, 6, and 7 and 8. Published Table 10 reproduces two columns of WP Table 14 with a different direct measure. Published Table 9 has no counterpart in the working paper.

period. Without cost information, θ must be restricted, because an unrestricted θ_t fits any data (Proposition 3.6). The usual restriction is that θ is constant, or at least uncorrelated with the instruments (WP p. 4).

Three features make sugar refining the right place for a test (WP pp. 3–4). First, the technology is simple. Raw sugar is turned into refined sugar at a fixed and known coefficient, both prices are observed, and the remaining costs are documented. A true price-cost margin can therefore be computed. Second, the harvest cycle of raw sugar and year-to-year weather generate supply variation that is plausibly exogenous to American demand. This variation helps identify demand and, through it, conduct. Third, the industry went through dramatic structural changes: the formation of a trust, repeated entry with price wars, renewed consolidation, and an antitrust prosecution. These episodes let us ask whether estimated conduct moves with structure, and whether the method can tell a change in conduct from a change in cost.

The test answers two standing objections to the NEIO (WP pp. 2–3). The first is that functional forms for demand impose strong restrictions on the relation between price and marginal cost. The second is the point of Corts (1999) developed in Section 3.6.2. The estimated conduct parameter measures the marginal response of the markup to the identifying shocks, and so may misstate its level. Genesove and Mullin note that no NEIO estimate had ever been checked against an independent measure of conduct. Their design makes three comparisons. The NEIO estimate $\hat{\theta}$ is compared with the direct measure L_ε. The NEIO estimates of the cost parameters are compared with their documented values. Finally, the estimates for different structural regimes are compared with the direct measures for the same regimes. Throughout, the maintained hypothesis is that L_ε measures conduct without error (WP p. 5).

3.7.2 The industry, 1887–1914

The American cane sugar refining industry of this period combined high concentration with repeated entry. Table 3.7 lists the main events (WP Tables 1 and 13). The account below follows WP pp. 6–8 and 13–15. These pages rely on Eichner (1969), Zerbe (1969) and Willett and Gray's *Weekly Statistical Sugar Trade Journal*, the source of most of the data.

Trust and first entry. After several failed attempts at collusion, the Sugar Trust was formed in December 1887. It consolidated 18 firms that controlled 80 percent of industry capacity, and it soon reduced their 20 plants to 10. The average refined price rose about 16 percent, from \$6.013 per hundred pounds in 1887 to \$7.007 in 1888 (WP p. 6, fn. 2). Entry followed. Claus Spreckels, a West Coast refiner, completed a plant in Philadelphia in December 1889, in retaliation for the Trust's purchase of a California refinery. A price war ensued. The Trust, reorganized in 1891 as the American Sugar Refining Company (ASRC), then bought the Spreckels plant and the remaining outsiders. By April 1892 it held 95 percent of capacity. Genesove and Mullin describe this episode as the template for the period: high concentration, punctuated by entry, price wars, and then acquisition of or accommodation with the entrants (WP p. 7).

Cartel and second entry. Between 1892 and 1896 five firms entered, each with a single plant of about 1,340 barrels of refined sugar per day on average. ASRC and its "friendly" companies had 49,500 barrels per day. ASRC acted as cartel leader, and by 1896 an understanding with the independents had evolved. The next challenge came from the Arbuckle Brothers, wholesale grocers and the dominant American coffee roasters. Their refinery began limited production in August 1898, and the Doscher refinery started in November. Each plant had a capacity of 3,000 barrels per day. A severe price war followed, with pricing at or below cost, shutdowns by independent refiners and partial exit of one entrant. Apart from one respite, the war lasted

Table 3.7: Chronology and structural regimes of the U.S. sugar refining industry

Panel A. Events (WP Table 1 and text)	
1887 (Dec.)	Sugar Trust formed: 18 firms with 80 percent of capacity
1889–1890	Entry by Spreckels (Philadelphia plant completed in Dec. 1889), price war
1891	Trust reorganized as the American Sugar Refining Company (ASRC)
1891–1892	Acquisition of Spreckels and others, ASRC reaches 95 percent of capacity
1892–1896	Small-scale entry by five single-plant firms, cartel operation
1898	Entry by Arbuckle Brothers (August) and Doscher (November)
1900 (May)	End of the Arbuckle war
1903	Cuban Reciprocity Treaty: Cuban raw sugar enters at 80 percent of full duty
1910	Federal antitrust suit (consent decree in 1922)
1914	World War I begins, the sample ends in June 1914
Panel B. Regimes used in the estimation (WP Table 13)	
Jan. 1890 to Feb. 1892	Spreckels entry, price war
Mar. 1892 to Sep. 1898	Acquisition of Spreckels, small-scale entry, cartel operation
Sep. 1898 to Apr. 1900	Entry by Arbuckle Brothers and Doscher, price war
May 1900 to 1910	After the Arbuckle war
Nov. 1910 to 1913	Government antitrust suit

Notes: Compiled from Genesove and Mullin (1995), WP Tables 1 and 13 and pp. 6–8. The two price-war regimes in Panel B are the "post-entry price wars" of Section 3.7.7.

until May 1900. It ended when Doscher merged with two major independents in a transaction organized by the president of ASRC (WP pp. 7–8).

Tariffs, antitrust and fringes. The tariff on refined sugar protected domestic refiners from European competition. From 1903, the Cuban Reciprocity Treaty admitted Cuban raw sugar at 80 percent of the full duty. In antitrust, the government challenged ASRC's purchase of several Philadelphia refineries in 1892, and the Supreme Court upheld the acquisition in 1895 (the *E. C. Knight* case). In 1910 the federal government sued for dissolution. The case ended in a consent decree only in 1922, but after the government's victories against Standard Oil and American Tobacco in 1911, ASRC began a partial "voluntary" dissolution (WP p. 8). Two competitive fringes disciplined the cane refiners. Domestic beet sugar supplied less than 1 percent of consumption until 1894, 5 percent by 1901 and 15 percent in 1908–1914. European beet refiners were a threat of imports, and ASRC's president testified in 1888 and 1894 that ASRC set prices so that no refined sugar would be imported (WP p. 14). Genesove and Mullin do not model the fringes. Their conduct measures are therefore "overall" measures that include the discipline of potential imports and beet sugar (WP p. 15).

Product, sunk costs and capacity. The standard grade of refined sugar, "standard granulated," was a homogeneous product. Refiners shipped it to grocers in barrels, and grocers repackaged it without identifying the manufacturer, so prices tended to uniformity (WP pp. 13–14). A refinery of 3,000 barrels per day cost between $1.5 and $2.5 million in 1900. Plant and machinery had little value outside sugar, while the waterfront land had considerable salvage value. Entry costs were thus largely, but not completely, sunk. Industry output stayed well below capacity throughout, and ASRC kept excess capacity even in the depths of the Arbuckle war (WP p. 13). ASRC's share of the market fell from 91 percent in 1892 to 43 percent in 1914 (WP Table 9).

3.7.3 Technology and the direct measurement of marginal cost

Refined sugar was made mostly from cane. Cane was first processed into raw sugar, which could be shipped and stored. The standard grade, "96 degree centrifugals," was 96 percent sucrose, and its sugar content was tested with a polariscope, which made the input homogeneous. Most raw sugar came from the tropics, especially Cuba, with Louisiana the main domestic source. Refiners melted, purified and crystallized it into refined sugar, which is pure sucrose. Witnesses for both ASRC and an independent testified that all refiners used a common process (WP p. 9).

Assumption 3.34 (Fixed-coefficient technology)**.** The marginal cost of producing one hundred pounds of refined sugar in period t is

$$c_t = c_0 + k\, P_t^{\text{raw}}. \tag{3.51}$$

Here P_t^{raw} is the price of one hundred pounds of raw sugar, and k is the quantity of raw sugar needed per unit of refined sugar. The term c_0 collects all other variable costs (labor, fuel, boneblack, packages, brokerage, net of the value of byproducts). Both c_0 (in constant dollars) and k are constant over time and do not depend on output.

The assumption that marginal cost does not depend on output is natural in an industry that always operated well below capacity. Genesove and Mullin maintain (3.51) throughout, and then measure k and c_0 from engineering and testimonial evidence.

The input coefficient. Raw sugar is 96 percent sucrose, so the physical minimum is $k = \frac{1}{0.96} = 1.042$. The working paper truncates this value and prints 1.041 (WP p. 10). Some sugar is lost in refining. A Treasury commission found in 1898 that one hundred pounds of raw sugar yielded 92.5 pounds of refined sugar. Genesove and Mullin put the yield at 92.5 to 93 pounds (WP p. 10). One pound of refined sugar therefore requires about $\frac{1}{0.93} = 1.075$ pounds of raw sugar, and Genesove and Mullin set $k = 1.075$. Audits of refiners' books by the Tariff Commission show that the coefficient did not change during the sample period or after it.

Non-sugar costs. The trade spoke of "the margin," the difference between the refined and the raw price. Because $k > 1$, that margin overstates the money left after paying for raw sugar. The relevant quantity is the *proper margin*

$$G_t \equiv P_t - k\, P_t^{\text{raw}} = c_0 + (P_t - c_t), \tag{3.52}$$

the refined price net of raw-sugar cost (WP pp. 10–11). By (3.51), the proper margin equals non-sugar cost plus the price-cost margin. Five pieces of evidence pin down c_0, all expressed in constant 1898 dollars per hundred pounds.

(i) The earliest evidence is testimony before the Industrial Commission in June 1899 (WP pp. 10–11). Henry Havemeyer, president of ASRC, said that he had never known a cost of refining below one-half cent a pound. At the formation of the trust it had been three-quarters of a cent. He agreed that at a margin of 50 cents a hundred pounds "the refineries are running at a loss" (WP p. 10, fn. 14). James Jarvie, a partner of Arbuckle Brothers, put the cost of refining at "50 to 60 points, or one-half to six-tenths of a cent per pound." He added that "if raw sugar costs $4\frac{1}{2}$ cents a pound, it will cost over 5 cents up to $5\frac{10}{100}$" (WP p. 11, fn. 15). The raw price in this statement is hypothetical. Subtracting its raw-sugar cost from the two totals gives, per hundred pounds,

$$c_0 = 500 - 1.075 \times 450 = 16.25 \text{ cents}, \qquad c_0 = 510 - 1.075 \times 450 = 26.25 \text{ cents}.$$

(ii) Another witness itemized non-sugar costs: 5 cents for brokerage and taxes, 10 cents for packages and 20 cents for wages, fuel, boneblack, repairs and sundries, less 10 cents of byproduct (syrup) revenue. The total is 25 cents.

(iii) At the Hardwick Committee hearings of 1911, refiners quoted a refining cost of 60 to 65 cents when raw sugar sold for \$4.00. A refining cost in this sense is $c - P^{\text{raw}} = c_0 + (k-1)P^{\text{raw}}$, so c_0 lies between $60 - 0.075 \times 400 = 30$ and 35 cents in current dollars, or 22 to 26 cents in 1898 dollars.

(iv) Tariff Commission audits for 1914 give a total refinery cost of \$0.420. Removing \$0.013 of accounting depreciation and \$0.056 of byproduct receipts leaves \$0.351 in current dollars, or 25 cents in 1898 dollars (WP p. 11, fn. 18).

(v) Behavior during the Arbuckle war bounds c_0 as well. The independents shut down or ran at "minimum capacity" at times. The minimum proper margin above which they always produced was 26 cents, and except for a couple of weeks they never produced below 9 cents. For example, they shut down when the refined price was \$4.71 and the raw price \$4.30, a proper margin of $4.71 - 1.075 \times 4.30 = 0.0875$ (WP p. 12, fn. 22).

Shutdown behavior cannot reveal a single break-even margin (WP p. 12). Prices are observed only on Fridays. Month-long contracts and the value of a reputation for reliable supply can justify producing at a loss. Costs of shutting down and restarting open a band of margins in which a firm sometimes produces and sometimes does not. The band is consistent with the direct estimates, however.

Genesove and Mullin adopt $c_0 = 0.26$, the value supported by the most and best evidence, and use 0.16 as a lower bound. The range reflects the researchers' ignorance. Cost differences among firms were small: a commission merchant for an independent refiner estimated that larger houses might refine 3 to 5 cents more cheaply (WP pp. 12–13). Non-sugar inputs are small: 4.5 percent of cost at $c_0 = 0.16$ and 7.5 percent at $c_0 = 0.26$ (WP p. 12). The direct measure of marginal cost is therefore

$$c_t = 0.26 + 1.075\, P_t^{\text{raw}}. \tag{3.53}$$

More than nine tenths of marginal cost is an observed input price that fluctuates a great deal. This is what makes sugar refining so well suited to a validation exercise.

3.7.4 Data, instruments and the demand system

Data. The sample is quarterly, from January 1890 to June 1914 (WP p. 26). Prices come from Willett and Gray's weekly quotations. Consumption data do not exist, so quantity is measured by *meltings* M_t, the quantity of raw sugar melted by refiners. Meltings track consumption closely because refined sugar deteriorates in storage and refiners produced to order with about a one-month lag (WP pp. 16–17). Prices are in dollars per hundred pounds, deflated to constant 1898 dollars with the wholesale price index of Hanes (1993). Meltings and Cuban imports are in hundreds of thousands of long tons per quarter. Cuban imports were zero in the third quarter of 1897, during the Cuban war of independence, and that quarter is dropped (Genesove and Mullin, 1998, pp. 365, 373). This leaves 97 quarters: 73 in the low season and 24 in the high season defined below. Table 3.8 reports the sample statistics.

Three facts stand out. Meltings are 22 percent higher in the high season ($\frac{5.11}{4.20} = 1.22$), while the refined price is only 15 cents higher and the raw price 8 cents higher. The proper margin

Table 3.8: Sample statistics, quarterly, 1890–1914

	Full sample		Low season		High season	
	Mean	S.D.	Mean	S.D.	Mean	S.D.
Refined price P	4.03	0.62	3.99	0.63	4.14	0.58
Raw price P^{raw}	3.30	0.59	3.28	0.61	3.36	0.53
Proper margin $P - 1.075\,P^{\text{raw}}$	0.48	0.19	0.46	0.18	0.53	0.21
Meltings M	4.43	1.11	4.20	1.04	5.11	1.07
Cuban imports	2.18	1.73	2.28	1.88	1.87	1.13
Observations	97		73		24	

Notes: Reproduced from Genesove and Mullin (1998), Table 2 (identical to WP Table 4). Prices in constant 1898 dollars per hundred pounds. Quantities in hundreds of thousands of long tons. The high season is the third quarter.

rises by about 7 cents between the seasons. Finally, the mean proper margin less $c_0 = 0.26$ is $0.48 - 0.26 = 0.22$, which is $\frac{0.22}{4.03} = 0.055$ of the mean price. Price exceeded marginal cost by only about 5 percent.

Frequency. Weekly data were available, but Genesove and Mullin use quarterly data on purpose (WP p. 16). With switching costs for grocers or consumers, short-run demand is less elastic than long-run demand. A high-frequency elasticity would imply a monopoly price far above what a forward-looking monopolist would charge. Observed prices would then look very competitive, and market power would be understated. Quarterly data are a compromise. Monthly data give qualitatively similar estimates.

The supply instrument. Demand estimation needs a variable that shifts supply but not demand. The raw sugar price is the obvious cost shifter, but the United States consumed about 25 percent of the world's sugar. A shock to American demand therefore moved the world raw price, which makes the raw price an invalid instrument (WP p. 17). Genesove and Mullin instrument instead with *Cuban imports* of raw sugar. Cuba was the closest and, after 1903, the tariff-preferred source of raw sugar for the East Coast refiners. Four arguments support exogeneity (WP pp. 17–23).

(a) Cuban exports went almost entirely to the United States. The share never fell below 85 percent and exceeded 98 percent in every year from 1900 to 1909 (WP Table 2). Cuban imports were inframarginal for the American market. The next destination, London, involved much higher shipping costs and the switching costs of an industry organized around New York.

(b) The sources of variation in Cuban supply were the seasonal harvest cycle, yearly weather, the war of independence of 1895–1898 with the Spanish-American War, and a secular increase in cane planting. The first three are exogenous to American demand. Cuban production fell from 1,004,264 tons in 1895 to 225,221 in 1896 and 212,051 in 1897 (WP Table 2). Much of the secular expansion responded to the 1903 treaty, a time trend in demand absorbs the rest, and cane yields harvests for five years with little tending.

(c) A negative American demand shock could induce Cuban suppliers to hold sugar back for a later quarter. This was impractical. Raw sugar was not warehoused in Cuba because the hot climate caused deterioration, and speculative storage took place in New York, which leaves imports unaffected. Delaying the harvest lost sucrose and risked the onset of the rainy season, which made the roads impassable.

(d) Quarterly aggregation further weakens any incentive to shift imports between periods.

A flexible family of demand curves. Genesove and Mullin specify industry demand as

$$Q(P) = \beta\,(\alpha - P)^{\gamma}. \tag{3.54}$$

In this section only, α, β and γ denote these demand parameters, to match the paper. They are unrelated to the price coefficient and taste parameters of the discrete-choice chapters. The parameter $\beta > 0$ scales the market, γ indexes convexity, and for $\gamma > 0$ the parameter α is the choke price. The next lemma collects the properties we use.

Lemma 3.35 (Properties of the demand family)**.** *For (3.54) with $\gamma > 0$ and $P < \alpha$, or with $\alpha = 0$ and $\gamma < 0$, in which case we read the family as $Q = \beta P^{\gamma}$, the following hold.*

(i) The price elasticity is $\varepsilon(P) = \frac{\gamma P}{\alpha - P}$, and the markup term is $m(P) \equiv \frac{Q(P)}{|Q'(P)|} = \frac{\alpha - P}{\gamma}$.

(ii) The family contains the quadratic ($\gamma = 2$), the linear ($\gamma = 1$) and the log-linear or constant-elasticity form ($\alpha = 0$, $\gamma < 0$, with $\varepsilon = -\gamma$). As $\alpha, \gamma \to \infty$ with $\frac{\gamma}{\alpha} = \lambda$ fixed (a local symbol, unrelated to the composite slope of Section 3.5), demand converges to the exponential form $Q \propto e^{-\lambda P}$, with $\varepsilon = \lambda P$ and $m = \frac{1}{\lambda}$.

(iii) The curvature of inverse demand, $\chi \equiv -\frac{QP''(Q)}{P'(Q)}$, equals $1 - \frac{1}{\gamma}$.

Proof. (i) Differentiate (3.54): $Q'(P) = -\gamma\beta(\alpha - P)^{\gamma-1}$. Then

$$\varepsilon(P) = -\frac{Q'(P)\,P}{Q(P)} = \frac{\gamma\beta(\alpha - P)^{\gamma-1}P}{\beta(\alpha - P)^{\gamma}} = \frac{\gamma P}{\alpha - P}, \qquad \frac{Q(P)}{|Q'(P)|} = \frac{\beta(\alpha - P)^{\gamma}}{\gamma\beta(\alpha - P)^{\gamma-1}} = \frac{\alpha - P}{\gamma}.$$

In the case $\alpha = 0$, $\gamma < 0$, demand is $Q = \beta P^{\gamma}$, so $Q' = \gamma\beta P^{\gamma-1}$, $\varepsilon = -\gamma$ and $\frac{Q}{|Q'|} = -\frac{P}{\gamma}$, which equals $\frac{\alpha - P}{\gamma}$ at $\alpha = 0$. (ii) The first three cases are immediate. For the limit, write $\gamma = \lambda\alpha$ and

$$(\alpha - P)^{\gamma} = \alpha^{\gamma}\left(1 - \frac{P}{\alpha}\right)^{\lambda\alpha} \longrightarrow \alpha^{\gamma}\,e^{-\lambda P} \qquad (\alpha \to \infty),$$

using $\left(1 - \frac{x}{n}\right)^{n} \to e^{-x}$. The factor α^{γ} is absorbed into the scale. The elasticity and markup term follow from (i): $\frac{\gamma P}{\alpha - P} = \frac{\lambda P}{1 - \frac{P}{\alpha}} \to \lambda P$ and $\frac{\alpha - P}{\gamma} = \frac{1}{\lambda} - \frac{P}{\gamma} \to \frac{1}{\lambda}$. (iii) Inverse demand is $P(Q) = \alpha - \left(\frac{Q}{\beta}\right)^{\frac{1}{\gamma}}$. Hence

$$P'(Q) = -\frac{1}{\gamma}\,\beta^{-\frac{1}{\gamma}}\,Q^{\frac{1}{\gamma}-1}, \qquad P''(Q) = -\frac{1}{\gamma}\left(\frac{1}{\gamma} - 1\right)\beta^{-\frac{1}{\gamma}}\,Q^{\frac{1}{\gamma}-2},$$

and $-\frac{QP''(Q)}{P'(Q)} = -\left(\frac{1}{\gamma} - 1\right) = 1 - \frac{1}{\gamma}$. In the case $\alpha = 0$, $\gamma < 0$, inverse demand is $P(Q) = \left(\frac{Q}{\beta}\right)^{\frac{1}{\gamma}}$. Both derivatives change sign, and their ratio is unchanged. □

Part (iii) places the family inside the pass-through analysis of Section 3.2.1. Linear demand has $\chi = 0$, quadratic demand $\chi = \frac{1}{2}$, exponential demand $\chi = 1$ and constant-elasticity demand $\chi = 1 + \frac{1}{\varepsilon}$. The four forms thus span the curvatures that Proposition 3.8 shows to matter for the link between pass-through and conduct.

Seasons as a demand rotator. Sugar is a complement of fruit in canning. The canning season begins at the end of May with the first New York strawberries and peaks in September (WP p. 24). Genesove and Mullin define the indicator $H_t = 1$ in the third quarter and $H_t = 0$ otherwise, and call the third quarter the *high season*. Write $s(t) \in \{L, H\}$ for the season of quarter t. Both the scale β and one shape parameter (α, γ or $\frac{\gamma}{\alpha}$, depending on the form) may differ by season. The high season can therefore raise demand proportionally and also change the monopoly price (WP p. 25). A change in β alone moves quantity at every price but leaves the markup term $m(P) = \frac{\alpha - P}{\gamma}$ unchanged. What identifies conduct here is a seasonal change in $m(P)$ at given prices, that is, in the elasticity of demand at a given price. Because marginal cost is assumed constant in output, such a change is enough, even when it is a parallel shift of linear demand (Section 3.5.4). In the estimates below, the high season changes both the level and the slope of demand, so canning demand also rotates it.

Estimating equations. For each season s, the four forms give the estimating equations (WP eqs. 6–9)

$$\text{Quadratic:} \quad \ln M_t = b_s + 2\ln(\alpha_s - P_t) + e_t, \tag{3.55}$$

$$\text{Linear:} \quad M_t = \beta_s \alpha_s - \beta_s P_t + e_t, \tag{3.56}$$

$$\text{Log-linear:} \quad \ln M_t = b_s + \gamma_s \ln P_t + e_t, \tag{3.57}$$

$$\text{Exponential:} \quad \ln M_t = b_s - \lambda_s P_t + e_t. \tag{3.58}$$

The constant b_s is the logarithm of the season's scale.[4] In the three logarithmic forms the error e_t is a proportional shift of demand, a shift in β. By (3.51) and the pricing rule derived below, such a shift does not move the profit-maximizing price at any θ. Demand shocks therefore do not enter the pricing equation, which justifies treating the two errors as uncorrelated later on.

The refined price is endogenous in (3.55)–(3.58). Within each season the instruments z_t^d are a constant and the logarithm of Cuban imports, $\ln CUBA_t$ (Genesove and Mullin, 1998, Table 3, notes). The moment conditions are $\mathbb{E}[e_t\, z_t^d] = 0$. Each season's equation has two parameters and two instruments, so the estimator is exactly identified. The quadratic form is nonlinear in α_s and is estimated by nonlinear instrumental variables (Amemiya, 1985). Standard errors are robust to heteroskedasticity and to serial correlation of up to four lags (Newey and West, 1987). The pooled specification of WP Table 5 adds a linear time trend in $\ln \beta$ and interacts price with H_t. Its trend coefficients are negative and insignificant, which Genesove and Mullin attribute to the spread of beet sugar (WP p. 26). The joint tests that both high-season terms are zero give $\chi^2_{(2)}$ statistics of 4.91, 22.73, 23.40 and 20.77 for the four forms (WP Table 5). Dropping the trend allows estimation season by season, which gives Table 3.9. All later calculations use these by-season estimates.

Reading the demand estimates. Every form agrees that the high season both shifts demand out and makes it less elastic. The $\chi^2_{(2)}$ statistics reject equality across seasons at the 5 percent level in the quadratic form (cutoff 5.99) and at below 1 percent in the other three. In the linear form the two demand curves are $M = 13.37 - 2.30P$ and $M = 10.74 - 1.36P$. They cross at $P = \frac{13.37 - 10.74}{2.30 - 1.36} = 2.80$, below every observed price, so over the relevant range high-season demand is larger and steeper. Panel (a) of Figure 3.12 draws the two curves. At the full-sample mean price the elasticity is about 2.0 to 2.2 in the low season and about 1.0 to 1.1 in the high season (Table 3.10 below). The fits are close to the data. At the season mean prices, the linear form predicts meltings of $13.37 - 2.30 \times 3.99 = 4.19$ and $10.74 - 1.36 \times 4.14 = 5.11$, against

[4] The working paper writes the constant as $-\ln \beta$. Only the estimated constant matters for what follows.

Table 3.9: Demand for refined sugar, estimated separately by season

	(1) Quadratic $\gamma = 2$	(2) Linear $\gamma = 1$	(3) Log-linear $\alpha = 0$	(4) Exponential $\gamma, \alpha \to \infty$
Low season ($N = 73$)				
Price coefficient	$\alpha_L = 7.72$	$-\beta_L = -2.30$	$\gamma_L = -2.03$	$-\lambda_L = -0.53$
	(0.86)	(0.48)	(0.48)	(0.12)
Intercept	−1.20	$\beta_L \alpha_L = 13.37$	4.19	3.52
	(0.47)	(1.90)	(0.65)	(0.48)
High season ($N = 24$)				
Price coefficient	$\alpha_H = 11.88$	$-\beta_H = -1.36$	$\gamma_H = -1.10$	$-\lambda_H = -0.26$
	(2.03)	(0.36)	(0.28)	(0.07)
Intercept	−2.48	$\beta_H \alpha_H = 10.74$	3.17	2.70
	(0.54)	(1.57)	(0.40)	(0.29)
$\chi^2_{(2)}$ test of equality across seasons	6.90	28.18	29.17	25.96

Notes: Reproduced from Genesove and Mullin (1998), Table 3, which prints each price coefficient next to the parameter it identifies (the quadratic column reports the choke price α_s itself). Instrument: log of Cuban imports. Newey-West standard errors (four lags) in parentheses. The $\chi^2_{(2)}$ statistic tests equality of the price and intercept coefficients across seasons. WP Table 6 is identical except for three rounding differences: 0.87 for the first standard error, and 4.18 and 3.16 for the log-linear intercepts.

sample means of 4.20 and 5.11. The quadratic form predicts $e^{-1.20}(7.72 - 3.99)^2 = 4.19$ and $e^{-2.48}(11.88 - 4.14)^2 = 5.02$.

3.7.5 The direct measure of conduct

With demand in hand, the supply relation (3.50) gives a pricing rule for every conduct parameter.

Proposition 3.36 (Pricing rules for the demand family)**.** *Let demand be* (3.54) *and marginal cost c be constant. The price that solves* (3.50) *is*

$$P(c;\theta) = \frac{\theta\alpha + \gamma c}{\gamma + \theta}, \qquad P^M(c) \equiv P(c;1) = \frac{\alpha + \gamma c}{1 + \gamma}. \tag{3.59}$$

In the log-linear case ($\alpha = 0$, $\gamma = -\varepsilon$) this is $P(c;\theta) = \frac{\varepsilon}{\varepsilon - \theta}\, c$, and in the exponential limit it is $P(c;\theta) = c + \frac{\theta}{\lambda}$. Pass-through is $\frac{\partial P}{\partial c} = \frac{\gamma}{\gamma + \theta}$.

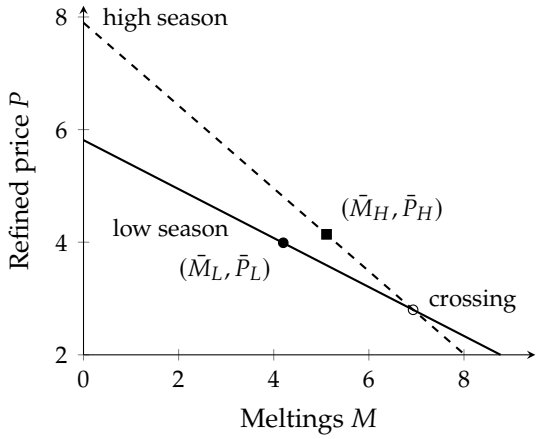
Proof. Since $P'(Q) = \frac{1}{Q'(P)}$, Lemma 3.35(i) gives

$$Q\,P'(Q) = \frac{Q(P)}{Q'(P)} = -\frac{\alpha - P}{\gamma}.$$

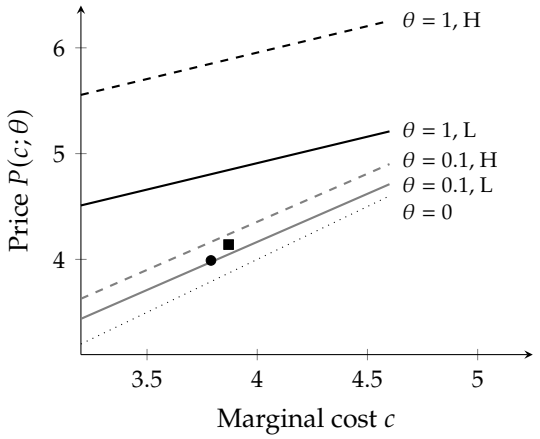
Substituting into (3.50),

$$P - \frac{\theta(\alpha - P)}{\gamma} = c \iff \gamma P + \theta P = \gamma c + \theta\alpha \iff P = \frac{\theta\alpha + \gamma c}{\gamma + \theta}.$$

Setting $\alpha = 0$ and $\gamma = -\varepsilon$ gives $P = \frac{-\varepsilon c}{\theta - \varepsilon} = \frac{\varepsilon}{\varepsilon - \theta} c$. In the exponential limit, $\frac{\alpha - P}{\gamma} \to \frac{1}{\lambda}$ by Lemma 3.35(ii), so the supply relation reads $P - \frac{\theta}{\lambda} = c$. Differentiating (3.59) in c gives the pass-through. □



(a) Demand: $M = 13.37 - 2.30P$ (solid) and $M = 10.74 - 1.36P$ (dashed).



(b) Pricing rules $P(c;\theta) = \frac{\theta\alpha_s + c}{1+\theta}$, low (solid) and high (dashed) season.

Figure 3.12: The canning season rotates demand. Panel (a) shows the estimated linear demand curves, which cross at $P = 2.80$, below all observed prices, and the season means. Panel (b) shows the implied pricing rules with $\alpha_L = 5.82$ and $\alpha_H = 7.91$ (Table 3.10). The monopoly price rises by $\frac{\alpha_H - \alpha_L}{2} = 1.05$ in the high season at given cost, while competitive pricing does not move. The markers are the season means of (c_t, P_t) with $c_t = 0.26 + 1.075\, P_t^{\text{raw}}$. Constructed from Genesove and Mullin (1998), Tables 2–4.

The pass-through formula agrees with Proposition 3.8. With flat marginal cost that proposition gives $\rho = \frac{1}{1+\theta(1-\chi)}$, and $\chi = 1 - \frac{1}{\gamma}$ from Lemma 3.35(iii) yields $\rho = \frac{1}{1+\frac{\theta}{\gamma}} = \frac{\gamma}{\gamma+\theta}$. Two features matter below. The pricing rule is affine in cost with a slope that depends on θ and γ only. Its intercept $\frac{\theta\alpha}{\gamma+\theta}$ moves with the season whenever α does, and by more the larger is θ. Under exponential demand the slope is one for every θ, so pass-through carries no information about conduct (Bulow and Pfleiderer, 1983).

Monopoly requires an elastic demand at the monopoly price. At P^M, $\alpha - P^M = \frac{\gamma(\alpha - c)}{1+\gamma}$, so $\varepsilon(P^M) = \frac{\gamma P^M}{\alpha - P^M} = \frac{\alpha + \gamma c}{\alpha - c}$. For $c > 0$ this exceeds one if and only if $\gamma > -1$ when $\alpha > c$, and $\gamma < -1$ when $\alpha < c$ (WP p. 24). In the log-linear form, the high-season elasticity of 1.10 barely satisfies this condition, and the implied monopoly price is enormous.

Table 3.10 reports the implied pricing rules, the elasticities at the full-sample mean, and the direct conduct measure.

Checking the derived estimates. Every entry follows from Table 3.9 and Proposition 3.36. In the quadratic form, $P^M = \frac{7.72}{3} + \frac{2}{3}c = 2.57 + 0.67c$, and the high-season intercept is $\frac{11.88}{3} = 3.96$. In the linear form the choke prices are $\alpha_L = \frac{13.37}{2.30} = 5.81$ and $\alpha_H = \frac{10.74}{1.36} = 7.90$, so $P^M = \frac{\alpha_s}{2} + \frac{c}{2}$ has intercepts 2.91 and 3.95. The printed 5.82, 7.91 and 3.96 reflect unrounded coefficients. In the exponential form, $\frac{1}{0.53} = 1.89$ and $\frac{1}{0.26} = 3.85$. In the log-linear form, the monopoly markup factor $\frac{\varepsilon}{\varepsilon - 1}$ equals $\frac{2.03}{1.03} = 1.97$ in the low season. In the high season it equals 11.0 at $\varepsilon_H = 1.10$, while the printed 10.1 corresponds to $\varepsilon_H \approx 1.11$. Near $\varepsilon = 1$ this factor is extremely sensitive to rounding. The elasticities at $\bar{P} = 4.03$ follow from Lemma 3.35(i). For example, $\frac{2 \times 4.03}{7.72 - 4.03} = 2.18$ and $\frac{2 \times 4.03}{11.88 - 4.03} = 1.03$ for the quadratic, $0.53 \times 4.03 = 2.14$ (2.13 in the table, from unrounded coefficients) and $0.26 \times 4.03 = 1.05$ for the exponential.

Observed prices are far below monopoly. At the low-season means, marginal cost is $c = 0.26 + 1.075 \times 3.28 = 3.79$. The linear monopoly price is then $2.91 + 0.5 \times 3.79 = 4.80$,

Table 3.10: Demand for refined sugar: derived estimates and the direct measure of conduct

	(1) Quadratic	(2) Linear	(3) Log-linear	(4) Exponential	(5) Lerner

Standard error	0.024	0.028	0.021	0.022	0.0046

Notes: Reproduced from Genesove and Mullin (1998), Table 4, which combines WP Tables 7 and 8. $L_\varepsilon = \varepsilon\,\frac{P-c}{P}$ with $c = 0.26 + 1.075\,P^{\text{raw}}$, computed quarter by quarter. The standard errors account for the estimation of demand (WP Table 8, column 4). Standard errors that ignore it are 0.010, 0.012, 0.008 and 0.009 (WP Table 8, column 3). WP Table 7 prints 7.88θ in the high-season linear rule.

against an observed mean of 3.99. In the high season, $c = 0.26 + 1.075 \times 3.36 = 3.87$ and $P^M = 3.96 + 0.5 \times 3.87 = 5.90$, against 4.14. The quadratic form puts the monopoly prices at 5.10 and 6.54, the exponential form at 5.68 and 7.72, and the log-linear form at 7.47 and about 39. Whatever the demand form, the industry priced far below the monopoly level (WP p. 27). Panel (b) of Figure 3.12 shows the gap.

The direct measure. The first estimation method uses everything. Marginal cost is (3.53), the elasticity comes from the season's demand curve evaluated at the quarter's price, and conduct is computed quarter by quarter:

$$L_{\varepsilon t} = \varepsilon_{s(t)}(P_t)\,\frac{P_t - c_t}{P_t} = \frac{P_t - c_t}{m_t}, \qquad m_t = \frac{\alpha_{s(t)} - P_t}{\gamma_{s(t)}}. \tag{3.60}$$

The second expression uses Lemma 3.35(i): conduct is the price-cost margin divided by the markup term $m_t = \frac{Q_t}{|Q'(P_t)|}$ of Section 3.6.2. The direct measure is a function of data and of the estimated demand parameters. Its standard error must reflect the second source of noise. Genesove and Mullin stack the demand moment conditions with the moment $\frac{1}{n}\sum_t \left(L_{\varepsilon t} - \bar{L}_\varepsilon\right) = 0$ and compute the usual GMM variance for the mean $\bar{L}_\varepsilon$ (WP p. 31, fn. 45). Accounting for estimated demand more than doubles the standard errors.

Results. The mean adjusted Lerner index lies between 0.095 and 0.107 across the four demand forms (Table 3.10). Genesove and Mullin take $\theta = 0.10$ as their direct measure. This is the conduct of a static symmetric Cournot oligopoly with ten firms. Both perfect competition and monopoly are rejected: the mean is about four standard errors above zero and far below one. The unadjusted Lerner index of 0.054 says that price exceeded marginal cost by only 5 percent. With demand elasticities near two, even this small margin corresponds to a conduct parameter of 0.10. With the lower bound $c_0 = 0.16$, the mean index rises to 0.14 (log-linear and exponential), 0.15 (quadratic) and 0.16 (linear). The value 0.15 corresponds to a symmetric Cournot oligopoly with about seven firms, so the conclusions do not change (WP p. 37).

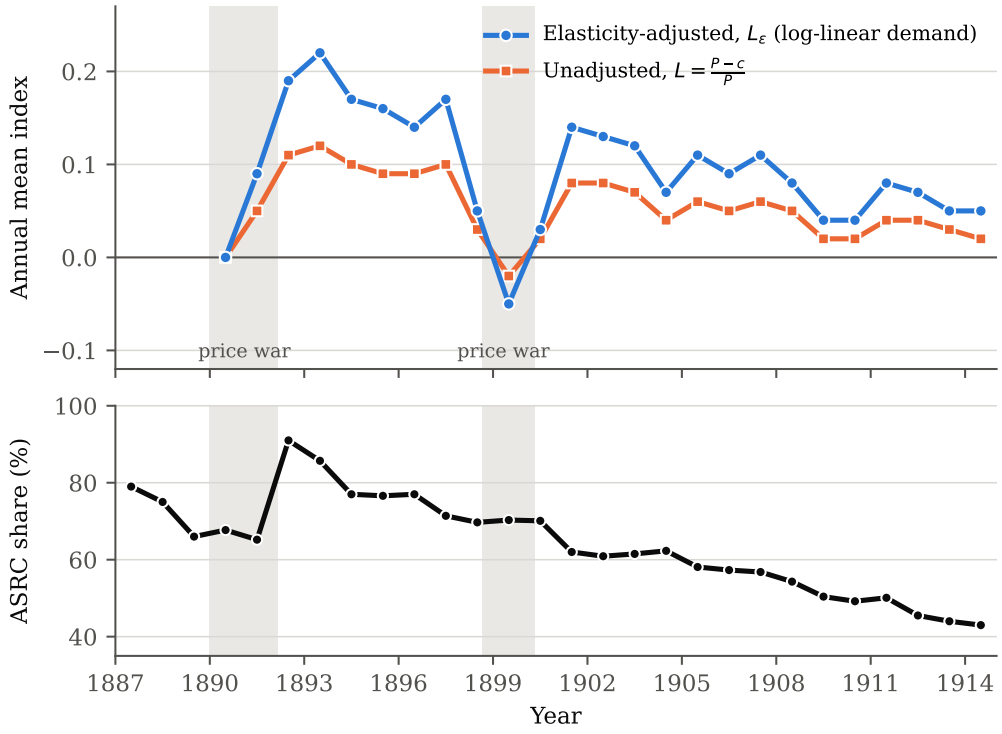

Figure 3.13: Annual means of the unadjusted Lerner index $\frac{P-c}{P}$ and of the elasticity-adjusted index L_ε (log-linear demand), top, and the market share of the American Sugar Refining Company, bottom. Shaded bands mark the two post-entry price wars (January 1890 to February 1892 and September 1898 to April 1900). Redrawn from Genesove and Mullin (1995), WP Table 9.

Conduct over time. Figure 3.13 plots the annual means of WP Table 9. Conduct follows structure. The adjusted index is zero in 1890 during the Spreckels war. It rises to between 0.14 and 0.22 in 1892–1897, after ASRC had consolidated 91 percent of the market. It collapses again in the Arbuckle war, to −0.05 in 1899, which means pricing below the measured marginal cost. Willett and Gray themselves reported in October 1898 that refiners were selling at "an actual loss" (WP p. 33, fn. 47). After 1900 the index drifts down from 0.14 to about 0.05 as ASRC's share falls toward 43 percent. Across the twenty years outside the price wars (excluding 1890, 1891 and 1898–1900), the correlation between the annual adjusted index and ASRC's share is 0.92 (our computation from WP Table 9). The averages over 1890–1914 are 0.09 for the adjusted index, 0.05 for the unadjusted index and 63.1 percent for ASRC's share.

Conduct over the year. Table 3.11 shows that conduct also varies within the year. It is least competitive in the second quarter and most competitive in the third, the high season. This pattern fits dynamic oligopoly models in which the expectation of better demand ahead helps collusion and the expectation of worse demand harms it (Rotemberg and Saloner, 1986; Haltiwanger and Harrington, 1991). Genesove and Mullin note a caveat. The unadjusted index is equal in the second and third quarters, so the pattern may be an artifact of attaching the inelastic high-season demand to the third quarter alone (WP pp. 33–34). Either way, conduct that varies systematically with a demand shifter contradicts the assumption of the NEIO method that θ is uncorrelated with the instruments. Genesove and Mullin argue that the proper test of a method is its success in doing what it is meant to do, whatever the truth of its

Table 3.11: Seasonality of the direct conduct measure

Notes: Reproduced from Genesove and Mullin (1995), WP Table 10. Means and standard deviations across quarters of the same type.

assumptions (WP p. 34). The next subsection shows that this seasonal pattern explains much of what the NEIO estimator finds.

The low level of the index, relative to the industry's concentration, has a natural explanation. Pricing was constrained by the threat of domestic entry and of foreign imports (WP p. 34). The price wars of 1890 and 1898–1900 show that the entry threat was not idle.

3.7.6 Estimating conduct with cost treated as unknown

We now put ourselves in the position of an NEIO researcher who observes prices, quantities, the raw sugar price and the instruments, but does not know c_0, k or both.

The pricing equation. Substituting (3.51) into (3.59) gives the reduced-form pricing equation (WP eq. 12)

$$P_t = \frac{\alpha_s \theta + c_0 \gamma_s}{\gamma_s + \theta} + \frac{\gamma_s}{\gamma_s + \theta} k P_t^{\text{raw}} + u_t, \qquad s = s(t), \tag{3.61}$$

where u_t is a pricing error from unobserved cost or conduct shocks. In the exponential case the equation is $P_t = \frac{\theta}{\lambda_s} + c_0 + k P_t^{\text{raw}} + u_t$ (WP p. 34, fn. 49). Multiplying (3.61) by $\gamma_s + \theta$ gives the moment condition that Genesove and Mullin estimate (WP eq. 13):

$$\mathbb{E}\Big[\big\{ (\gamma_s + \theta) P_t - \alpha_s \theta - c_0 \gamma_s - \gamma_s k P_t^{\text{raw}} \big\} \, z_t \Big] = 0. \tag{3.62}$$

The demand parameters (α_s, γ_s) are fixed at their estimates in Table 3.9. The unknowns are θ and whichever cost parameters the researcher does not know.

The raw price must be instrumented. Whether u_t is a cost shock or a conduct shock, a positive u_t raises the refined price and lowers the quantity of refined sugar demanded. Refiners then demand less raw sugar, which lowers the raw price. The pricing error is therefore negatively correlated with P_t^{raw} (WP p. 34). Log Cuban imports again serve as the excluded cost shifter.

The information hierarchy. Genesove and Mullin organize the comparison by what the researcher knows about cost (WP p. 35).

(I) Neither c_0 nor k is known. The unknowns are (θ, c_0, k), and the instruments are $z_t = (1, H_t, \ln CUBA_t)$.

(II) The input coefficient $k = 1.075$ is known, and c_0 is not. The unknowns are (θ, c_0), and the instruments are $z_t = (1, H_t)$. This is the position of the cigarette studies of Sumner

(1981), Sullivan (1985) and Ashenfelter and Sullivan (1987) (Section 3.2). In those studies an excise tax enters marginal cost with a known coefficient of one.

(III) Both $c_0 = 0.26$ and $k = 1.075$ are known. Then θ is observed directly, as in (3.60).

The fourth combination, c_0 known and k unknown, is implausible in this industry and is not explored. In both (I) and (II) the number of instruments equals the number of unknowns, so the nonlinear instrumental variables (NLIV) estimator solves the sample analogue of (3.62) exactly. Estimating demand first and the pricing equation second is the two-step method. Stacking the demand moments and (3.62) in a single GMM problem is the joint version of the same estimator.

Standard errors with estimated demand. The two-step estimator inherits the noise in the demand estimates. Let $b = (\theta, c_0, k)^\top$, let a be the demand parameters with $\sqrt{n}(\hat{a} - a_0) \to N(0, W_1)$, and let $\bar{g}_n(b, a)$ be the sample analogue of (3.62). A mean-value expansion of $\bar{g}_n(\hat{b}, \hat{a}) = 0$ around (b_0, a_0) gives

$$0 = \bar{g}_n(b_0, a_0) + D\,(\hat{b} - b_0) + C\,(\hat{a} - a_0) + o_p\!\left(n^{-\frac{1}{2}}\right), \qquad D = \mathbb{E}\left[\frac{\partial g}{\partial b^\top}\right], \quad C = \mathbb{E}\left[\frac{\partial g}{\partial a^\top}\right].$$

Solving for $\hat{b} - b_0$,

$$\sqrt{n}\,(\hat{b} - b_0) = -D^{-1}\sqrt{n}\,\bar{g}_n(b_0, a_0) - D^{-1}C\,\sqrt{n}\,(\hat{a} - a_0) + o_p(1).$$

If the pricing moments and the demand estimates are asymptotically uncorrelated, the asymptotic variance is

$$\operatorname{Avar}(\hat{b}) = W_2 + D^{-1}C\,W_1\,C^\top\left(D^{-1}\right)^\top, \qquad W_2 = D^{-1}S\left(D^{-1}\right)^\top, \tag{3.63}$$

where S is the long-run variance of the pricing moments. Genesove and Mullin estimate S and W_1 by Newey-West with four lags (WP p. 36). The zero-correlation assumption fits their interpretation: demand errors are proportional shifts that do not move the pricing rule. Without it, the joint GMM estimator delivers correct standard errors directly (Appendix A).

Table 3.12: NLIV estimates of conduct and cost parameters

Notes: Reproduced from Genesove and Mullin (1995), WP Table 11. Columns (1), (3), (5) and (7) estimate (θ, c_0, k) with instruments $(1, H_t, \ln CUBA_t)$. Columns (2), (4), (6) and (8) impose $k = 1.075$ and use $(1, H_t)$. Demand parameters from Table 3.9. Newey-West standard errors (four lags), corrected for estimated demand, in parentheses. Column (9) is the direct measure. $N = 97$.

Results. Table 3.12 reports the estimates. Genesove and Mullin draw four conclusions (WP pp. 36–37). First, the NLIV estimate of θ is close to the direct measure. It lies between 0.035

and 0.045 in all eight specifications. Monopoly is rejected everywhere, as is any θ above 0.11. Perfect competition cannot be rejected: the t ratios are between 1.46 and 1.61. The estimates are below the direct measure in every case. The upper limits of the 95 percent confidence intervals run from 0.082 to 0.100 (our computation), so the direct value of 0.10 sits at or just beyond their edge. Second, the estimates are robust to the form of demand. This answers the common complaint that conduct estimates hinge on functional form. Third, the cost parameters are recovered less well. The coefficient k is underestimated in all four forms, although $k = 1.075$ is never rejected. The parameter c_0 is overestimated, by 50 cents in the log-linear case (0.760 against 0.26). Fourth, knowing k hardly changes $\hat{\theta}$. It sharpens the estimate of c_0, which falls to 0.38–0.39 with standard errors near 0.06. Because c_0 does not enter the NLIV estimator, setting $c_0 = 0.16$ leaves Table 3.12 unchanged and moves only the benchmark, from 0.10 to about 0.15.

What identifies θ: the seasonal shift. Why does the method deliver 0.04? In the quadratic, linear and exponential forms only the intercept of (3.61) differs across seasons. The equation can then be written as a linear regression,

$$P_t = \pi_0 + \pi_1 H_t + \pi_2 P_t^{\text{raw}} + u_t. \tag{3.64}$$

For the linear and quadratic forms, with γ common to both seasons,

$$\pi_0 = \frac{\theta\alpha_L + \gamma c_0}{\gamma + \theta}, \qquad \pi_1 = \frac{\theta\,(\alpha_H - \alpha_L)}{\gamma + \theta}, \qquad \pi_2 = \frac{\gamma k}{\gamma + \theta}.$$

For the exponential form, $\pi_0 = \frac{\theta}{\lambda_L} + c_0$, $\pi_1 = \theta\left(\frac{1}{\lambda_H} - \frac{1}{\lambda_L}\right)$ and $\pi_2 = k$. In each case the map from (θ, c_0, k) to (π_0, π_1, π_2) is one to one. For the linear and quadratic forms, inverting it gives

$$\theta = \frac{\gamma\,\pi_1}{(\alpha_H - \alpha_L) - \pi_1}, \qquad k = \frac{\gamma + \theta}{\gamma}\,\pi_2, \qquad c_0 = \frac{(\gamma + \theta)\pi_0 - \theta\alpha_L}{\gamma}. \tag{3.65}$$

The conduct parameter is identified only through π_1, the seasonal shift of the pricing rule at a given raw price. If the season changed only the scale β, so that $\alpha_H = \alpha_L$, then $\pi_1 = 0$ for every θ and conduct would not be identified. A seasonal change in α suffices, even a parallel shift of linear demand. Identification therefore rests on the restriction that marginal cost is constant in output (Section 3.5.4). The general rotation argument of Proposition 3.28 and Theorem 3.30 is needed only when the slope of marginal cost is unknown. At $\theta = 1$, π_1 equals the seasonal shift of the monopoly price, $\frac{\alpha_H - \alpha_L}{1+\gamma}$. The estimator thus compares the observed seasonal price shift with the shift that a monopolist would make.

Column (3) of Table 3.13 estimates (3.64) by instrumental variables. The refined price rises by only 8 cents in the high season at a given raw price. The demand estimates imply much larger shifts of the monopoly price: $\frac{\alpha_H - \alpha_L}{2} = 1.05$ for linear demand and $\frac{1}{\lambda_H} - \frac{1}{\lambda_L} = 3.85 - 1.89 = 1.96$ for exponential demand. Under exponential demand the intercept is $\frac{\theta}{\lambda_s} + c_0$, so

$$\hat{\theta} \approx \frac{0.08}{1.96} \approx 0.04$$

(WP p. 38). Under linear demand, (3.65) with $\gamma = 1$ and $\alpha_H - \alpha_L = 7.91 - 5.82 = 2.09$ gives

$$\theta = \frac{0.08}{2.09 - 0.08} = 0.040, \quad k = 1.040 \times 1.01 = 1.050, \quad c_0 = 1.040 \times 0.66 - 0.040 \times 5.82 = 0.455.$$

These reproduce column (3) of Table 3.12, (0.038, 0.465, 1.052), up to rounding. The quadratic form gives (0.039, 0.52, 1.03) against (0.037, 0.529, 1.033). The same arithmetic explains the cost

Table 3.13: Linear pricing equations for refined sugar

$\chi^2_{(2)}$ test		21.67			6.66	

Notes: Reproduced from Genesove and Mullin (1995), WP Table 12. Dependent variable: refined price, $N = 97$. Instruments in columns (1) and (2): high season, log Cuban imports and their interaction. The $\chi^2_{(2)}$ statistic tests that the coefficients on high season and its interaction with the raw price are both zero.

estimates. The raw-price coefficient of 1.01 forces k below 1.075, because the slope $\frac{\gamma k}{\gamma+\theta}$ is close to k when θ is small. With θ understated, c_0 must absorb the remaining margin between the refined and raw prices, so c_0 is overstated (WP p. 38).

A closed form when k is known. When k is known, the estimator has an explicit form that links it to the direct measure. Divide the expression in braces in (3.62) by γ_s and use Lemma 3.35(i):

$$\frac{(\gamma_s+\theta)P_t - \alpha_s\theta - c_0\gamma_s - \gamma_s k P_t^{\text{raw}}}{\gamma_s} = \left(P_t - kP_t^{\text{raw}}\right) - c_0 - \theta\,\frac{\alpha_s - P_t}{\gamma_s} = G_t - c_0 - \theta\, m_t.$$

The pricing equation thus says that the proper margin equals non-sugar cost plus conduct times the markup term. This holds in all four forms, and in the exponential form $m_t = \frac{1}{\lambda_s}$.

Proposition 3.37 (The NLIV estimator with known k)**.** *Suppose k is known, the instruments are $(1, H_t)$, and demand is quadratic, linear or exponential. Let $\bar{G}_s$ and $\bar{m}_s$ be the season means of the proper margin and of the markup term. Then*

$$\hat{\theta} = \frac{\bar{G}_H - \bar{G}_L}{\bar{m}_H - \bar{m}_L}, \qquad \hat{c}_0 = \bar{G}_L - \hat{\theta}\,\bar{m}_L. \tag{3.66}$$

If the true marginal cost is (3.51) and θ_t denotes true conduct, then

$$\hat{\theta} = \frac{\overline{(\theta m)}_H - \overline{(\theta m)}_L}{\bar{m}_H - \bar{m}_L}, \tag{3.67}$$

where $\overline{(\theta m)}_s$ is the season mean of $\theta_t m_t$.

Proof. In the quadratic and linear forms γ is common to both seasons, so multiplying each moment by the constant $\frac{1}{\gamma}$ does not change the solution. In the exponential form the moment is $G_t - c_0 - \theta m_t$ to begin with. The sample moments with instruments 1 and H_t are $\sum_t (G_t - c_0 - \theta m_t) = 0$ and $\sum_t H_t(G_t - c_0 - \theta m_t) = 0$. Their difference is the sum over low-season quarters, so the two conditions are equivalent to $\bar{G}_s = c_0 + \theta\,\bar{m}_s$ for $s = L, H$. Subtracting the low-season equation from the high-season equation gives $\hat{\theta}$, and the low-season equation then gives $\hat{c}_0$. For the second part, the definition of true conduct in (3.60) gives $P_t - c_t = \theta_t m_t$, so $G_t = c_0 + \theta_t m_t$ by (3.52). Taking season means and substituting into (3.66) gives (3.67). □

The estimator is a Wald ratio. It divides the seasonal change in the proper margin by the seasonal change in the markup term predicted by demand. With the published season means, $\bar{G}_H - \bar{G}_L = 0.53 - 0.46 = 0.07$ (Table 3.8). In the linear form, $\bar{m}_s = \alpha_s - \bar{P}_s$, so $\bar{m}_H - \bar{m}_L = 2.09 - 0.15 = 1.94$. In the exponential form, $\bar{m}_H - \bar{m}_L = 1.96$. Hence

$$\text{linear:} \quad \hat{\theta} = \frac{0.07}{1.94} = 0.036, \qquad \hat{c}_0 = 0.46 - 0.036 \times 1.83 = 0.39,$$
$$\text{exponential:} \quad \hat{\theta} = \frac{0.07}{1.96} = 0.036, \qquad \hat{c}_0 = 0.46 - 0.036 \times 1.89 = 0.39.$$

Columns (4) and (8) of Table 3.12 report $(0.037, 0.39)$ and $(0.037, 0.389)$. The rounding of the season means to two decimals limits the precision of this check to about ± 0.005 in $\hat{\theta}$. The formula also explains the robustness across forms. Each form predicts nearly the same seasonal change in the markup term at observed prices, between 1.8 dollars (log-linear, $\frac{4.14}{1.10} - \frac{3.99}{2.03}$ at the season means) and 2.0 dollars (quadratic). The four forms differ greatly far from the data, as their monopoly prices show, but they agree near it.

The Corts critique in the sugar data. Equation (3.67) is the IV estimand of Proposition 3.31 with the season indicator as the instrument. It equals average conduct only if conduct does not differ between seasons. In the exponential form the markup term is constant within a season, $m_t = \frac{1}{\lambda_s}$. Writing $\bar{\theta}_s$ for the season mean of the direct measure, (3.67) becomes

$$\hat{\theta} = \frac{\frac{\bar{\theta}_H}{\lambda_H} - \frac{\bar{\theta}_L}{\lambda_L}}{\frac{1}{\lambda_H} - \frac{1}{\lambda_L}} = \frac{3.85\,\bar{\theta}_H - 1.89\,\bar{\theta}_L}{1.96} = \bar{\theta}_H - 0.96\left(\bar{\theta}_L - \bar{\theta}_H\right).$$

Table 3.11 gives $\bar{\theta}_H = 0.071$ for the exponential form. The low-season quarters average about 0.105, weighting quarters I, II and IV by their numbers of observations. Then $\hat{\theta} = 0.071 - 0.96 \times 0.034 = 0.038$, essentially the reported 0.037. Implied non-sugar cost is $0.26 + (0.105 - 0.038) \times 1.89 = 0.39$, the reported 0.389. The NLIV estimate lies below even the high-season conduct, because conduct is lower exactly when the rotator is on. If conduct had stayed at its mean of about 0.10 throughout, the proper margin would have risen by $0.10 \times 1.96 = 0.20$ in the high season. It rose by 0.07. The understatement of θ and the overstatement of c_0 both reflect the mechanism of Corts (1999). The estimator measures the response of the margin to the rotation, and here that response understates the level of conduct.[5]

The log-linear form. Under log-linear demand the slope of the pricing rule, $\frac{\varepsilon_s}{\varepsilon_s - \theta} k$, differs by season, so the linear reparameterization needs an interaction, column (2) of Table 3.13. The lower high-season elasticity predicts a steeper pricing rule in the high season, and the interaction is positive and significant (0.31). The intercept $\frac{\varepsilon_s c_0}{\varepsilon_s - \theta}$ should also be higher in the high season, yet the high-season coefficient is -0.97. Using the slopes alone gives $\theta = 0.46$. With $r = \frac{0.93+0.31}{0.93}$ the ratio of the slopes, the condition $\frac{\varepsilon_H(\varepsilon_L - \theta)}{\varepsilon_L(\varepsilon_H - \theta)} = r$ solves for $\theta = 0.463$. Using the intercepts alone gives the nonsensical 2.09 (WP p. 39). The NLIV estimator forces the ratio of intercept to slope to be the same in both seasons, $\frac{c_0}{k}$, and so returns estimates close to the other forms. Its implied pricing rules are $P = 0.777 + 0.978\,P^{\text{raw}}$ in the low season and $P = 0.792 + 0.997\,P^{\text{raw}}$ in the high season (our computation from column (5)).[6] None of the

[5] This decomposition is ours. Genesove and Mullin report the seasonal pattern and the NLIV estimates separately, and attribute the pattern to dynamic oligopoly (WP pp. 33–34).

[6] WP p. 39, fn. 52, prints $0.793 + 0.997\,P^{\text{raw}}$ for the low season and $0.777 + 0.977\,P^{\text{raw}}$ for the high season. The factor $\frac{\varepsilon_s}{\varepsilon_s - \theta}$ is larger for the smaller high-season elasticity, so the steeper rule must belong to the high season. The labels in the footnote appear to be interchanged.

four forms is consistent with the unrestricted estimates of column (2) (WP p. 39). Equal slopes, which the other three forms require, are rejected by the $\chi^2_{(2)}$ statistic of 21.67. The low-season slope of 0.93, which Genesove and Mullin describe as significantly below 1.075, contradicts log-linear demand, under which price rises more than one for one with cost.

Ignoring the seasons. Column (1) of Table 3.13 drops all seasonal effects, as a researcher would who used the known k but ignored the rotation. The only remaining information on conduct is the slope of the pricing rule, $\frac{\gamma k}{\gamma+\theta} = 1.02$. Solving,

$$\theta = \gamma\left(\frac{1.075}{1.02} - 1\right) = 0.054\,\gamma.$$

The implied conduct is proportional to the assumed curvature. It equals 0.054 for linear demand and 0.108 for quadratic demand (WP p. 39). Quadratic demand without seasons, $\ln M = 7.37 + 2\ln(8.63 - P)$, with standard errors 0.50 and 1.17, also gives an excellent estimate of non-sugar cost, $\hat{c}_0 = 0.23$. The researcher would have no way to know which answer is right. This is the curvature critique of pass-through tests in Section 3.2 in another guise: the slope identifies conduct only given γ. With exponential demand the slope is k for every θ, and θ and c_0 are not even separately identified (Bulow and Pfleiderer, 1983).

Notes: Reproduced from Genesove and Mullin (1998), Table 9. Linear demand estimated by season. Cost parameters constrained to be nonnegative. Columns (1), (3), (5) and (7) estimate k with a constant and log Cuban imports as instruments. Columns (2), (4), (6) and (8), where $\hat{k}$ is blank, impose $k = 1.075$ and use a constant only (p. 371, n. 30). In columns (1) to (8), $\widehat{\Delta P}$ is the predicted rise in the refined price. The shock is the rise in the raw price by 68 cents per hundred pounds from the third quarter of 1896 to the third quarter of 1897. Column (9) reports the realized rise (p. 374).

Imposing a behavioral model. The published article adds an exercise that shows what goes wrong when conduct is assumed (Table 9, reproduced in Table 3.14). The researcher fixes θ at the value implied by a behavioral model, estimates the cost parameters from the linear pricing equation, and predicts the effect of a cost shock. Competition sets $\theta = 0$ and monopoly sets $\theta = 1$. *Cournot I* assumes identical constant marginal costs and no capacity constraints, so $\theta_t = \frac{1}{N_t}$ when N_t firms are active in quarter t (Genesove and Mullin, 1998, p. 372). *Cournot II* gives all firms the same marginal cost up to capacities that differ. ASRC could serve the whole market, so the equilibrium is that of a dominant firm facing a fringe that produces at capacity. ASRC then prices as a monopolist on market demand less total fringe capacity (Genesove and Mullin, 1998, p. 373).

The shock is the Cuban war of independence. Cuban imports fell to zero in the third quarter of 1897, a quarter excluded from estimation. The raw price rose by 68 cents per hundred pounds

from the third quarter of 1896. With linear demand, constant conduct and both quarters in the same season, the pricing rule (3.59) with $\gamma = 1$ gives the predicted change (Genesove and Mullin, 1998, p. 374)

$$\widehat{\Delta P} = \frac{\hat{k} \times 0.68}{1 + \theta}.$$

Under competition this gives $1.015 \times 0.68 = 0.69$ with k estimated and $1.075 \times 0.68 = 0.73$ with k imposed. Under monopoly it gives $\frac{0.529 \times 0.68}{2} = 0.18$ and $\frac{1.075 \times 0.68}{2} = 0.365$. The refined price rose by 70.2 cents over the same period, a pass-through of 1.03. For Cournot I, the prediction with k imposed implies $1 + \theta = \frac{0.731}{0.608} \approx 1.20$. This is $\theta \approx 0.20$, the value of $\frac{1}{N_t}$ with five firms (our computation).

Cournot II predicts the same rise as monopoly when k is imposed (0.365). Linear demand explains why. Let $\bar{K}$ be total fringe capacity, so that ASRC sells $q^d = \beta_s(\alpha_s - P) - \bar{K}$. Its marginal revenue is $P - \frac{q^d}{\beta_s}$. Setting marginal revenue equal to c gives the first equation below. Substituting q^d and solving for P gives the second:

$$P - c = \frac{q^d}{\beta_s}, \qquad P = \frac{1}{2}\left(\alpha_s - \frac{\bar{K}}{\beta_s} + c\right).$$

With $\bar{K}$ fixed, the fringe leaves pass-through at $\frac{1}{2}$, as under monopoly. It lowers the price level, however, so with k estimated Cournot II gives $\hat{k} = 0.883$ against 0.529 under monopoly. With linear demand the supply relation (3.50) reads $P - c = \frac{\theta Q}{\beta_s}$. Cournot II is therefore the supply relation with $\theta_t = \frac{q_t^d}{Q_t}$, ASRC's share of output (our computation). Because $\bar{K}$ is fixed, this share falls as the price rises. The constant-conduct formula above therefore does not apply to Cournot II. Genesove and Mullin trace the large shortfalls of Cournot II and monopoly to their low estimates of k and to the less competitive conduct they assume (Genesove and Mullin, 1998, pp. 374–375).

Monopoly fails because the monopoly price level is far above the data. The linear monopoly rule is $P = \frac{\alpha_s}{2} + \frac{c}{2}$. At the low-season mean price of 3.99, the term $\frac{\alpha_L}{2} = 2.91$ leaves only 1.08 for $\frac{c}{2}$, so mean marginal cost would be 2.16, far below the raw-sugar cost of $1.075 \times 3.28 = 3.53$. In the high season, $\frac{\alpha_H}{2} = 3.96$ leaves only 0.18 (our computation). To fit the price level with nonnegative c_0, the estimator pushes c_0 to zero and k to 0.529, far below the physical minimum of about 1.04. It then predicts that refined prices rise by only 18 cents after a 68-cent rise in the raw price. Competition and Cournot I predict 0.61 to 0.73, close to the realized rise of 0.702. The shortfall of Cournot I is not statistically significant (Genesove and Mullin, 1998, p. 374). Wrong conduct assumptions thus produce wrong costs and wrong counterfactuals at the same time.

3.7.7 Conduct and structure: price wars

A second test asks whether the method detects changes in conduct across structural regimes. Genesove and Mullin compare the two post-entry price wars of Table 3.7, Panel B, with all other periods. Let $WAR_t = 1$ in the price-war quarters and let conduct be

$$\theta_t = \theta_0 + (\theta_1 - \theta_0)\, WAR_t. \tag{3.68}$$

The NLIV moment (3.62) is otherwise unchanged. The instruments add WAR_t: they are $(1, \ln CUBA_t, H_t, WAR_t)$ when k is unknown and $(1, H_t, WAR_t)$ when k is known (WP p. 41, fn. 54). The benchmark is the direct measure for the same regimes, from the log-linear form.

Table 3.15: Conduct in price-war regimes

Notes: Panel A reproduced from Genesove and Mullin (1998), Table 10. It matches columns (3) and (4) of WP Table 14, except for $\hat{c}_0 = 0.374$ in column (3) and the direct measures, which are 0.11 and −0.09 in the working paper. Panel B reproduced from Genesove and Mullin (1995), WP Table 15. Columns (1), (3), (5) and (7) of Panel B and column (1) of Panel A estimate k. Columns (2), (4), (6) and (8) of Panel B and column (2) of Panel A impose $k = 1.075$. Standard errors in parentheses. Price-war regimes: January 1890 to February 1892 and September 1898 to April 1900.

Constant costs. Panel A of Table 3.15 shows the linear case. Normal-period conduct is $\hat{\theta}_0 = 0.046$, and conduct falls by 0.11 in the price wars, so $\hat{\theta}_1 = 0.046 - 0.112 = -0.066$. The direct measures are 0.129 and −0.127, which put conduct in the wars at $0.129 - 0.127 = 0.002$, essentially competitive. The estimated fall has about the right size. The level in normal times is again understated. WP Table 14 gives the same picture for all four forms: $\hat{\theta}_0$ between 0.043 and 0.047, and falls between 0.065 and 0.112. Perfect competition in normal periods ($\theta_0 = 0$) is now rejected at or near the 5 percent level in all eight specifications (WP p. 42). Genesove and Mullin also describe the fall in conduct as "statistically significant at conventional levels of significance" in all four demand forms (WP p. 42). Our computation from WP Table 14 qualifies that claim. The falls have t ratios between 2.1 and 2.8 when k is imposed, so they are significant at 5 percent. When k is estimated the t ratios run from 1.6 to 1.8, which is significant at 10 percent only.

Costs allowed to change. Genesove and Mullin call this a weak test (WP p. 42). Price wars are defined by collapsing margins, and θ is the only parameter allowed to differ across regimes, so the method is bound to find a fall in θ. A stronger test lets non-sugar cost change as well, $c_t = c_0 + (c_1 - c_0)WAR_t + kP_t^{\text{raw}}$. It asks whether a researcher who sees refined prices fall can tell a cost change from a conduct change. Panel B gives the answer. The estimated fall in conduct shrinks to between 0.015 and 0.024, and the method attributes the price wars to a fall in non-sugar cost of 10 to 18 cents. The direct evidence says that costs did not change.

Neither regime difference is statistically significant in any column, so the data cannot separate the two explanations. In the price wars the markup term varies only through the handful of high-season war quarters, which leaves little variation to tell a shift in c_0 from a shift in θm_t.[7] The lesson is that a priori information about cost, here the knowledge that costs were stable across regimes, does the work of distinguishing conduct from cost (WP p. 42).

Conduct as a function of market share. A final specification makes conduct linear in ASRC's market share S_t, measured in percent: $\theta_t = a_\theta + b_\theta S_t$ (WP Table 16, p. 44). Genesove and Mullin view it as a summary of the data. The NLIV slopes are 0.005 to 0.006 when k is estimated and 0.003 when k is known, with standard errors of 0.001 to 0.002. The intercepts $\hat{a}_\theta$ run from -0.278 to -0.316 when k is estimated and from -0.156 to -0.179 when it is known. Regressing the direct measure on the share gives -0.068 (0.041) plus 0.0026 (0.0006) per percentage point. With a compromise slope of 0.004, the fall in ASRC's share from 90 to 60 percent predicts a fall in conduct of 0.12, against 0.078 from the direct slope (WP p. 43). The cost estimates are now much worse. With k unknown, $\hat{c}_0$ ranges from 1.13 to 1.37 and $\hat{k}$ from 0.77 to 0.85.

3.7.8 Assessment

Genesove and Mullin conclude that their results "should be reassuring to NEIO adherents" (WP p. 45). The NLIV estimates of conduct are close to the direct measure, robust to the form of demand, and correctly ordered across structural regimes. Whether we should declare success depends on which question we ask.

The level of market power. The method places the industry correctly between perfect competition and Cournot behavior, and it rejects monopoly decisively. It understates the level, 0.04 against 0.10, and it cannot reject perfect competition. A researcher testing $\theta = 0$ with these data would not reject competitive pricing, even under nearly ideal conditions. Proposition 3.37 shows that the understatement is no accident. Conduct was lowest in the canning season, which is the very variation that identifies θ. The estimate therefore measures the response of the margin to the rotation, as Corts (1999) warned. In sugar the bias was large in relative terms and small in absolute terms. In industries where conduct varies more with demand, as in the dynamic collusion models of Section 3.6.2, the bias can be larger and of either sign.

Costs and counterfactuals. The cost parameters are recovered poorly. The coefficient k is understated and c_0 is overstated by 12 to 50 cents, which is about 47 to 190 percent of its true value. Errors in cost matter whenever the estimates feed a counterfactual. Table 3.14 shows how an incorrect conduct assumption distorts both cost and predicted pass-through. The regime comparison captures the fall in conduct during price wars only when the researcher imposes stable costs. Given the freedom, the method attributes the wars to falling costs. A priori cost information is decisive, and most applications lack it.

The conditions of the test. The sugar industry offered nearly ideal conditions. It had a fixed-coefficient technology, an observed input price that moved a great deal, a credible supply instrument, a clear demand rotator and a homogeneous product. Genesove and Mullin note that a failure here would have been a reason for serious doubt (WP p. 45). A success here is weaker evidence for applications where cost is a black box, demand is estimated less precisely, or no rotator exists. Some features of the study also limit its scope. Meltings proxy for consumption, and the competitive fringes of beet sugar and imports are not modeled. Demand in the high season rests on 24 observations. The seasonal pattern of conduct contradicts the

[7] This reading of the imprecision is ours. The instrument list for WP Table 15 is not stated in the working paper.

static model that underlies both measures. The direct measure itself relies on the estimated demand elasticity. An error in demand would move the benchmark and the NLIV estimate together.

Economic lessons. The study also answers a substantive question. Average conduct in turn-of-the-century sugar refining was only mildly collusive, far below what the industry's concentration would suggest (WP p. 45). Conduct rose with ASRC's share and collapsed when entrants triggered price wars. This points to the threat of entry and of imports as the main constraints on a dominant firm with persistent excess capacity. It also supports the view of Section 3.1.3 that structure alone does not determine conduct. The later history of the same industry is the subject of Genesove and Mullin (2001). They use the records of the Sugar Institute, the trade association of the cane refiners from 1927 to 1936, to study how communication supports collusion (Chapter 13).

Contribution. Genesove and Mullin provided the first direct test of the conduct-parameter method against an independent measure of conduct. They showed that the method can recover the order of magnitude of market power and its movements across regimes. They also documented its characteristic failures: understated levels, poorly identified costs, and an inability to separate conduct from cost without prior information. Similar validation exercises exist for other industries with observable costs. They include British electricity (Wolfram, 1999, Section 3.8) and the whiskey industry of 1882–1898. That period spans the distillers' pools and the Whiskey Trust, which formed in 1887 (Clay and Troesken, 2003, p. 153). Clay and Troesken (2003, p. 162) identify conduct in whiskey from changes in the tax on spirits. The method somewhat overstates conduct there, with estimates of 0.17 to 0.35 against a direct measure of 0.09 (Clay and Troesken, 2003, p. 165). The combined message of these studies, developed in Section 3.9, is that conduct estimates are informative when the identifying variation is understood, and misleading when it is not.

3.8 The British electricity spot market: Wolfram (1999)

The sugar study of Section 3.7 validated the conduct-parameter method with historical cost data. Wolfram (1999) performs a second validation in a modern market where marginal cost is close to observable. Electricity generation suits the exercise. Short-run marginal cost is almost entirely the cost of fuel, and fuel cost depends only on the fuel price and on how efficiently a plant converts fuel into electricity. After the British industry was privatized in 1990, two firms owned most fossil-fuel generation in England and Wales, and demand was extremely inelastic. Standard oligopoly models therefore predicted very high markups. Wolfram measures markups directly, compares them with these predictions, and checks them against two methods that ignore cost data. The section ends with the studies of restructured US and Spanish markets that built on her design (Section 3.8.8).

3.8.1 The question and the institutions

The question. How much market power did the two dominant generators exercise in the British electricity spot market, and do standard oligopoly models predict their prices? A second question is methodological. Do approaches that treat marginal cost as unobserved recover the markups that cost data reveal? The answers matter beyond Britain. The British reform was one of the first attempts to build a fully competitive market for electricity generation, and

the United States and other countries were preparing similar reforms (Wolfram, 1999, p. 805). Cournot and supply function models were the standard tools for predicting market power in such markets (Green and Newbery, 1992; Borenstein and Bushnell, 1999).

Why electricity. Several features make electricity markets prone to market power and well suited to measuring it (Kellogg and Reguant, 2021, pp. 687–688). Electricity is a homogeneous good, but plants with very different technologies and costs produce it at the same time. It has been extremely difficult to store economically, and demand is quite inelastic in the short and medium run. Together these features create large price fluctuations and moments of scarcity in which market power can be substantial. Supply must match demand second by second over a shared grid, so a central authority coordinates dispatch. The data are unusually granular, and plausible shifters of both supply and demand are observed.

Britain's reform was followed by restructuring in many countries. In the United States the process was partial and slow. It began in California, New England and the Pennsylvania-New Jersey-Maryland market (PJM). Restructuring elsewhere was put on hold after the California crisis of 2000 and 2001, and large areas still regulate generation on a cost-of-service basis (Kellogg and Reguant, 2021, p. 688). Cicala (2022) measures what the move to markets achieved. He exploits the staggered entry of US power control areas into market-based dispatch between 1999 and 2012. A *power control area* is a region of the grid in which a single operator balances supply and demand. His data cover hourly demand, the hourly output of most plants and engineering estimates of their costs. For each hour he compares actual generation cost with the least cost of producing the same quantity, which is the merit-order calculation of Section 3.8.2. A difference-in-differences comparison finds that joining a market raised the gains from trade between areas by 55 percent. It cut departures from the least-cost merit order within an area by 16 percent (Kellogg and Reguant, 2021, p. 689).

Industry structure. Before April 1990 a single state body, the Central Electricity Generating Board (CEGB), owned and operated the generating plants and the transmission grid. It sold to twelve government-owned Area Boards, which distributed electricity in England and Wales. At privatization the Area Boards became twelve Regional Electricity Companies (RECs), distributors with local franchises and price-capped distribution charges. Transmission went to the National Grid Company. The CEGB's plants were split three ways. Nuclear Electric received the twelve nuclear stations, with about 9 gigawatts (GW) of capacity, and stayed in the public sector for six years. National Power received 52 percent of the CEGB's capacity (roughly 30 GW) and PowerGen 33 percent (roughly 20 GW). Interconnectors with Scotland and France and two pumped-storage stations supplied several more gigawatts. Between March 1990 and the end of 1994 about 7 GW of new capacity entered, more than half of it owned by firms other than National Power and PowerGen (Wolfram, 1999, pp. 806–807).

The Pool. All wholesale trade passed through a central market, the *Pool*, which worked financially as a day-ahead spot market. Each day is divided into 48 half-hour periods, with one price per period. Every day each generator submits a bid schedule stating the prices at which it will supply power from each of its generating units on the following day. The Pool administrator ranks the bids and, using its demand forecast, finds for each half-hour the bid of the most expensive unit needed to meet demand. That bid is the *system marginal price* (SMP). The *pool price* adds a capacity payment to the SMP, and a charge called uplift is added after demand is realized to cover forecast errors and ancillary services (Wolfram, 1999, p. 807 and n. 7).

Contracts. Most trade was hedged by financial contracts between generators and their

customers. A *two-way contract*, or *contract for differences*, fixes a strike price for a contracted volume. The generator pays the customer the excess of the pool price over the strike price and receives the shortfall when the pool price is lower. A *one-way contract* protects only the customer, who never pays more than the strike price. At privatization the government set up initial contracts between the RECs and the generators that ran from one to three years. In the first year they covered 85 to 90 percent of the capacity of National Power and PowerGen. By fiscal year 1993 cover had fallen to just above 70 percent. All initial contracts expired at the end of March 1993, and their replacements covered only about half of the generators' capacity (Wolfram, 1999, p. 808). Little information on the terms of the contracts is public (n. 8).

Regulatory oversight. Pool prices were not regulated directly. The industry regulator, who headed the Office of Electricity Regulation (OFFER), held a blunt instrument. He could refer the generators to the Monopolies and Mergers Commission (MMC), which could break up National Power and PowerGen. By the end of 1994 OFFER had issued four statements on pool prices. The first three recommended minor institutional changes but expressed concern about price levels and market power. In the fourth, in February 1994, the regulator offered a deal. He would not refer the generators if they sold 10 to 15 percent of their plant to potential competitors and accepted a price cap from April 1, 1994 (Wolfram, 1999, p. 808). The cap applied to the time-weighted average pool price over the fiscal year, with a higher cap on the demand-weighted average (Wolfram, 1999, p. 818).

Why theory predicts high markups. Short-run electricity demand is very inelastic. Static oligopoly theory then predicts markups so large that an interior equilibrium may fail to exist.

Proposition 3.38 (Inelastic demand and Cournot equilibrium)**.** *Let firms compete in quantities with marginal costs $MC_i > 0$, and let market demand have constant elasticity $\varepsilon > 0$. In any interior Cournot equilibrium,*

(i) Each firm's Lerner index is $L_i = \frac{s_i}{\varepsilon}$.

(ii) Every active firm has a share $s_i < \varepsilon$.

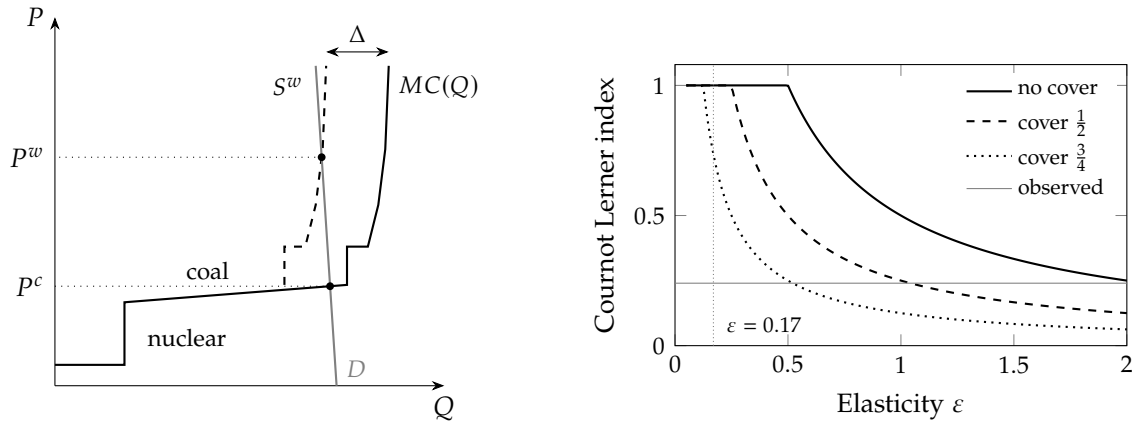
(iii) With N symmetric firms, an interior equilibrium requires $N > \frac{1}{\varepsilon}$.

Proof. Firm i's first-order condition is $P + q_i P'(Q) = MC_i$. Dividing by P and using $-\frac{QP'}{P} = \frac{1}{\varepsilon}$ gives

$$\frac{P - MC_i}{P} = -\frac{q_i P'(Q)}{P} = \frac{q_i}{Q} \cdot \frac{1}{\varepsilon} = \frac{s_i}{\varepsilon},$$

which is (i). Since $MC_i > 0$, the Lerner index is below one, so $s_i < \varepsilon$, which is (ii). With symmetric firms $s_i = \frac{1}{N}$, and (ii) becomes $N > \frac{1}{\varepsilon}$. □

Part (ii) restates Remark 2.66. The proposition has a stark implication for Britain. With $\varepsilon = 0.17$, the value used below, an interior Cournot equilibrium needs at least six symmetric firms. With two firms of equal size the formula gives $L_i = \frac{0.5}{0.17} = 2.9$, an impossible markup. Each firm's perceived marginal revenue $P(1 - \frac{s_i}{\varepsilon})$ is negative, so cutting output raises revenue and lowers cost. Firms keep withholding output until something else binds. Demand may become more elastic at high prices, as it does on a linear demand curve. Capacity constraints may bind, or the regulator may step in. Panel (a) of Figure 3.14 shows why withholding is so profitable here. The industry marginal cost curve is flat over a wide range and then nearly vertical. Demand is nearly vertical too. A small reduction in the quantity offered moves the market onto the steep segment and multiplies the price.



(a) Merit order and withholding

(b) Cournot markups and contract cover

Figure 3.14: Why oligopoly theory predicts high electricity markups. Panel (a) is a schematic. The industry marginal cost curve $MC(Q)$ ranks plants from cheapest to most expensive. Demand D is nearly vertical, so withholding a quantity Δ of low-cost capacity shifts the offered supply to S^w and raises the price from P^c to P^w. Panel (b) plots the Cournot Lerner index $\min\{1, \frac{s_i}{\varepsilon}(1 - \frac{x_i}{q_i})\}$ of a firm with share $s_i = \frac{1}{2}$ and contract cover $\frac{x_i}{q_i}$, from (3.78). The value one marks the region with no interior equilibrium. The gray horizontal line is the observed average Lerner index of 0.24.

3.8.2 Data and the measurement of marginal cost

The data. The sample covers 25,639 half-hour periods: nearly every half-hour of six months (January, February, March, April, July and November) in each of 1992, 1993 and 1994, 18 months in all. About 40 periods are missing. The Pool data come from the National Grid Company, which lacked some variables before 1992 (Wolfram, 1999, pp. 810, 822 and n. 49). Price is the SMP, which excludes the capacity payment, because the cost measure covers only fuel. Quantity is the energy metered in each half-hour, including transmission losses. Appendix Table A1 of the paper reports a mean SMP of £22.26 per megawatt-hour (MWh), with a standard deviation of 7.10. The pool selling price, which adds the capacity payment and uplift, has a mean of £24.40 and a standard deviation of 10.17. Mean quantity is 16,211 MWh per half-hour, with a standard deviation of 2,839. Energy of 16,211 MWh delivered in half an hour is an average rate of about 32 GW.

Plant marginal cost. The short-run marginal cost of a fossil-fuel plant is the cost of the fuel it burns per unit of electricity. Let plant k burn fuel with price w_k in pounds per gigajoule (GJ) and convert fuel energy into electricity with *thermal efficiency* $e_k \in (0, 1)$. One MWh equals 3.6 GJ, so the plant needs $\frac{3.6}{e_k}$ GJ of fuel per MWh, a quantity called its *heat rate* h_k. Its marginal cost is

$$mc_k = w_k\, h_k = \frac{3.6\, w_k}{e_k} \quad \text{(pounds per MWh)}. \tag{3.69}$$

For illustration, take coal at £1.50 per GJ plus £0.08 of transport and a hypothetical coal plant with an efficiency of 36 percent. Then $mc_k = \frac{3.6 \times 1.58}{0.36} = 15.8$, inside the range of the flat coal segment of Figure 3.15.

Each input of (3.69) is measured with unusual precision (Wolfram, 1999, p. 810). Before privatization, the *CEGB Statistical Yearbook* published the thermal efficiency of every coal, oil and gas plant. Green and Newbery (1992) distilled 20 years of these figures into efficiencies under

optimal operating conditions, and Wolfram replaces them with later engineering estimates where plants had been upgraded. Such data later became competitively sensitive. They are available only because the industry had recently been public. New combined-cycle gas turbine (CCGT) plants are assumed to have an efficiency of 45 percent. Fuel prices for oil, gas peaking and CCGT plants are market prices. Coal was bought from British Coal under contracts. The first contracts, which expired in March 1993, were effectively take-or-pay and supplied more coal than the generators burned. To capture the replacement cost of coal, Wolfram uses the prices of the next two contracts. Coal burned before the end of March 1994 is valued at 150 pence per GJ, and coal burned afterwards at 137 pence. Transport costs average 8 pence per GJ, about 5 percent of fuel costs. Nuclear stations are assigned £13 (Magnox, the first-generation gas-cooled reactors) and £11 (advanced gas-cooled reactors) per MWh. These figures are too high, but nuclear plants are never marginal. Pumped storage is costed at the average pool price during pumping, adjusted for efficiency, and imports from Scotland and France at their bid prices.

Capacity and the merit order. A plant's available capacity varies with maintenance and age. Generators may also withhold capacity strategically to raise capacity payments (Wolak and Patrick, 1997). Wolfram therefore assigns each plant a capacity equal to the mean plus one half standard deviation of its declared daily capacity in the month. This is on average 85 percent of the maximum capacity the plant declared for the year. Weighted by plant size the average is 100 percent. The high-availability case of Table 3.17, the mean plus a full standard deviation, raises the unweighted average to 92 percent (Wolfram, 1999, pp. 810–811, 816). Sorting plants by marginal cost gives the industry marginal cost curve, called the *merit order*. Index months by μ, and let month μ have plants ordered so that $mc_{(1)} \le mc_{(2)} \le \dots$, with capacities $K_{(1)}, K_{(2)}, \dots$. Then

$$MC_\mu(Q) = mc_{(j)} \qquad \text{for } \sum_{l<j} K_{(l)} < Q \le \sum_{l \le j} K_{(l)}. \tag{3.70}$$

This nondecreasing step function is the marginal cost of producing Q at least cost. Each half-hour t of month μ yields a markup $L_t = \frac{P_t - MC_\mu(Q_t)}{P_t}$.

Remark 3.39 (What the merit-order cost measures). Without firm-level quantities, Wolfram cannot compute each firm's own marginal cost. The merit order supplies an industry marginal cost directly. Under least-cost dispatch every running plant has $mc_k \le MC_\mu(Q_t)$ and the marginal plant has exactly $MC_\mu(Q_t)$. If every firm operates a plant at the margin, then $MC_{it} = MC_\mu(Q_t)$ for all i, and any weights in Proposition 3.2 give the same industry marginal cost. If firms withhold low-cost units, the units that run are more expensive than least-cost dispatch requires. The measured markup then compares price with the efficient marginal cost, so it also counts the productive inefficiency that withholding creates.

What the data show. Figure 3.15 reproduces the paper's Figure 2 for January and July 1993, a winter and a summer month at the midpoint of the sample (n. 17). The marginal cost curve rises over the first few gigawatt-hours, where nuclear and other cheap plants sit. It is then almost flat, between about £14 and £17 per MWh, over a wide range where coal plants are marginal. Near capacity it turns almost vertical, around 26 to 28 GWh per half-hour in January and 21 to 23 GWh in July, when plants are out for summer maintenance. Every observed price lies above marginal cost. In January prices run from about £17 to £35, and the gap widens with quantity. July prices are more dispersed, with a band near £31 at low quantities, a cluster around £50 and one price above £100. Prices were more volatile after March 1993, when the

initial contracts expired (n. 17). The clouds sit on the flat part of the cost curve, far from the steep segment where withholding by a duopoly would push them.

3.8.3 The model and the direct measure of conduct

Demand, cost and the firm supply relation. Wolfram's framework is the supply relation of Section 3.1 written for half-hours t (Wolfram, 1999, pp. 808–809). Demand is

$$D_t = D(P_t, X_t, u_t^d),$$

with observed demand shifters X_t such as weather and a demand shock u_t^d. Pool demand does respond to price. Some large users buy directly from the Pool or on contracts tied to pool prices. They switch to backup generators, shut down energy-intensive processes, or reschedule maintenance when prices are high. Demand also depends on prices in other half-hours, which the notation suppresses (n. 10). Generator i has marginal cost $MC_{it} = MC_i(q_{it}, Z_{it}, u_{it}^s)$, with cost shifters Z_{it} and a cost shock u_{it}^s, and profit

$$\Pi_{it} = P(Q_t, X_t, u_t^d)\, q_{it} - C_i(q_{it}, Z_{it}, u_{it}^s).$$

Its first-order condition, written with a firm-level conduct parameter $\tilde{\theta}_{it}$, is

$$P_t = MC_i(q_{it}, Z_{it}, u_{it}^s) - \tilde{\theta}_{it}\, q_{it}\, P_Q(Q_t, X_t, u_t^d), \tag{3.71}$$

where P_Q is the slope of inverse demand. Cournot conduct is $\tilde{\theta}_{it} = 1$ and price taking is $\tilde{\theta}_{it} = 0$. In the language of Corollary 3.3, $\tilde{\theta}_{it} = 1 + r_i$.

Aggregation. Firm-level quantities are not available, so the analysis works with the industry. Applying Proposition 3.2 to (3.71) with weights φ_{it} gives

$$P_t = MC(Q_t, \mathbf{Z}_t, u_t^s) + \frac{P_t}{\varepsilon_t}\,\theta_t, \qquad \theta_t = \sum_{i=1}^{N} \varphi_{it}\,\frac{q_{it}}{Q_t}\,\tilde{\theta}_{it}, \tag{3.72}$$

which is Wolfram's eq. (5). Rearranging gives her eq. (6),

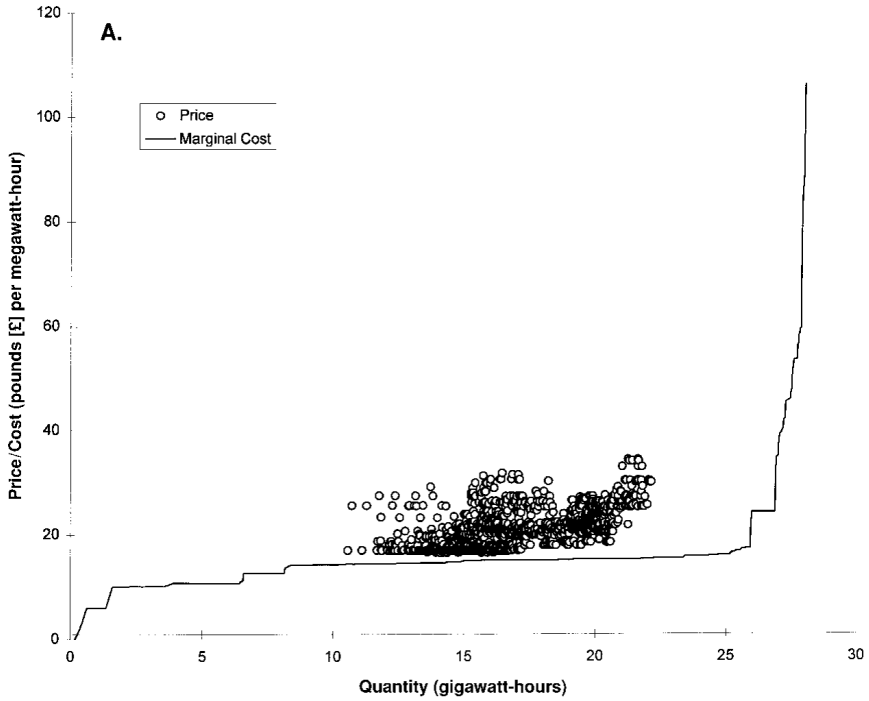
$$\theta_t = \varepsilon_t\,\frac{P_t - MC_t}{P_t}. \tag{3.73}$$

Wolfram writes η for the elasticity and κ_{it} for the weights. With $\varphi_{it} = \frac{1}{N}$ and a common $\tilde{\theta}_t$, industry conduct is $\theta_t = \frac{\tilde{\theta}_t}{N}$. It equals 1 for joint profit maximization, $\frac{1}{N}$ for Cournot and 0 for perfect competition. For this reason $\frac{1}{\theta_t}$ is sometimes read as an "equivalent number of firms." Wolfram treats θ_t as a summary measure, the elasticity-adjusted markup. She makes no claim about the conjectures that firms hold (n. 12, citing Corts, 1999).

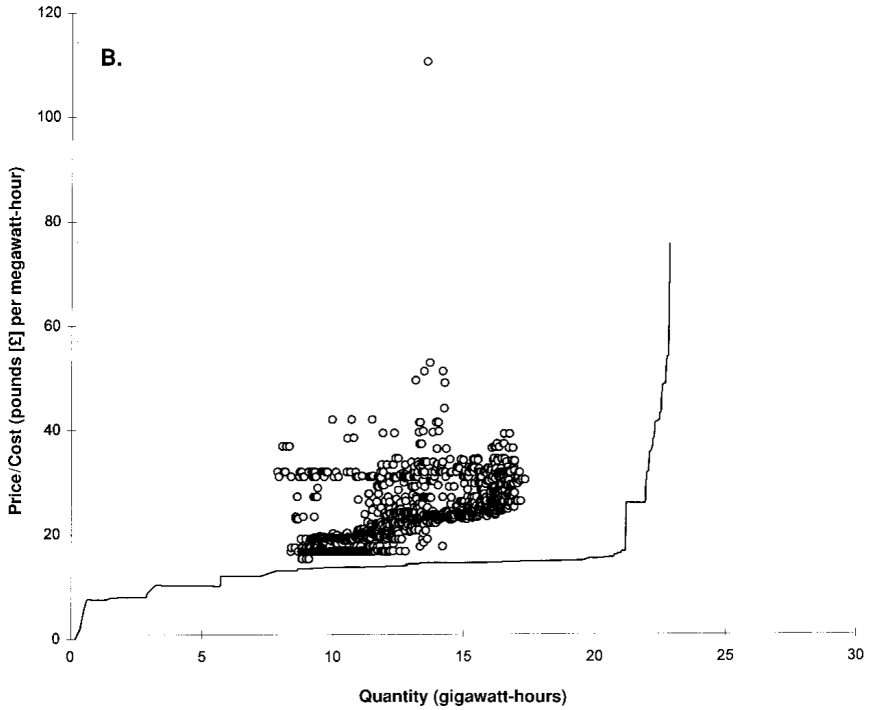
Remark 3.40 (Markups as transfers). With very inelastic demand, even large markups cause little deadweight loss. Approximate demand by a straight line near the equilibrium and take marginal cost as flat. Pricing at P instead of MC reduces quantity by about $\varepsilon Q\frac{P-MC}{P}$, so the Harberger triangle is

$$DWL \approx \frac{1}{2}(P - MC)\,\varepsilon Q\,\frac{P - MC}{P} \qquad \Longrightarrow \qquad \frac{DWL}{PQ} \approx \frac{1}{2}\,\varepsilon L^2 = \frac{1}{2}\,\theta L.$$

With $\varepsilon = 0.17$ and $L = 0.24$, the loss is about 0.5 percent of expenditure, while the transfer $\frac{(P-MC)Q}{PQ} = L$ is 24 percent. This is why Wolfram also reports quantity-weighted average markups, which speak to the surplus transferred to producers (p. 814).



(a) January 1993



(b) July 1993

Figure 3.15: Pool prices (circles, one per half-hour) and the merit-order marginal cost curve (line), in pounds per MWh against quantity in gigawatt-hours per half-hour. Source: Wolfram (1999), Figure 2.

The demand slope. Marginal cost is measured, so only the elasticity is missing from (3.73). Wolfram does not estimate it for this purpose. She assumes linear demand with slope $D_p = \frac{\partial D}{\partial P} = -125$, which makes her numbers comparable with the simulations of Green and Newbery (1992) (Wolfram, 1999, p. 811). The units are MWh per half-hour per pound per MWh. A fall of 125 MWh within a half-hour is an average rate of 250 megawatts, or 0.25 GW, which is the slope $b = 0.25$ that Green and Newbery report in gigawatts. Their low and high cases correspond to $D_p = -50$ and $D_p = -250$. With linear demand,

$$\varepsilon_t = -D_p \frac{P_t}{Q_t} \qquad \Longrightarrow \qquad \theta_t = \varepsilon_t \frac{P_t - MC_t}{P_t} = -D_p \frac{P_t - MC_t}{Q_t}. \tag{3.74}$$

At the sample means, $\varepsilon = \frac{125 \times 22.26}{16{,}211} = 0.17$. This is in the range of short-run elasticities found elsewhere (Taylor, 1975). The largest elasticity that Patrick and Wolak (1997) find for customers on pool-price contracts is about 0.3, for water companies, a group unusually sensitive to price. With an average Lerner index of 0.241, (3.74) at the means gives $\theta = \frac{125 \times 0.241 \times 22.26}{16{,}211} = 0.041$.

Later work confirms that short-run electricity demand is very inelastic. One reason is that many households face retail prices that do not vary with wholesale conditions (Kellogg and Reguant, 2021, p. 709). Reiss and White (2005) exploit the tiers of California tariffs in household survey data. They find an average elasticity of -0.39, which reflects medium-run to long-run responses. Ito (2014) compares households on either side of a utility border in Orange County. He finds an elasticity of about -0.08 with respect to the average price. Shaffer (2020) estimates about -0.04 from bunching at a tariff kink in British Columbia (Kellogg and Reguant, 2021, pp. 710–711). These are retail residential elasticities, and none measures the response of pool demand. Still, they bracket the value of 0.17 assumed here and the rotation estimates of about 0.1 in Section 3.8.6.

Example 3.41 (The Cournot benchmark under the assumed demand)**.** Extend the linear demand through the sample means: $Q = 125(\bar{\alpha} - P)$ with choke price $\bar{\alpha} = 22.26 + \frac{16{,}211}{125} = 151.95$. Let a symmetric duopoly have flat marginal cost $c = 16$, roughly the level of the coal segment. Inverse demand is $P = \bar{\alpha} - \frac{Q}{125}$, and the symmetric Cournot price with N firms is $\frac{\bar{\alpha} + Nc}{N+1}$. With $N = 2$,

$$P^C = \frac{151.95 + 2 \times 16}{3} = 61.32, \qquad Q^C = 125\,(151.95 - 61.32) = 11{,}329.$$

The Lerner index is $\frac{61.32 - 16}{61.32} = 0.74$. The elasticity at this point is $\frac{125 \times 61.32}{11{,}329} = 0.68$, and $\theta = 0.68 \times 0.74 = 0.5 = \frac{1}{N}$, as it must be. The benchmark price is almost three times the mean SMP. The calculation extrapolates the linear demand far outside the sample and is only an illustration of the scale of the predicted markups.

Benchmarks for conduct. Price taking gives $\theta = 0$ and joint profit maximization gives $\theta = 1$. Cournot gives $\theta = \sum_i \varphi_{it} s_{it}$ (Corollary 3.3). This is $\frac{1}{2}$ for a symmetric duopoly. For the two asymmetric generators, Wolfram uses 0.52 (p. 818). That value matches a Herfindahl index computed with shares in the ratio of the initial capacities, $\left(\frac{52}{85}\right)^2 + \left(\frac{33}{85}\right)^2 = 0.52$. The fourth benchmark comes from a model built for electricity markets.

Supply function equilibrium. In the Pool, firms bid supply schedules that state a price for each quantity. Klemperer and Meyer (1989) model such competition. Each firm commits to a supply function before a demand shock is realized, and the market clears where total supply meets demand. Green and Newbery (1992) were the first to apply the concept to the Pool. They calibrate cost functions for the two effective duopolists and a demand curve, and they

solve for the supply function equilibria, including asymmetric ones. The equilibria range from marginal-cost pricing to one that reproduces the Cournot quantities and prices. The highest-price equilibrium implies large markups. Observed prices showed no such markups, and Green and Newbery suggest that the generators' forward sales of much of their capacity may explain the gap. A long-run version of the model finds that entry incentives depend strongly on the demand elasticity and on the incumbents' pricing strategies (Hortaçsu and Perrigne, 2021, pp. 145–146). Wolfram (1998) later treated the bids as a uniform-price multi-unit auction. A higher bid raises the price paid on all accepted units if it sets the price, but it lowers the chance that the unit is accepted (Kellogg and Reguant, 2021, p. 695). Her evidence is consistent with strategic withholding of supply (Hortaçsu and Perrigne, 2021, p. 146). The next result derives the equilibrium condition and shows where supply function markups fall. Remark 2.57 states its Lerner form without proof.

Proposition 3.42 (Supply function equilibrium markups)**.** *Two firms have cost functions C_i with $C_i' \geq 0$. Demand is $D(P) + u$, with $D' < 0$ and a shock u whose support is an interval. Before u is known, firm i chooses a differentiable, nondecreasing supply function $S_i(P)$, and the price clears $S_1(P) + S_2(P) = D(P) + u$. Suppose each S_i maximizes firm i's profit for every realization of u, given S_j. Then at every clearing price*

$$S_i(P) = \big(P - C_i'(S_i(P))\big)\big(S_j'(P) - D'(P)\big), \qquad i \neq j, \tag{3.75}$$

and the Lerner index of firm i is

$$L_i = \frac{s_i}{\varepsilon + s_j\,\eta_j}, \qquad \eta_j = \frac{P\,S_j'(P)}{S_j(P)} \geq 0, \tag{3.76}$$

where $s_i = \frac{S_i}{Q}$ and $\varepsilon = -\frac{PD'(P)}{Q}$. Hence $0 \leq L_i \leq \frac{s_i}{\varepsilon}$, and firm i's conduct parameter is $\tilde{\theta}_i = \frac{\varepsilon}{\varepsilon + s_j\eta_j} \in (0, 1]$.

Proof. Fix S_j and a realization u. Whatever S_i is, firm i ends up at some price P and sells its residual demand $R_i(P, u) = D(P) + u - S_j(P)$. Choosing a supply function is therefore equivalent to choosing, for each u, a price on the residual demand curve. Profit at price P is $PR_i(P, u) - C_i(R_i(P, u))$, and the first-order condition is

$$R_i(P, u) + \big(P - C_i'(R_i(P, u))\big)\big(D'(P) - S_j'(P)\big) = 0.$$

The shock shifts residual demand horizontally without changing its slope, so different realizations select different optimal prices. The supply function S_i implements all these optima only if $S_i(P) = R_i(P, u)$ at each optimal pair, which gives (3.75). Divide (3.75) by P and then numerator and denominator by Q:

$$\frac{P - C_i'}{P} = \frac{S_i}{P(S_j' - D')} = \frac{\frac{S_i}{Q}}{\frac{S_j}{Q}\cdot\frac{PS_j'}{S_j} - \frac{PD'}{Q}} = \frac{s_i}{s_j\eta_j + \varepsilon}.$$

Since $\eta_j \geq 0$, $L_i \leq \frac{s_i}{\varepsilon}$. Comparing with the firm supply relation $L_i = \tilde{\theta}_i\frac{s_i}{\varepsilon}$ of Proposition 3.2 gives $\tilde{\theta}_i$. □

The proposition places supply function equilibria between competition and Cournot. If the rival's supply does not respond to price ($\eta_j = 0$), firm i faces the Cournot residual demand.

As the rival's supply becomes very elastic ($\eta_j \to \infty$), the markup goes to zero. The formula also shows why the concept suits electricity. As demand becomes perfectly inelastic, the Cournot markup explodes, while the supply function markup stays finite at $\frac{s_i}{s_j \eta_j}$, disciplined by the rival's supply response. In the symmetric case (3.75) becomes the differential equation $S'(P) = \frac{S(P)}{P - C'(S(P))} + D'(P)$, which has a continuum of solutions. Klemperer and Meyer show that the equilibria form a range when the shock has bounded support. Wolfram computes the *highest* supply function equilibrium, the solution that passes through the symmetric Cournot point on the right-most demand curve (pp. 813–814). Following Green and Newbery, she assumes a symmetric duopoly. The right-most demand curve has slope −125 and passes through the monopoly price at a quantity of 30 in the gigawatt units of the paper. The largest quantity in the sample is 24, so this choice is conservative (n. 22). The benchmark θ is the margin in the supply function equilibrium times the elasticity under $D_p = -125$. Both are evaluated at the equilibrium point, where the price is higher and the elasticity larger than in the data. Because marginal cost rises so steeply, the lowest supply function equilibrium gives very similar markups (n. 23).

3.8.4 Markups and conduct

Table 3.16 reproduces Table 1 of Wolfram (1999). Each entry averages over half-hours, and the standard deviations in parentheses describe the dispersion across half-hours. The first column is the Lerner index computed from the merit order. The second multiplies each half-hour's Lerner index by its elasticity under $D_p = -125$, as in (3.74). The third gives θ in the highest supply function equilibrium.

Table 3.16: Price-cost markups calculated with measured marginal cost

Period	(i) $\frac{P-MC}{P}$	(ii) $\theta = \varepsilon \frac{P-MC}{P}$	(iii) θ, highest SFE	(iv) Observations

below median	0.018 (0.398)	0.027 (0.073)	0.26 (0.02)	2,772

Notes: Reproduced from Wolfram (1999), Table 1. The unit of observation is a half-hour. Standard deviations across half-hours in parentheses. Columns (ii) and (iii) assume linear demand with slope $D_p = -125$, so that $\varepsilon = -D_p \frac{P}{Q}$. SFE: supply function equilibrium. The three periods sum to 25,639 half-hours, and each pair of quantity rows sums to its period total. Column (ii) is a mean of ratios, so it differs from column (i) times 0.17.

Levels. Prices exceed measured marginal cost by more than 20 percent on average, so the market is far from competitive. The averages are precise. Two-sided t-tests at the 1 percent level reject an average markup below 0.19 in the last period and above 0.245 in the first. Serial

correlation makes these tests somewhat optimistic (p. 811 and n. 21). Conduct, however, is small. The values of θ between 0.043 and 0.067 are far from collusion ($\theta = 1$) and far below Cournot (0.5 or 0.52). They are also far below the highest supply function equilibrium, between 0.28 and 0.33. A value of 0.05 corresponds to symmetric Cournot competition among 20 firms. The values are significantly above zero, so the Bertrand model of homogeneous price competition is rejected as well. Wolfram notes features that should have made collusion easy (p. 813). The firms bid daily, an infinitely repeated game, and as former parts of one organization they knew each other's plants well.

How wrong would the assumed elasticity have to be to reverse these conclusions? Column (ii) is column (i) times the elasticity. Joint profit maximization would require an elasticity of about $\frac{1}{0.25} = 4$, and asymmetric Cournot conduct one of about $\frac{0.52}{0.25} = 2.1$. Matching the highest supply function equilibrium would require an elasticity above about 3, because that benchmark itself rises as demand becomes more elastic (p. 818). Even long-run electricity elasticities rarely exceed 1.5 (Taylor, 1975). The qualitative conclusion is therefore robust to the demand assumption, even though the level of θ is not.

Patterns. Markups rise with quantity, mildly before April 1994 and dramatically afterwards: 0.554 above the median quantity against 0.018 below. The price cap explains the later pattern. It applied to the time-weighted average price, so the generators could stay under it by cutting prices when demand was low and raising them when demand was high (p. 814). Quantity-weighted averages, which track the surplus transferred, are close to the time-weighted ones before April 1994, at 0.248 and 0.264. After March 1994 the quantity-weighted average is 0.262, against a time-weighted 0.208. Markups are also much higher in the four weeks before a regulatory decision (0.329) than in the four weeks after (0.156). The dispersion across half-hours is large, with standard deviations comparable to the means. Variation by quantity explains less than 5 percent of it (n. 26). Marginal cost is constant within a month, so the volatility comes from prices.

Robustness. Table 3.17 reproduces the paper's Table 2. High fuel costs value coal at the take-or-pay contract price of 180 pence per GJ before April 1993. They also raise oil and gas prices by 20 percent and add £1 per MWh to nuclear costs. Low fuel costs set coal at world prices (120 and then 110 pence per GJ) and lower the other fuels symmetrically. Low and high availability assign each plant the monthly mean, or the mean plus a full standard deviation, of its declared capacity. The last column measures the margin against the pool selling price, which adds capacity payments and uplift to the SMP.

Markups are sensitive to fuel costs. Before April 1994 the two fuel cases move them by 54 to 60 percent in each direction. After March 1994 the high-cost case lowers them by only 14 percent, while the low-cost case raises them by about 63 percent. Markups are much less sensitive to availability. About 90 percent of the fuel-cost sensitivity comes from the coal assumptions. Coal plants set the price most of the time, and in the 12 months to March 1997 they set the SMP in 82 percent of half-hours (n. 33). Changing coal costs shifts the long flat segment of the merit order, which moves almost every markup. Changing availability only lengthens or shortens that segment. Margins over the pool selling price are 15 to 30 percent higher, because the extra charges are 5 to 10 percent of the pool price.

Three further checks support the cost measure (Wolfram, 1999, p. 817). First, it implies producer surplus of about 25 percent of the generators' SMP revenue. SMP is about 90 percent of the pool price, and pool revenue is about 70 percent of National Power's total revenue. Fuel costs are therefore about $0.75 \times 0.9 \times 0.7 = 47$ percent of revenue, close to the 40 and 45 percent reported in the two companies' 1994 annual reports. Second, a regression version of

Table 3.17: Lerner indices under alternative assumptions

Period	(i) Benchmark	Fuel prices (ii) High	Fuel prices (iii) Low	Plant capacity (iv) Low avail.	Plant capacity (v) High avail.	Plant capacity (vi) Declared	(vii) Pool selling price
Jan. 1992 to Mar. 1993	0.241 (0.129)	0.097 (0.154)	0.384 (0.105)	0.231 (0.130)	0.250 (0.127)	0.231 (0.130)	0.278 (0.147)
Apr. 1993 to Mar. 1994	0.259 (0.228)	0.119 (0.269)	0.399 (0.184)	0.246 (0.231)	0.268 (0.226)	0.245 (0.233)	0.314 (0.233)
After Mar. 1994	0.208 (0.416)	0.179 (0.432)	0.338 (0.352)	0.196 (0.421)	0.215 (0.415)	0.195 (0.422)	0.270 (0.417)

Notes: Reproduced from Wolfram (1999), Table 2. Entries are average Lerner indices $\frac{P-MC}{P}$ with standard deviations across half-hours in parentheses. Column (i) is column (i) of Table 3.16. Column (vi) uses each plant's actual declared daily capacity. Observations: 12,704, 8,637 and 4,298.

(3.72) imposes constant conduct and a constant elasticity. Solving $P_t = MC_t + \frac{P_t}{\varepsilon}\theta$ for P_t gives Wolfram's eq. (7),

$$P_t = \omega\, MC_t + e_t, \qquad \omega = \frac{\varepsilon}{\varepsilon - \theta}. \tag{3.77}$$

The coefficient ω is the constant-elasticity pass-through rate of Corollary 3.9, with total marginal cost in place of a tax. On all the data $\hat{\omega} = 1.92$ (robust standard error 0.75), which implies $\theta = \varepsilon(1 - \frac{1}{\hat{\omega}}) = 0.17 \times (1 - \frac{1}{1.92}) = 0.081$. Instrumenting marginal cost with the demand shifters, to address measurement error, raises the estimate slightly and insignificantly. Third, the functional form of demand matters little. With a constant elasticity of 0.17, θ is 0.041, 0.044 and 0.035 in the three periods. With a concave demand curve whose elasticity is 0.17 at the means, it is 0.043, 0.060 and 0.077 (n. 37).

3.8.5 Why are markups so low?

Prices respond to the generators' incentives, yet they stay far below static oligopoly predictions. Wolfram weighs three explanations (pp. 814–815): contracts, the threat of regulation, and the threat of entry.

Contracts. A generator that has sold part of its output forward gains less from a high spot price. The next result makes this precise. It is the spot-market stage of the model of Allaz and Vila (1993), and it restates Example 2.65.

Proposition 3.43 (Forward contracts and spot markups)**.** *Firm i holds two-way contracts for x_i units at strike price F_i and then chooses its output q_i as a Cournot competitor. Its profit is*

$$\Pi_i = P(Q)\,(q_i - x_i) + F_i\, x_i - C_i(q_i),$$

and at an interior optimum

$$L_i = \frac{P - MC_i}{P} = \frac{s_i}{\varepsilon}\Big(1 - \frac{x_i}{q_i}\Big). \tag{3.78}$$

Proof. The firm sells q_i at the spot price and pays $(P - F_i)x_i$ on its contracts, so $\Pi_i = Pq_i - (P - F_i)x_i - C_i(q_i) = P(q_i - x_i) + F_i x_i - C_i(q_i)$. The first-order condition is

$$P + P'(Q)\,(q_i - x_i) - MC_i = 0 \quad \Longrightarrow \quad P - MC_i = -P'(Q)\,q_i\Big(1 - \frac{x_i}{q_i}\Big).$$

Dividing by P and using $-\frac{P'Q}{P} = \frac{1}{\varepsilon}$ and $\frac{q_i}{Q} = s_i$ gives (3.78). □

The firm cares about the price only on its uncontracted output $q_i - x_i$. Full cover makes it a price taker, and cover above output makes it want a price below marginal cost. In conduct terms, $\tilde{\theta}_i = 1 - \frac{x_i}{q_i}$. A one-way contract works differently. The generator refunds the excess of the pool price over the strike price, so cover dampens its incentive only when the price is above the strike. Panel (b) of Figure 3.14 plots (3.78) for a firm with half the market.

The British data allow a test. Wolfram estimates that the initial contracts covered about 75 percent of the generators' output and their replacements about half (p. 814). With $s_i = 0.5$ and $\varepsilon = 0.17$, (3.78) predicts $L_i = \frac{0.5}{0.17} \times 0.25 = 0.74$ under the initial contracts. Under the replacements it predicts $L_i = \frac{0.5}{0.17} \times 0.5 = 1.47$, which again leaves no interior equilibrium. The model thus predicts a sharp rise after March 1993, from 0.74 to a level at which no interior equilibrium exists. Table 3.16 shows a rise from 0.241 to 0.259. A fall of more than 20 percentage points in contract cover raised markups by less than 2 percentage points. Contracts may restrain prices slightly, but they cannot explain why oligopoly models predict so poorly.

The contracts in Britain were imposed at privatization. Allaz and Vila (1993) show that duopolists choose to sell forward even when nobody forces them to. The following example shows the mechanism in the simplest case. Section 2.7.5 sketches the same calculation, and we give it in full here.

Example 3.44 (Strategic forward sales)**.** Two firms with constant marginal cost c face inverse demand $P = a - bQ$. In stage 1 each firm sells x_i forward. Arbitrage sets the forward price equal to the spot price, which is known in this deterministic model. In stage 2 the firms choose outputs. Stage-2 first-order conditions from Proposition 3.43 are

$$a - b(q_i + q_j) - b(q_i - x_i) - c = 0, \qquad i = 1, 2,$$

so that

$$q_i = \frac{a - c + 2bx_i - bx_j}{3b}, \qquad P - c = \frac{a - c - b(x_i + x_j)}{3}.$$

A forward sale raises the firm's own output by $\frac{2}{3}$ and lowers the price by $\frac{b}{3}$ per unit. Since the forward price equals the spot price, firm i's total profit is $(P - c)q_i$. Its stage-1 condition is

$$-\frac{b}{3} q_i + \frac{2}{3}(P - c) = 0 \quad \Longrightarrow \quad P - c = \frac{b\, q_i}{2}.$$

In a symmetric equilibrium, substituting $q = \frac{a-c+bx}{3b}$ and $P - c = \frac{a-c-2bx}{3}$ gives

$$\frac{a - c - 2bx}{3} = \frac{a - c + bx}{6} \quad \Longrightarrow \quad x = \frac{a - c}{5b}, \qquad q = \frac{2(a - c)}{5b}, \qquad P - c = \frac{a - c}{5}.$$

Each firm covers half of its output. The margin falls from the Cournot level $\frac{a-c}{3}$ to $\frac{a-c}{5}$, and both firms earn less. Each sells forward to commit itself to aggressive spot behavior, a prisoner's dilemma.

Green (1999) builds contracts into the supply function framework and shows that pool prices fall as contract cover rises (Wolfram, 1999, p. 810). Contracts are therefore a coherent mechanism. The British evidence suggests that they were not the main force restraining prices.

The threat of regulation. Prices react to the regulator's calendar. In the four weeks before OFFER's statements on pool prices the Lerner index averages 0.329, and in the four weeks after

it averages 0.156. Two-sided t-tests reject that markups around these decisions equal markups at other times, and the differences persist after controlling for demand factors (n. 27). The generators knew when a statement was being prepared, and the regulator analyzed prices from earlier months. Wolfram suggests that the generators raised prices while the regulator could not yet see them and restrained prices afterwards, when attention was on the Pool (pp. 814–815). In the model of Glazer and McMillan (1992), the threat of regulation leads a monopolist to price below the monopoly level. The firm raises its price as the probability of future regulation rises. The response to the 1994 price cap, documented above, is direct evidence that regulation shaped pricing, and of the distortions a cap on average prices creates.

The threat of entry. Two pieces of evidence point to entry deterrence (p. 815). First, pool prices sat just below the long-run average cost of a new entrant. Following Green and Newbery, a new CCGT plant had capital and non-fuel operating costs of roughly £85 per kilowatt of capacity. Treating this as an annual cost, a plant that runs 90 to 95 percent of the year has non-fuel costs of $\frac{85{,}000}{8{,}760\times 0.95} = 10.2$ to $\frac{85{,}000}{8{,}760\times 0.90} = 10.8$ pounds per MWh. Adding fuel costs of roughly £16 gives an average cost of £26 to £27 per MWh. Pool prices averaged £23.6 per MWh in fiscal years 1993 and 1994. Second, pool prices moved with the price of natural gas, the fuel of potential entrants, even in high-demand periods when no existing CCGT plant was marginal. In a regression of the pool price on the demand variables and the gas price interacted with a dummy for demand above 15 GW, the gas coefficient is 0.024 (standard error 0.008). A 10 percent rise in the gas price thus raises the pool price by less than 1 percent. Pricing just below the entrant's cost would imply a nearly one-to-one relation between gas and pool prices. Wolfram suggests that the generators may follow a more complex strategy, or that the gas price an entrant faces is measured with error (n. 29).

Limit pricing of this kind keeps prices low to make entry unprofitable. Game-theoretic models of limit pricing rely on entrants being uncertain about incumbents' costs, which is implausible here, although entrants could be unsure about regulatory constraints (n. 30). Some entry did occur. All independent plants added after privatization were at least partly owned by RECs, which could pass their costs to franchise customers whatever the pool price. Entry decisions may therefore have depended on more than pool prices.

3.8.6 Estimates that ignore cost data

Section IV of the paper asks what a researcher without cost data would conclude. Wolfram applies two methods. The first is new and exploits the distortion created by the price cap. The second is the demand-rotation approach of Section 3.5.

A bound from the price cap. The cap on the time-weighted average price rotated the industry supply curve counterclockwise. Prices fell at low demand and rose at high demand. Figure 3.16 redraws the paper's stylized Figure 3. Wolfram sorts half-hours into 25 groups by quantity, in bands of 0.5 GWh. For each group g she compares the average price after the cap, $P_{H,g}$, with the average price before, $P_{L,g}$. The *rotation axis* is the lowest quantity at which prices after the cap exceed prices before. Eleven groups lie to its left and fourteen to its right.

The logic is a revealed-preference bound. Suppose prices before the cap were at least as high as marginal cost after the cap, $P_{L,g} \geq MC_g$. Then for each group to the right of the axis

$$\frac{P_{H,g} - P_{L,g}}{P_{H,g}} \leq \frac{P_{H,g} - MC_g}{P_{H,g}} = L_g. \tag{3.79}$$

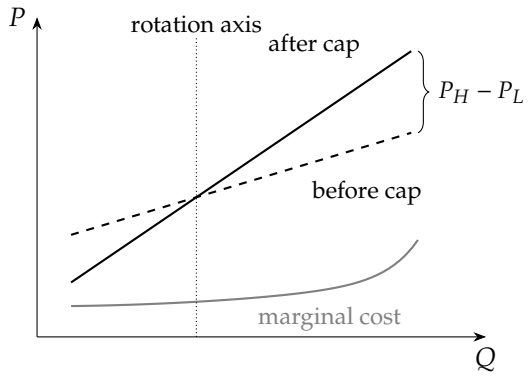

Figure 3.16: The price cap rotates the supply relation. The solid and dashed lines are average prices by quantity after and before the cap of April 1994. To the right of the rotation axis the gap $P_H - P_L$ bounds the Lerner index from below. Schematic redrawn after Wolfram (1999), Figure 3.

The condition holds if the generators priced at or above cost before the cap and costs did not rise. The coal price fell from 150 to 137 pence per GJ in April 1994, which only helps. Averaging the left side over the fourteen groups, weighted by their numbers of half-hours, gives 0.277 (standard deviation 0.145). If prices had equaled marginal cost before the cap, this would approximate the Lerner index above the median quantity after March 1994. That index is 0.554 in Table 3.16, so the bound captures about half of the measured markup (p. 819). Groups to the left of the axis are excluded, because the generators may have priced below cost at low demand to stay under the cap (n. 39). The method compares pricing regimes, like Porter (1983a), but here regulation creates the regimes. It also resembles the tax-based test of Ashenfelter and Sullivan (1987) (n. 41).

Comparative statics in demand. The second method estimates linear demand and a linear supply relation, with θ identified by a demand rotation (Wolfram, 1999, pp. 820–821). The demand equation, her eq. (8), lets the price coefficient differ between winter weekdays and other periods. Its coefficients α, β_w and β_s, like γ and δ below, are local symbols that follow the paper:

$$Q_t = X_t\alpha - \beta_w P_t \mathbf{1}\{\text{winter weekday}\}_t - \beta_s P_t \mathbf{1}\{\text{summer or weekend}\}_t + u_t^d. \tag{3.80}$$

Winter weekdays are 9 a.m. to 5 p.m. on weekdays in January, February and March. The Pool's demand forecasters reported that elasticities differ most between these periods and the rest. Write demand as $Q_t = a_t - b_t P_t$, with intercept $a_t = X_t\alpha$ and slope $b_t \in \{\beta_w, \beta_s\}$. Under linear demand $\frac{P_t}{\varepsilon_t} = \frac{Q_t}{b_t}$, and with linear marginal cost $MC_t = Z_t\tilde{\gamma} + \tilde{\delta}Q_t + u_t^s$ the supply relation (3.72) becomes

$$P_t = Z_t\tilde{\gamma} + \tilde{\delta}\,Q_t + \theta\,\frac{Q_t}{b_t} + u_t^s. \tag{3.81}$$

Substituting $\frac{Q_t}{b_t} = \frac{a_t}{b_t} - P_t$ and solving for P_t gives Wolfram's eq. (9),

$$P_t = Z_t\gamma + \delta\,Q_t + \frac{\theta}{1+\theta}\,\frac{a_t}{b_t} + \frac{u_t^s}{1+\theta}, \qquad \gamma = \frac{\tilde{\gamma}}{1+\theta}, \quad \delta = \frac{\tilde{\delta}}{1+\theta},$$

which she estimates with a_t and b_t replaced by their demand estimates. She reports similar results for the form (3.81) (n. 43).

Identification follows Proposition 3.28. If b_t were constant, $\frac{Q_t}{b_t}$ would be proportional to Q_t, and (3.81) would identify only $\tilde{\delta} + \frac{\theta}{b}$, the observational equivalence of Proposition 3.26.

Weather and other shifters in X_t move demand in parallel and trace out the slope of the supply relation. The switch of the demand slope between winter weekdays and other periods is a rotator. It separates the markup term from the slope of marginal cost.

Price in (3.80) is endogenous, so it needs a cost shifter as instrument. Wolfram uses *nuclear availability*, the MWh of nuclear capacity available each day. Nuclear plants have very low marginal cost and run continuously. When one is out of service, more expensive plants run at every level of demand, so the merit order shifts up. Planned outages are scheduled for low-demand periods and are treated as available. Only unplanned outages, which are random and unrelated to demand, count as unavailable. The data needed to build the instrument exist only for fiscal year 1994 (April 1993 to March 1994), which leaves 7,523 half-hours. The demand shifters are weather variables used by the Pool's forecasters: temperature, its square, the cooling power of the wind, cloud cover, and dusk and night dummies. The demand equation also has winter-weekday, month, time-of-day by weekday and time-of-day by weekend fixed effects. Both equations are estimated by two-stage least squares. The corrected standard errors use the Newey-West estimator for serial correlation and, in the supply relation, the correction of Newey (1984) for the generated regressor $\frac{a_t}{b_t}$ (Appendix A).

Table 3.18: Market power from comparative statics in demand

Variable	Coefficient	Standard error	Corrected standard error
Demand equation (dependent variable Q_t)			
Price × winter weekday	−71.4	24.9	108.2
Price × summer or weekend	−45.1	20.8	78.4
Temperature	−331	15	57
Temperature squared	9.86	0.54	1.66
Cooling power	5.38	1.46	4.32
Clouds	49.8	5.4	12.5
Dusk	518	74	223
Night	1,816	177	674
Supply relation (dependent variable P_t)			
Constant	11.0	2.2	5.13
Nuclear availability	−0.001	0.0005	0.0007
Winter	−8.20	0.20	0.84
Quantity	0.001	0.0004	0.0007
θ	0.012	0.002	0.044

Notes: Reproduced from Wolfram (1999), Table 3. Two-stage least squares, N = 7,523 half-hours in fiscal year 1994. The last column corrects for serial correlation (Newey and West, 1987) and, in the supply relation, for the generated regressor (Newey, 1984). Price is the pool purchase price in pounds per MWh and quantity is in MWh per half-hour. The demand equation also includes winter-weekday, month, time-of-day × weekday and time-of-day × weekend fixed effects.

Table 3.18 reports the results. The price coefficients are small, and the winter-weekday coefficient is about 1.6 times the other one. At the means of fiscal year 1994 they imply elasticities of $\frac{71.4 \times 23.0}{19{,}911} = 0.08$ and $\frac{45.1 \times 23.3}{15{,}777} = 0.07$, which Wolfram describes as approximately 0.1. They are imprecise. With corrected standard errors, we cannot reject that the two price coefficients are equal, or even that demand does not slope down. Estimates on daily averages are similar, $\beta_w = 101$ (125) and $\beta_s = 62$ (86). In the supply relation, nuclear availability lowers costs, and costs are lower in winter, when fewer plants are in maintenance. The positive quantity coefficient fits rising marginal cost. The estimate of θ is 0.012, essentially zero.

How does this compare with the direct measure? The direct θ for fiscal year 1994 is 0.057 (Table 3.16). With the corrected standard error of 0.044, we cannot reject $\theta = 0.057$, and we cannot reject $\theta = 0$ either. With the conventional standard error of 0.002, the gap of 0.045 would be more than twenty standard errors. Corts (1999, p. 245) worked from the 1997 working papers of this study and of the sugar study. He reported that equality of the estimate and the direct measure could be rejected in both (Section 3.6.2). In the published version, the corrected standard error no longer allows that rejection for electricity. An earlier version of the paper found the estimates of θ particularly sensitive to the specification of demand (n. 48).

3.8.7 Assessment

Interpretation. The robust finding is a gap. Prices are well above marginal cost, but conduct is far from what static oligopoly models predict for a duopoly facing inelastic demand. The gap survives every cost assumption in Table 3.17 and any plausible elasticity. The cost-free methods agree with it. The price-cap bound shows that the generators could raise prices sharply when regulation made it pay. The rotation estimate puts conduct near zero. The most plausible reading is that forces outside the static model kept prices down, chiefly the threats of entry and of regulation. The generators' quick responses to the regulator's calendar and to the cap show that they could move prices and chose not to exploit their position fully.

Critiques of the first-order-condition method. Computing θ_t half-hour by half-hour from (3.74) is sometimes called the first-order-condition method. Five concerns qualify it.

(1) *The demand slope is assumed.* By (3.74), θ_t is proportional to $-D_p$. Green and Newbery's low and high slopes would multiply every entry of column (ii) by 0.4 or by 2. The ranking against Cournot survives, since even the high case gives period averages of at most 0.134. The level of θ and comparisons over time do not, because the elasticity may have changed. More customers became eligible to buy directly from the Pool in April 1994, and a pilot let twelve large customers bid demand from December 1993 (p. 818).

(2) *Marginal cost is fuel cost.* Start-up costs, no-load costs and limits on how fast units can change output are omitted. They can make the cost of serving one more MWh exceed the fuel cost of the marginal unit, especially at peaks. Capacity withholding and the capacity payment add further wedges (Wolak and Patrick, 1997). The markups move most with coal prices (Table 3.17). Later studies confirm that such dynamic costs bias static markups (Section 3.8.8).

(3) *Conduct varies.* The standard deviations of θ_t are as large as its means, and conduct moves with the regulatory calendar, with demand and with the cap. A single θ summarizes a distribution. If conduct varies with demand, Proposition 3.31 shows that a constant-θ estimator measures the slope of the supply relation. The rotation estimate below the direct average fits that pattern.

(4) *Periods are linked.* Demand in one half-hour depends on prices in others, which the static demand ignores. Within-day cross-price effects appear small (n. 42), but daily repeated bidding makes the game dynamic. The bids also form a multi-unit auction. von der Fehr and Harbord (1993) model the Pool as a first-price, sealed-bid, multi-unit auction whose equilibria have prices above marginal cost.

(5) *Industry conduct is an average.* Quantity Q_t includes nuclear output, imports and new entrants, which behave as price takers. By Proposition 3.2, their shares enter θ_t with

$\tilde{\theta} = 0$ and pull it toward zero. The strategic conduct of National Power and PowerGen is therefore higher than θ_t suggests, although not by enough to approach the oligopoly benchmarks.

Contribution. The paper made three contributions. It measured markups directly over a long period in a market where the necessary cost data are reliable, and compared them with explicit oligopoly benchmarks. It showed that a highly concentrated market facing inelastic demand priced far below those benchmarks. This shifted attention to entry, regulation and contracts as sources of discipline. It introduced a way of measuring markups from a regulatory distortion and documented how a cap on average prices reshapes pricing. Together with Section 3.7, it remains the main evidence on how well the conduct-parameter method performs when the truth is known. Its design of a competitive benchmark built from plant costs became a standard tool for studying restructured electricity markets (Kellogg and Reguant, 2021, p. 692), the subject of the next subsection.

3.8.8 Later evidence from restructured markets

Restructuring in the United States and elsewhere produced a second generation of studies built on Wolfram's design. Most of them measure marginal cost plant by plant. Several also observe the output and the bids of each firm. Kellogg and Reguant (2021, sec. 4.2) organize this literature around a single first-order condition. We derive it first, because it nests the pricing rules of this chapter. We then review the main findings.

The residual-demand first-order condition. Let market demand in period t be $D_t(P)$, and let each rival $j \neq i$ offer a supply schedule $S_{jt}(P)$. The *residual demand* of firm i is the demand left at price P once its rivals have supplied,

$$R_{it}(P) = D_t(P) - \sum_{j \neq i} S_{jt}(P). \tag{3.82}$$

Abstract from uncertainty and from the rule that offers must rise with price. Whatever schedule firm i submits, it ends up at some price on R_{it}, as in the proof of Proposition 3.42. Choosing a schedule is therefore equivalent to choosing a price on the residual demand curve (Kellogg and Reguant, 2021, pp. 691–692). Suppose the firm has sold x_{it} units forward at a fixed price F_{it}, as in Proposition 3.43. Its profit at price P is

$$\Pi_{it}(P) = P\, R_{it}(P) - C_{it}\big(R_{it}(P)\big) - (P - F_{it})\, x_{it}.$$

Differentiating with respect to P gives the first-order condition

$$R_{it}(P) + P\, R'_{it}(P) - C'_{it}\big(R_{it}(P)\big)\, R'_{it}(P) - x_{it} = 0.$$

Collect the two terms in $R'_{it}(P)$ and divide by $R'_{it}(P) < 0$:

$$P = C'_{it} - \frac{R_{it}(P) - x_{it}}{R'_{it}(P)}. \tag{3.83}$$

This is eq. (24) of Kellogg and Reguant (2021, p. 694). Without a forward position it reduces to their eq. (23), $P = C'_{it} - \frac{R_{it}(P)}{R'_{it}(P)}$ (p. 692). In equilibrium the firm produces $q_{it} = R_{it}(P)$. Define the elasticity of residual demand as $\varepsilon^R_{it} = -\frac{P\, R'_{it}(P)}{R_{it}(P)}$. Dividing (3.83) by P gives

$$\frac{P - C'_{it}}{P} = \frac{R_{it} - x_{it}}{-P\, R'_{it}} = \frac{1}{\varepsilon^R_{it}}\left(1 - \frac{x_{it}}{q_{it}}\right). \tag{3.84}$$

Holding the slope of residual demand fixed, a firm marks up more when its uncontracted output is larger.

Remark 3.45 (One condition, several pricing rules). Equation (3.83) nests the pricing rules derived earlier in the chapter.

(i) *Cournot rivals.* If rivals' outputs do not respond to price, $R'_{it} = D'_t$. Then $\varepsilon^R_{it} = -\frac{PD'_t}{Q_t} \cdot \frac{Q_t}{q_{it}} = \frac{\varepsilon}{s_{it}}$, and (3.84) becomes (3.78). With $x_{it} = 0$ it is the Cournot rule of Proposition 3.38.

(ii) *Supply function rivals.* If the rival's schedule slopes up, $R'_{it} = D'_t - S'_{jt}$. With one rival and $x_{it} = 0$, (3.83) is (3.75), and (3.84) is (3.76).

(iii) *Residual demand estimation.* With $x_{it} = 0$, the markup equals the inverse elasticity of residual demand, the object that Baker and Bresnahan (1988) estimate with firm-specific cost shifters (Section 3.4). In electricity markets rivals' bids are often observed, so the ex post residual demand can be computed instead of estimated (Kellogg and Reguant, 2021, p. 695).

(iv) *Net buyers.* If $x_{it} > q_{it}$, the firm's contract obligations exceed its output, so it is a net buyer at the spot price. The markup in (3.84) is then negative, and the firm may exercise monopsony power (Kellogg and Reguant, 2021, p. 694). It bids below marginal cost on the part of its schedule below x_{it} (Hortaçsu and Perrigne, 2021, p. 145).

California: Borenstein, Bushnell and Wolak (2002). Borenstein et al. (2002), BBW below, study the California wholesale market from 1998 to 2000, the run-up to the crisis of 2000 and 2001 in which prices soared. Several cost shocks hit the market in this period, among them a severe drought, higher prices for nitrogen oxide (NOx) emissions and higher natural gas prices. The authors therefore build a competitive benchmark price P_t^{comp} at the actual level of costs. In the benchmark every firm offers its output at marginal cost and water is allocated efficiently. They simulate plant outages by Monte Carlo methods and assign the limited hydroelectric supply to the hours in which it is most valuable. They also estimate the supply curve of imports, which provide about 25 percent of California's consumption. The Lerner index is then

$$L_t = \frac{P_t^{\text{obs}} - P_t^{\text{comp}}}{P_t^{\text{obs}}}$$

(Kellogg and Reguant, 2021, p. 693). This is Wolfram's direct measure, with the merit order replaced by a simulated competitive market.

The index was modest in 1998 and 1999 and rose sharply in 2000. Scarcity moved the market up its supply curve into the region where market power is greatest. The authors then decompose the rise in consumers' costs into higher production costs, higher competitive rents and higher market-power rents. Competitive rents can rise steeply along a convex supply curve, because low-cost plants are paid the marginal price. Even so, about 59 percent of the increase in costs between the summer of 1999 and the summer of 2000 is attributed to market power (p. 693). The benchmark involves no model of conduct, so it cannot say whether firms behaved as Cournot competitors or colluded (p. 694).

Firm conduct: Puller (2007). Puller (2007) asks which model of conduct fits the same California market. He estimates the pricing condition (3.83) of individual firms with $x_{it} = 0$, which is eq. (23) of Kellogg and Reguant (2021). He tests whether it is consistent with Cournot behavior. Cournot conduct corresponds to $\tilde{\theta}_{it} = 1$ in (3.71). The slope of residual demand comes from

the supply of fringe firms. He estimates its elasticity using forecast demand as the instrument. The condition also allows for capacity constraints, which can affect marginal cost (Kellogg and Reguant, 2021, p. 694). The *shadow value* of capacity is the extra profit that one more unit of capacity would earn. It adds to marginal cost when a plant runs at its limit. Before the crisis, pricing is consistent with Cournot. From June to November 2000, firms exercised more market power than Cournot predicts but stayed far from perfect collusion. Wolfram does not observe the output of each firm (Kellogg and Reguant, 2021, p. 693). Puller, by contrast, measures conduct at the level of the firm (Hortaçsu and Perrigne, 2021, p. 146). Kim and Knittel (2006) repeat the validation exercise for California from 1998 to 2000. Their direct measure is the elasticity-adjusted Lerner index. It combines the BBW marginal costs, capped at the price, with the residual demand elasticities estimated in the paper. The conduct estimates generally overstate market power and vary widely across demand specifications, while the direct measures barely change. The estimates also point to market power only in 2000. The direct elasticity-adjusted index, by contrast, varies little across the three years, although the unadjusted Lerner index rises markedly in 2000.

Forward positions: Bushnell, Mansur and Saravia (2008). The crisis did not spread to the other restructured markets. Natural gas prices also spiked in the eastern states, yet prices in New England and PJM rose much less. Bushnell et al. (2008), BMS below, ask whether forward positions explain the difference. A *forward position* is output committed at a preset price. It can be a physical contract, a contract for differences, or the retail sales of a vertically integrated firm at regulated retail prices. Its price must not depend on the spot market. In (3.83) such a position reduces the inframarginal quantity $R_{it} - x_{it}$ on which the firm gains from a higher price (Allaz and Vila, 1993). The authors assemble data on California, PJM and New England. Forward positions are observed through vertical arrangements, and they are zero in California. They compare three models: a competitive model in the spirit of BBW, a Cournot model that ignores forward positions, and a Cournot model with forward positions in the first-order condition.

The Cournot model with forward positions fits the observed prices well. The competitive model systematically underpredicts prices, and the Cournot model without vertical arrangements overstates market power (Kellogg and Reguant, 2021, pp. 694–695). Part of the overstatement comes from the Cournot assumption itself. Cournot rivals offer perfectly inelastic schedules, so they do nothing to flatten residual demand (n. 36). The absence of forward contracting can thus explain part of the California crisis. The contrast with Britain is instructive. There, contract cover fell by more than 20 percentage points in 1993 while markups barely moved (Section 3.8.5).

Bid data: Hortaçsu and Puller (2008). Electricity markets are typically organized as multi-unit uniform-price auctions. Researchers often observe each firm's bid schedule as well as its realized output (Kellogg and Reguant, 2021, p. 695). Hortaçsu and Puller (2008) use bids and measured marginal costs from the Texas spot market. Suppose uncertainty only shifts residual demand in parallel. Then the slope of residual demand at each price is enough to construct the optimal supply schedule, and the schedule is optimal ex post as well as ex ante (p. 695). Contract positions are unobserved, yet (3.83) reveals them. At the quantity where the bid schedule crosses marginal cost, $P = C'_{it}$, so $R_{it} = x_{it}$ (Kellogg and Reguant, 2021, p. 697). The crossing point of the two curves therefore identifies the contract position (Hortaçsu and Perrigne, 2021, p. 146, n. 24).

With costs and contracts in hand, the authors test whether bids are static best responses instead of assuming it. Large firms bid close to the profit-maximizing benchmark. Small firms submit supply schedules that are too inelastic and leave substantial profits unclaimed. The

finding is surprising, since small firms have less market power and should bid closer to marginal cost. The productive inefficiency that these inelastic bids create exceeds the inefficiency caused by market power (Hortaçsu and Perrigne, 2021, p. 146). Hortaçsu et al. (2019) rationalize the pattern with a level-k model of strategic sophistication. Level-0 bidders are not strategic, level-1 bidders best respond to level-0 bidders, and higher levels respond to the mix below them. The estimated levels line up with observable measures of the firms' experience (pp. 146–147).

Dynamic costs: Mansur (2008) and Reguant (2014). Most of these studies take marginal cost to be the fuel cost of the marginal unit, the simplification behind critique (2) of Section 3.8.7. Real plants face costs of ramping output up or down, technical minimum output levels and start-up costs (Kellogg and Reguant, 2021, p. 699). Three findings show that the omission matters. First, Bushnell et al. (2008) find markups that appear negative at night and attribute them to dynamic considerations. Second, Mansur (2008) studies PJM with a flexible model that predicts each plant's production from observables. A dynamic Bellman equation motivates the covariates, mostly lags and leads of price-cost margins. The model is fit to behavior before restructuring. A static cost benchmark implies that production costs after restructuring exceeded the competitive level by 13 to 21 percent. Against the flexible benchmark the excess is only 3 to 8 percent (p. 699).

Third, Reguant (2014) studies the Spanish market. There firms can submit "complementary" bids that state the minimum revenue a unit needs before it starts, and these bids identify start-up costs. A static analysis finds negative markups at night. Her dynamic model shows that pricing below marginal cost at night is optimal for competitive and strategic firms alike. Market power still raises prices in every hour. When demand peaks for only a few periods, few plants run and competition is limited, so a static model understates market power at the peak (pp. 699–700). Once start-up costs are accounted for, firms appear to have more market power (Hortaçsu and Perrigne, 2021, p. 147).

What the later studies add. These studies extend Wolfram's conclusions in four ways. First, cost-based benchmarks measure markups, but a model of conduct is needed to explain them. BBW measure the markup, while Puller and BMS test models of how it arose. Second, forward positions help explain market power in US markets, as Proposition 3.43 predicts, even though the British contract changes of 1993 did little. Third, observed bids and costs turn residual demand from an estimated object into data. Conduct then need not be assumed to identify the model (Kellogg and Reguant, 2021, p. 696). This removes much of the identification problem of Section 3.5 at the level of the firm, and it lets researchers test optimizing behavior instead of assuming it. Fourth, ignoring dynamic costs can mislead in either direction. It makes night-time markups look negative and peak markups too small, and it overstates the cost inefficiency of restructured markets.

3.9 Synthesis: what conduct parameters can and cannot tell us

This chapter has presented a sequence of methods for measuring market power in homogeneous-goods industries. Each method trades data requirements against maintained assumptions. This section compares the methods side by side, draws seven lessons from them, and sketches where the field has gone since.

3.9.1 The methods compared

Table 3.19 collects the approaches. The columns state what variation identifies each method, what it assumes, what it delivers, what its leading application found, and where it is weakest. The table complements the taxonomy of Table 3.1, which organizes the same methods by data requirements.

Table 3.19: Methods for measuring market power in homogeneous-goods industries compared

Method	Identifying variation	Maintained assumptions	Output	Main finding	Main weakness
Pass-through (Sumner, 1981), §3.2	Changes in state excise taxes	Tax exogenous, flat marginal cost, known demand curvature	Test of $\theta = 0$, and θ given curvature	$\hat{\rho} = 1.074$ rejects competition. θ of 0.02 to 0.06 for industry elasticities of 0.3 to 0.8	Identifies only $\theta(\chi - 1)$. Composition bias. Clustered errors much larger
Tax bounds (Sullivan, 1985; Ashenfelter and Sullivan, 1987), §3.3	Changes in taxes	Taxes trace out demand, nondecreasing cost	Upper bound on θ, local test of monopoly	Cartel pricing of cigarettes rejected	Inequalities only. State quantities noisy
Revenue test (Panzar and Rosse, 1987), §3.3.3	Factor prices across firms	Cost homogeneous in factor prices, long-run equilibrium	Sign of ψ	$\hat{\psi} > 0$ for newspapers, so monopoly rejected (Rosse and Panzar, 1977)	Every factor price needed. Oligopoly leaves ψ unsigned
Residual demand (Baker and Bresnahan, 1988), §3.4	Firm-specific cost shifters	Own shifters excluded from rivals' supply. Special conduct for a markup reading	Slope of one firm's residual demand	Inverse elasticities 0.745 (Coors), 0.058 (Pabst), 0.312 (Anheuser-Busch before 1975)	21 annual observations. Markup reading needs a conduct assumption
Demand rotation (Bresnahan, 1982; Lau, 1982), §3.5	Shifters that change the demand slope	Forms of demand and cost, constant θ	Point estimate of θ and of the cost slope	θ identified unless demand has a single index	Needs rotators. $\hat{\theta}$ is a slope when conduct varies
Observed cost: sugar (Genesove and Mullin, 1998), §3.7	Cuban imports, canning season, known technology	Fixed proportions, demand form	$\hat{\theta}$ against direct L_ε	Estimates 0.035 to 0.045 against direct 0.10	Cost parameters poorly recovered. Price wars read as cost drops
Observed cost: electricity (Wolfram, 1999), §3.8	Plant fuel costs, price cap, nuclear outages	Demand slope $D_p = -125$, fuel-only cost	θ_t each half-hour, a bound, and $\hat{\theta}$	L about 0.24 and θ 0.04 to 0.07, against 0.28 to 0.33 in the highest SFE. $\hat{\theta} = 0.012$ (0.044)	θ_t scales with the assumed slope. Static model

Notes: Our construction from Tables 3.2, 3.5, 3.12, 3.16 and 3.18. The Baker and Bresnahan figures are the absolute values of the estimated residual demand slopes. The sugar estimates are the NLIV estimates with both cost parameters free (Genesove and Mullin, 1995, Table 11).

3.9.2 Seven lessons

1. Without restrictions, conduct explains anything. Proposition 3.6 shows that a conduct parameter free to vary by observation fits any data exactly. Every method in the chapter buys empirical content with restrictions. Some hold conduct constant or constant within regimes. Others

bound it between zero and one, or fix it by a specific game. The question to ask of any estimate is which restriction delivered it.

2. Cost shocks bound conduct, demand rotations identify it. A market-wide cost shifter moves the supply relation along the demand curve. It therefore traces out demand and reveals conduct only through the response of price, which mixes conduct with curvature (Propositions 3.10 and 3.15). Such designs yield tests and bounds. A demand shifter traces out the supply relation but confounds conduct with the slope of marginal cost (Proposition 3.26). Only variation that changes the slope of demand, or two shifters that do not collapse to one index, separates the two (Proposition 3.28 and Theorem 3.30). Firm-specific cost shifters identify a single firm's residual demand instead.

3. Curvature and the slope of marginal cost are the recurring confounders. The same two unknowns reappear in every design. In the pass-through test, curvature χ and conduct enter only through $\theta(\chi - 1)$. With rising marginal cost, competitive pass-through falls below one. In the linear model, conduct and the slope of marginal cost enter only through $b_1 - \frac{\theta}{a_1}$. In the sugar study, exponential demand makes the price $c + \frac{\theta}{\lambda}$, so without the seasonal rotation of λ conduct cannot be separated from the non-sugar cost. Methods differ mainly in how they pin down these two objects: by assumption, by outside information, or by rotations.

4. Estimates track direct measures but understate them. Most estimates of conduct lie strictly between zero and one (Table 1.7). The two validation studies show what such numbers are worth. In sugar, constant-θ estimates of 0.035 to 0.045 compare with a direct measure of 0.10. In electricity, the rotation estimate of 0.012 compares with a direct value of 0.057 for the same year. The methods get the order of magnitude right and correctly reject monopoly and the static oligopoly benchmarks. They understate the level, as Corts (1999) predicts, and they recover cost parameters poorly.

5. Conduct varies, so a constant θ measures a slope. Conduct changes with price wars in sugar and with the regulatory calendar, the level of demand and the price cap in electricity. The half-hourly θ_t in Table 3.16 have standard deviations as large as their means. When conduct moves with the variables that identify it, an estimated constant θ measures how the markup responds at the margin, which need not equal its average level (Proposition 3.31). Bounds that allow conduct to vary freely within $[0, 1]$ avoid this problem at the cost of precision (Section 3.6.3).

6. A priori cost information is decisive. In sugar, when the researcher imposes constant costs, the estimates detect the fall in conduct during price wars. When non-sugar costs may also change in price wars, the same data attribute the wars to cost drops of 0.10 to 0.18. Conduct then falls by only 0.015 to 0.024 (Genesove and Mullin, 1995, Table 15). Costs were in fact constant. The data cannot separate a change in conduct from a change in cost unless the researcher knows something about cost. Electricity makes the same point from the other side. Once cost is measured, a single assumption about demand delivers conduct.

7. Low conduct in concentrated markets points to forces outside static models. Both validation studies find conduct far below what concentration suggests. A sugar industry dominated by a single trust behaved, on average, like a symmetric ten-firm Cournot industry. A duopoly facing an elasticity of 0.17 behaved like a twenty-firm one. The explanations lie outside the static model: the threat of entry and imports, the threat of regulation or antitrust action, and contracts. In US electricity markets, the absence of forward positions helps explain why California suffered more market power than New England or PJM (Section 3.8.8). This echoes Stigler (1964).

Structure alone does not determine conduct, and the forces that discipline prices must be studied directly.

3.9.3 Where the field went

Bresnahan (1989, pp. 1053–1054) surveyed the first wave of this research. He concluded that "although the NEIO has had a great deal to say about measuring market power, it has had very little, as yet, to say about the causes of market power." He called for work on entry, predation and long-run strategic competition. Four lines of research took up the methods and questions of this chapter.

First, conduct is now usually tested as a choice among a few discrete models within a differentiated-products demand system. Bresnahan (1987) compared collusion and competition in the 1955 automobile market (Chapter 6). Nevo (1998) extended the identification analysis to differentiated products, and Nevo (2001) compared the markups implied by alternative models of conduct with accounting margins for breakfast cereals (Chapter 8). Berry and Haile (2014, p. 1749) derived testable restrictions that discriminate among models of conduct in nonparametric models. They call these restrictions the first general formalization of the intuition of Bresnahan (1982). Backus et al. (2021a) and Duarte et al. (2024) developed formal tests of conduct based on the model-selection test of Rivers and Vuong (2002). Their instruments must move markups but not marginal cost, a set much broader than demand rotations (Backus et al., 2021a, p. 4). The rotation logic of Section 3.5 survives in these tests as a special case. Backus, Conlon and Sinkinson find that own-firm profit maximization fits ready-to-eat cereal better than pricing under common ownership. Duarte et al. (2024, p. 573) favor the model in which yogurt manufacturers set retail prices.

Second, explicit dynamic models of collusion replaced the static conduct parameter as the account of how firms sustain high prices. Price wars, monitoring and punishment are modeled directly (Chapter 12), and regime-switching estimators measure their incidence (Chapter 13). Third, merger simulation turned the estimated supply relation into a predictive tool. It estimates demand, backs out marginal cost from an assumed model of conduct, and solves for post-merger prices (Chapter 11). Fourth, the production approach recovers markups from cost minimization alone. A variable input's output elasticity divided by its revenue share equals the markup, with no assumption on demand or conduct (Hall, 1988; De Loecker and Warzynski, 2012). Applied to firm-level accounts, it underlies the recent evidence on rising markups (De Loecker et al., 2020), discussed in Chapter 1. Each line keeps the central insight of this chapter. Market power is measured industry by industry, and every estimate rests on explicit assumptions about demand, cost and conduct that the data alone cannot supply.

3.10 Bibliographic notes

Bresnahan (1989) remains the essential survey of the methods in this chapter. It states the supply relation, the identification arguments and the record of early estimates in one framework. Perloff et al. (2007) give a book-length treatment of the estimation of market power, and Reiss and Wolak (2007) use the conduct parameter to illustrate the logic of structural econometric models. The first studies to infer cost from pricing behavior include Rosse (1970) on newspapers and Iwata (1974) on conjectural variations. Gollop and Roberts (1979) and Appelbaum (1979, 1982) combined the supply relation with flexible cost functions.

Excise taxes were the first source of credible cost variation. Sumner (1981) introduced the

pass-through test, Sullivan (1985) turned it into a bound, and Ashenfelter and Sullivan (1987) recast it as a revealed-preference test. The theory of pass-through goes back to Bulow and Pfleiderer (1983). Weyl and Fabinger (2013) give the general treatment with conduct. Miller et al. (2017a) estimate pass-through of fuel costs above one in US portland cement and use it to measure the incidence of carbon pricing. Bergquist and Dinerstein (2020) estimate the effect of coordination among Kenyan maize traders from first-order conditions, with experimental instruments (Asker and Nocke, 2021, p. 214, n. 86). The revenue test of Panzar and Rosse (1987) was applied early to newspapers by Rosse and Panzar (1977) and to banking by Shaffer (1982). Residual demand estimation begins with Baker and Bresnahan (1985, 1988), and Scheffman and Spiller (1987) adapted it to the definition of antitrust markets.

The identification of conduct by demand rotations is due to Bresnahan (1982) and Lau (1982), with an early application on the buying side by Just and Chern (1980). Berry and Haile (2014) place the argument within the nonparametric identification of differentiated-products models. The modern practice of testing a menu of conduct models starts with Bresnahan (1987) and Nevo (1998, 2001) and continues in Backus et al. (2021a) and Duarte et al. (2024). The critique of Corts (1999) is the reference point for interpreting a conduct estimate, and Rosen (2007) develops the bounds that replace it when conduct varies. Stigler (1964) is the origin of the detection-based theory of collusion that Green and Porter (1984) formalized (Chapter 12).

Validation studies compare conduct estimates with direct measures. Genesove and Mullin (1998) for sugar and Wolfram (1999) for electricity are the classic pair. Clay and Troesken (2003) and Kim and Knittel (2006) extend the exercise to whiskey and to California electricity. Kellogg and Reguant (2021, sec. 4) survey the industrial organization of electricity markets, and Hortaçsu and Perrigne (2021, sec. 7) treat electricity markets as multi-unit auctions. Plant-level cost benchmarks became a standard tool for restructured markets (Kellogg and Reguant, 2021, p. 692), as in Borenstein et al. (2002). Puller (2007) tests the conduct of individual California firms, and Bushnell et al. (2008) show how forward positions shape market power across US markets. Wolfram (1998) and Hortaçsu and Puller (2008) use bid data to study strategic bidding directly, and Mansur (2008) and Reguant (2014) bring dynamic production costs into the measurement of markups. The production approach of Hall (1988) and De Loecker and Warzynski (2012) measures markups without a model of demand or conduct. De Loecker et al. (2020) apply it to the long-run evolution of markups.

3.11 Exercises

1. *Choosing a method.* The campus coffee shop of Chapter 1 is the only seller of coffee in its building.

   (a) Suppose a researcher observes only its daily prices. Which method of this chapter, if any, can say something about its market power? State the maintained assumptions.

   (b) Suppose a researcher observes prices and quantities, and a city tax of 10 cents per cup is introduced midway through the sample. Explain what the price response reveals under Proposition 3.10. Which outcome would reject competition, and which would be consistent with any conduct?

   (c) Suppose that during examination weeks the shop's customers are mostly students working late, who are less price sensitive than the daytime crowd. Explain why this is a candidate demand rotator. State the exclusion restriction it must satisfy, and give one reason it might fail.

(d) Suppose a rival cafe opens next door. Can the change in the shop's price separate a change in conduct from a change in the shop's residual demand? Relate the answer to Section 3.4.

2. *Ad valorem taxes.* A tax at rate τ is levied on the consumer price, so firms receive $(1-\tau)P$ per unit. Marginal cost c is constant and conduct θ does not depend on τ.

(a) Write the supply relation with the tax. Show that under constant-elasticity demand $P = \frac{\varepsilon}{\varepsilon-\theta} \cdot \frac{c}{1-\tau}$.

(b) Show that $\frac{\mathrm{d}\ln P}{\mathrm{d}\tau} = \frac{1}{1-\tau}$ for every θ. Explain why a regression of $\ln P$ on $-\ln(1-\tau)$ with market fixed effects cannot reveal conduct under constant elasticity.

(c) Under linear inverse demand $P = A - BQ$, show that $P = \frac{\theta A + \frac{c}{1-\tau}}{1+\theta}$ and $\frac{\mathrm{d}P}{\mathrm{d}\tau}\big|_{\tau=0} = \frac{c}{1+\theta}$. Why does the response depend on the level of cost, and what extra information would a researcher need to recover θ from it?

3. *Curvature and the pass-through test.* Let inverse demand be the power family $P = a - bQ^{\gamma}$, with $b\gamma > 0$, and let marginal cost be flat.

(a) Derive $\rho(\theta) = \frac{1}{1+\theta\gamma}$ directly from the supply relation, without using Proposition 3.8.

(b) Show that for $\gamma > 0$ every $\theta > 0$ gives $\rho < 1$, so a test of $\rho = 1$ against $\rho > 1$ never rejects competition. For which (θ, γ) is the estimate $\hat{\rho}$ closest to one?

(c) Let $\gamma < 0$ and $b < 0$. Show that $\rho > 1$, provided the stability condition $1 + \theta\gamma > 0$ holds. Compute the conduct implied by $\hat{\rho} = 1.075$ when $\gamma = -0.5$ and when $\gamma = -0.07$, and relate the two answers to Figure 3.2.

(d) Show that log demand $P = a_0 - b_0 \ln Q$ is the limit of this family as $\gamma \to 0$ with $b\gamma = b_0$ and $a - b = a_0$ held fixed. Deduce that log demand makes every conduct look competitive in a pass-through test.

4. *Observational equivalence and rotation.* Use the linear example of Section 3.5.1.

(a) Verify that the competitive model ($MC^c = 2 + 1.1Q$) and the monopoly model ($MC^m = 2 + 0.1Q$) both produce $E_1 = (3.81, 6.19)$ under D_1 and $E_2 = (4.76, 7.24)$ under D_2.

(b) Let inverse demand have slope $-s$ and let the competitive marginal cost have slope b_1^c. Find the marginal cost slope that makes a monopolist observationally equivalent. When is it nonnegative?

(c) Rotate demand through E_1 to D_4: $P = 8.476 - 0.6Q$. Check that D_4 passes through E_1, and compute the competitive and the monopoly equilibria.

(d) Repeat (c) for $\theta = 0.25$, with the marginal cost slope chosen to fit E_1 and E_2. Verify that (3.40) recovers $\theta = 0.25$ from the response of quantity.

5. *Lau's condition in two demand systems.* Use Theorem 3.30.

(a) Let demand be $Q = Y\,h(P)$ with h decreasing. Show that inverse demand has a single index. For a given $\theta' \geq 0$, construct the marginal cost function that rationalizes the data, following the proof of part (i).

(b) Let demand be $Q = Y_1 P^{-\varepsilon(Y_2)}$, with $\varepsilon(\cdot)$ positive and differentiable. Show that the Jacobian of (f, f_Q) with respect to (Y_1, Y_2) has determinant $\frac{f^2\,\varepsilon'(Y_2)}{\varepsilon(Y_2)^3\,Q\,Y_1}$, where f is inverse demand.

(c) Interpret the condition $\varepsilon'(Y_2) \neq 0$. Give an economic example of a variable that could play the role of Y_2 in a homogeneous-goods market.

6. *Varying conduct and the instrumental-variables estimand.* Demand takes a low and a high state with equal probability. The instrument Z_t is an indicator of the high state, and the markup term is m_L or $m_H > m_L$. Conduct is $\theta_t = \vartheta_0 - \vartheta_1 m_t$ with $\vartheta_1 > 0$, and marginal cost is constant with an unknown level.

   (a) Show that the estimand of Proposition 3.31 is $\vartheta_0 - \vartheta_1(m_L + m_H)$, while average conduct is $\vartheta_0 - \frac{\vartheta_1}{2}(m_L + m_H)$.

   (b) Evaluate both for $\vartheta_0 = 1$, $\vartheta_1 = 0.2$, $m_L = 1.5$ and $m_H = 4$. When is the estimand negative in general?

   (c) Explain how the same mechanism produces a negative estimate in the Bertrand supergame of Section 3.6.2 at $\delta = 0.51$. Which feature of that model plays the role of $\vartheta_1 > 0$?

7. *The sugar rotation.* Use the linear demand estimates of Tables 3.9 and 3.10, with choke prices $\alpha_L = 5.82$ and $\alpha_H = 7.91$.

   (a) Write $P^M(c)$ and $P(c;\theta)$ for each season. Compute the predicted high-season rise in price at a given marginal cost for $\theta \in \{0, 0.1, 1\}$.

   (b) Suppose the observed high-season rise at a given raw sugar price were 12 cents. Back out θ and compare it with the direct measure of 0.10 and with the estimate of Section 3.7.6.

   (c) With $k = 1.075$ imposed, predict the change in the refined price after a 40-cent fall in the raw sugar price within one season, under $\theta = 0.1$. Compare the prediction with those under competition and monopoly.

   (d) Suppose true conduct is 0.10 in the low season and 0.07 in the high season. Using the season mean prices of Table 3.8, compute the estimand of Proposition 3.37. Explain the result with Proposition 3.31.

8. *Electricity, contracts and supply functions.* Let the market elasticity be $\varepsilon = 0.17$.

   (a) Compute the Cournot Lerner index of firms with shares 0.5 and 0.3. Explain what the numbers imply about the existence of an interior equilibrium.

   (b) Repeat (a) with contract cover of 85 percent and of 50 percent, using (3.78). Compare the results with the observed average Lerner index of about 0.24.

   (c) With cover of 85 percent and a share of 0.5, what elasticity would make the Cournot Lerner index equal 0.24?

   (d) In a symmetric duopoly supply function equilibrium, find the elasticity η_j of the rival's supply that yields a Lerner index of 0.24 under (3.76). Is that elasticity plausible near the flat coal segment of the merit order?

   (e) A generator faces residual demand $R(P) = 20 - 2P$ and has constant marginal cost 4. It holds a forward position x. Use (3.83) to find its price and output when $x = 0$ and when $x = 6$. For which x does it price below marginal cost? Relate the answer to Remark 3.45.

(f) Discuss which forces outside these models could discipline prices, and what data would distinguish them.

Chapter 4

Oligopoly with Differentiated Products

Breakfast cereals, automobiles, airline tickets and prescription drugs are each sold by a handful of firms. Each firm offers several products, and consumers do not regard any two of them as perfect substitutes. Markets like these are the main subject of empirical industrial organization. The tools of Chapters 2 and 3 were built for a homogeneous good, with one price, an obvious set of competitors and a single conduct parameter. With differentiated products every product has its own price, and the boundary of the market is a matter of degree. Market power then depends on the whole matrix of own and cross price effects. This chapter develops the theory of price competition in such markets. It also assembles the toolkit that later chapters use to measure market power, simulate mergers and value new goods.

The organizing object is the first-order condition of a multi-product firm. It links the demand system, the ownership of products, prices and marginal costs. In matrix form it inverts into the markup formula $p = mc - (\Omega \odot \Delta^\top)^{-1} q$. The *ownership matrix* Ω records which products each firm prices jointly, and Δ collects the price derivatives of demand. Almost every empirical model in this book closes its supply side with this formula. Once demand has been estimated, the formula recovers marginal costs without accounting data. Changing Ω or costs and solving the formula again yields counterfactual prices after a merger, a tax or the entry of a product.

The chapter has two halves. The first takes demand as given and studies the supply side. Section 4.1 explains why differentiation is the normal case and which questions require a demand system. Section 4.2 derives the multi-product Bertrand-Nash pricing conditions, inverts them for markups and works through linear and logit examples. Section 4.3 rewrites the pricing rule in terms of diversion ratios, the quantities that govern the unilateral effects of mergers. Section 4.4 asks when a price equilibrium exists, when it is unique and what happens when it is not, with a full treatment of the existence theorem of Caplin and Nalebuff (1991). Section 4.5 puts the pricing rule to work. It recovers marginal costs, compares models of conduct, computes counterfactuals and derives pass-through.

The second half turns to the choice of demand system. Section 4.6 contrasts demand written over products with demand written over product characteristics, and it shows how the dimension of the characteristics space shapes competition. Section 4.7 studies the linear, constant elasticity of substitution (CES) and logit systems, which tame the dimensionality of product space by imposing symmetry. It derives their representative-consumer and discrete-choice foundations, the theme of the book by Anderson et al. (1992). A two-sector CES model of monopolistic competition then asks whether markets supply the right number of products. Section 4.8 develops the location models of Hotelling (1929) and Salop (1979), a symmetric oligopoly with i.i.d. tastes and the vertical model of quality choice. These models add product

choice and entry to price competition. They also show when free entry yields too many products.

A simulated market of 25 logit products owned by five firms runs through the chapter. We compute its equilibrium in Example 4.8 and verify that the equilibrium is unique in Example 4.26. We then recover its costs under alternative models of conduct (Example 4.29) and simulate a merger in it (Example 4.36). Two smaller examples recur as well. A linear duopoly has closed-form solutions (Example 4.6), and a logit duopoly with two consumer segments has two equilibria (Example 4.27).

The chapter builds on Chapter 2, whose monopoly pricing rule, Bertrand paradox and pass-through formulas reappear here product by product. It replaces the conduct parameter of Chapter 3 with an ownership matrix and shows how the two are related (Remark 4.33). The rest of the book uses its results throughout. The demand systems of Chapters 5 to 8 supply the derivatives in Δ, and Chapters 8 and 9 estimate demand and costs together. Upward pricing pressure and merger simulation in Chapter 11 apply Sections 4.3 and 4.5 directly. Full collusion corresponds to a matrix Ω of ones, the benchmark of Chapter 12. Appendix B collects the contraction mapping and implicit function theorems used in the proofs, and Appendix C returns to the 25-product market as a worked problem.

4.1 Why product differentiation matters

This section explains why differentiation is the normal case, which economic questions it raises, and how theory and empirical work divide the resulting problem between them.

4.1.1 Differentiation is the rule

Products are *differentiated* when consumers do not regard them as perfect substitutes. Products differ in physical characteristics (horsepower, sugar content, screen size) and in location (a gasoline station on one corner or the next). They also differ in brand and reputation, in the service that comes with them, and in timing (a morning or an evening flight). Two consumers facing the same prices often buy different products. The same consumer may switch products when relative prices change, but not all of her demand moves at once.

Differentiation appears even in markets that look homogeneous. A branded drug and its generic version are chemically identical, yet the branded version keeps a large share at a much higher price. Gasoline is a standardized commodity, yet stations differ in location, brand and amenities, and nearby stations compete far more intensely than distant ones. Near-homogeneous markets exist, but they are rare. Wholesale electricity and refined sugar are two examples, and they are the settings of Wolfram (1999) and Genesove and Mullin (1998), studied in Chapter 3.

Differentiation changes the objects that describe a market. Let $q_j(p)$ be the demand for product j as a function of the whole price vector $p = (p_1, \ldots, p_J)^\top$. Three consequences follow.

(i) There is no single market price. There is a vector of prices, one for each product, and these prices can differ persistently.

(ii) There is no natural boundary of the market. Every product substitutes for many others to some degree, so the set of "competitors" is a matter of degree.

(iii) The own-price elasticity of product j,

$$\varepsilon_j(p) = -\frac{\partial q_j(p)}{\partial p_j}\frac{p_j}{q_j(p)},$$

depends on rivals' prices and on how close rival products are in the eyes of consumers. Market power is no longer summarized by one elasticity. It depends on the whole matrix of own and cross effects.

Differentiation also resolves a puzzle from Chapter 2. With a homogeneous good, two price-setting firms with equal constant costs drive price down to marginal cost (Proposition 2.48). The reason is that a small price cut captures the whole market, so demand is discontinuous in prices. With differentiated products a small price cut attracts only the marginal consumers, demand is continuous, and price competition among a few firms leaves positive margins.

4.1.2 Questions that require a demand system

A *demand system* is the vector of demand functions $q(p, z) = (q_1(p, z), \ldots, q_J(p, z))^\top$ for all J products, as functions of all prices p and of demand shifters z (characteristics, income, season). Many central questions of industrial organization cannot be answered without one. Table 4.1 lists five of them with the object each requires. We discuss each in turn.

Table 4.1: Questions about differentiated-product markets and the demand objects they require

Question	Demand object required	Treated in
Measuring market power	Own and cross price derivatives at observed prices, plus a model of price setting	Sections 4.2 and 4.5
Welfare effects of mergers	Diversion between the merging products and their margins, or the full system for simulation	Section 4.3, Chapter 11
Effects of taxes and tariffs	Pass-through, which depends on second derivatives of demand and on strategic responses	Proposition 4.38, Chapter 2
Product introduction and positioning	Demand for products not yet sold, so tastes over characteristics	Sections 4.6 and 4.8
Welfare from new goods and price indices	Demand far from observed prices, up to the price at which demand for the new good is zero	Chapter 10

Measuring market power. Accounting data rarely measure marginal cost (Chapter 1). The approach of the New Empirical Industrial Organization (Bresnahan, 1989) infers markups from behavior instead. With differentiated products this requires the own and cross price derivatives of demand at observed prices and a model of how firms set prices. Given both, Section 4.2.3 shows that markups follow from a matrix inversion, and Section 4.5 turns them into estimates of marginal cost.

Mergers. A merger of two sellers of substitutes raises prices when the merged firm internalizes the sales that each product loses to the other. The size of this effect depends on the share of one product's lost customers who would switch to the other, a quantity called the diversion ratio (Section 4.3). It also depends on the margins earned on those customers. Predicting post-merger prices requires the full demand system and a model of supply (Section 4.5.4, Chapter 11).

Taxes and tariffs. The incidence of a tax or tariff depends on how much of a cost increase firms pass on to prices. In Chapter 2 pass-through depends on the curvature of demand. With

differentiated products it also depends on how rivals respond to one another's price changes. This requires second derivatives of the demand system (Proposition 4.38).

Product introduction. Whether a firm should launch a new product depends on how many sales the product takes from rivals and how many it takes from the firm's own products. Answering this before launch requires a model that predicts demand for a product nobody has bought yet. This pushes us toward demand defined over product characteristics (Section 4.6) and toward models of product choice (Section 4.8).

New goods and price indices. A consumer price index that ignores new goods overstates the increase in the cost of living. Valuing a new good requires the price at which its demand would be zero, the *virtual price*, and the area under the demand curve above the observed price. Hausman (1997) computes it for a new breakfast cereal from an estimated demand system (Chapter 10). The calculation extrapolates demand far from observed prices, so it depends heavily on functional form.

4.1.3 Demand systems and market definition

In a homogeneous-good industry the market is the set of sellers of the identical good, and concentration measures such as the Herfindahl index $HHI = \sum_i s_i^2$ are computed on it (Chapter 1, Section 2.1.2). With differentiated products this boundary does not exist, yet antitrust practice still needs one. Agencies and courts draw it with the *hypothetical monopolist test*. Imagine a profit-maximizing firm that owned every product in a candidate set. The set is a relevant market if this firm would impose a *small but significant and non-transitory increase in price* (SSNIP) on at least one of them. The SSNIP is usually taken to be 5 or 10 percent (Farrell and Shapiro, 2010, footnote 58). Page, footnote and inequality numbers for Farrell and Shapiro (2010) refer to its 2008 working-paper version. Starting from the products of the merging firms, the analyst adds the next-closest substitutes until the test is passed (Section 11.2.1).

Whether a SSNIP is profitable is a question about the demand system. When the hypothetical monopolist raises the price of one product in the set, some of the lost customers switch to other products in the set and are recaptured. The test therefore depends on own and cross elasticities or, equivalently, on diversion ratios. Let the price rise by a fraction X, let $\bar{m} = \frac{p-mc}{p}$ be the percentage margin, and let ℓ be the fraction of unit sales lost (both symbols are local to this subsection). Profit per dollar of initial revenue moves from $\bar{m}$ to $(X + \bar{m})(1 - \ell)$. The increase is unprofitable exactly when

$$\begin{aligned}(X + \bar{m})(1 - \ell) < \bar{m} &\iff X - (X + \bar{m})\,\ell < 0 \\ &\iff \ell > \frac{X}{X + \bar{m}}.\end{aligned}$$

The threshold $\frac{X}{X+\bar{m}}$ is the *break-even loss*, the largest loss of sales that leaves the increase profitable. With $X = 0.05$ and $\bar{m} = 0.45$ it equals $\frac{0.05}{0.50} = 0.10$. High margins make the break-even loss small. Section 11.2.2 derives the actual loss from demand, compares the two numbers and explains why high margins can make the test misleading.

A fully specified demand system makes market definition a by-product. Once we know how each price affects each quantity, we can compute the price effects of a merger directly. Upward pricing pressure needs only diversion ratios and margins (Section 4.3). Merger simulation solves for the new equilibrium (Section 4.5.4, Chapter 11). Neither requires a decision about which products are "in" the market.

Concentration still plays a central role in practice. The 1992 Horizontal Merger Guidelines (U.S. Department of Justice and Federal Trade Commission, 1992) set a presumption in Section 1.51(c), which Farrell and Shapiro (2010, p. 26) quote. When the post-merger HHI exceeds 1800, a merger that raises the HHI by more than 100 points is presumed likely to create or enhance market power or facilitate its exercise. A merger of two of seven symmetric firms raises the HHI from 1,429 to 1,837 and so meets this presumption (same page). The 2010 Horizontal Merger Guidelines (U.S. Department of Justice and Federal Trade Commission, 2010) keep safe harbors and presumptions of harm that depend on both the post-merger HHI and its change (Asker and Nocke, 2021, p. 226). Chapter 11 compares the thresholds of the 1992 and 2010 Guidelines and of the 2023 Merger Guidelines (U.S. Department of Justice and Federal Trade Commission, 2023) in Table 11.4, and it studies how well such screens predict merger effects.

4.1.4 How theory and empirical work divide the problem

The theory of imperfect competition began with homogeneous goods. Cournot (1838) solved for the equilibrium outputs of firms producing an identical good. Bertrand (1883) objected that price is the natural strategic variable, and with identical goods price competition drives price to marginal cost. Edgeworth (1897) showed that capacity constraints can destroy the existence of a pure-strategy price equilibrium. Hotelling (1929) then argued that imperfect substitutability softens price competition, because a firm does not take all its rivals' business by undercutting slightly. His model of firms located along a street is the first model of product differentiation. It also exposed the main technical difficulty of the field. A firm may prefer either a high price aimed at the consumers who like its product most or a low price aimed at the mass market to any intermediate price. Profit is then not *quasi-concave* in own price, meaning that its upper contour sets are not intervals. A pure-strategy price equilibrium can then fail to exist (Caplin and Nalebuff, 1991, pp. 1–3 of the discussion-paper version).

The theory of differentiated products that grew from these beginnings studies mainly the supply side. Given a demand system, which prices and which products arise in equilibrium? Representative contributions are the discrete-choice foundations of Anderson et al. (1992), the models of quality competition of Shaked and Sutton (1982, 1983), and the existence results of Caplin and Nalebuff (1991). This theory has two branches. The first studies price competition among a given set of products. Caplin and Nalebuff provide conditions for existence of equilibrium that cover a wide class of demand models (Section 4.4). The second studies competition in product space, in which firms choose locations or qualities, with or without subsequent price competition. Examples are Hotelling's line, the circle of Salop (1979), and quality ladders. Empirical work concentrates almost entirely on the first branch. We study the second in Section 4.8, and much room remains for empirical work on it.

Empirical work, in turn, concentrates on the demand side. There are three reasons. Prices, quantities and product characteristics are observed far more often than costs, so the data speak most directly to demand. The supply model can be general, because the same pricing rule applies across industries once demand is known. And demand for differentiated products is complex enough to absorb most of the modeling effort. The supply side is therefore modeled simply, almost always as the static multi-product Bertrand-Nash game of Section 4.2. This is why we develop supply first. It is nearly identical across applications, and it shows which features of demand matter for the questions of Section 4.1.2.

In some industries demand is the natural object even without a supply model. Electricity distribution, water, postal services and parts of health care set prices through regulation or other non-market mechanisms. Price there is a policy choice rather than an equilibrium

outcome. To evaluate a change in a regulated price we need the demand response and the resulting change in consumer welfare, but no model of price setting.

Demand aggregates the choices of many individuals, and each of us can introspect about our own choices. This invites ever richer models: more heterogeneity, more characteristics, more realistic substitution. We should resist the pull and treat added richness as an investment with costs and benefits. Richer models carry more assumptions, which are harder to test. They are harder to compute and to estimate reliably. They are also harder to communicate to the courts, agencies and managers who use the results.

The benefit of richness is what it buys for the question at hand. If a richer model changes the answer to the question we are asking, and the data can discipline its extra parameters, the cost is worth paying. If the added value is small, a simpler and less realistic model can be the better tool. A model should always be judged against the question it is meant to answer and the data available to answer it. This principle guides the choices among demand models in the remainder of the book. The rest of this chapter follows the division just described: supply first (Sections 4.2 to 4.5), then the choice of demand system (Sections 4.6 to 4.8).

4.2 Multi-product Bertrand-Nash pricing

This section develops the supply model that every later chapter uses. Firms own several products and set all their prices simultaneously, taking rivals' prices as given. We derive the first-order conditions, write them in matrix form, invert them for markups, and work through linear and logit examples. The section ends with a numerical market of 25 logit products that we revisit later in the book.

4.2.1 Environment and equilibrium

Assumption 4.1 (Multi-product price competition)**.**

(a) *Products.* There are J inside products, $j = 1, \dots, J$, and an outside good $j = 0$ whose price is normalized to zero.

(b) *Ownership.* There are F firms. Firm f owns the set of products $\mathcal{J}_f$, the sets $\mathcal{J}_1, \dots, \mathcal{J}_F$ partition $\{1, \dots, J\}$, and $f(j)$ denotes the owner of product j.

(c) *Demand.* Demand for product j is $q_j(p) = M s_j(p)$, with market size M and share $s_j(p)$. On an open set $\mathcal{P}$ of price vectors each q_j is twice continuously differentiable and positive, $\frac{\partial q_j}{\partial p_j} < 0$, and $\frac{\partial q_k}{\partial p_j} \geq 0$ for all $k \neq j$, including the outside good. Products are *gross substitutes*.

(d) *Costs.* Product j has a cost function $C_j(q_j)$ that is increasing and differentiable, with marginal cost $mc_j(q_j) = C_j'(q_j)$. Costs are separable across products.

(e) *Timing and information.* Firms know demand and costs. They choose prices simultaneously, once, and then serve all the demand at those prices.

We write $p_{\mathcal{J}_f}$ for the vector of firm f's prices and $p_{-\mathcal{J}_f}$ for the prices of all other products. Firm f's profit is

$$\pi_f(p) = \sum_{k \in \mathcal{J}_f} \Big[p_k \, q_k(p) - C_k\big(q_k(p)\big) \Big]. \tag{4.1}$$

Definition 4.2 (Bertrand-Nash equilibrium)**.** The *best response* of firm f to rivals' prices is the set $BR_f(p_{-\mathcal{J}_f}) = \arg\max_{p_{\mathcal{J}_f}} \pi_f(p_{\mathcal{J}_f}, p_{-\mathcal{J}_f})$. A price vector p^* is a *Bertrand-Nash equilibrium* if, for every firm f and every $p_{\mathcal{J}_f}$,

$$\pi_f\left(p^*_{\mathcal{J}_f}, p^*_{-\mathcal{J}_f}\right) \geq \pi_f\left(p_{\mathcal{J}_f}, p^*_{-\mathcal{J}_f}\right).$$

Equivalently, $p^*_{\mathcal{J}_f} \in BR_f(p^*_{-\mathcal{J}_f})$ for every f, so p^* is a fixed point of the joint best-response map.

Is price setting a sensible description of conduct? In many differentiated-product markets firms post prices and then sell whatever consumers demand at those prices. Cars, consumer electronics and breakfast cereals fit this description. Differentiation also removes the Bertrand paradox of Proposition 2.48, so the model predicts positive margins with few firms. With differentiated products, price and quantity competition lead to different outcomes, and price competition yields lower prices when the goods are substitutes (Singh and Vives, 1984).

The model fits less well when firms commit to capacity before they set prices and capacity binds. Proposition 2.52 shows, following Kreps and Scheinkman (1983), that capacity choice followed by price competition can reproduce Cournot outcomes with a homogeneous good. The right model then depends on the timing of commitments and on whether capacity is slack. The model is also static. It ignores repeated interaction, which can sustain higher prices (Chapter 12), and it ignores costs of adjusting prices.

Assuming Bertrand-Nash conduct is a choice of the analyst. Chapter 3 treated conduct as an unknown parameter θ to be estimated. The differentiated-products literature instead imposes Nash pricing and spends its identifying power on demand. The assumption can still be tested. Alternative models of conduct correspond to alternative ownership matrices in the pricing equations below, and Section 4.5 compares them.

4.2.2 The first-order conditions

We derive the first-order condition of firm f for the price of one of its products, p_j with $j \in \mathcal{J}_f$. Rivals' prices are held fixed, as the Nash assumption requires. Write the profit (4.1) with the summation index k, so that j is free to denote the price being changed. Profit is a sum of revenue terms $p_k q_k(p)$ and cost terms $C_k(q_k(p))$. The product rule applied to a revenue term gives

$$\frac{\partial}{\partial p_j}\left[p_k\, q_k(p)\right] = \mathbf{1}\{k = j\}\, q_k(p) + p_k \frac{\partial q_k(p)}{\partial p_j},$$

because p_k depends on p_j only when $k = j$. The chain rule applied to a cost term gives

$$\frac{\partial}{\partial p_j} C_k\left(q_k(p)\right) = mc_k(q_k) \frac{\partial q_k(p)}{\partial p_j}.$$

Summing over $k \in \mathcal{J}_f$ and subtracting the cost terms from the revenue terms,

$$\frac{\partial \pi_f(p)}{\partial p_j} = q_j(p) + \sum_{k \in \mathcal{J}_f} p_k \frac{\partial q_k(p)}{\partial p_j} - \sum_{k \in \mathcal{J}_f} mc_k(q_k) \frac{\partial q_k(p)}{\partial p_j}.$$

Collecting the two sums and setting the derivative to zero gives the first-order condition

$$q_j(p) + \sum_{k \in \mathcal{J}_f} \left(p_k - mc_k\right) \frac{\partial q_k(p)}{\partial p_j} = 0, \qquad j \in \mathcal{J}_f. \tag{4.2}$$

We call $m_j = p_j - mc_j$ the (dollar) *markup* of product j and $m = (m_1, \dots, m_J)^\top$ the vector of markups. Separating the term $k = j$ from the others, (4.2) reads

$$\underbrace{q_j}_{\text{inframarginal gain}} + \underbrace{m_j \frac{\partial q_j}{\partial p_j}}_{\text{lost margin}} + \underbrace{\sum_{k \in \mathcal{J}_f \setminus \{j\}} m_k \frac{\partial q_k}{\partial p_j}}_{\text{recaptured margin}} = 0.$$

Each term has an economic meaning. A one-dollar increase in p_j earns one more dollar on each of the q_j units still sold. It loses the margin m_j on each of the $-\frac{\partial q_j}{\partial p_j}$ buyers who stop buying product j. Some of those buyers switch to the firm's other products, and the firm earns m_k on each of the $\frac{\partial q_k}{\partial p_j}$ who switch to product k. A single-product firm has no third term. A multi-product firm internalizes the *cannibalization* among its own products, so the third term makes raising p_j more attractive.

There is one condition per product, so (4.2) is a system of J equations in the J prices. The conditions are necessary for an interior equilibrium. They are sufficient when each firm's profit is concave in its own prices, or quasi-concave with a nonzero gradient at every price that is not a maximizer. We assume this here. Section 4.4 studies when it holds and what can go wrong. Dividing (4.2) by the market size M gives the same condition in shares, $s_j + \sum_{k \in \mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} = 0$. With constant marginal costs, equilibrium markups therefore do not depend on market size.

4.2.3 Matrix form and the markup equation

Stacking the J conditions gives a compact form that is easy to compute with. Three objects are needed.

- The *ownership matrix* Ω is the $J \times J$ matrix with $\Omega_{jk} = 1$ if products j and k have the same owner, $f(j) = f(k)$, and $\Omega_{jk} = 0$ otherwise. In particular $\Omega_{jj} = 1$.
- The *demand Jacobian* Δ is the $J \times J$ matrix with (j, k) element $\Delta_{jk} = \frac{\partial q_j}{\partial p_k}$. Its row j collects the effects of all prices on product j's demand. Its column j collects the effects of p_j on all demands.
- The *element-wise* (Hadamard) *product* of two matrices of the same size is $(A \odot B)_{jk} = A_{jk} B_{jk}$.

The (j, k) element of $\Omega \odot \Delta^\top$ is

$$\left(\Omega \odot \Delta^\top\right)_{jk} = \Omega_{jk} \Delta_{kj} = \Omega_{jk} \frac{\partial q_k}{\partial p_j}.$$

Row j of the product of this matrix with the markup vector is therefore

$$\left[\left(\Omega \odot \Delta^\top\right)(p - mc)\right]_j = \sum_{k=1}^{J} \Omega_{jk} \frac{\partial q_k}{\partial p_j}(p_k - mc_k) = \sum_{k \in \mathcal{J}_{f(j)}} (p_k - mc_k) \frac{\partial q_k}{\partial p_j},$$

because Ω_{jk} keeps exactly the products owned by $f(j)$. Adding q_j gives the left side of (4.2). The J first-order conditions are therefore

$$q + \left(\Omega \odot \Delta^\top\right)(p - mc) = 0. \tag{4.3}$$

When $\Omega \odot \Delta^\top$ is nonsingular we can solve for the markups,

$$p = mc - \left(\Omega \odot \Delta^\top\right)^{-1} q. \tag{4.4}$$

Price equals marginal cost plus a markup, and the markup vector is $m = -(\Omega \odot \Delta^\top)^{-1} q$. In shares, $q = Ms$ and $\Delta = M\Delta^s$ with $\Delta^s_{jk} = \frac{\partial s_j}{\partial p_k}$, so the market size cancels and $m = -(\Omega \odot \Delta^{s\top})^{-1} s$.

Equation (4.4) is not a closed form for equilibrium prices, because q and Δ depend on p. It is a fixed-point condition that equilibrium prices satisfy. At observed prices and quantities, however, it gives markups directly once the derivatives of demand are known. This is the basis of cost recovery in Section 4.5.

Remark 4.3 (Element-wise versus matrix product, and special cases). The element-wise product is essential. The ordinary matrix product $\Omega\Delta^\top$ would add up derivatives across products owned by the same firm and has no economic meaning. Three ownership structures are useful benchmarks.

(i) Single-product firms: $\Omega = I_J$, the identity, so $\Omega \odot \Delta^\top$ is the diagonal matrix of own-price derivatives.

(ii) Monopoly, or full collusion among all firms: $\Omega = \mathbf{1}\mathbf{1}^\top$, a matrix of ones, so $\Omega \odot \Delta^\top = \Delta^\top$.

(iii) A merger of firms f and g switches the entries Ω_{jk} with $j \in \mathcal{J}_f$ and $k \in \mathcal{J}_g$ (and their mirror images) from 0 to 1.

If products are ordered by owner, Ω is block diagonal, and so is $\Omega \odot \Delta^\top$. The markup equation then splits into one block per firm, $m_{\mathcal{J}_f} = -[(\Delta^\top)_{\mathcal{J}_f\mathcal{J}_f}]^{-1} q_{\mathcal{J}_f}$, where $(\Delta^\top)_{\mathcal{J}_f\mathcal{J}_f}$ keeps the rows and columns of $\Delta^\top$ in $\mathcal{J}_f$. Given prices, each firm's markups depend only on the demand derivatives among its own products.

Remark 4.4 (When is the demand Jacobian symmetric?). The transpose in (4.3) matters only when Δ is not symmetric. Some texts write $(\Omega \odot \Delta)^{-1}$ in place of $(\Omega \odot \Delta^\top)^{-1}$, which is correct whenever $\frac{\partial q_j}{\partial p_k} = \frac{\partial q_k}{\partial p_j}$ for every pair of jointly owned products, in particular when Δ is symmetric. Three cases arise.

(i) *Quasi-linear representative consumer.* If demand comes from maximizing $U(q) + z$, with z a numeraire, Marshallian demand for the inside goods does not depend on income. It then coincides with Hicksian demand, and Slutsky symmetry gives $\frac{\partial q_j}{\partial p_k} = \frac{\partial q_k}{\partial p_j}$.

(ii) *Random utility with price entering linearly.* Let consumer i have utility $u_{ij} = \tilde{\delta}_j - \alpha_i p_j + \epsilon_{ij}$, where $\tilde{\delta}_j$ does not depend on prices. Write $v_{ij} = \tilde{\delta}_j - \alpha_i p_j$ and let $G_i(v_i) = \mathbb{E}[\max_k (v_{ik} + \epsilon_{ik})]$ be her expected maximum utility. By the Williams-Daly-Zachary theorem (McFadden, 1981), her choice probabilities are $s_{ij} = \frac{\partial G_i}{\partial v_{ij}}$. Hence

$$\frac{\partial s_{ij}}{\partial p_k} = -\alpha_i \frac{\partial^2 G_i}{\partial v_{ij}\, \partial v_{ik}},$$

which is symmetric in (j, k). Integrating over consumers preserves symmetry. For the generalized extreme value (GEV) family, defined in Section 4.7.5, the representation is explicit. McFadden (1984, eq. 3.31, p. 1421) writes the choice probabilities in terms of a linearly homogeneous function H as

$$s_j = \frac{\partial \ln H(e^{v_1}, \ldots, e^{v_J})}{\partial v_j}, \qquad \text{so} \qquad \frac{\partial s_j}{\partial v_k} = \frac{\partial^2 \ln H}{\partial v_j\, \partial v_k},$$

which is symmetric. For the logit, (4.8) below gives $\frac{\partial s_k}{\partial p_j} = \alpha s_j s_k = \frac{\partial s_j}{\partial p_k}$ directly. For a mixture of logits with consumer-specific α_i and a distribution F of consumers, the cross derivative $\int \alpha_i s_{ij} s_{ik}\, dF(i)$ is again symmetric.

(iii) *Income effects.* Berry et al. (1995, eq. 2.7a, p. 849) use $u_{ij} = \alpha \ln(y_i - p_j) + x_j\beta + \xi_j + \sum_k \sigma_k x_{jk} \nu_{ik} + \epsilon_{ij}$, with income y_i. With logit shocks, consumer i's cross derivatives are

$$\frac{\partial s_{ik}}{\partial p_j} = \frac{\alpha}{y_i - p_j} s_{ij} s_{ik}, \qquad \frac{\partial s_{ij}}{\partial p_k} = \frac{\alpha}{y_i - p_k} s_{ij} s_{ik}.$$

The marginal utility of income differs across products with different prices, so Δ is not symmetric and the transpose matters. Berry, Levinsohn and Pakes define a matrix with (j, r) element $-\frac{\partial s_r}{\partial p_j}$ for jointly owned products (their eq. 3.4, p. 853). That matrix is $-(\Omega \odot \Delta^{s\top})$ in our notation, so their markup formula (eq. 3.5) agrees with (4.4).

The markup formula is useful only if it delivers positive markups. The next result gives a simple sufficient condition. It asks that an increase in p_j reduce the total sales of inside products, which holds whenever some of product j's lost customers move to the outside good.

Proposition 4.5 (Positive markups)**.** *Let Assumption 4.1 hold at a price vector $p \in \mathcal{P}$, and suppose that for every product j*

$$-\frac{\partial q_j(p)}{\partial p_j} > \sum_{k \neq j,\, k \geq 1} \frac{\partial q_k(p)}{\partial p_j}. \tag{4.5}$$

Then $\Omega \odot \Delta^\top$ is nonsingular and every element of the markup vector $m = -(\Omega \odot \Delta^\top)^{-1} q$ is strictly positive. In a discrete-choice model with fixed market size, condition (4.5) holds if and only if $\frac{\partial s_0}{\partial p_j} > 0$ for every j.

Proof. We proceed in five steps.

Step 1 (the outside good). In a discrete-choice model the shares of all goods, including the outside good, sum to one at every price vector, $\sum_{k=0}^{J} s_k(p) = 1$. Differentiating with respect to p_j gives $\sum_{k=0}^{J} \frac{\partial s_k}{\partial p_j} = 0$, or

$$-\frac{\partial s_j}{\partial p_j} = \sum_{k \neq j,\, k \geq 1} \frac{\partial s_k}{\partial p_j} + \frac{\partial s_0}{\partial p_j}.$$

Multiplying by M shows that (4.5) holds exactly when $\frac{\partial s_0}{\partial p_j} > 0$.

Step 2 (diagonal dominance). Let $A = -(\Omega \odot \Delta^\top)$. Its diagonal elements are $A_{jj} = -\frac{\partial q_j}{\partial p_j} > 0$, since $\Omega_{jj} = 1$. Its off-diagonal elements are $A_{jk} = -\Omega_{jk} \frac{\partial q_k}{\partial p_j} \leq 0$ by gross substitutability. Because Ω only deletes nonnegative terms,

$$\sum_{k \neq j} |A_{jk}| = \sum_{k \neq j} \Omega_{jk} \frac{\partial q_k}{\partial p_j} \leq \sum_{k \neq j} \frac{\partial q_k}{\partial p_j} < A_{jj},$$

where the last inequality is (4.5). Each row of A is strictly diagonally dominant.

Step 3 (a nonnegative matrix with small row sums). Let $D_A = \operatorname{diag}(A_{11}, \ldots, A_{JJ})$ and $\mathcal{N} = I_J - D_A^{-1} A$. Then $A = D_A(I_J - \mathcal{N})$. The diagonal elements of $\mathcal{N}$ are zero, and its off-diagonal

elements $\mathcal{N}_{jk} = -\frac{A_{jk}}{A_{jj}}$ are nonnegative. Row j of $\mathcal{N}$ sums to $\frac{\sum_{k\neq j}|A_{jk}|}{A_{jj}} < 1$ by Step 2. The maximum row-sum norm therefore satisfies $\|\mathcal{N}\|_\infty < 1$.

Step 4 (the Neumann series). Since $\|\mathcal{N}^n\|_\infty \leq \|\mathcal{N}\|_\infty^n$, the partial sums $\sum_{n=0}^{K}\mathcal{N}^n$ converge as $K \to \infty$. Moreover $(I_J - \mathcal{N})\sum_{n=0}^{K}\mathcal{N}^n = I_J - \mathcal{N}^{K+1}$, which converges to I_J. Hence $I_J - \mathcal{N}$ is nonsingular with

$$(I_J - \mathcal{N})^{-1} = \sum_{n=0}^{\infty}\mathcal{N}^n.$$

Every term of the series is nonnegative, and the term $n = 0$ is the identity. So $(I_J - \mathcal{N})^{-1}$ is nonnegative with diagonal elements of at least one. It follows that A is nonsingular, with $A^{-1} = (I_J - \mathcal{N})^{-1}D_A^{-1}$. This inverse is nonnegative and its diagonal elements are at least $\frac{1}{A_{jj}} > 0$. Since $\Omega \odot \Delta^\top = -A$, it is nonsingular too.

Step 5 (positive markups). The first-order conditions (4.3) read $-Am = -q$, so $m = A^{-1}q$. Every element of A^{-1} is nonnegative and every q_k is positive. Therefore

$$m_j = \sum_{k=1}^{J}\left(A^{-1}\right)_{jk}q_k \geq \left(A^{-1}\right)_{jj}q_j > 0.$$

□

A matrix with nonpositive off-diagonal elements and a nonnegative inverse is called a nonsingular *M-matrix*, and Steps 3 and 4 are a standard route to that property (Berman and Plemmons, 1994). The proposition concerns the inversion at any price vector, whether or not it is an equilibrium. It therefore also serves as a diagnostic. If estimated demand implies a negative markup at observed prices, the estimated derivatives at those prices violate gross substitutability or (4.5).

If marginal costs vary with output, (4.2) and (4.4) still hold with $mc_k(q_k)$ evaluated at the equilibrium quantities. Inverting the first-order conditions at observed prices then recovers marginal cost at observed output. Learning how marginal cost varies with output requires variation in quantities across markets or periods and a model for the cost function (Section 4.5).

4.2.4 Single-product firms and the inverse semi-elasticity rule

With single-product firms, $\Omega = I_J$ and row j of (4.3) involves only product j. The markup is

$$p_j - mc_j = -\frac{q_j}{\frac{\partial q_j}{\partial p_j}} = \frac{1}{-\frac{\partial \ln q_j}{\partial p_j}}. \tag{4.6}$$

The quantity $-\frac{\partial \ln q_j}{\partial p_j}$ is the absolute *semi-elasticity* of demand, the percentage fall in quantity per dollar increase in price. The dollar markup of a single-product firm equals the reciprocal of this semi-elasticity. Dividing (4.6) by p_j gives the Lerner rule

$$\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j}, \qquad \varepsilon_j = -\frac{\partial q_j}{\partial p_j}\frac{p_j}{q_j},$$

where ε_j is the own-price elasticity of product j holding all other prices fixed. This is the monopoly pricing rule of Section 2.2, equation (2.6), applied to the firm's residual demand, the

demand for its product given rivals' prices. Section 3.4 shows how a residual demand curve can be estimated directly (Baker and Bresnahan, 1988).

With multi-product firms the markup of product j also depends on the cross terms. Divide (4.2) by q_j:

$$1 + \frac{m_j}{q_j}\frac{\partial q_j}{\partial p_j} + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \frac{m_k}{q_j}\frac{\partial q_k}{\partial p_j} = 0.$$

Substitute $\frac{1}{q_j}\frac{\partial q_j}{\partial p_j} = -\frac{\varepsilon_j}{p_j}$ and $\frac{\partial q_k}{\partial p_j} = \varepsilon_{kj}\frac{q_k}{p_j}$, where $\varepsilon_{kj} = \frac{\partial q_k}{\partial p_j}\frac{p_j}{q_k}$ is the cross elasticity:

$$1 - \frac{m_j}{p_j}\varepsilon_j + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \frac{m_k q_k}{p_j q_j}\varepsilon_{kj} = 0.$$

Solving for the Lerner index of product j,

$$\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j}\left[1 + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \frac{m_k q_k}{p_j q_j}\,\varepsilon_{kj}\right]. \tag{4.7}$$

The bracket exceeds one when the firm's other products are substitutes with positive markups. A multi-product firm therefore sets a higher Lerner index than the inverse own elasticity. Read the other way, if marginal costs are positive the Lerner index is below one, and (4.7) implies $\varepsilon_j > 1 + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \frac{m_k q_k}{p_j q_j}\varepsilon_{kj} \geq 1$. Each product is priced on the elastic part of its own demand, more so the more of its lost sales the firm recaptures.

4.2.5 Worked example: a linear differentiated duopoly

Example 4.6 (Linear duopoly, separate and joint ownership)**.** Two products have demands

$$q_1 = a - bp_1 + dp_2, \qquad q_2 = a - bp_2 + dp_1,$$

with $b > d \geq 0$ and a common constant marginal cost c satisfying $a > (b - d)c$. The parameter b is the own-price slope and d the cross-price slope. Here d is unrelated to the diversion ratio D defined below, even though $D = \frac{d}{b}$ in this example. Section 4.7 derives these demands from a quadratic utility function.

Separate owners. Each firm maximizes $(p_j - c)q_j$ over p_j. The first-order condition (4.2) for firm 1 is

$$\begin{aligned} q_1 + (p_1 - c)\frac{\partial q_1}{\partial p_1} &= 0 \\ a - bp_1 + dp_2 - b(p_1 - c) &= 0 \\ a - 2bp_1 + dp_2 + bc &= 0. \end{aligned}$$

Solving for p_1 gives the best response

$$BR_1(p_2) = \frac{a + bc + dp_2}{2b}.$$

Its slope $\frac{d}{2b}$ lies in $[0, \frac{1}{2})$. Prices are *strategic complements*: a higher rival price raises the best response. Profit is strictly concave in own price, so the condition defines the global maximum. By symmetry the equilibrium has $p_1 = p_2 = p^N$, which solves $p^N = \frac{a+bc+dp^N}{2b}$:

$$p^N = \frac{a + bc}{2b - d}, \qquad m^N = p^N - c = \frac{a + bc - (2b - d)c}{2b - d} = \frac{a - (b - d)c}{2b - d}.$$

Since both best responses have slope below $\frac{1}{2}$, the best-response map is a contraction and the equilibrium is unique. A *contraction* is a map that shrinks every distance by a factor below one, and it has a unique fixed point (Appendix B).

Joint owner. One firm owns both products and maximizes $(p_1 - c)q_1 + (p_2 - c)q_2$. The first-order condition for p_1 now contains the recaptured margin on product 2:

$$\begin{aligned} q_1 + (p_1 - c)\frac{\partial q_1}{\partial p_1} + (p_2 - c)\frac{\partial q_2}{\partial p_1} &= 0 \\ a - bp_1 + dp_2 - b(p_1 - c) + d(p_2 - c) &= 0 \\ a - 2bp_1 + 2dp_2 + (b - d)c &= 0. \end{aligned}$$

The Hessian of joint profit,

$$\begin{pmatrix} -2b & 2d \\ 2d & -2b \end{pmatrix},$$

is negative definite because $b > d$, so the two first-order conditions characterize the joint optimum. Imposing symmetry, $p_1 = p_2 = p^J$ solves $2(b - d)p^J = a + (b - d)c$:

$$p^J = \frac{a + (b - d)c}{2(b - d)}, \qquad m^J = \frac{a + (b - d)c - 2(b - d)c}{2(b - d)} = \frac{a - (b - d)c}{2(b - d)}.$$

Diversion and the markup ratio. The *diversion ratio* from product 1 to product 2 is the fraction of product 1's lost sales that product 2 captures when p_1 rises, $D_{12} = -\frac{\partial q_2}{\partial p_1}\left(\frac{\partial q_1}{\partial p_1}\right)^{-1}$, as defined in (4.11). Here $D = D_{12} = D_{21} = \frac{d}{b}$. The ratio of joint to separate markups is

$$\frac{m^J}{m^N} = \frac{2b - d}{2(b - d)} = \frac{2 - D}{2 - 2D},$$

where the second equality divides numerator and denominator by b. The ratio equals one at $D = 0$, when the products are independent. Its derivative with respect to D is $\frac{2}{(2-2D)^2} > 0$, so it increases with diversion, and it grows without bound as D approaches one. The price effect of joint ownership is governed by how closely the products substitute for each other.

Matrix check. The demand Jacobian is

$$\Delta = \begin{pmatrix} -b & d \\ d & -b \end{pmatrix},$$

which is symmetric. With separate owners, $\Omega = I_2$ and (4.4) gives $m_j = \frac{q_j}{b}$. At the symmetric equilibrium $q^N = a - (b - d)p^N$, and $m^N = \frac{q^N}{b}$ reproduces the formula above. With a joint owner, $\Omega = \mathbf{1}\mathbf{1}^\top$ and $\Omega \odot \Delta^\top = \Delta$. Its inverse is

$$\Delta^{-1} = \frac{1}{b^2 - d^2}\begin{pmatrix} -b & -d \\ -d & -b \end{pmatrix},$$

so $m = -\Delta^{-1} q$ gives, at equal quantities $q_1 = q_2 = q^J$,

$$m_j = \frac{(b+d)q^J}{b^2 - d^2} = \frac{q^J}{b-d}.$$

Substituting $q^J = a - (b-d)p^J$ and $m_j = p^J - c$ gives $(b-d)(p^J - c) = a - (b-d)p^J$, which is the joint-owner condition $2(b-d)p^J = a + (b-d)c$ again.

Numbers. Take $a = 10$, $b = 2$, $d = 1$ and $c = 1$. With separate owners, $p^N = \frac{12}{3} = 4$, $q^N = 10 - 4 = 6$ and $m^N = 3$, so each firm earns 18. With a joint owner, $p^J = \frac{11}{2} = 5.5$, $q^J = 10 - 5.5 = 4.5$ and $m^J = 4.5$, so each product earns 20.25. Diversion is $D = \frac{1}{2}$ and the markup ratio is $\frac{4.5}{3} = 1.5 = \frac{2-\frac{1}{2}}{2-1}$. Figure 4.1 shows the two configurations.

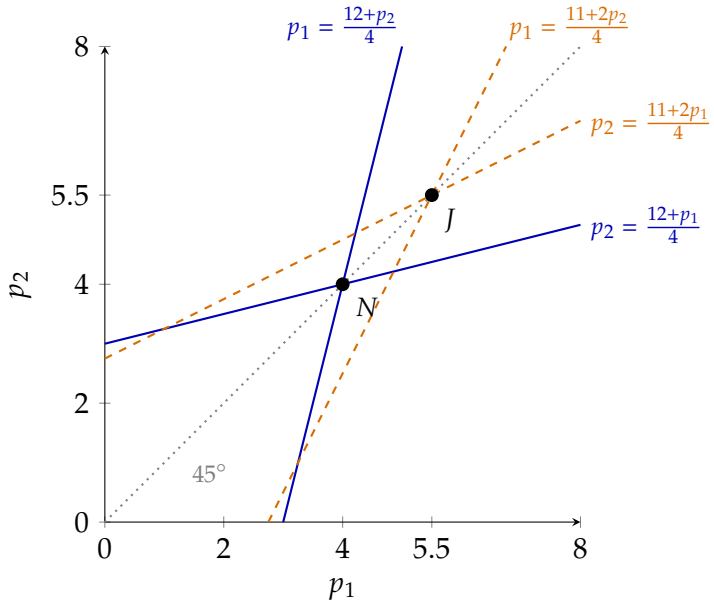

Figure 4.1: Linear duopoly of Example 4.6 with $a = 10$, $b = 2$, $d = 1$ and $c = 1$. Solid lines are the best responses of separate owners, which cross at $N = (4, 4)$. Dashed lines are the first-order loci of a single owner of both products, each giving the optimal price of one product for a fixed price of the other. They cross at $J = (5.5, 5.5)$. The dashed loci are not best responses of independent firms. Their slope equals the diversion ratio $D = \frac{1}{2}$, twice the slope of the separate best responses, because the joint owner recaptures half of the sales that each product loses.

4.2.6 Worked example: logit demand

The logit model gives closed forms for every object in Section 4.2.3. Chapters 6 and 7 derive it from random utility. Here we take the market shares as given. Let market size be one, so quantities equal shares. Mean utility is $\delta_j = x_j\beta - \alpha p_j + \xi_j$, with observed characteristics x_j, unobserved quality ξ_j and price coefficient $\alpha > 0$. With the mean utility of the outside good normalized to zero, shares are

$$s_j(p) = \frac{e^{\delta_j}}{\Phi}, \qquad s_0(p) = \frac{1}{\Phi}, \qquad \Phi = 1 + \sum_{k=1}^{J} e^{\delta_k}.$$

We call Φ the *logit denominator*.

Derivatives. Changing p_j affects only e^{δ_j}, with $\frac{\partial e^{\delta_j}}{\partial p_j} = -\alpha e^{\delta_j}$, so also $\frac{\partial \Phi}{\partial p_j} = -\alpha e^{\delta_j}$. The quotient rule gives the own derivative

$$\begin{aligned}\frac{\partial s_j}{\partial p_j} &= \frac{(-\alpha e^{\delta_j})\,\Phi - e^{\delta_j}\,(-\alpha e^{\delta_j})}{\Phi^2} \\ &= -\alpha \frac{e^{\delta_j}}{\Phi}\left(1 - \frac{e^{\delta_j}}{\Phi}\right) = -\alpha s_j(1 - s_j).\end{aligned}$$

For $k \neq j$ the numerator e^{δ_k} does not depend on p_j, so $\frac{\partial s_k}{\partial p_j} = -\frac{e^{\delta_k}(-\alpha e^{\delta_j})}{\Phi^2} = \alpha s_j s_k$. The same step applies to $s_0 = \frac{1}{\Phi}$. Collecting,

$$\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j), \qquad \frac{\partial s_k}{\partial p_j} = \alpha s_j s_k \quad (k \neq j,\ k \geq 1), \qquad \frac{\partial s_0}{\partial p_j} = \alpha s_0 s_j. \tag{4.8}$$

These derivatives sum to zero over $k = 0, \ldots, J$, as they must. Since $\frac{\partial s_0}{\partial p_j} > 0$, Proposition 4.5 applies at every price vector. The own and cross elasticities are

$$\varepsilon_j = \alpha p_j(1 - s_j), \qquad \varepsilon_{kj} = \frac{\partial s_k}{\partial p_j}\frac{p_j}{s_k} = \alpha p_j s_j \quad \text{for every } k \neq j.$$

A change in p_j moves every other product's share by the same percentage. This is the *independence of irrelevant alternatives* (IIA), whose consequences Chapter 7 discusses.

Proposition 4.7 (Logit markups)**.** *Under logit demand with constant marginal costs, every solution of the first-order conditions (4.2) gives all products of firm f the same markup,*

$$p_j - mc_j = m_f = \frac{1}{\alpha(1 - S_f)} \quad \textit{for all } j \in \mathcal{J}_f, \qquad S_f = \sum_{k \in \mathcal{J}_f} s_k.$$

A single-product firm sets $p_j - mc_j = \frac{1}{\alpha(1-s_j)}$.

Proof. Write the first-order condition for $j \in \mathcal{J}_f$ in shares, $s_j + \sum_{k \in \mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} = 0$, and substitute (4.8):

$$s_j - \alpha s_j(1 - s_j)m_j + \sum_{k \in \mathcal{J}_f \setminus \{j\}} \alpha s_j s_k m_k = 0.$$

Split the second term as $-\alpha s_j m_j + \alpha s_j s_j m_j$ and merge $\alpha s_j s_j m_j$ into the sum:

$$s_j - \alpha s_j m_j + \alpha s_j \sum_{k \in \mathcal{J}_f} s_k m_k = 0.$$

Divide by $\alpha s_j > 0$:

$$m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k.$$

The right side is the same for every $j \in \mathcal{J}_f$, so all of the firm's products share one markup m_f. Substituting $m_k = m_f$ gives $m_f = \frac{1}{\alpha} + S_f m_f$. Since $S_f \leq 1 - s_0 < 1$, we can solve: $m_f = \frac{1}{\alpha(1-S_f)}$. A single-product firm has $S_f = s_j$. □

The proposition characterizes markups without giving them in closed form, because S_f depends on prices. It still has several sharp implications. Markups are bounded below by $\frac{1}{\alpha}$, whatever the number of competitors. They depend on the firm only through its combined share. Product quality and cost affect markups only by changing shares. Within a firm, dollar markups are equal, so a firm's high-cost products carry lower percentage margins, $\frac{m_f}{p_j} = \frac{1}{\alpha p_j (1-S_f)}$. Finally, a firm with a large combined share sets high markups on all its products, including those with tiny shares.

As an illustration, suppose one firm owns products 1 and 2 with shares s_1 and s_2. It sets the markup $\frac{1}{\alpha(1-s_1-s_2)}$ on both. If the products had separate owners, their markups would be $\frac{1}{\alpha(1-s_1)}$ and $\frac{1}{\alpha(1-s_2)}$. Joint ownership raises the markup of the smaller product by more. Under logit, the diversion ratio from product k to product j is $\frac{s_j}{1-s_k}$ (Section 4.3.4). Diversion from the small product to the large one is therefore the larger of the two, so joint ownership recaptures a larger fraction of the small product's lost sales.

The best response in closed form. For a single-product firm the first-order condition $\alpha m_j(1-s_j) = 1$ is implicit, because s_j depends on p_j. It can nevertheless be solved explicitly. Define the mean utility of product j at marginal-cost pricing and the logit denominator without product j,

$$v_j = x_j\beta + \xi_j - \alpha\, mc_j, \qquad \Phi_{-j} = 1 + \sum_{l \neq j} e^{\delta_l}.$$

Then $\delta_j = v_j - \alpha m_j$, and Φ_{-j} depends only on rivals' prices. The share and its complement are

$$s_j = \frac{e^{\delta_j}}{\Phi_{-j} + e^{\delta_j}}, \qquad 1 - s_j = \frac{\Phi_{-j}}{\Phi_{-j} + e^{\delta_j}}.$$

Substitute the complement into the first-order condition and multiply by $\Phi_{-j} + e^{\delta_j}$:

$$\begin{aligned} \alpha m_j \Phi_{-j} &= \Phi_{-j} + e^{\delta_j} \\ (\alpha m_j - 1)\Phi_{-j} &= e^{v_j - \alpha m_j}. \end{aligned}$$

Multiply both sides by $\frac{e^{\alpha m_j - 1}}{\Phi_{-j}}$:

$$(\alpha m_j - 1)\, e^{\alpha m_j - 1} = \frac{e^{v_j - 1}}{\Phi_{-j}}.$$

The *Lambert W function* $W(z)$ solves $W(z)e^{W(z)} = z$ (Corless et al., 1996). For $z > 0$ the equation $ye^y = z$ has exactly one real root, which is positive. Indeed $ye^y \leq 0$ for $y \leq 0$, while ye^y rises strictly from 0 to infinity on $y > 0$. Setting $y = \alpha m_j - 1$ gives the best response

$$BR_j(p_{-j}) = mc_j + \frac{1}{\alpha}\left[1 + W\left(\frac{e^{v_j - 1}}{\Phi_{-j}}\right)\right]. \tag{4.9}$$

The formula shows three properties at a glance. The best-response markup exceeds $\frac{1}{\alpha}$ because $W(z) > 0$. It rises with the product's quality net of cost, v_j. And it rises with every rival price, because a higher p_l lowers Φ_{-j} and W is increasing. Logit prices are strategic complements.

The stationary point in (4.9) is the global maximizer of $\pi_j = m_j s_j$. The derivative of profit factors as

$$\frac{\partial \pi_j}{\partial p_j} = s_j + m_j \frac{\partial s_j}{\partial p_j} = s_j\, g(p_j), \qquad g(p_j) = 1 - \alpha(p_j - mc_j)\big(1 - s_j(p_j)\big).$$

If $p_j \le mc_j$, then $g(p_j) \ge 1$ and profit is increasing. If $p_j > mc_j$, both $\alpha(p_j - mc_j)$ and $1 - s_j(p_j)$ are positive and strictly increasing in p_j, so g is strictly decreasing. As $p_j \to \infty$, $g(p_j) \to -\infty$. Hence g crosses zero exactly once, from above. Profit rises before the crossing and falls after it, so the crossing is the unique global maximizer.

The multi-product analogue follows the same steps. By Proposition 4.7, a stationary point of firm f's problem has a common markup m_f, so $e^{\delta_k} = e^{v_k - \alpha m_f}$ for $k \in \mathcal{J}_f$. Let $E_f = \sum_{k \in \mathcal{J}_f} e^{v_k}$ and $\Phi_{-f} = 1 + \sum_{l \notin \mathcal{J}_f} e^{\delta_l}$. The firm's combined share is

$$S_f = \frac{E_f e^{-\alpha m_f}}{\Phi_{-f} + E_f e^{-\alpha m_f}}.$$

Repeating the algebra above with E_f in place of e^{v_j} and S_f in place of s_j gives

$$m_f^{BR}(p_{-\mathcal{J}_f}) = \frac{1}{\alpha}\left[1 + W\left(\frac{E_f e^{-1}}{\Phi_{-f}}\right)\right], \qquad p_k = mc_k + m_f^{BR} \text{ for } k \in \mathcal{J}_f. \tag{4.10}$$

Showing that this stationary point is the firm's global optimum takes one more step. The firm's problem reduces to the choice of a common markup, and the single-crossing argument then applies to S_f in place of s_j. Steps 1 and 2 of the proof of Theorem 4.25 give the details, and Section 4.10 asks for the algebra behind (4.10).

4.2.7 A numerical illustration: 25 logit products

We now compute equilibria in a simulated market. The market reappears in Section 4.4, where we check uniqueness, and as a worked problem in Appendix C.

Example 4.8 (A 25-product logit market)**.** There are $J = 25$ products and market size one. Each product has three observed characteristics: a constant, a continuous characteristic and a binary one, $x_j = (1, x_{j2}, x_{j3})$. It also has unobserved quality ξ_j and a cost shock ω_j. Demand is logit with $\beta = (0.1, 0.25, 0.1)$ and $\alpha = 2$. Marginal cost is $mc_j = x_j\gamma + \omega_j$ with $\gamma = (0.2, 0.25, 0.3)$, and it ranges from 0.164 to 1.236. All primitives are common knowledge, and firms set prices simultaneously. We compare two ownership structures.

(S) Every product has its own owner, so $\Omega = I_{25}$.

(M) Five owners, labeled 0 to 4, hold 3, 3, 6, 6 and 7 products.

Products are numbered 0 to 24 and owners 0 to 4, as in the data set of Appendix C. Here the label 0 names an inside product, and s_0 still denotes the share of the outside good. In (S) the first-order conditions are $s_j + (p_j - mc_j)\frac{\partial s_j}{\partial p_j} = 0$ for all j. In (M) they are $s + (\Omega \odot \Delta^{s\top})(p - mc) = 0$ with the owners' Ω. A Nash equilibrium is a price vector at which no owner can raise its profit by changing its own prices, which is a fixed point of the best-response map.

Remark 4.9 (Computing the equilibrium). We compute each equilibrium by best-response iteration.

1. Start from $p^{(0)} = mc + \frac{1}{\alpha}$, the lower bound on logit markups.
2. Given $p^{(n)}$, compute for every owner f the quantities E_f and $\Phi_{-f}(p^{(n)})$, the markup m_f from (4.10), and set $p_k^{(n+1)} = mc_k + m_f$ for $k \in \mathcal{J}_f$. In (S) every owner has one product and the step is (4.9).

3. Stop when $\|p^{(n+1)} - p^{(n)}\|_\infty < 10^{-12}$. Otherwise return to step 2.
4. Check that the first-order residuals $s + (\Omega \odot \Delta^{s\top})(p - mc)$ vanish and that each owner's markup equals $\frac{1}{\alpha(1-S_f)}$.

The iteration converges in 10 steps in (S) and 15 steps in (M). As a cross-check we also iterate on the markup equation, $p \leftarrow mc - (\Omega \odot \Delta^s(p)^\top)^{-1}s(p)$, which converges in 14 and 30 steps to the same prices (largest difference 1.4×10^{-13}). The largest first-order residual is below 2×10^{-14}. Markup iteration is simple and fast here, but it is not guaranteed to converge in general (Section 4.5.4).

Table 4.2 reports the results by owner, and Figure 4.2 shows every product's markup. In (S) each product is priced by a separate firm, and the owner rows aggregate those products for comparison with (M). Consumer surplus is measured by $\frac{1}{\alpha}\ln\Phi$, the logit expected maximum utility in money units (Chapter 7). We measure it relative to a market in which only the outside good is available, where $\Phi = 1$. Its level is then the surplus that consumers get from the inside goods, so percentage changes are meaningful.

Table 4.2: Bertrand-Nash equilibrium in the 25-product logit market

		Combined share S_f (%)		Markup		Profit ×100	
Owner	Products	(S)	(M)	(S)	(M)	(S)	(M)
Panel A. Owners							
0	3	18.32	18.87	0.552	0.616	10.112	11.632
1	3	4.12	4.67	0.508	0.524	2.094	2.449
2	6	13.27	13.68	0.516	0.579	6.841	7.925
3	6	22.62	21.40	0.529	0.636	11.971	13.616
4	7	28.00	25.36	0.541	0.670	15.145	16.989
Panel B. Market							
Outside share s_0				0.1367	0.1601		
Logit denominator $\Phi^* = \frac{1}{s_0}$				7.314	6.246		
Consumer surplus $\frac{1}{\alpha}\ln\Phi^*$				0.9949	0.9159		
Total profit				0.4616	0.5261		
Total surplus (consumer surplus plus profit)				1.4565	1.4421		
Share-weighted mean price				1.2599	1.3553		

Notes: (S) single-product firms, (M) five multi-product owners. In column (S) the owner rows add up shares and profits of products that are priced independently, and the markup is the share-weighted mean over the owner's products. In column (M) every product of an owner carries the same markup $\frac{1}{\alpha(1-S_f)}$. Market size is one, so profits and consumer surplus are per consumer. Computed with `figures/ch04/src/logit25.py`.

The results illustrate the theory of this section in five ways.

First, single-product markups lie between 0.502 and 0.566, close to the floor $\frac{1}{\alpha} = 0.5$. Each product has a small share, so $\frac{1}{\alpha(1-s_j)}$ barely exceeds $\frac{1}{\alpha}$. The largest markups belong to the products with the largest shares, products 20 and 5, whose shares are 11.7 and 11.4 percent.

Second, multi-product ownership raises every owner's markup to $\frac{1}{\alpha(1-S_f)}$. The common markups range from 0.524 for owner 1, whose products have a combined share near 5 percent, to 0.670 for owner 4, whose combined share is about 25 percent. A product with a share of half a percent, such as product 7, carries the same markup as owner 4's largest product. Its price rises the most, by 0.167.

Third, every price rises, by amounts from 0.015 (product 11) to 0.167 (product 7). Two forces combine. Each owner internalizes cannibalization among its own products, and prices

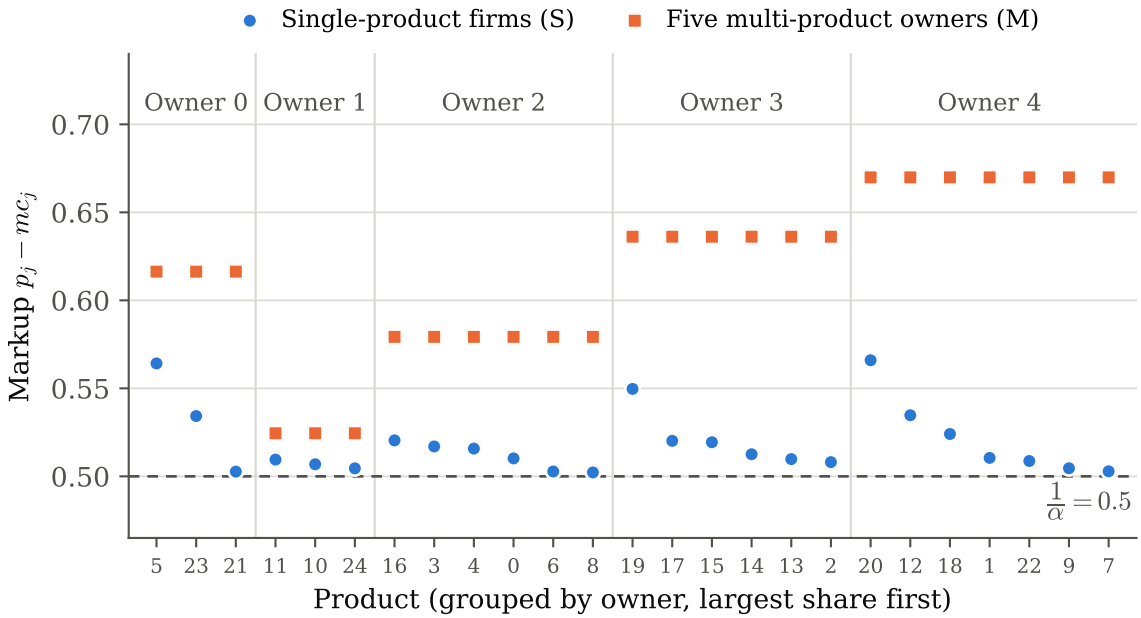

Figure 4.2: Equilibrium markups $p_j - mc_j$ in the 25-product logit market. Circles show single-product firms (S), squares show the five multi-product owners (M). Products are grouped by owner and sorted by share. Under (S) markups are close to the floor $\frac{1}{\alpha} = 0.5$ and rise with the product's own share. Under (M) all products of an owner share the markup $\frac{1}{\alpha(1-S_f)}$.

are strategic complements, so each owner also responds to the higher prices of the others. To isolate the second force, we recomputed the equilibrium with only owner 4 consolidating its seven products and all other products independent. Owner 4's prices rise by 0.089 to 0.152, and rivals' prices rise by 0.0001 to 0.0040 through strategic complementarity. In that exercise rivals' combined profit rises from 0.3102 to 0.3296, while owner 4's profit rises only from 0.1515 to 0.1553. The non-consolidating firms gain more than the firm that consolidates.

Fourth, shares move away from the owners that raise prices most. The two largest owners lose share, owner 4 from 28.00 to 25.36 percent and owner 3 from 22.62 to 21.40 percent. The three smaller owners gain. Fifteen of the 25 products lose share, and the outside share rises from 0.137 to 0.160.

Fifth, total profit rises by about 14 percent, from 0.4616 to 0.5261. Consumer surplus falls by 0.079, or 7.9 percent, and total surplus falls from 1.4565 to 1.4421. In equilibrium the logit denominator equals $\frac{1}{s_0}$, which falls from 7.314 to 6.246. Section 4.4 shows that this aggregate pins down the whole equilibrium. It uses this to prove that the logit equilibrium is unique for any ownership structure (Konovalov and Sándor, 2010; Nocke and Schutz, 2018), and Example 4.26 confirms numerically that the two equilibria in Table 4.2 are the only ones.

4.3 Diversion ratios

The pricing rule of Section 4.2 depends on own-price and cross-price derivatives of demand. Elasticities summarize these derivatives product by product. Diversion ratios summarize them pair by pair: they record where the customers of a product go when its price rises. This makes

them the natural language for three questions that recur in this book. Which products compete most closely? How does a multi-product firm price products that cannibalize one another? Which mergers create an incentive to raise prices? This section defines diversion ratios, rewrites the first-order condition in terms of them, computes them in the standard demand systems, and lists what they cannot tell us.

4.3.1 Definitions and basic properties

We keep the environment of Assumption 4.1. To lighten the notation we write

$$\partial_k q_j \equiv \frac{\partial q_j(p)}{\partial p_k}$$

for the derivative of the demand for product j with respect to the price of product k. In this notation the (j,k) element of Δ is $\partial_k q_j$. The *cross-price derivative* $\partial_j q_k$ is the change in the sales of product k when the price of product j rises by one dollar. The *cross-price elasticity* is $\varepsilon_{kj} = \frac{\partial q_k}{\partial p_j}\frac{p_j}{q_k}$, and the own-price elasticity is the positive number $\varepsilon_j = -\frac{\partial q_j}{\partial p_j}\frac{p_j}{q_j}$.

Definition 4.10 (Diversion ratio)**.** For two inside products $j \neq k$, the *diversion ratio* from j to k is

$$D_{jk} = -\frac{\partial_j q_k}{\partial_j q_j}. \tag{4.11}$$

The *diversion ratio to the outside good* is $D_{j0} = 1 - \sum_{k\geq 1, k\neq j} D_{jk}$, and the *aggregate diversion ratio* of product j is $\sum_{k\geq 1, k\neq j} D_{jk} = 1 - D_{j0}$.

The numerator and the denominator of (4.11) refer to the same experiment, a small increase $\mathrm{d}p_j$ in the price of product j with all other prices fixed. Product j loses $-\partial_j q_j \,\mathrm{d}p_j$ units of sales. Product k gains $\partial_j q_k \,\mathrm{d}p_j$ units. The diversion ratio is the fraction of the lost units that product k recaptures. Read in reverse, it is the number of units of k that are lost when p_j falls by enough to sell one more unit of j. The first index always names the product whose price changes. In general $D_{jk} \neq D_{kj}$.

Proposition 4.11 (Adding up)**.** *Suppose that each of M consumers buys exactly one unit of one of the options $0, 1, \ldots, J$, so that $\sum_{k=0}^{J} q_k(p) = M$ for every price vector p. Then for every inside product j,*

$$\sum_{k\geq 1,\, k\neq j} D_{jk} + D_{j0} = 1, \qquad \text{with} \qquad D_{j0} = -\frac{\partial_j q_0}{\partial_j q_j}. \tag{4.12}$$

If all products, including the outside good, are gross substitutes, every diversion ratio lies in $[0,1]$.

Proof. Differentiate the identity $\sum_{k=0}^{J} q_k(p) = M$ with respect to p_j. The right side does not depend on prices, so

$$\partial_j q_j + \sum_{k\geq 1,\, k\neq j} \partial_j q_k + \partial_j q_0 = 0.$$

Divide by $-\partial_j q_j > 0$:

$$-1 + \sum_{k\geq 1,\, k\neq j} \left(-\frac{\partial_j q_k}{\partial_j q_j}\right) + \left(-\frac{\partial_j q_0}{\partial_j q_j}\right) = 0.$$

The terms in parentheses are D_{jk} and $-\frac{\partial_j q_0}{\partial_j q_j}$, which gives (4.12). Under gross substitutes each term is nonnegative. Nonnegative numbers that sum to one each lie in $[0,1]$. □

In unit-demand models the residual D_{j0} in Definition 4.10 is the share of lost customers who stop buying any inside product. A large D_{j0} then means that the products in the group constrain one another little. This is why the aggregate diversion ratio appears in market definition (Chapter 11). Some demand systems have no explicit outside option, such as the linear and CES systems of Section 4.7. Their quantities need not add up in units, so D_{j0} is only the residual of Definition 4.10. It changes when we rescale the units of one product, and in CES it can be negative. Reading it as the fraction of j's lost units that the group does not recapture requires units that are comparable across products.

Diversion ratios and elasticities carry the same information, arranged differently. Write each derivative in terms of an elasticity:

$$\partial_j q_k = \varepsilon_{kj} \frac{q_k}{p_j}, \qquad \partial_j q_j = -\varepsilon_j \frac{q_j}{p_j}.$$

Substituting into (4.11), the price p_j cancels and

$$D_{jk} = \frac{\varepsilon_{kj}}{\varepsilon_j} \frac{q_k}{q_j}. \tag{4.13}$$

A large cross elasticity does not imply a large diversion ratio. If product k is small, a large percentage gain for k is a small number of units. Conversely, a large product can capture many of j's customers even when its own percentage gain is modest.

Measurement. Diversion ratios can be computed from an estimated demand system (Chapters 7 and 8). They can also be measured more directly, which is a large part of their appeal to antitrust agencies. Firms often track whom they lose business to, and surveys can ask buyers of j what they would have bought instead (Farrell and Shapiro, 2010, p. 16). Natural experiments that remove a product, such as stock-outs, recalls and exits, reveal where its customers go. In bidding markets the diversion ratio from j to k can be read as the probability that k is the runner-up when j wins (Farrell and Shapiro, 2010, p. 16).

These sources do not all measure the same object. Conlon and Mortimer (2021) view a diversion ratio as a treatment effect and stress that the size of the price change matters. Second-choice data describe what happens when product j disappears, which is a price increase to infinity. The pricing incentive in (4.16) below involves a marginal price change. A mixture of logits shows the difference. Let consumer types i have distribution F, price coefficient α_i and logit choice probabilities s_{ij}, so that $s_j = \int s_{ij} \, \mathrm{d}F(i)$. Using (4.8) type by type, the marginal diversion ratio is

$$D_{jk} = \frac{\int \alpha_i s_{ij} s_{ik} \, \mathrm{d}F(i)}{\int \alpha_i s_{ij}(1 - s_{ij}) \, \mathrm{d}F(i)} = \int \varpi_i \, \frac{s_{ik}}{1 - s_{ij}} \, \mathrm{d}F(i), \qquad \varpi_i = \frac{\alpha_i s_{ij}(1 - s_{ij})}{\int \alpha_{i'} s_{i'j}(1 - s_{i'j}) \, \mathrm{d}F(i')}. \tag{4.14}$$

When j is removed, a type-i buyer of j moves to k with probability $\frac{e^{\delta_{ik}}}{\sum_{l \neq j} e^{\delta_{il}}} = \frac{s_{ik}}{1 - s_{ij}}$, where δ_{il} is the mean utility of option l for type i. Averaging over the buyers of j gives the second-choice diversion ratio

$$D^{\mathrm{SC}}_{jk} = \int \tilde{\varpi}_i \, \frac{s_{ik}}{1 - s_{ij}} \, \mathrm{d}F(i), \qquad \tilde{\varpi}_i = \frac{s_{ij}}{s_j}. \tag{4.15}$$

Both are weighted averages of the same type-level ratios $\frac{s_{ik}}{1 - s_{ij}}$. The marginal ratio weights types by $\alpha_i s_{ij}(1 - s_{ij})$, which is large for price-sensitive consumers near the margin of buying j. The second-choice ratio weights all current buyers of j equally. With one type both reduce to the logit formula $\frac{s_k}{1 - s_j}$. With heterogeneous consumers they differ, and a survey answer needs a model before it can be plugged into a pricing formula.

4.3.2 The first-order condition in diversion form

The multi-product first-order condition (4.2) can be rewritten so that diversion ratios appear explicitly. For firm f and a product $j \in \mathcal{J}_f$ the condition reads

$$q_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k)\, \partial_j q_k = 0.$$

We first split off the term $k = j$:

$$q_j + (p_j - mc_j)\, \partial_j q_j + \sum_{k \in \mathcal{J}_f \setminus \{j\}} (p_k - mc_k)\, \partial_j q_k = 0.$$

Next we divide by $\partial_j q_j < 0$:

$$\frac{q_j}{\partial_j q_j} + (p_j - mc_j) + \sum_{k \in \mathcal{J}_f \setminus \{j\}} (p_k - mc_k) \frac{\partial_j q_k}{\partial_j q_j} = 0.$$

Solving for p_j gives

$$p_j = mc_j - \frac{q_j}{\partial_j q_j} - \sum_{k \in \mathcal{J}_f \setminus \{j\}} (p_k - mc_k) \frac{\partial_j q_k}{\partial_j q_j}.$$

Finally, $-\frac{\partial_j q_k}{\partial_j q_j} = D_{jk}$ by (4.11), so

$$p_j = mc_j + \frac{q_j}{-\partial_j q_j} + \sum_{k \in \mathcal{J}_f \setminus \{j\}} D_{jk}\, (p_k - mc_k). \tag{4.16}$$

The price of product j has three parts. The first is marginal cost. The second is the markup a single-product firm would charge, the reciprocal of the absolute semi-elasticity of q_j. The third is the *value of diverted sales*: each unit of j's lost sales that moves to a sibling product k earns the firm the margin $p_k - mc_k$. This term is an opportunity cost of selling j, because every extra unit of j cannibalizes D_{jk} units of k. Define the *effective marginal cost* $\widetilde{mc}_j = mc_j + \sum_{k \in \mathcal{J}_f \setminus \{j\}} D_{jk}(p_k - mc_k)$. Then (4.16) becomes $p_j - \widetilde{mc}_j = \frac{q_j}{-\partial_j q_j}$, and dividing by p_j,

$$\frac{p_j - \widetilde{mc}_j}{p_j} = \frac{1}{\varepsilon_j}.$$

A multi-product firm prices each product by the inverse elasticity rule, applied to an effective marginal cost that includes the value of diverted sales. The 2010 US Horizontal Merger Guidelines use this phrase for the units diverted to a product multiplied by that product's margin (U.S. Department of Justice and Federal Trade Commission, 2010, Section 6.1, p. 21). The term in (4.16) is this value per unit of lost sales of j.

Stacking (4.16) over products gives a compact matrix version. Let $m_j^{\mathrm{s}} = \frac{q_j}{-\partial_j q_j}$ be the single-product markup, with vector m^{s}, let $m = p - mc$, and let $\mathcal{D}$ be the $J \times J$ *diversion matrix* with $\mathcal{D}_{jk} = D_{jk}$ for $k \neq j$ and zeros on the diagonal. Since $\Omega_{jk} = 1$ exactly when j and k have the same owner,

$$m = m^{\mathrm{s}} + (\Omega \odot \mathcal{D})\, m, \qquad \text{so} \qquad m = (I - \Omega \odot \mathcal{D})^{-1} m^{\mathrm{s}}. \tag{4.17}$$

This is the stacked first-order condition (4.3) with row j divided by $-\partial_j q_j$, and its solution coincides with the markup equation (4.4).

Remark 4.12. Equation (4.17) gives a short proof that markups are positive. Suppose that every outside diversion ratio is positive, $D_{j0} > 0$. Row j of $\Omega \odot \mathcal{D}$ has nonnegative entries that sum to at most $\sum_{k \neq j} D_{jk} = 1 - D_{j0} < 1$. The sup-norm of $\Omega \odot \mathcal{D}$ is therefore below one, and the Neumann series $(I - \Omega \odot \mathcal{D})^{-1} = \sum_{n=0}^{\infty} (\Omega \odot \mathcal{D})^n$ converges to a matrix with nonnegative entries and diagonal entries of at least one. Hence $m \geq m^{\mathrm{s}} > 0$ element by element. Every product of a multi-product firm carries at least its single-product markup, in line with Proposition 4.5.

Two examples from Section 4.2 show the formula at work. In the linear duopoly of Example 4.6, $\partial_1 q_1 = -b$ and $\partial_1 q_2 = d$, so $D_{12} = \frac{d}{b} \equiv D$. For a joint owner, (4.16) reads $m_1 = \frac{q_1}{b} + D\, m_2$. At a symmetric solution $m(1 - D) = \frac{q}{b}$ with $q = a - (b - d)(c + m)$. Multiplying by b and using $b(1 - D) = b - d$,

$$(b - d)\, m = a - (b - d)c - (b - d)m \quad \Longrightarrow \quad m^J = \frac{a - (b - d)c}{2(b - d)},$$

the joint-owner markup found in Example 4.6. In the multi-product logit model the derivatives (4.8) give $D_{jk} = \frac{s_k}{1 - s_j}$ and $m_j^{\mathrm{s}} = \frac{1}{\alpha(1 - s_j)}$. With the common markup m_f of Proposition 4.7, (4.16) becomes

$$m_f = \frac{1}{\alpha(1 - s_j)} + \frac{S_f - s_j}{1 - s_j}\, m_f \quad \Longrightarrow \quad m_f\, \frac{1 - S_f}{1 - s_j} = \frac{1}{\alpha(1 - s_j)} \quad \Longrightarrow \quad m_f = \frac{1}{\alpha(1 - S_f)},$$

where $S_f = \sum_{k \in \mathcal{J}_f} s_k$. The firm's combined share enters because the recaptured fraction $\frac{S_f - s_j}{1 - s_j}$ grows with the shares of the sibling products.

4.3.3 Why diversion governs the unilateral effects of mergers

Equation (4.16) explains why diversion ratios dominate the analysis of *unilateral effects*. These are the price effects of a merger that arise because the merged firm internalizes competition between its own products, with the conduct of rivals unchanged. A merger adds the acquired products to $\mathcal{J}_f \setminus \{j\}$ and so adds terms $D_{jk}(p_k - mc_k)$ to the effective marginal cost of product j. The size of these terms depends on how close the merging products are as substitutes. The merging firms' shares of a predefined market play no direct role.

Consider two single-product Bertrand firms, A selling product 1 and B selling product 2, with constant marginal costs. Before the merger, firm A's first-order condition is $q_1 + (p_1 - mc_1)\, \partial_1 q_1 = 0$. After the merger, one owner maximizes $\pi_1 + \pi_2$. Evaluated at the pre-merger prices, the derivative of joint profit with respect to p_1 is

$$\frac{\partial(\pi_1 + \pi_2)}{\partial p_1} = \underbrace{q_1 + (p_1 - mc_1)\, \partial_1 q_1}_{= 0 \text{ before the merger}} + (p_2 - mc_2)\, \partial_1 q_2 = (p_2 - mc_2)\, \partial_1 q_2 > 0.$$

The merged firm wants to raise p_1. Dividing by $-\partial_1 q_1 > 0$ measures this incentive per unit of product 1's lost sales. The result, $D_{12}(p_2 - mc_2)$, is the increase in the effective marginal cost of product 1. Farrell and Shapiro (2010, p. 9) interpret it as a "first-round tax" that the merged firm's headquarters would levy on division A to make it internalize the sales it takes from division B.

A merger can also lower marginal costs. Let E_1 be the proportional reduction in the marginal cost of product 1, so that the merger saves $E_1 mc_1$ per unit. The symbol E_1 is unrelated to the logit aggregate E_f of Section 4.2.6. The *upward pricing pressure* (UPP) on product 1 is

$$UPP_1 = D_{12}(p_2 - mc_2) - E_1\, mc_1, \tag{4.18}$$

evaluated at pre-merger prices and margins. Farrell and Shapiro (2010, p. 12, inequality (1)) propose to presume harm when $UPP_1 > 0$. In the symmetric case, with equal prices p, costs mc, diversion ratios D and efficiencies E, the condition divides through by $p - mc$ to give

$$D > E\,\frac{mc}{p - mc}.$$

This is their inequality (2), which they state in terms of the relative margin $\frac{p-mc}{p}$. They use $E = 0.1$ as an illustrative default (Farrell and Shapiro, 2010, p. 10). With a Lerner index of $\frac{1}{3}$ we have $\frac{mc}{p-mc} = 2$, and the merger is flagged when $D > 0.2$. Allowing both prices to respond to each other, the symmetric condition becomes $\frac{D}{1-D} > E\frac{mc}{p-mc}$ (Farrell and Shapiro, 2010, p. 14, inequality (4)). With the same numbers it reads $\frac{D}{1-D} > 0.2$, so the threshold falls to $D > \frac{1}{6} \approx 0.167$. Their footnote 35 reports both thresholds, 20 and 16.7 percent. It also notes that the symmetric condition is equivalent to equation (6) of Werden (1996).

The *gross upward pricing pressure index* (GUPPI) scales the cannibalization term by the price of the product under study:

$$GUPPI_1 = \frac{D_{12}(p_2 - mc_2)}{p_1} = D_{12}\,\frac{p_2 - mc_2}{p_2}\,\frac{p_2}{p_1}. \tag{4.19}$$

For example, $D_{12} = 0.2$, a margin of 40 percent on product 2 and equal prices give

$$GUPPI_1 = 0.2 \times 0.4 \times 1 = 0.08.$$

The merger raises the effective marginal cost of product 1 by 8 percent of its price. UPP and GUPPI need only diversion ratios and margins, and no full demand system. Farrell and Shapiro (2010, p. 12, Proposition 1) show that net upward pricing pressure on both products, with no more than the default efficiencies, implies that both prices rise. A full merger simulation instead solves the post-merger first-order conditions $q + (\Omega^{post} \odot \Delta^{\top})(p - mc) = 0$ with recovered marginal costs (Section 4.5.4). The derivation with efficiencies, the role of pass-through, the GUPPI thresholds used in practice and applications are in Chapter 11.

Example 4.13 (From UPP to price effects in the linear duopoly)**.** The linear duopoly of Example 4.6 shows how a diversion-based pricing pressure translates into a price change. Before the merger each markup is $m^N = \frac{a-(b-d)c}{2b-d}$. After it, each markup is m^J, and the ratio is

$$\frac{m^J}{m^N} = \frac{2b - d}{2(b - d)} = \frac{2 - D}{2 - 2D}, \qquad D = \frac{d}{b}.$$

The ratio equals 1.056, 1.167, 1.5 and 2.5 for $D = 0.1$, 0.25, 0.5 and 0.75. In levels,

$$m^J - m^N = m^N\left(\frac{2 - D}{2 - 2D} - 1\right) = \frac{D\,m^N}{2(1 - D)}.$$

Without efficiencies the pre-merger UPP on each product is $D\,m^N$, so the price change is $\frac{1}{2(1-D)}$ times the UPP. The factor arises in three rounds. Holding the rival's price fixed, a firm facing linear demand passes through one half of a cost increase, since its best response $\frac{a+b(c+t)+dp_k}{2b}$ rises by $\frac{t}{2}$ for a cost increase t. If both products bear the tax t and both prices adjust, the symmetric equilibrium price $\frac{a+b(c+t)}{2b-d}$ rises by $\frac{t}{2-D}$. If the tax is then recomputed at the new

margins, $t = D(m^N + \Delta p)$. Solving $\Delta p\,(2 - D) = D(m^N + \Delta p)$ gives $\Delta p = \frac{D\,m^N}{2-2D}$, the full effect. The three rounds follow the iterative procedure of Farrell and Shapiro (2010, p. 9). We impose the internal taxes, let the oligopoly re-equilibrate, re-calculate the taxes at the new prices and outputs, and repeat these steps until convergence. Their footnote 24 adds that with strategic complements each round raises prices, so with constant costs and diversion ratios the taxes rise from round to round. With $a = 10$, $b = 2$, $d = 1$ and $c = 1$, we have $m^N = 3$, $D = \frac{1}{2}$ and $UPP = 1.5$. The price rises from 4 to 5.5, by exactly the UPP, because $\frac{1}{2(1-D)} = 1$ when $D = \frac{1}{2}$.

4.3.4 Diversion in standard demand systems

Each demand system used in practice implies a pattern of diversion. Often the pattern is imposed by the functional form, which is worth knowing before a system is used to evaluate mergers.

Logit. With logit shares, (4.8) gives $\partial_j s_j = -\alpha s_j(1 - s_j)$, $\partial_j s_k = \alpha s_j s_k$ and $\partial_j s_0 = \alpha s_j s_0$. Hence

$$D_{jk} = \frac{\alpha s_j s_k}{\alpha s_j(1 - s_j)} = \frac{s_k}{1 - s_j}, \qquad D_{j0} = \frac{s_0}{1 - s_j}. \tag{4.20}$$

Customers who leave j spread over the remaining options in proportion to their shares. A product similar to j and a product very different from it receive the same diversion if they have the same share. This is the independence of irrelevant alternatives property (Chapter 7). It also means that a logit-based UPP adds no information beyond shares and margins.

CES. Consider the CES system of Section 4.7 with elasticity of substitution $\sigma > 1$. This σ is unrelated to the nesting parameter. Demand is $q_j = \frac{p_j^{-\sigma}}{\sum_k p_k^{1-\sigma}}\, y$, with income y and expenditure shares $s_j = \frac{p_j q_j}{y}$. The quantity diversion ratio is

$$D_{jk} = \frac{(\sigma - 1)\, p_j\, q_k}{y\,[\sigma - (\sigma - 1)s_j]} = \frac{(\sigma - 1)\, s_k}{\sigma - (\sigma - 1)s_j}\,\frac{p_j}{p_k}, \tag{4.21}$$

which Proposition 4.44 derives from the CES elasticities. Diversion is proportional to the quantity q_k, again with no role for similarity.

Linear demand. If $q = a + Ap$ for a vector a and a $J \times J$ matrix A, then $\partial_j q_k = A_{kj}$ and $D_{jk} = -\frac{A_{kj}}{A_{jj}}$. Diversion is constant, and in the symmetric duopoly it equals $\frac{d}{b}$. A linear system can represent any pattern of diversion at one point, at the cost of J^2 price parameters (Section 4.6).

Nested logit. Group the inside products into nests and let $\sigma^{\mathrm{NL}} \in [0, 1)$ be the nesting parameter of Chapter 7, written with a superscript in this section to avoid a clash with the CES elasticity. Let $s_{j|g}$ be the share of product j within its nest g and s_g the share of the nest. We use the form of Berry (1994), and Chapter 7 derives the share derivatives. With respect to p_j they are

$$\partial_j s_j = -\frac{\alpha s_j\left[1 - \sigma^{\mathrm{NL}} s_{j|g} - (1 - \sigma^{\mathrm{NL}})s_j\right]}{1 - \sigma^{\mathrm{NL}}}, \qquad \partial_j s_k = \frac{\alpha s_k\left[\sigma^{\mathrm{NL}} s_{j|g} + (1 - \sigma^{\mathrm{NL}})s_j\right]}{1 - \sigma^{\mathrm{NL}}}$$

for k in the nest of j, and $\partial_j s_k = \alpha s_k s_j$ for k in another nest or $k = 0$. Taking ratios and using

$s_k = s_{k|g} s_g$ and $s_j = s_{j|g} s_g$,

$$D_{jk} = \begin{cases} \dfrac{s_{k|g}\left[\sigma^{\mathrm{NL}} + (1-\sigma^{\mathrm{NL}})s_g\right]}{1 - \sigma^{\mathrm{NL}} s_{j|g} - (1-\sigma^{\mathrm{NL}})s_j} & \text{if } k \text{ is in the nest of } j, \\ \dfrac{(1-\sigma^{\mathrm{NL}})\, s_k}{1 - \sigma^{\mathrm{NL}} s_{j|g} - (1-\sigma^{\mathrm{NL}})s_j} & \text{otherwise, including } k = 0. \end{cases} \tag{4.22}$$

At $\sigma^{\mathrm{NL}} = 0$ both lines reduce to (4.20). As σ^{NL} approaches one, diversion outside the nest vanishes and the within-nest ratio approaches $\frac{s_{k|g}}{1-s_{j|g}}$. Diversion concentrates within the nest.

Figure 4.3 shows how much this matters. Four inside products sit in two nests, $\{1, 2\}$ and $\{3, 4\}$. All prices equal 1 and the price coefficient equals 1. For each value of the nesting parameter we set a common mean utility so that every inside share is 0.15 and the outside share is 0.40. Shares, prices and margins are therefore identical across the four models. Under logit, the diversion from product 1 is 0.1765 to each rival and 0.4706 to the outside good. With $\sigma^{\mathrm{NL}} = 0.5$ the diversion to product 2 is 0.4815, against 0.1111 to products 3 and 4 and 0.2963 to the outside good. With $\sigma^{\mathrm{NL}} = 0.7$ the values are 0.6529, 0.0744, 0.0744 and 0.1983. With $\sigma^{\mathrm{NL}} = 0.9$ they are 0.8692, 0.0280, 0.0280 and 0.0748. Each row sums to one, as Proposition 4.11 requires. For given margins, the GUPPI of a merger between products 1 and 2 is 3.7 times larger under the nested logit with $\sigma^{\mathrm{NL}} = 0.7$ than under the logit ($\frac{0.6529}{0.1765} = 3.70$). Shares alone cannot distinguish these markets.

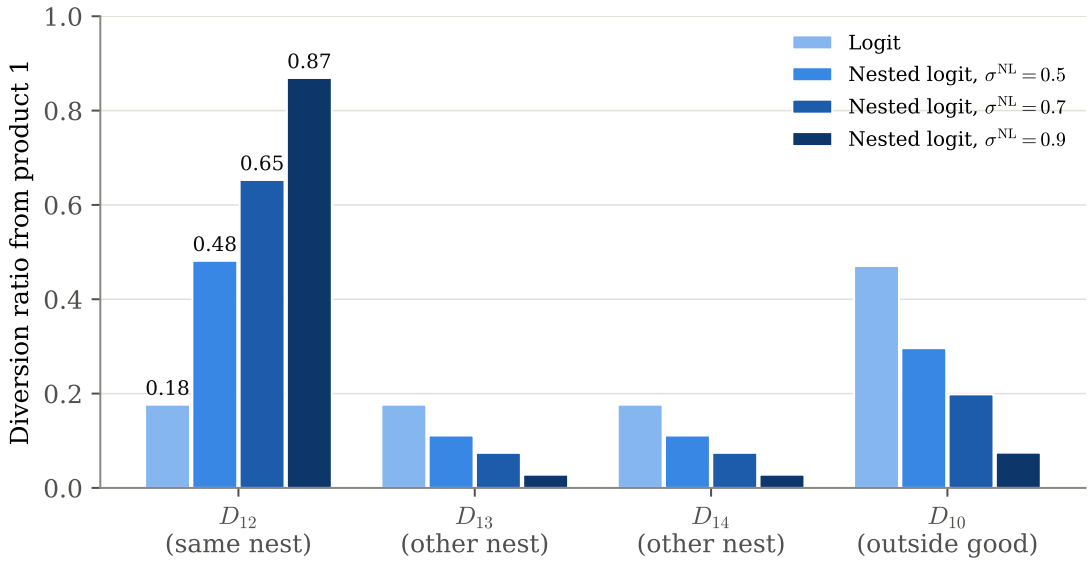

Figure 4.3: Diversion ratios from product 1 in four demand models with identical shares. Products 1 and 2 form one nest and products 3 and 4 the other. Every inside share is 0.15 and the outside share is 0.40. The logit spreads lost sales in proportion to shares. The nested logit sends most of them to the other product in the same nest, more so as σ^{NL} rises. Computed with `figures/ch04/src/diversion_nl.py`.

4.3.5 What diversion ratios do not tell us

Diversion ratios are local. They are derivatives evaluated at current prices, and except under linear demand they change when prices change. A merger moves prices, so diversion at the

post-merger prices differs from the pre-merger value that enters UPP. Example 4.13 shows that even with constant diversion the full price effect differs from UPP by a factor that depends on D.

Diversion ratios give the direction of the pricing incentive. The size of the price change also requires pass-through, which depends on the curvature of demand (Proposition 4.38, Chapter 2). For a single-product firm facing a fixed rival price, pass-through is $\frac{1}{2}$ with linear demand, $1 - s_j$ with logit demand and $\frac{\varepsilon}{\varepsilon - 1} > 1$ with constant-elasticity demand. The same UPP can therefore produce very different price increases. Farrell and Shapiro (2010, Section 3) use this point to argue that a screen should rely on the sign of pricing pressure, leaving magnitudes to a later stage.

Diversion is directional. When Δ is symmetric, (4.11) implies $-D_{12}\,\partial_1 q_1 = \partial_1 q_2 = \partial_2 q_1 = -D_{21}\,\partial_2 q_2$, so $D_{21} = D_{12}\frac{\partial_1 q_1}{\partial_2 q_2}$. Under logit $D_{12} = \frac{s_2}{1-s_1}$ and $D_{21} = \frac{s_1}{1-s_2}$: diversion from a small product to a large one exceeds diversion in the reverse direction. A merger between a large and a small firm thus creates more pressure on the small firm's price, for given margins.

Finally, diversion ratios describe demand for a fixed set of products and fixed non-price attributes. They are silent about entry, repositioning and changes in quality after a merger (Chapter 11). When diversion comes from a demand system rather than from direct evidence, it inherits the system's restrictions. Under logit, "measured" diversion restates an assumption about substitution.

4.4 Existence, uniqueness and multiplicity of price equilibria

The pricing rules of Sections 4.2 and 4.3 are first-order conditions. They describe an equilibrium only if an equilibrium exists and if each firm's first-order condition identifies a global profit maximum. They predict a single outcome only if the equilibrium is unique. This section asks when these properties hold. We first explain why existence is a problem in price games with differentiated products. Next we give conditions on demand that make profit quasi-concave and present the existence theorem of Caplin and Nalebuff (1991). Finally we prove uniqueness for the logit model with any ownership structure and construct a simple market with two equilibria. Throughout we take the set of products and their characteristics as given. This is the first of the two branches of theory described in Section 4.1.4, and product choice waits until Section 4.8.

4.4.1 The existence problem

Consider F firms. Firm f chooses the prices $p_{\mathcal{J}_f}$ of its products from a compact box $P_f = \prod_{j\in\mathcal{J}_f}[\underline{p}_j, \bar{p}_j]$ and earns $\pi_f(p)$. A *pure-strategy Bertrand-Nash equilibrium* is a fixed point of the best-response correspondence $BR(p) = \prod_f BR_f(p_{-\mathcal{J}_f})$, where $BR_f(p_{-\mathcal{J}_f}) = \arg\max_{p_{\mathcal{J}_f}\in P_f} \pi_f(p_{\mathcal{J}_f}, p_{-\mathcal{J}_f})$. The standard tool is *Kakutani's fixed-point theorem*. A correspondence from a nonempty, compact, convex subset of $\mathbb{R}^J$ into itself has a fixed point if it has a closed graph and nonempty convex values.

Two of these requirements are usually easy. Berge's maximum theorem concerns a continuous function of a choice variable and a parameter, maximized over a fixed compact set. It says that the maximizers, as a correspondence of the parameter, have nonempty compact values and a closed graph. If demand is continuous, profit is continuous, and the theorem applies to each firm's best response. The difficulty is convexity. The best-response set is convex

when π_f is *quasi-concave* in the firm's own prices, that is, when its upper contour sets are convex. Without restrictions on demand, quasi-concavity can fail. A firm may prefer either a high price aimed at a small group of consumers for whom its product is well positioned or a low price aimed at the mass market. Both can dominate every intermediate price (Caplin and Nalebuff, 1991, p. 2). The best response then jumps between two prices, and the jump can leave the best-response map without a fixed point. Example 4.27 below builds such a profit function. Here and throughout the chapter, page, proposition, theorem, example and footnote numbers for Caplin and Nalebuff (1991) refer to the version we checked, Cowles Foundation Discussion Paper 937 (February 1990). The published article may number them differently.

Continuity can fail as well. In Hotelling's model with linear transport costs, a firm that undercuts its rival by more than the transport cost between them captures the rival's entire market, so demand jumps. d'Aspremont et al. (1979) showed that this discontinuity rules out a pure-strategy price equilibrium when the firms are close together (Section 4.8). Mixed-strategy equilibria exist in such discontinuous games (Dasgupta and Maskin, 1986), and Osborne and Pitchik (1987) computed them for Hotelling's model. Their complexity, however, rules out the comparative statics that applications need (Caplin and Nalebuff, 1991, p. 2).

Before Caplin and Nalebuff (1991), positive results came from special models in which demand is concave in own price or log price (Gabszewicz and Thisse, 1979; Shaked and Sutton, 1982; Lane, 1980; Hauser, 1988; Economides, 1989). These models are one-dimensional and have consumers distributed uniformly over the market. We will see below that concavity of demand is too strong a condition to go further.

4.4.2 Sufficient conditions on demand

This subsection collects conditions on a firm's residual demand that make its profit quasi-concave in own price. Consider a single-product firm with constant marginal cost c. Fix the rivals' prices and write $q(p)$ for its residual demand, assumed nonincreasing in its own price p. Let $\bar{p}$ be the price at which demand reaches zero, possibly $+\infty$, so that $q > 0$ exactly on $(-\infty, \bar{p})$. Profit is $\pi(p) = (p - c)\, q(p)$.

Prices below cost never matter for quasi-concavity. For $p < c$ profit is nonpositive and nondecreasing, because a higher price reduces both sales and the loss per unit. Formally, where q is differentiable, $\pi'(p) = q(p) + (p - c)q'(p) \geq 0$ for $p < c$, since $q \geq 0$, $p - c < 0$ and $q' \leq 0$. Every result below therefore concerns prices $p \geq c$.

Lemma 4.14 (Log-concave demand)**.** *If* $\ln q$ *is concave on* $(c, \bar{p})$*, then* π *is quasi-concave in* p*, and the set of profit-maximizing prices, when nonempty, is a closed interval. If* $\ln q$ *is strictly concave there, the maximizer is unique.*

Proof. On $(c, \bar{p})$ profit is positive and

$$\ln \pi(p) = \ln(p - c) + \ln q(p).$$

The first term is concave in p and the second is concave by assumption. A sum of concave functions is concave, so π is log-concave on $(c, \bar{p})$. A log-concave function is quasi-concave, because its upper contour sets are those of the concave function $\ln \pi$. Outside $(c, \bar{p})$ profit is nonpositive, and it is nondecreasing below c. Hence for any $t > 0$ the upper contour set $\{p : \pi(p) \geq t\}$ is a subset of $(c, \bar{p})$ and an interval. For $t \leq 0$ it contains every price above c, and with the prices below c at which $\pi \geq t$ it forms a half-line. All upper contour sets are intervals, which is quasi-concavity. If a maximum exists and q is positive somewhere above

c, the maximum is positive, so the argmax is an upper contour set of the concave function $\ln \pi$, a closed interval. Strict concavity of $\ln q$ makes $\ln \pi$ strictly concave, so the maximizer is unique. □

The next condition is weaker. It requires only that $\frac{1}{q}$ be convex.

Lemma 4.15 (Convex reciprocal demand)**.** *If $\frac{1}{q}$ is convex on $(-\infty, \bar{p})$, then π is quasi-concave in p (Caplin and Nalebuff, 1991, Proposition 3).*

Proof. We follow Caplin and Nalebuff (1991, p. 29). Suppose π is not quasi-concave. Then there are prices $p_0 < p_1$ and $\lambda \in (0,1)$ such that, with $p_\lambda = \lambda p_0 + (1-\lambda)p_1$,

$$\pi(p_0) > \pi(p_\lambda) \qquad \text{and} \qquad \pi(p_1) > \pi(p_\lambda).$$

By the argument above, $p_0 \geq c$, since otherwise p_λ would earn at least as much as p_0. Hence $p_\lambda > c$. If $q(p_1) = 0$, then $\pi(p_1) = 0 > \pi(p_\lambda)$ requires $p_\lambda < c$, a contradiction. So $q(p_1) > 0$, and because q is nonincreasing, $q(p_0) \geq q(p_\lambda) \geq q(p_1) > 0$. Divide the first inequality by $q(p_0)q(p_\lambda)$ and the second by $q(p_1)q(p_\lambda)$:

$$\frac{p_0 - c}{q(p_\lambda)} > \frac{p_\lambda - c}{q(p_0)}, \qquad \frac{p_1 - c}{q(p_\lambda)} > \frac{p_\lambda - c}{q(p_1)}.$$

Multiply the first by λ, the second by $1-\lambda$, and add. The left side sums to $\frac{p_\lambda - c}{q(p_\lambda)}$, so

$$\frac{p_\lambda - c}{q(p_\lambda)} > (p_\lambda - c)\Big[\frac{\lambda}{q(p_0)} + \frac{1-\lambda}{q(p_1)}\Big].$$

Dividing by $p_\lambda - c > 0$ gives $\frac{1}{q(p_\lambda)} > \frac{\lambda}{q(p_0)} + \frac{1-\lambda}{q(p_1)}$, which contradicts the convexity of $\frac{1}{q}$. □

Convexity of $\frac{1}{q}$ has a familiar meaning. Let $P(\cdot)$ be the inverse demand function, so that revenue as a function of quantity is $Q\,P(Q)$. For twice differentiable demand,

$$\frac{\mathrm{d}^2}{\mathrm{d}p^2}\Big(\frac{1}{q}\Big) = \frac{2q'^2 - q\,q''}{q^3}, \qquad \frac{\mathrm{d}^2}{\mathrm{d}Q^2}\big(Q\,P(Q)\big) = 2P' + QP'' = \frac{2q'^2 - q\,q''}{q'^3},$$

where the second expression uses $P' = \frac{1}{q'}$ and $P'' = -\frac{q''}{q'^3}$, evaluated at $Q = q(p)$. Since $q > 0$ and $q' < 0$, the first is nonnegative exactly when the second is nonpositive. Convex reciprocal demand is concave revenue in quantity. Caplin and Nalebuff (1991, p. 14 and footnote 11) observe that concavity of revenue is equivalent to quasi-concavity of profit for every convex cost function, so the condition is as weak as possible if costs are unrestricted.

A third condition works with logarithms of both price and quantity. It covers demand curves that Lemma 4.15 handles only at the boundary, such as CES demand.

Lemma 4.16 (Log-log concave demand)**.** *Let $c \geq 0$. If $\ln q$ is a concave function of $\ln p$ where $q > 0$, then π is quasi-concave on the set of prices where it is positive (Caplin and Nalebuff, 1991, Proposition 11).*

Proof. Write $x = \ln p$. Where profit is positive,

$$\ln \pi = \ln(e^x - c) + \ln q(e^x).$$

The second term is concave in x by assumption. The first has derivative $\frac{e^x}{e^x-c} = 1 + \frac{c}{e^x-c}$, which is nonincreasing in x when $c \geq 0$, so it is concave. Hence π is log-concave, and so quasi-concave, as a function of $\ln p$. Quasi-concavity of a function of one variable means that its upper contour sets are intervals. The map $p \mapsto \ln p$ is increasing and sends intervals to intervals, so π is quasi-concave in p as well. □

Since $\frac{\mathrm{d}\ln q}{\mathrm{d}\ln p} = -\varepsilon(p)$, the condition of Lemma 4.16 says that the elasticity of demand is nondecreasing in price. Three examples locate the conditions. Linear demand $q = a - bp$ is concave, hence log-concave. The logit residual demand $s_j(p_j) = \frac{e^{v-\alpha p_j}}{\Phi_{-j}+e^{v-\alpha p_j}}$, with v the price-free part of mean utility, satisfies $\frac{\mathrm{d}\ln s_j}{\mathrm{d}p_j} = -\alpha(1-s_j)$ and $\frac{\mathrm{d}^2\ln s_j}{\mathrm{d}p_j^2} = -\alpha^2 s_j(1-s_j) < 0$, so it is strictly log-concave. Constant-elasticity demand $q = Ap^{-\varepsilon}$ with $\varepsilon > 1$ is log-convex, since $\frac{\mathrm{d}^2\ln q}{\mathrm{d}p^2} = \frac{\varepsilon}{p^2} > 0$. Yet $\frac{1}{q} = \frac{p^\varepsilon}{A}$ is convex, and $\ln q = \ln A - \varepsilon \ln p$ is linear in $\ln p$, so Lemmas 4.15 and 4.16 both apply. Cobb-Douglas demand $q = \frac{1}{p}$ sits on the boundary of both: $\frac{1}{q} = p$ and $\ln q = -\ln p$ are linear (Caplin and Nalebuff, 1991, p. 22). The same curvature conditions govern pass-through: log-concave demand implies pass-through below one (Chapter 2).

A single family of concavity notions orders these conditions and also describes distributions of consumer tastes. Appendix B develops it with proofs (Definition B.153 and Lemma B.154), and we restate what this chapter needs. For $\varrho \in [-\infty, \infty]$, $\lambda \in [0,1]$ and $a, b \geq 0$, the *power mean* is $\mathcal{M}_\varrho(a,b;\lambda) = [\lambda a^\varrho + (1-\lambda)b^\varrho]^{\frac{1}{\varrho}}$ for $\varrho \neq 0$, with the limits $\mathcal{M}_0 = a^\lambda b^{1-\lambda}$, $\mathcal{M}_\infty = \max\{a,b\}$ and $\mathcal{M}_{-\infty} = \min\{a,b\}$. A function $\psi \geq 0$ with convex support $B \subset \mathbb{R}^L$ is *ϱ-concave* if for all $v_0, v_1 \in B$ and $\lambda \in [0,1]$,

$$\psi(\lambda v_0 + (1-\lambda)v_1) \geq \mathcal{M}_\varrho\big(\psi(v_0), \psi(v_1); \lambda\big),$$

where for $\varrho < 0$ the inequality is only required when $\psi(v_0)\psi(v_1) > 0$ (Caplin and Nalebuff, 1991, p. 5). Caplin and Nalebuff (1991) write ρ for the index, a symbol this book reserves for pass-through.

For $\varrho > 0$, ϱ-concavity means that ψ^ϱ is concave. For $\varrho < 0$ it means that ψ^ϱ is convex. The case $\varrho = 1$ is ordinary concavity, $\varrho = 0$ is log-concavity, $\varrho = -\infty$ is quasi-concavity, and $\varrho = +\infty$ forces ψ to be constant on its support, the uniform case. Power means are nondecreasing in ϱ, so a ϱ-concave function is ϱ'-concave for every $\varrho' < \varrho$. Applied to demand as a function of own price, the conditions above form a chain, with ϱ equal to 1, 0, −1 and $-\infty$ from left to right:

$$\text{concave} \implies \text{log-concave} \implies \frac{1}{q}\,\text{convex} \implies \text{quasi-concave}.$$

Lemma 4.15 says that (-1)-concave demand gives quasi-concave profit. The question becomes which primitives of consumer preferences produce (-1)-concave demand.

4.4.3 The Caplin-Nalebuff existence theorem

Caplin and Nalebuff (1991) answer this question for a large family of models. Their central result is that a pure-strategy price equilibrium exists for any number of single-product firms selling any set of products, with products differentiated in any number of dimensions. The conditions restrict individual preferences and the distribution of preferences across consumers. They cover location models, the characteristics approach and probabilistic choice models, including the logit, probit and random coefficients models of Chapters 6 to 8. We present the

model, the two assumptions, the aggregation theorem that drives the result and the proofs of the main steps.

Model. There are J firms, and firm j sells one product with characteristics $x_j \in X \subset \mathbb{R}^K$ at constant marginal cost c_j. Characteristics are fixed when firms set prices simultaneously. Each consumer buys one unit of exactly one product. Initially all consumers have the same income $y > 0$ and there is no outside good. Consumers have preferences over a product's characteristics x and a numeraire z. In this subsection z denotes the numeraire, and a consumer who buys product j consumes $z = y - p_j$. Preferences differ across consumers through a *type* $v \in \mathbb{R}^L$, with utility $U(v, x, z)$. Types have density ψ with support B. We normalize the mass of consumers to one. In this subsection L is the dimension of the type space, which Caplin and Nalebuff (1991) call the dimension of the market. It is unrelated to the Lerner index.

Assumption 4.17 (A1, preferences linear in the type)**.** Utility takes the form

$$U(v, x, z) = \sum_{l=1}^{L} v_l \, t_l(x) + g(z) \, t_{L+1}(x) + t_{L+2}(x), \tag{4.23}$$

where $t = (t_1, \ldots, t_{L+2}) : X \to \mathbb{R}^{L+2}$, g is strictly increasing and concave, and $t_{L+1}(x) > 0$.

All consumers agree on the *benefits* $t_l(x)$ that a product provides. They differ in the weights v_l they attach to the first L benefits. The benefit t_{L+1} scales the utility of money, and t_{L+2} is valued equally by all. In most applications the l-th benefit depends only on the l-th characteristic and $K = L$ (Caplin and Nalebuff, 1991, p. 5).

Assumption 4.18 (A2, concavity of the type density)**.** The density ψ is ϱ-concave with $\varrho = -\frac{1}{L+1}$, on a convex support $B \subset \mathbb{R}^L$ with positive volume.

Since $-\frac{1}{L+1} < 0$, every log-concave density satisfies A2. A2 should be read jointly with A1: it suffices that some parameterization of preferences satisfies both (Caplin and Nalebuff, 1991, p. 6). Table 4.3 lists the cases that Caplin and Nalebuff (1991) show to be covered.

Two entries need comment. Logit fits A1 through Example 3.2: with one unobserved characteristic per product, $U(v, x_j, z) = \beta x_j^o + v_j + z$, and the type vector collects the product-specific tastes. The type-I extreme value density $e^{-u}\exp(-e^{-u})$ has $\frac{\mathrm{d}^2}{\mathrm{d}u^2}\ln(\cdot) = -e^{-u} < 0$, so a product of independent such densities is log-concave and satisfies A2. Models with a random price coefficient, $u_{ij} = x_j\beta_i - \alpha_i p_j + \epsilon_{ij}$, are covered only after dividing utility by α_i. The transformed utility $\frac{x_j\beta_i + \epsilon_{ij}}{\alpha_i} - p_j$ is linear in the money-metric types $\frac{\beta_i}{\alpha_i}$ and $\frac{\epsilon_{ij}}{\alpha_i}$, so A1 holds with $g(z) = z$. A2 then restricts the distribution of these ratios, which need not be ϱ-concave. Example 4.27 exploits exactly this gap.

Reservation prices and demand. Because utility is strictly increasing in z, each type has a reservation price for each product. Fix the other prices p_{-j} and let $\bar{U}_j(v) = \max_{k \neq j} U(v, x_k, y - p_k)$ be the best alternative. The reservation price of type v for product j is

$$R_j(v; p_{-j}) = \begin{cases} y & \text{if } U(v, x_j, 0) \geq \bar{U}_j(v), \\ y - z_j & \text{if } U(v, x_j, z_j) = \bar{U}_j(v) \text{ has a solution } z_j, \\ -\infty & \text{if } U(v, x_j, z) < \bar{U}_j(v) \text{ for all } z. \end{cases}$$

Type v buys j exactly when $p_j \leq R_j(v; p_{-j})$, up to ties. Demand for product j is the mass of types whose reservation price exceeds the price,

$$q_j(p_j) = \int_{\{v \,:\, R_j(v; p_{-j}) \geq p_j\}} \psi(v) \, \mathrm{d}v, \tag{4.24}$$

Table 4.3: Distributions and utility functions covered by Assumptions A1 and A2

Panel A. Type densities that satisfy A2	
Log-concave densities ($\varrho = 0$)	Multivariate beta, Dirichlet, exponential, gamma, Laplace, normal, uniform, Weibull and Wishart, with the parameter restrictions of Prékopa (1971) where log-concavity requires them
Beyond log-concavity	Multivariate t with $a \geq 1$ degrees of freedom, including the Cauchy ($a = 1$), and Pareto and F under the parameter conditions of Borell (1975). These families are $\left(-\frac{1}{L}\right)$-concave, and A2 restricts their parameters
Transformations	Any truncation to a convex set of a density above
Excluded	Lognormal
Panel B. Utility functions that satisfy A1	
CES in characteristics	$U = \sum_l \nu_l x_l^\eta + z^\eta$
Linear in characteristics ($\eta = 1$)	$U = \beta x^o + \nu x^u + z$, observed x^o, unobserved x^u: logit, probit and random coefficients models (Example 3.2)
Cobb-Douglas	$U = \sum_l \nu_l \ln x_l + \ln z$, or $U = \sum_l \nu_l \ln x_l + z$
Quadratic transport costs	$U = -\|x - \nu\|^2 + z$, linear in ν after expanding the square
Vertical differentiation	$U = x(z + \nu)$, $\nu \in \mathbb{R}$
Direct translog	$U = g(z) + \sum_k \nu_k \ln x_k + \frac{1}{2} \sum_k \sum_l \nu_{kl} \ln x_k \ln x_l$, with $L = \frac{K(K+3)}{2}$
Johansen additive utility	Covered after a change of variables (Example 3.3)
Not covered	Hotelling's linear distance, $U = z - \|\nu - x\|$, whose demand is discontinuous

Notes: η denotes the CES exponent in Panel B. Example numbers refer to Caplin and Nalebuff (1991). In Example 3.2 the unobserved characteristics are unit vectors, so ν_j is a consumer's idiosyncratic taste for product j. Logit takes the ν_j to be i.i.d. type-I extreme value (which Caplin and Nalebuff (1991) call Weibull) and probit takes them to be normal. Random coefficients on observed characteristics enter linearly and are covered when their density satisfies A2. Source: Caplin and Nalebuff (1991, pp. 6–9).

which is equation (4.1) of Caplin and Nalebuff (1991). Given rivals' prices, firm j faces a monopoly problem with a population of reservation prices, and (4.24) is nonincreasing in p_j.

Call products j and k *distinct* if their benefit vectors $(t_1, \dots, t_L)$ differ, and *equivalent* if $t(x_j) = t(x_k)$. Demand is continuous in all prices when products are distinct (Caplin and Nalebuff, 1991, Proposition 1). Caplin and Nalebuff state the condition as $t(x_j) \neq t(x_k)$, and their proof uses the first L benefits. Under A1 the types indifferent between j and k satisfy one linear equation in v,

$$\sum_{l=1}^{L} v_l \left[t_l(x_k) - t_l(x_j) \right] = b_{jk}(p_j, p_k),$$

with $b_{jk} = t_{L+2}(x_j) - t_{L+2}(x_k) + t_{L+1}(x_j) g(y - p_j) - t_{L+1}(x_k) g(y - p_k)$. This set is a hyperplane, which has zero mass under a density. Each consumer's demand jumps at her reservation price, but the population smooths the jumps away. Hotelling's linear-distance model fails this test: its demand jumps even for distinct products, so no transformation of it can satisfy A1 and A2 (Caplin and Nalebuff, 1991, p. 9).

Aggregation. The key step is to show that the integral in (4.24) inherits concavity from ψ. For sets $A_0, A_1 \subset \mathbb{R}^L$ and $\lambda \in [0,1]$, the *Minkowski average* is $A_\lambda = \lambda A_0 + (1-\lambda) A_1 = \{\lambda a_0 + (1-\lambda) a_1 : a_0 \in A_0,\ a_1 \in A_1\}$. The tool is the Prékopa-Borell theorem, which Theorem B.159 states in full. Let ψ be a probability density on $\mathbb{R}^L$ with convex support B, and let A_0 and A_1 be measurable sets that intersect B. If ψ is ϱ-concave with $\varrho \geq -\frac{1}{L}$, then for every $\lambda \in [0,1]$,

$$\int_{A_\lambda} \psi(v)\, \mathrm{d}v \;\geq\; \left[\lambda \Big(\int_{A_0} \psi \Big)^{\varrho^*} + (1-\lambda) \Big(\int_{A_1} \psi \Big)^{\varrho^*} \right]^{\frac{1}{\varrho^*}}, \qquad \varrho^* = \frac{\varrho}{1 + L\varrho}. \tag{4.25}$$

The theorem is due to Prékopa (1971) for log-concave densities and to Borell (1975) in general. Das Gupta (1980) gives proofs and the history, and Caplin and Nalebuff (1991, p. 11) state it in this form. The right side of (4.25) is the power mean $\mathcal{M}_{\varrho^*}$ of the two probabilities. A ϱ-concave density thus defines a ϱ^*-concave measure over sets. Three cases help. A uniform density ($\varrho = \infty$) gives $\varrho^* = \frac{1}{L}$, the Brunn-Minkowski inequality $\mathrm{vol}(A_\lambda)^{\frac{1}{L}} \geq \lambda \,\mathrm{vol}(A_0)^{\frac{1}{L}} + (1-\lambda)\,\mathrm{vol}(A_1)^{\frac{1}{L}}$. A log-concave density ($\varrho = 0$) gives a log-concave measure ($\varrho^* = 0$). As ϱ falls to $-\frac{1}{L}$, ϱ^* falls to $-\infty$, so only quasi-concavity survives. Since $\frac{\mathrm{d}\varrho^*}{\mathrm{d}\varrho} = \frac{1}{(1+L\varrho)^2} > 0$, more concave densities give more concave measures.

Theorem 4.19 (Concavity of demand)**.** *Suppose A1 holds, ψ is ϱ-concave with $\varrho \geq -\frac{1}{L}$ on a convex support, and products are distinct. Then each firm's demand is ϱ^*-concave in its own price, with $\varrho^* = \frac{\varrho}{1+L\varrho}$, on the interval of prices where demand is positive (Caplin and Nalebuff, 1991, Theorem 1).*

Proof. Fix p_{-j} and let $\mathcal{A}_j(p_j)$ be the set of types who weakly prefer j at price p_j to every other product. Take prices p_0 and p_1 with positive demand, $\lambda \in [0,1]$, and $p_\lambda = \lambda p_0 + (1-\lambda) p_1$. Let $v_0 \in \mathcal{A}_j(p_0)$ and $v_1 \in \mathcal{A}_j(p_1)$. By A1, for every $k \neq j$,

$$\sum_l v_{0l} t_l(x_j) + g(y - p_0) t_{L+1}(x_j) + t_{L+2}(x_j) \geq \sum_l v_{0l} t_l(x_k) + g(y - p_k) t_{L+1}(x_k) + t_{L+2}(x_k),$$
$$\sum_l v_{1l} t_l(x_j) + g(y - p_1) t_{L+1}(x_j) + t_{L+2}(x_j) \geq \sum_l v_{1l} t_l(x_k) + g(y - p_k) t_{L+1}(x_k) + t_{L+2}(x_k).$$

Multiply the first line by λ, the second by $1-\lambda$, and add. Both sides are affine in the type, and p_k is the same in both lines, so with $v_\lambda = \lambda v_0 + (1-\lambda)v_1$,

$$\sum_l v_{\lambda l} t_l(x_j) + \big[\lambda g(y-p_0) + (1-\lambda) g(y-p_1)\big] t_{L+1}(x_j) + t_{L+2}(x_j) \\ \geq \sum_l v_{\lambda l} t_l(x_k) + g(y-p_k) t_{L+1}(x_k) + t_{L+2}(x_k).$$

Concavity of g gives $g(y-p_\lambda) \geq \lambda g(y-p_0) + (1-\lambda) g(y-p_1)$, and $t_{L+1}(x_j) > 0$. Replacing the bracket by $g(y-p_\lambda)$ therefore raises the left side, so type v_λ weakly prefers j at price p_λ. We have shown

$$\mathcal{A}_j(p_\lambda) \supseteq \lambda \mathcal{A}_j(p_0) + (1-\lambda)\mathcal{A}_j(p_1).$$

Ties have zero mass because products are distinct, so $q_j(p) = \int_{\mathcal{A}_j(p)} \psi$. Monotonicity of the integral and the Prékopa-Borell inequality (4.25) give

$$q_j(p_\lambda) \geq \int_{\lambda \mathcal{A}_j(p_0) + (1-\lambda)\mathcal{A}_j(p_1)} \psi \geq \mathcal{M}_{\varrho^*}\big(q_j(p_0), q_j(p_1); \lambda\big),$$

which is ϱ^*-concavity of q_j in p_j (Caplin and Nalebuff, 1991, p. 28). □

The proof uses A1 in one place: the set of buyers at an intermediate price contains the Minkowski average of the buyer sets at the two end prices. Linearity in v lets the two preference inequalities be averaged, and concavity of g handles the price.

Example 4.20 (Uniform types on a simplex)**.** Let types be uniform on the L-dimensional unit simplex $\{v \geq 0 : \sum_l v_l \leq 1\}$ and let reservation prices be $R(v) = 1 - \sum_l v_l$ (Caplin and Nalebuff, 1991, Example 4.1). This arises, for example, from $U = \sum_l v_l x_l + z$ when a rival product with characteristics $(1, \ldots, 1)$ sells at price 1 and our product has characteristics $(0, \ldots, 0)$. At price $p \in [0,1]$ the buyers are the types with $\sum_l v_l \leq 1-p$, a copy of the simplex scaled by $1-p$. Its volume is $(1-p)^L$ times the volume of the simplex, so

$$q(p) = (1-p)^L, \qquad q(p)^{\frac{1}{L}} = 1-p.$$

Demand is $\frac{1}{L}$-concave and no more, which is exactly the bound $\varrho^* = \frac{1}{L}$ of Theorem 4.19 for a uniform density. The buyer set at p_λ equals the Minkowski average of the buyer sets at p_0 and p_1, because $\lambda(1-p_0)T + (1-\lambda)(1-p_1)T = (1-p_\lambda)T$ for the convex simplex T. Figure 4.4 draws the case $L = 2$.

A concave density behaves like an extra dimension of uniform types. Let $L = 1$, $\psi(v) = 2v$ on $[0,1]$ and $R(v) = 1 - v$. Then

$$q(p) = \int_0^{1-p} 2v \, \mathrm{d}v = (1-p)^2,$$

the same demand as uniform types on the two-dimensional simplex (Caplin and Nalebuff, 1991, Example 4.2). The density is linear, hence 1-concave, and Theorem 4.19 gives $\varrho^* = \frac{1}{1+1} = \frac{1}{2}$, again exactly attained. More generally, a density with $\psi^{\frac{1}{n}}$ concave for a positive integer n yields the bound $\frac{1}{L+n}$ of a uniform density in $L+n$ dimensions.

The bounds of Theorem 4.19 cannot be improved (Caplin and Nalebuff, 1991, Proposition 2). For every $\varrho > -\frac{1}{L}$ some model satisfies A1 with a ϱ-concave density and has q^{ϱ^*} affine in

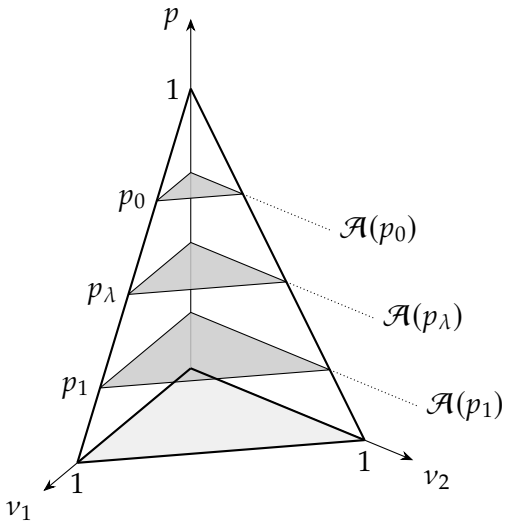

Figure 4.4: Buyer sets when types are uniform on the two-dimensional simplex and $R(v) = 1 - v_1 - v_2$. At price p the set of buyers $\mathcal{A}(p)$ is the triangle $\{v \geq 0 : v_1 + v_2 \leq 1 - p\}$, which shrinks linearly as p rises, so $q(p) = (1-p)^2$. With $p_\lambda = \lambda p_0 + (1-\lambda)p_1$ (here $\lambda = \frac{1}{2}$), the set $\mathcal{A}(p_\lambda)$ is the Minkowski average of $\mathcal{A}(p_0)$ and $\mathcal{A}(p_1)$. Redrawn from Caplin and Nalebuff (1991), Figure 1.

price. Such a demand is ϱ^*-concave and no more. In the following examples $U = \sum_l v_l x_l + z$, our product has characteristics $(1, 0, \ldots, 0)$, and a rival with characteristics $(0, \ldots, 0)$ sells at price zero. Type v then buys our product exactly when $v_1 \geq p$, so $R(v) = v_1$. In each example ψ^ϱ, or $\ln \psi$ when $\varrho = 0$, is affine on the support, so ψ is ϱ-concave.

- For $\varrho > 0$, let ψ be proportional to $(1 - \sum_l v_l)^{\frac{1}{\varrho}}$ on the unit simplex. Then $q(p) = (1-p)^{\frac{1+L\varrho}{\varrho}}$ on $[0, 1]$.
- For $\varrho = 0$, let $\psi(v) = e^{-\sum_l v_l}$ on $\mathbb{R}^L_+$. Then $q(p) = e^{-p}$.
- For $-\frac{1}{L} < \varrho < 0$, let ψ be proportional to $(1 + \sum_l v_l)^{\frac{1}{\varrho}}$ on $\mathbb{R}^L_+$, which is integrable because $\frac{1}{\varrho} < -L$. Then $q(p) = (1+p)^{\frac{1+L\varrho}{\varrho}}$ for $p \geq 0$. It falls with price because the exponent is negative.

Each demand follows by integrating out $v_2, \ldots, v_L$ and then v_1 from p upward. In every case q^{ϱ^*} is affine in p, because $\frac{1+L\varrho}{\varrho} = \frac{1}{\varrho^*}$.

The examples also show why earlier work, which assumed concave demand, could not go far. Theorem 4.19 guarantees concave demand only if $\varrho^* = 1$. Since $\varrho^* \leq \frac{1}{L}$ for every ϱ, this guarantee holds only when $L = 1$ and $\varrho = \infty$: a uniform distribution of consumers in a one-dimensional market (Caplin and Nalebuff, 1991, p. 14). The bound holds for the whole class and does not cap the concavity of each model. In the setup of the examples above with $L = 1$, the density $\psi(v) = 2v$ on $[0, 1]$ has the bound $\varrho^* = \frac{1}{2}$, yet its demand $q(p) = 1 - p^2$ is concave.

Proposition 4.21 (Quasi-concave profit)**.** *Under A1 and A2, with distinct products, each firm's profit is quasi-concave in its own price (Caplin and Nalebuff, 1991, Proposition 4).*

Proof. A2 sets $\varrho = -\frac{1}{L+1}$, which exceeds $-\frac{1}{L}$, so Theorem 4.19 applies. The implied concavity

index of demand is

$$\varrho^* = \frac{\varrho}{1 + L\varrho} = \frac{-\frac{1}{L+1}}{1 - \frac{L}{L+1}} = \frac{-\frac{1}{L+1}}{\frac{1}{L+1}} = -1.$$

Demand is (-1)-concave, that is, $\frac{1}{q_j}$ is convex where $q_j > 0$. Demand is nonincreasing by (4.24). Lemma 4.15 then gives quasi-concavity of profit. □

The value $\varrho = -\frac{1}{L+1}$ in A2 is thus chosen to deliver exactly (-1)-concave demand, the weakest condition that guarantees quasi-concave profit. Solving $\frac{\varrho}{1+L\varrho} = -1$ for ϱ gives $\varrho = -1 - L\varrho$, so $\varrho(1 + L) = -1$ and $\varrho = -\frac{1}{L+1}$.

Theorem 4.22 (Existence)**.** *Under A1 and A2, for any number of single-product firms and any products, a pure-strategy Bertrand-Nash equilibrium exists (Caplin and Nalebuff, 1991, Theorem 2).*

Proof. We follow Caplin and Nalebuff (1991, pp. 14–15) in three steps.

Distinct products, all costs below income. Restrict firm j to prices in $[c_j, y]$ and let $Z = \prod_j [c_j, y]$, a nonempty, compact, convex set. Prices above y sell nothing, and prices below c_j earn at most zero, which the price c_j also earns. Hence a maximizer on $[c_j, y]$ is a global best response. Demand is continuous because products are distinct, so profits are continuous in all prices. By Berge's maximum theorem, the restricted best-response correspondence has nonempty compact values and a closed graph. By Proposition 4.21, profit is quasi-concave in own price, and the set of maximizers of a quasi-concave function on an interval is an interval. Kakutani's theorem gives a fixed point, which is an equilibrium because every firm plays a global best response.

Equivalent products. If several products are equivalent, all consumers buy the cheapest of them, as in homogeneous Bertrand competition. In each such group, select a lowest-cost producer and solve the game with distinct products among the selected firms. Each selected firm faces the added constraint that it prices no higher than the cost of the next-lowest-cost producer in its group. Let the remaining firms price at cost. They are undercut, sell nothing, and cannot gain by deviating.

Costs above income. Firms with $c_j > y$ can sell nothing at a profit. Solving the game without them and letting them price at cost preserves the equilibrium. □

Interpretation and related work. The theorem holds for any number of firms and any configuration of products, with no symmetry. It gives *sufficient* conditions, and equilibria often exist when they fail. Caplin and Nalebuff (1991, p. 15) relate their approach to the independent work of Dierker (1989). Dierker takes the joint distribution of consumers' valuations of the products as the primitive and assumes it is log-concave. Prékopa's theorem then makes demand log-concave. Caplin and Nalebuff (1991) instead start from a model of the characteristics space and of preference parameters, and derive the valuations. Their framework supplies a large set of utility models for which the joint distribution of valuations is log-concave for every set of products.

Extensions. Caplin and Nalebuff (1991, Section 8) extend the result in several directions. We summarize them briefly.

- *Unequal incomes.* Income enters as an additional type. Assumption A1′ of Caplin and Nalebuff (1991, p. 20) is A1 with $g(z) = z$. Then the reservation price of type (v, y) for

product j is

$$R_j(v, y) = y + \frac{v \cdot \boldsymbol{t}_j + t_{L+2}(x_j) - \max_{k \neq j}\left[v \cdot \boldsymbol{t}_k + (y - p_k)t_{L+1}(x_k) + t_{L+2}(x_k)\right]}{t_{L+1}(x_j)},$$

with $\boldsymbol{t}_j = (t_1(x_j), \ldots, t_L(x_j))$. A maximum of affine functions is convex, so R_j is concave in (v, y). The buyer sets therefore satisfy the Minkowski inclusion of the proof of Theorem 4.19, now in $\mathbb{R}^{L+1}$. Assumption A2′ requires the joint density of types and income to be $\left(-\frac{1}{L+2}\right)$-concave on a convex support in $\mathbb{R}^{L+1}$, with bounded income. With $L+1$ in place of L, the computation in the proof of Proposition 4.21 again gives $\varrho^* = -1$, and an equilibrium exists (their Proposition 10). The vertical model $U = xz$ (Gabszewicz and Thisse, 1979; Shaked and Sutton, 1982) is a special case. Uniqueness extends as well. Under A1′, if the logarithm of the joint density is concave and differentiable where the density is positive, the duopoly equilibrium is unique and the pricing game is log-supermodular. Pure vertical differentiation, with identical preferences and different incomes, is the one-dimensional case of their Proposition 7 (p. 20).

- *An outside good.* Add a fictitious firm 0 selling $x_0 = 0$ at the fixed price $p_0 = 0$. Existence is unaffected, but the duopoly uniqueness result below no longer applies, because the market becomes a three-firm oligopoly. In location models the product $x_0 = 0$ is a differentiated product located at the origin, not the absence of consumption. Non-purchase can still be modeled by a utility loss from buying nothing that is concave in the type (pp. 20–21).
- *Variable and non-exclusive demand.* The reservation-price argument no longer applies. With individual demands $d_j(v, y, p_j)$, aggregate demand is $\int \psi(v, y)\, d_j(v, y, p_j)\, \mathrm{d}v\, \mathrm{d}y$. Prékopa (1973) shows that integrating a jointly log-concave function over some of its arguments yields a log-concave function of the rest. If $\ln d_j$ is concave in $(v, y, \ln p_j)$ and $\ln \psi$ is concave, aggregate demand is log-concave in $\ln p_j$, and Lemma 4.16 gives quasi-concave profit. Cobb-Douglas preferences satisfy these conditions, and an equilibrium exists with two or more firms and positive costs, unique in duopoly.
- *CES.* The representative-consumer CES model generates the same demands as a discrete-continuous choice model with i.i.d. extreme value tastes (Caplin and Nalebuff, 1991, eq. (8.3)). Hence an equilibrium exists in the CES model with two or more firms and positive costs, unique in duopoly (Caplin and Nalebuff, 1991, Proposition 14). Sections 4.7.2 and 4.7.4 derive the representation and explain why one firm is not enough.
- *Translog.* With indirect translog demands and an own-price coefficient common to all consumers, $\ln d_j$ is concave in its arguments, and log-concave densities give quasi-concave profit.
- *Unbounded markets.* With infinitely many products in an unbounded space, any price vector that satisfies all first-order conditions, and at which A1 and A2 hold, is an equilibrium (Caplin and Nalebuff, 1991, Proposition 15). This validates the first-order approach of Stiglitz (1986) with quadratic transport costs.

Contribution and limits. Before Caplin and Nalebuff (1991), existence results required one-dimensional products, uniform consumers or complete symmetry. Their theorem covers multi-dimensional characteristics, asymmetric products and the discrete choice models that empirical work uses. It also brought ϱ-concavity and the Prékopa-Borell theorem into industrial organization. The limits are as instructive. Each firm sells one product, and the proof does not

extend to multi-product firms, whose profit need not be quasi-concave in the vector of own prices. The density condition excludes type distributions with separated groups of consumers, such as finite mixtures of logits with very different price sensitivities. Products are fixed, so the theorem says nothing about product choice. Finally, uniqueness requires more, as the next subsection shows.

Caplin and Nalebuff close by pointing to product choice as the next step (pp. 26–27). Where the equilibrium is both existent and unique, as in the logit with any number of products and in duopoly, firms can predict their profits for any configuration of competing products. Product design can then be studied with price competition in the second stage. Prescott and Visscher (1977) had studied sequential location with fixed prices. Caplin and Nalebuff also cite a 1989 working paper by Feenstra and Levinsohn that uses a variant of their model to map consumer preferences for the characteristics of cars. Section 4.8 studies product choice in the simplest settings.

4.4.4 Uniqueness

Uniqueness matters for counterfactuals: a model that predicts several outcomes after a merger predicts none of them reliably. The classical sufficient condition is a dominant diagonal of the matrix of second derivatives of profit (Friedman, 1977). We state it for single-product firms.

Proposition 4.23 (Diagonal dominance)**.** *Let firm j choose $p_j \in P_j = [\underline{p}_j, \bar{p}_j]$ and let $P = \prod_j P_j$. Suppose that*

(i) Each π_j is twice continuously differentiable on an open set containing P.

(ii) For every p_{-j}, $\pi_j(\cdot, p_{-j})$ has a unique maximizer $BR_j(p_{-j})$ in the interior of P_j, at which $\frac{\partial^2 \pi_j}{\partial p_j^2} < 0$.

(iii) At every such maximizer, $\sum_{k \neq j} \left| \frac{\partial^2 \pi_j}{\partial p_j \partial p_k} \right| < \left| \frac{\partial^2 \pi_j}{\partial p_j^2} \right|$.

Then the best-response map $BR : P \to P$ is a contraction in the sup norm. The game has exactly one Bertrand-Nash equilibrium, and best-response iteration converges to it from every starting point in P.

Proof. Best responses satisfy the first-order condition $\frac{\partial \pi_j}{\partial p_j}(BR_j(p_{-j}), p_{-j}) = 0$. By (ii) the derivative of the left side with respect to p_j is nonzero at the maximizer, so the implicit function theorem makes BR_j continuously differentiable, with

$$\frac{\partial BR_j}{\partial p_k} = -\left(\frac{\partial^2 \pi_j}{\partial p_j^2}\right)^{-1} \frac{\partial^2 \pi_j}{\partial p_j \partial p_k}\bigg|_{p_j = BR_j(p_{-j})}.$$

By (iii), $\sum_{k \neq j} \left| \frac{\partial BR_j}{\partial p_k} \right| < 1$ at every p_{-j}. This sum is continuous on the compact set $\prod_{k \neq j} P_k$, so its maximum ℓ_j is below one. Let $\ell = \max_j \ell_j < 1$. For $p, p' \in P$, apply the mean value theorem to $t \mapsto BR_j(p'_{-j} + t(p_{-j} - p'_{-j}))$ on $[0,1]$. For some intermediate point $\tilde{p}_{-j}$,

$$|BR_j(p_{-j}) - BR_j(p'_{-j})| \le \sum_{k \neq j} \left| \frac{\partial BR_j}{\partial p_k}(\tilde{p}_{-j}) \right| |p_k - p'_k| \le \ell \, \|p - p'\|_\infty .$$

Taking the maximum over j gives $\|BR(p) - BR(p')\|_\infty \le \ell \|p - p'\|_\infty$. The contraction mapping theorem (Appendix B) gives a unique fixed point and convergence of the iteration $p^{(n+1)} = BR(p^{(n)})$ from any $p^{(0)} \in P$. □

The argument survives two changes of variables that are often useful. Best responses do not change if profit is replaced by an increasing transformation, such as $\ln \pi_j$, or if prices are replaced by smooth increasing functions of prices. Diagonal dominance may hold for the transformed problem when it fails for the original, and the conclusion about uniqueness carries over. A second route avoids best responses altogether. Stack the first-order conditions as $G(p) = 0$ with $G_j = \frac{\partial \pi_j}{\partial p_j}$. A *P-matrix* is a square matrix whose principal minors are all positive. If the Jacobian of $-G$ is a P-matrix everywhere on a rectangle, G is one-to-one there (Gale and Nikaidô, 1965). The first-order conditions then have at most one solution. A matrix with positive diagonal and strictly dominant diagonal rows is a P-matrix. Negative own second derivatives together with the inequality of (iii) at every point of the rectangle therefore suffice.

Uniqueness in the Caplin-Nalebuff framework. Caplin and Nalebuff (1991, Section 6) establish uniqueness in three cases, in the "differentiable case" where g is twice differentiable and ψ is differentiable. In a duopoly with A1 and a log-concave type density, the equilibrium is unique (their Proposition 6). In a one-dimensional market with a log-concave density on an interval, there is at most one equilibrium with a given set of active firms (Proposition 7). In the logit model the equilibrium is unique for any number of single-product firms, a result first noted for duopoly by Anderson and de Palma (1988). Firms with zero demand create no real indeterminacy. Any equilibrium in which some firms sell nothing has a counterpart with the same demands and profits in which those firms price at marginal cost (Proposition 5). Uniqueness thus refers to market outcomes.

The proofs change variables from p_j to the utility from money, $u_j = g(y - p_j)\, t_{L+1}(x_j)$. In a duopoly, demand depends on the two utilities only through the difference $u_1 - u_2$. Write $\tilde{q}_1(u_1 - u_2)$ for firm 1's demand and $\tilde{p}_1(u_1) = y - g^{-1}\left(\frac{u_1}{t_{L+1}(x_1)}\right)$ for the price that delivers u_1. Then

$$\ln \pi_1 = \ln\bigl(\tilde{p}_1(u_1) - c_1\bigr) + \ln \tilde{q}_1(u_1 - u_2).$$

The first term is strictly concave in u_1 because $\tilde{p}_1$ is concave. The second is concave because the Prékopa-Borell theorem makes demand log-concave in u_1. Because $\tilde{q}_1$ depends on $u_1 - u_2$ only,

$$\frac{\partial^2 \ln \tilde{q}_1}{\partial u_1^2} = -\frac{\partial^2 \ln \tilde{q}_1}{\partial u_1 \partial u_2} \leq 0, \qquad \text{so} \qquad \frac{\partial^2 \ln \pi_1}{\partial u_1^2} < \frac{\partial^2 \ln \tilde{q}_1}{\partial u_1^2} = -\frac{\partial^2 \ln \pi_1}{\partial u_1 \partial u_2}.$$

This is diagonal dominance for $\ln \pi_1$ in the utility variables, and the remark after Proposition 4.23 gives uniqueness (Caplin and Nalebuff, 1991, p. 30). The cross partial $\frac{\partial^2 \ln \pi_1}{\partial u_1 \partial u_2}$ is nonnegative, which is the next property.

Log-supermodularity. A positive payoff $\pi_j(p_j, p_{-j})$ is *log-supermodular* if $\ln \pi_j$ has increasing differences in (p_j, p_k) for every $k \neq j$. For smooth payoffs this means $\frac{\partial^2 \ln \pi_j}{\partial p_j \partial p_k} \geq 0$: a higher rival price raises the marginal return, in logs, to a higher own price. A price game with interval strategy sets and log-supermodular payoffs is a supermodular game (Milgrom and Roberts, 1990; Vives, 1990). Caplin and Nalebuff (1991, p. 16) summarize what log-supermodularity adds to uniqueness, drawing on Milgrom and Roberts (1990):

- There are no other equilibria in mixed or correlated strategies.
- The equilibrium is globally stable under many learning and adjustment processes, including best-response dynamics, Bayesian learning and fictitious play.
- The game is *dominance solvable*, meaning that iterated deletion of strictly dominated strategies leaves a single strategy profile. The equilibrium strategy is therefore each

firm's unique *rationalizable* strategy, the only one consistent with common knowledge of rationality.

- A parameter change that raises the marginal return to price for some firm, such as an increase in one firm's cost, raises every firm's equilibrium price.

The logit is log-supermodular. With single-product firms, $\ln \pi_j = \ln(p_j - c_j) + \ln s_j$ and $\frac{\partial \ln s_j}{\partial p_j} = -\alpha(1 - s_j)$, so

$$\frac{\partial^2 \ln \pi_j}{\partial p_j \partial p_k} = \alpha \frac{\partial s_j}{\partial p_k} = \alpha^2 s_j s_k > 0.$$

The single-product logit. For the logit model we can compute the slopes of the best responses directly.

Proposition 4.24 (Logit best responses)**.** *Consider single-product firms with constant marginal costs c_j and logit demand. The best response of firm j is continuously differentiable, with slopes*

$$\frac{\partial BR_j}{\partial p_k} = \frac{s_j s_k}{1 - s_j} \in (0, 1), \qquad k \neq j, \tag{4.26}$$

evaluated at $(BR_j(p_{-j}), p_{-j})$. Prices are strategic complements, the row sums satisfy $\sum_{k \neq j} \frac{\partial BR_j}{\partial p_k} = \frac{s_j(1 - s_j - s_0)}{1 - s_j} < s_j$, and the equilibrium is unique.

Proof. From Proposition 4.7 the best response solves $\alpha m_j(1 - s_j) = 1$ with $m_j = p_j - c_j$, and it is the global maximizer because $\frac{\partial \pi_j}{\partial p_j} = s_j[1 - \alpha m_j(1 - s_j)]$ changes sign once (Section 4.2.6). Define $G_j(p) = \alpha(p_j - c_j)(1 - s_j(p)) - 1$, so that $G_j = 0$ at the best response. Using (4.8),

$$\frac{\partial G_j}{\partial p_j} = \alpha(1 - s_j) - \alpha m_j \frac{\partial s_j}{\partial p_j} = \alpha(1 - s_j) + \alpha^2 m_j s_j (1 - s_j) = \alpha(1 - s_j)(1 + \alpha m_j s_j),$$
$$\frac{\partial G_j}{\partial p_k} = -\alpha m_j \frac{\partial s_j}{\partial p_k} = -\alpha^2 m_j s_j s_k.$$

The implicit function theorem gives

$$\frac{\partial BR_j}{\partial p_k} = -\left(\frac{\partial G_j}{\partial p_j}\right)^{-1} \frac{\partial G_j}{\partial p_k} = \frac{\alpha m_j s_j s_k}{(1 - s_j)(1 + \alpha m_j s_j)}.$$

At the best response $\alpha m_j = \frac{1}{1 - s_j}$. The numerator becomes $\frac{s_j s_k}{1 - s_j}$. The denominator becomes $(1 - s_j)\left(1 + \frac{s_j}{1 - s_j}\right) = 1$. This proves (4.26). Summing over $k \neq j$ and using $\sum_{k \neq j} s_k = 1 - s_j - s_0$ gives the row sum, which is below s_j because $s_0 > 0$.

For uniqueness we bound s_j at the best response uniformly. Section 4.2.6 showed that $\alpha m_j - 1 = W(z_j)$ with $z_j = \frac{e^{v_j - 1}}{\Phi_{-j}}$, where W is the Lambert W function and $v_j = x_j\beta + \xi_j - \alpha c_j$. Then $s_j = 1 - \frac{1}{\alpha m_j} = \frac{W(z_j)}{1 + W(z_j)}$. Since $\Phi_{-j} \geq 1$ and W is increasing, $s_j \leq \bar{s}_j \equiv \frac{W(e^{v_j - 1})}{1 + W(e^{v_j - 1})} < 1$ for every p_{-j}. Every row sum is therefore below $\ell = \max_j \bar{s}_j < 1$, uniformly in prices. Best responses lie in the compact box $\prod_j [c_j + \frac{1}{\alpha},\ c_j + \frac{1 + W(e^{v_j - 1})}{\alpha}]$, so the argument of Proposition 4.23 applies on that box. The best-response map is a contraction with modulus ℓ and has a unique fixed point. □

Multi-product logit. Proposition 4.24 does not cover multi-product firms, and Caplin and Nalebuff (1991) do not either. Uniqueness nevertheless holds for every ownership structure. Konovalov and Sándor (2010, Theorem 7) prove it for multi-product firms with logit demand. Nocke and Schutz (2018) develop an aggregative-games approach for multi-product pricing that covers the logit and CES demand systems (Asker and Nocke, 2021, p. 229, n. 127). We give a self-contained proof along aggregative lines.

Theorem 4.25 (Uniqueness with multi-product logit firms)**.** *With logit demand, constant marginal costs and any partition of the J products among F firms, the Bertrand-Nash pricing game has exactly one equilibrium.*

Proof. Let $v_k = x_k\beta + \xi_k - \alpha\, mc_k$, $m_k = p_k - mc_k$ and $E_f = \sum_{k\in\mathcal{J}_f} e^{v_k}$. Then $e^{\delta_k} = e^{v_k - \alpha m_k}$. Firm f takes $\Phi_{-f} = 1 + \sum_{l\notin\mathcal{J}_f} e^{\delta_l}$ as given.

Step 1 (given its total, a firm sets a common markup). Let $\chi_k = e^{v_k-\alpha m_k}$ for $k \in \mathcal{J}_f$, so $m_k = \frac{v_k - \ln\chi_k}{\alpha}$, and let $a = \sum_{k\in\mathcal{J}_f}\chi_k$. Firm f's profit is

$$\pi_f = \frac{\sum_{k\in\mathcal{J}_f} m_k\chi_k}{\Phi_{-f}+a} = \frac{1}{\alpha}\,\frac{\sum_{k\in\mathcal{J}_f}\chi_k(v_k - \ln\chi_k)}{\Phi_{-f}+a}.$$

For fixed a the denominator is fixed. The numerator is strictly concave in (χ_k), because $-\chi\ln\chi$ is strictly concave, and its slope in χ_k tends to $+\infty$ as $\chi_k \to 0$. Its maximum on $\{\chi > 0 : \sum_k \chi_k = a\}$ is therefore unique and interior. The Lagrangian first-order condition $v_k - \ln\chi_k - 1 = \mu$ gives $\alpha m_k = v_k - \ln\chi_k = 1 + \mu$ for all $k \in \mathcal{J}_f$. All of the firm's products carry the same markup m, and then $a = E_f e^{-\alpha m}$.

Step 2 (the firm's best response). Since a and m are in one-to-one correspondence, the firm's problem reduces to choosing m to maximize $m\,S_f(m)$ with $S_f(m) = \frac{E_f e^{-\alpha m}}{\Phi_{-f}+E_f e^{-\alpha m}}$. This is a single-product logit problem with mean utility $\ln E_f$. Since $\frac{\mathrm{d}S_f}{\mathrm{d}m} = -\alpha S_f(1-S_f)$,

$$\frac{\mathrm{d}(mS_f)}{\mathrm{d}m} = S_f\big[1 - \alpha m(1-S_f(m))\big].$$

The bracket is positive for $m \le 0$. For $m > 0$ it is strictly decreasing, because m and $1 - S_f(m)$ are positive and increasing, and it tends to $-\infty$. It therefore changes sign once. The best response is unique and is characterized by

$$\alpha m_f(1-S_f) = 1. \tag{4.27}$$

Step 3 (one equation per firm). In any equilibrium let $\Phi = 1 + \sum_k e^{\delta_k}$. Then $S_f = \frac{E_f e^{-\alpha m_f}}{\Phi}$, and (4.27) gives $\alpha m_f = \frac{1}{1-S_f}$. Substituting,

$$S_f = \frac{E_f}{\Phi}\, e^{-\frac{1}{1-S_f}} \quad\Longleftrightarrow\quad h(S_f) \equiv S_f\, e^{\frac{1}{1-S_f}} = \frac{E_f}{\Phi}.$$

The function h satisfies $h(0) = 0$, $h(S) \to \infty$ as $S \to 1$, and

$$h'(S) = e^{\frac{1}{1-S}}\left[1 + \frac{S}{(1-S)^2}\right] > 0.$$

For each $\Phi > 0$ there is a unique $S_f(\Phi) \in (0,1)$ with $h(S_f(\Phi)) = \frac{E_f}{\Phi}$. It is continuous and strictly decreasing in Φ.

Step 4 (one equation for the aggregate). Shares add up to one, and $s_0 = \frac{1}{\Phi}$. Hence Φ solves

$$\Psi(\Phi) \equiv \sum_{f=1}^{F} S_f(\Phi) + \frac{1}{\Phi} = 1.$$

Ψ is continuous and strictly decreasing. At $\Phi = 1$, $\Psi(1) = 1 + \sum_f S_f(1) > 1$. As $\Phi \to \infty$, $\Psi(\Phi) \to 0$. There is exactly one root $\Phi^* > 1$.

Step 5 (existence and uniqueness of prices). Any equilibrium must have $\Phi = \Phi^*$, shares $S_f^* = S_f(\Phi^*)$, markups $m_f^* = \frac{1}{\alpha(1-S_f^*)}$ and prices $p_k^* = mc_k + m_{f(k)}^*$, where $f(k)$ is the owner of k. So there is at most one equilibrium. Conversely, at these prices, $1 + \sum_f E_f e^{-\alpha m_f^*} = 1 + \Phi^* \sum_f S_f^* = 1 + \Phi^*\left(1 - \frac{1}{\Phi^*}\right) = \Phi^*$, so the aggregate is consistent. Each firm's markup satisfies (4.27), which by Step 2 makes it a best response. The prices form an equilibrium. □

The aggregative proof also yields a contraction. Differentiating the multi-product Lambert W best response $m_f = \frac{1}{\alpha}\left[1 + W\left(\frac{E_f e^{-1}}{\Phi_{-f}}\right)\right]$ with $W'(z) = \frac{W(z)}{z(1+W(z))}$ gives $\frac{\partial BR_k}{\partial p_l} = \frac{S_f s_l}{1-S_f}$ for $k \in \mathcal{J}_f$ and $l \notin \mathcal{J}_f$, and zero for $l \in \mathcal{J}_f$. Row sums equal $\frac{S_f(1-S_f-s_0)}{1-S_f} < S_f$, and $S_f \le \frac{W(E_f e^{-1})}{1+W(E_f e^{-1})} < 1$ at any best response. Best-response iteration therefore converges from any starting point.

Example 4.26 (Uniqueness in the 25-product market)**.** In the 25-product market of Example 4.8, we evaluated $\Psi(\Phi) - 1$ on a grid of 2,000 points spaced evenly in logarithms over $[1, 10^4]$. It changes sign exactly once, at $\Phi^* = 7.314$ under single-product ownership and at $\Phi^* = 6.246$ under the five multi-product owners. In each case Φ^* equals $\frac{1}{s_0}$ at the equilibrium of Table 4.2, with outside shares 0.1367 and 0.1601. Best-response iteration from $p^{(0)} = mc + \frac{1}{\alpha}$ converges in 11 and 16 iterations to a sup-norm tolerance of 10^{-13}, one iteration more than the looser tolerance of Remark 4.9 requires. From 500 random starting points $p^{(0)} = mc + U[0,5]^{25}$, and from $p^{(0)} = mc$ and $mc + 20$, it reaches the same prices to within 6×10^{-15} and 3×10^{-14}. The contraction modulus at the equilibrium, $\max_f \frac{S_f(1-S_f-s_0)}{1-S_f}$, is 0.099 and 0.199. Computed with `figures/ch04/src/logit_uniqueness_check.py`.

When no theorem applies. Most demand systems estimated in practice, such as random coefficients logit with multi-product firms, lack a uniqueness theorem. Researchers then check numerically. They solve the first-order conditions from many starting values and compare the solutions. They monitor the contraction property of the iteration they use, and they can trace solutions by homotopy as a parameter moves from a case with a known unique equilibrium. A *homotopy* deforms one system of equations continuously into another. Each candidate should also be checked for global optimality, for instance by a grid search over each firm's own prices. When profit is not quasi-concave, a solution of the first-order conditions need not be an equilibrium.

4.4.5 Multiple equilibria

Elasticities and diversion ratios depend on prices. The first-order conditions are therefore a nonlinear system, which can have several solutions. Multiplicity arises naturally when consumers form separated groups, because a firm may then target either group. The following example has two equilibria.

Example 4.27 (A two-segment logit duopoly)**.** Two single-product firms have marginal cost $c = 1$. The market has mass one and an outside good. Consumer i in segment $h \in \{A, B\}$ has utility $u_{ij} = \delta - \alpha_h p_j + \epsilon_{ij}$ for $j = 1, 2$ and $u_{i0} = \epsilon_{i0}$, with $\delta = 3$ and i.i.d. type-I extreme value shocks. Segment A has mass $M_A = 0.9$ and price coefficient $\alpha_A = 2$. Segment B has mass $M_B = 0.1$ and $\alpha_B = 0.2$. Demand is a mixture of two logits:

$$s_j(p) = \sum_{h \in \{A,B\}} M_h \, s_{hj}(p), \qquad s_{hj}(p) = \frac{e^{\delta - \alpha_h p_j}}{1 + e^{\delta - \alpha_h p_1} + e^{\delta - \alpha_h p_2}}.$$

Firm j earns $\pi_j = (p_j - c)\, s_j(p)$. Since $\frac{\partial s_{hj}}{\partial p_j} = -\alpha_h s_{hj}(1 - s_{hj})$, the first-order condition $s_j + (p_j - c)\frac{\partial s_j}{\partial p_j} = 0$ gives

$$p_j - c = \frac{\sum_h M_h s_{hj}}{\sum_h M_h \, \alpha_h s_{hj}(1 - s_{hj})}. \tag{4.28}$$

The markup is the reciprocal of a share-weighted average of the segments' semi-elasticities. At low prices both segments buy, the price-sensitive segment dominates the denominator, and the markup is small. At high prices only segment B buys, and the markup approaches $\frac{1}{\alpha_B(1 - s_{Bj})}$.

We computed best responses by maximizing profit globally over own prices in $[1, 25]$ on a grid of step 0.0005, followed by local refinement. We then searched for fixed points of BR and of $BR \circ BR$ on $[1, 25]$. There are exactly two equilibria, both symmetric, and no asymmetric equilibrium.

- The *mass-market equilibrium* L has $p_1 = p_2 = 1.804$. Each firm's share is 0.283 (0.261 in segment A and 0.483 in segment B), its profit is 0.227 and the outside share is 0.434.
- The *niche equilibrium* H has $p_1 = p_2 = 9.711$. Each firm's share is 0.043, almost entirely from segment B (0.426 of it), its profit is 0.371 and the outside share is 0.915.

The markups 0.804 and 8.711 satisfy (4.28). At H the formula gives $\frac{1}{0.2 \times (1 - 0.426)} = 8.71$ because segment A buys almost nothing. Neither equilibrium admits a profitable deviation to the other local maximum of profit. At L the best niche price, 7.486, earns 0.150 against 0.227. At H the best mass-market price, 1.915, earns 0.321 against 0.371.

The best response jumps. When the rival's price rises past 7.988, firm j abandons the mass market: its best response jumps from 1.904 to 9.168, the two prices giving the same profit of 0.317. A second jump occurs for rival prices below 1.045, where the rival takes so much of segment A that the niche becomes more profitable. Neither jump creates an equilibrium. The slopes of the best response at L and H are 0.075 and 0.316. Figure 4.5 shows the best responses and the bimodal profit function at the upper jump.

Firms prefer H, where each earns 0.371 instead of 0.227. Consumers prefer L. Measured by the log-sum formula $\sum_h \frac{M_h}{\alpha_h} \ln\!\left(1 + e^{\delta - \alpha_h p_1} + e^{\delta - \alpha_h p_2}\right)$, consumer surplus is 2.02 at L and 0.96 at H, up to a common constant. Computed with `figures/ch04/src/multiple_equilibria.py`.

The example violates the Caplin-Nalebuff conditions in an instructive way. Dividing utility by α_h, a consumer of segment h buys j when $\frac{\delta + \epsilon_{ij} - \epsilon_{i0}}{\alpha_h} - p_j$ is largest. A1 holds with $g(z) = z$ and money-metric types $v_{ij} = \frac{\delta + \epsilon_{ij} - \epsilon_{i0}}{\alpha_h}$. Within a segment, the vector (v_{i1}, v_{i2}) is a linear transformation of independent extreme value shocks and has a log-concave density. Across segments, its density is a mixture of a component concentrated near $\frac{\delta}{\alpha_A} = 1.5$ and a component spread around $\frac{\delta}{\alpha_B} = 15$. The mixture is bimodal. It is not even quasi-concave, so A2 fails, and profit inherits two peaks from the two groups of consumers.

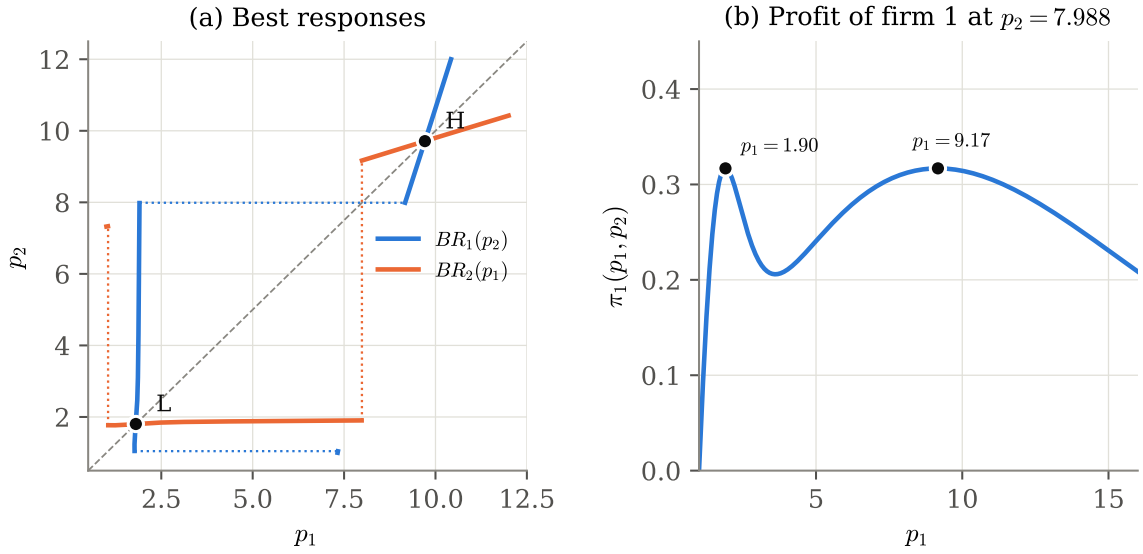

Figure 4.5: Two equilibria in the two-segment logit duopoly of Example 4.27. Panel (a): best responses $BR_1(p_2)$ and $BR_2(p_1)$, with dotted segments marking the jumps. They cross on the 45-degree line at the mass-market equilibrium L ($p^* = 1.804$) and at the niche equilibrium H ($p^* = 9.711$). Panel (b): firm 1's profit as a function of its own price when $p_2 = 7.988$. Two local maxima, at $p_1 = 1.904$ and $p_1 = 9.168$, give the same profit, so profit is not quasi-concave. Computed with `figures/ch04/src/multiple_equilibria.py`.

Consequences for empirical work. Multiplicity does not affect the estimation methods of this chapter. At the estimation stage, prices are data. We evaluate the first-order conditions at observed prices and invert them for marginal costs as in (4.31), so we never solve for an equilibrium. Whichever equilibrium generated the data, the first-order conditions hold at the observed prices. In games of entry and in dynamic games, by contrast, multiplicity complicates estimation itself.

Counterfactuals are different. A merger simulation or a policy experiment must solve for new prices, and with several solutions the researcher must choose among them. Three selection rules are common. The first starts the solver at the status quo prices. Merger simulations usually iterate from pre-merger prices, which selects the equilibrium in whose basin of attraction the status quo lies. The *basin of attraction* of an equilibrium is the set of starting points from which the iteration converges to it. The second picks the equilibrium the firms prefer, which here is H. The third requires stability under best-response dynamics. In Example 4.27 both equilibria are stable. Simultaneous best-response iteration from a symmetric start converges to L for starting prices below 7.988 and to H above. From an asymmetric start such as $(2, 12)$, however, it cycles between $(1.804, 9.711)$ and $(9.711, 1.804)$, although neither point is an equilibrium. Alternating best responses avoid the cycle. Stability depends on the adjustment process, and a careful counterfactual reports how its answer depends on the selection rule (Section 4.5.4).

These problems explain part of the popularity of demand systems with known uniqueness results, such as the logit and CES with multi-product firms (Theorem 4.25 and Nocke and Schutz, 2018). For richer systems, the checks listed at the end of Section 4.4.4 are the practical safeguard. They cannot prove uniqueness, but they can reveal multiplicity when it is present.

4.5 Using the supply side: costs, conduct and counterfactuals

Sections 4.2 to 4.4 characterized the pricing equilibrium and the conditions under which it exists and is unique. We now put the pricing rule to work. The first-order conditions (4.3) tie together four objects: the demand system and its derivatives, the ownership matrix, prices and marginal costs. Given any three of them, the conditions restrict the fourth. This section uses them in three directions. With estimated demand, observed prices and an assumed ownership structure, they recover marginal costs without any cost data (Section 4.5.2). With demand and independent information on margins, they let us compare models of conduct (Section 4.5.3). With demand, recovered costs and a changed environment, they predict the new equilibrium (Sections 4.5.4 and 4.5.5). We begin with the reasons for modeling supply at all.

4.5.1 Why model supply when we estimate demand?

Write the markup equation (4.4) product by product, and let marginal cost depend on observed *cost shifters* w_j (variables that move cost but not utility) and an unobserved cost shock ω_j:

$$p_j = mc_j(w_j, \omega_j) + m_j(p, x, \xi;\, \theta_d, \Omega), \qquad m = -\left(\Omega \odot \Delta^\top\right)^{-1} q. \tag{4.29}$$

Here θ_d collects the demand parameters, x and ξ stack the observed and unobserved characteristics of all products, and m_j is the jth element of the markup vector m. Equation (4.29) is a model of price. A product's price moves with its own cost and with every determinant of its markup, including the characteristics and prices of all other products. Three reasons to model supply follow from it.

Prices are endogenous, and supply tells us which instruments are valid. Take the logit demand of Section 4.2.6, with mean utility $\delta_j = x_j\beta - \alpha p_j + \xi_j$. Firms observe the unobserved quality ξ_j when they set prices, so p_j responds to it. For a single-product firm the pricing condition is $p_j = mc_j + \frac{1}{\alpha(1-s_j)}$ by Proposition 4.7. Hold rivals' prices fixed and define

$$F(p_j, \xi_j) \equiv p_j - mc_j - \frac{1}{\alpha(1 - s_j)} = 0.$$

The logit derivatives (4.8) give $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$, and the same algebra gives $\frac{\partial s_j}{\partial \xi_j} = s_j(1 - s_j)$. Differentiating F,

$$\begin{aligned}
\frac{\partial F}{\partial p_j} &= 1 - \frac{1}{\alpha(1 - s_j)^2}\frac{\partial s_j}{\partial p_j} = 1 + \frac{s_j}{1 - s_j} = \frac{1}{1 - s_j}, \\
\frac{\partial F}{\partial \xi_j} &= -\frac{1}{\alpha(1 - s_j)^2}\frac{\partial s_j}{\partial \xi_j} = -\frac{s_j}{\alpha(1 - s_j)}.
\end{aligned}$$

By the implicit function theorem (Appendix B),

$$\frac{dp_j}{d\xi_j} = -\frac{\frac{\partial F}{\partial \xi_j}}{\frac{\partial F}{\partial p_j}} = \frac{s_j}{\alpha(1 - s_j)}(1 - s_j) = \frac{s_j}{\alpha} > 0. \tag{4.30}$$

Products with high unobserved quality carry high prices. In the logit estimating equation $\ln s_j - \ln s_0 = x_j\beta - \alpha p_j + \xi_j$ of Chapter 7, the regressor p_j is therefore positively correlated

with the error ξ_j. Least squares biases the price coefficient $-\alpha$ toward zero, and estimated demand looks too inelastic.

The price equation also tells us which variables can serve as instruments. A valid instrument moves p_j and is uncorrelated with ξ_j. By (4.29) three groups of variables move prices. Cost shifters w_j move mc_j and are excluded from utility. Characteristics of other products move m_j through shares and diversion ratios, and they are excluded from the utility of product j. Changes in ownership move m_j through Ω. Berry et al. (1995, eq. (4.1)) state the identifying assumption as $\mathbb{E}[\xi_j \mid z] = \mathbb{E}[\omega_j \mid z] = 0$, where z stacks the characteristics and cost shifters of all products. Chapters 7 and 8 develop these instruments, and Section 6.1.4 explains why instruments built from characteristics fail when firms choose characteristics with knowledge of ξ_j.

The pricing equation adds information about demand. Suppose we specify $mc_j = w_j\gamma + \omega_j$ and fix Ω. For any candidate value of θ_d we can compute the markups $m(\theta_d)$ at observed prices and quantities, and with them the implied cost shock

$$\omega_j(\theta_d, \gamma) = p_j - m_j(\theta_d) - w_j\gamma.$$

Moment conditions $\mathbb{E}[z_j\, \omega_j(\theta_d, \gamma)] = 0$ then restrict θ_d as well as γ. A price coefficient that is too small in absolute value, for example, implies markups that are too large. The implied costs are then too low exactly where markups are high, and they become correlated with instruments that shift markups. Berry et al. (1995) estimate demand and the pricing equation jointly for this reason (Chapter 8).

Markups, costs and counterfactuals require a model of price setting. Demand alone yields elasticities and diversion ratios. Markups require a model of how prices are set, and so do the marginal costs inferred from them. Every counterfactual that changes prices, such as a merger, a new product or a tax, requires solving for a new equilibrium.

These reasons come with a trade-off. Demand can usually be estimated without specifying supply in full. Instruments motivated by supply, such as cost shifters, remain valid whatever the exact model of conduct, as long as they are excluded from utility and uncorrelated with ξ_j. Adding the pricing equation brings more information and more assumptions. If conduct or the cost function is misspecified, joint estimation transmits the error into the demand estimates. The researcher therefore trades efficiency against robustness. Counterfactuals need a model of supply in any case, so the assumptions return at that stage even when estimation avoids them.

4.5.2 Recovering marginal costs

Suppose demand has been estimated, with parameter estimate $\hat{\theta}_d$, and that we observe prices p and quantities q in a market. The demand Jacobian $\Delta(p; \hat{\theta}_d)$ can then be evaluated at the observed prices. We rearrange (4.3) in two steps:

$$\begin{aligned}\left(\Omega \odot \Delta^\top\right)(p - mc) &= -q, \\ p - mc &= -\left(\Omega \odot \Delta^\top\right)^{-1} q.\end{aligned}$$

Solving for marginal cost gives the *implied* (or recovered) marginal cost

$$\widehat{mc} = p + \left(\Omega \odot \Delta(p; \hat{\theta}_d)^\top\right)^{-1} q. \tag{4.31}$$

Proposition 4.5 guarantees that the inverse exists and that the implied markups are positive whenever some of every product's lost sales go to the outside good. With market size M,

$q = Ms$ and $\Delta = M\Delta^s$, so the same formula holds with shares and share derivatives. The computation is done market by market, and it uses no cost data.

Remark 4.28 (What cost recovery assumes). Formula (4.31) rests on four assumptions. (i) The demand model is correctly specified and $\hat{\theta}_d$ is consistent. (ii) Observed prices satisfy the first-order conditions of a static simultaneous-move pricing game, with interior prices. (iii) The matrix Ω describes conduct correctly. (iv) Marginal cost is constant, or the recovered value is read as marginal cost at the observed output. The formula does not require the equilibrium to be unique. Berry et al. (1995, fn. 12) note that "none of the properties of the estimates require uniqueness of equilibrium." Uniqueness matters only at the counterfactual stage (Section 4.5.4).

With logit demand the inversion has a closed form. By Proposition 4.7 every product of firm f carries the markup $\frac{1}{\alpha(1-S_f)}$, where S_f is the firm's combined share. Hence

$$\widehat{mc}_j = p_j - \frac{1}{\hat{\alpha}\left(1 - S_{f(j)}\right)}. \tag{4.32}$$

Within a firm, differences in recovered costs equal differences in prices. Across firms, a product of a firm with a larger combined share is assigned a larger markup, and so a lower cost at a given price.

Example 4.29 (Cost recovery under three models of conduct)**.** Treat the multi-product equilibrium (M) of Example 4.8 as data. Its prices range from 0.744 to 1.852, and the true marginal costs range from 0.164 to 1.236. We apply (4.31) with the true $\alpha = 2$ and three ownership matrices.

1. With the true owners, the recovered costs equal the true costs up to rounding error.
2. If we wrongly assume single-product firms ($\Omega = I_{25}$), the implied markups are $\frac{1}{\alpha(1-s_j)}$, between 0.502 and 0.568. The recovered costs then exceed the true costs by 0.014 to 0.168, by 0.098 on average, against a mean true cost of 0.767.
3. If we assume that one owner sets all 25 prices ($\Omega = \mathbf{1}\mathbf{1}^\top$), every markup equals $\frac{1}{\alpha s_0} = \frac{1}{2\times 0.1601} = 3.12$. All 25 recovered costs are negative, with mean -1.74.

Assuming too little internalization overstates costs, and assuming too much understates them. The third case shows that implausible implied costs can reject a model of conduct outright.

Why the New Empirical IO avoids accounting costs. Formula (4.31) is the answer of the New Empirical Industrial Organization to the unreliability of accounting cost data (Bresnahan, 1989), discussed in Chapters 1 and 3. Accounting data have four problems for our purpose. First, they report average (variable) cost, which differs from marginal cost unless returns to scale are constant. Second, multi-product firms share plants, distribution and advertising, and accountants allocate these common costs across products by conventions without economic content. Third, accounting depreciation follows tax and reporting rules, and the opportunity cost of capital and of owned inputs is missing (Fisher and McGowan, 1983). Fourth, the data are reported by firm or division, not by product and market. The structural approach trades these measurement problems for dependence on the demand model and on the assumed conduct. Accounting data then become a check on the model. Nevo (2001, p. 333), for example, uses accounting margins only as a crude benchmark. He treats Census margins, built from average variable costs, as an upper bound on price-cost margins.

The cost equation. We often want to know what determines the recovered costs: input prices, returns to scale, the cost of characteristics, or the savings from a merger. The standard specification projects marginal cost on cost shifters:

$$mc_j = w_j\gamma + \omega_j \qquad \text{or} \qquad \ln mc_j = w_j\gamma + \omega_j, \tag{4.33}$$

where w_j is a row vector of observed cost shifters and ω_j is the unobserved cost shock. Berry et al. (1995, eq. (3.1)) use the log form. Their w_j contains product characteristics, and they note that ω_j may be correlated with ξ_j because larger cars, or cars with higher unobserved quality, may cost more to produce (p. 853).

Berry et al. (1995) write the first-order conditions with the opposite sign convention. Their $J \times J$ matrix has element (j, r) equal to $-\frac{\partial s_r}{\partial p_j}$ when products r and j have the same owner and zero otherwise (their eq. 3.4). In our notation it is $-(\Omega \odot \Delta^{s\top})$. Their first-order conditions read $s - \Delta^{\text{BLP}}(p - mc) = 0$, and their markup is

$$b(p, x, \xi; \theta) = \left(\Delta^{\text{BLP}}\right)^{-1} s = -\left(\Omega \odot \Delta^{s\top}\right)^{-1} s \tag{4.34}$$

(their eq. 3.5). Substituting into (4.33) gives the *pricing equation* that is taken to the data,

$$p_j - b_j(\hat{\theta}_d) = w_j\gamma + \omega_j \qquad \text{or} \qquad \ln\left(p_j - b_j(\hat{\theta}_d)\right) = w_j\gamma + \omega_j, \tag{4.35}$$

where the log version is their eq. (3.6). The left side is the recovered marginal cost $\widehat{mc}_j$.

Why the error enters additively. Because ω_j enters (4.35) additively, we can solve for it at any parameter value: $\omega_j(\theta_d, \gamma) = \widehat{mc}_j(\theta_d) - w_j\gamma$. Given instruments z_j, the moment conditions

$$\mathbb{E}\left[z_j^\top \, \omega_j(\theta_{d0}, \gamma_0)\right] = 0 \tag{4.36}$$

are linear in γ for fixed θ_d, so γ is estimated by linear instrumental variables. If the cost shock entered nonseparably, for example as $mc_j = c(w_j, \omega_j)$ with c not invertible in ω_j, we could not compute the residual and these moments would be unavailable. Additivity is what makes the econometrics simple.

When the cost equation needs instruments. With θ_d known and constant marginal cost, (4.35) is a regression of cost on its determinants, and least squares is consistent if $\mathbb{E}[\omega_j \mid w_j] = 0$. Three features of applications break this condition. First, w_j often includes output, as in $\ln mc_j = w_j\gamma + \gamma_q \ln q_j + \omega_j$, to allow for returns to scale. A high ω_j raises p_j and lowers q_j, so q_j is correlated with the error. Second, the characteristics in w_j may have been chosen with knowledge of ω_j. Third, tests of conduct place the markup on the right side with a free coefficient ϑ, as in $p_j = w_j\gamma + \vartheta\, b_j + \omega_j$. Here Berry et al. (1995, p. 854) point out that "since p is a function of ω, $b(p, x, \xi; \theta)$ is a function of ω" and cannot be assumed uncorrelated with it. In each case we need excluded instruments, such as demand shifters and characteristics of rival products, which move output or markups but are mean independent of ω_j.

The recovered cost is a generated regressand. The left side of (4.35) depends on $\hat{\theta}_d$. Consistency of $\hat{\gamma}$ follows from consistency of $\hat{\theta}_d$. The usual standard errors are wrong, however, because they ignore the estimation error in $\hat{\theta}_d$. With least squares on the stacked cost shifters $\mathcal{W}$, a first-order expansion gives

$$\hat{\gamma} - \gamma_0 \approx \left(\mathcal{W}^\top\mathcal{W}\right)^{-1}\mathcal{W}^\top\left[\omega + \frac{\partial\, \widehat{mc}(\theta_{d0})}{\partial \theta_d^\top}\left(\hat{\theta}_d - \theta_{d0}\right)\right]. \tag{4.37}$$

The second term adds variance, and it is correlated across all products and markets that share $\hat{\theta}_d$. There are two remedies. We can stack the demand and supply moments into one GMM problem and use its joint asymptotic variance (Chapter 8 and Appendix A). Or we can bootstrap, resampling markets and re-estimating demand in each replication.

Example 4.30 (Cost regressions under three models of conduct)**.** Continue Example 4.29. The true costs satisfy $mc_j = x_j\gamma + \omega_j$ with $\gamma = (0.2, 0.25, 0.3)$, where x_j contains a constant, a continuous characteristic and a binary characteristic. A least squares regression of the true costs on x_j gives $\hat{\gamma} = (0.182, 0.250, 0.310)$, with standard errors $(0.025, 0.010, 0.020)$. Costs recovered with the true owners give the same estimates. Costs recovered under single-product conduct give $(0.303, 0.239, 0.305)$. Costs recovered under one owner give $(-2.301, 0.235, 0.316)$. The conduct error loads almost entirely on the intercept here, because logit markups vary little with the characteristics. In richer demand models markup errors are correlated with characteristics, and they bias the slopes too.

4.5.3 Conduct and the ownership matrix

Bertrand-Nash pricing with the true owners is one model of conduct. We now embed it in a family of models indexed by profit weights. This makes conduct comparable with the conduct parameter θ of Chapter 3.

Definition 4.31 (Profit weights and the generalized ownership matrix)**.** Let $\kappa_{fg} \in [0, 1]$ be the weight that firm f places on the profit of firm g, with $\kappa_{ff} = 1$. Firm f chooses the prices of its products to maximize

$$\pi_f + \sum_{g \neq f} \kappa_{fg}\, \pi_g, \tag{4.38}$$

taking the prices of other firms as given. The *generalized ownership matrix* $\Omega(\kappa)$ has elements $\Omega(\kappa)_{jk} = \kappa_{f(j)f(k)}$, where $f(j)$ is the owner of product j.

The symbol κ denotes profit weights throughout this chapter. Chapter 3 uses the same letter for a different object.

Lemma 4.32 (First-order conditions with profit weights)**.** *With profit weights κ, the first-order conditions of all firms are*

$$q + \big(\Omega(\kappa) \odot \Delta^\top\big)(p - mc) = 0. \tag{4.39}$$

Proof. Firm g's profit is $\pi_g = \sum_{k \in \mathcal{J}_g} (p_k - mc_k) q_k(p)$ with constant marginal costs. Take $j \in \mathcal{J}_f$ and differentiate (4.38) with respect to p_j. The own-profit term gives $q_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial q_k}{\partial p_j}$, as in (4.2). The term for firm $g \neq f$ gives $\kappa_{fg} \sum_{k \in \mathcal{J}_g} (p_k - mc_k) \frac{\partial q_k}{\partial p_j}$, because p_j enters π_g only through the quantities. Adding the terms and using $\kappa_{ff} = 1$,

$$q_j + \sum_{k=1}^{J} \kappa_{f(j)f(k)} \, (p_k - mc_k) \frac{\partial q_k}{\partial p_j} = 0.$$

The coefficient of $(p_k - mc_k)$ is $\Omega(\kappa)_{jk}\Delta_{kj} = (\Omega(\kappa) \odot \Delta^\top)_{jk}$, so stacking over j gives (4.39). □

Row j of $\Omega(\kappa)$ describes the objective of the firm that sets p_j. The matrix need not be symmetric, because κ_{fg} and κ_{gf} can differ. Cost recovery (4.31), counterfactuals and pass-through all go through with $\Omega(\kappa)$ in place of Ω. Four cases are standard.

1. *Nash pricing* sets $\kappa_{fg} = 0$ for $f \neq g$, so $\Omega(\kappa) = \Omega$.
2. *Full collusion*, or joint profit maximization, sets $\kappa_{fg} = 1$ for all f and g, so $\Omega(\kappa) = \mathbf{1}\mathbf{1}^\top$. Whether such conduct can be sustained is the subject of Chapter 12.
3. A *merger* of firms f and g sets $\kappa_{fg} = \kappa_{gf} = 1$ and leaves the other weights at zero.
4. *Partial internalization* has weights strictly between zero and one. Common ownership and joint ventures produce such weights.

Common ownership. O'Brien and Salop (2000) derive profit weights from ownership stakes. Let investors $h = 1, \dots, H$ hold cash-flow shares λ_{gh} in firm g, and let η_{fh} be investor h's share of control over firm f. (The symbols λ, η, h and H are local to this paragraph.) Suppose the manager of firm f maximizes the control-weighted sum of its investors' portfolio profits:

$$\sum_{h=1}^{H} \eta_{fh} \sum_{g=1}^{F} \lambda_{gh}\, \pi_g = \sum_{g=1}^{F} \Big(\sum_{h=1}^{H} \eta_{fh} \lambda_{gh} \Big) \pi_g .$$

Dividing by the coefficient on π_f leaves the maximizer unchanged and gives the form (4.38) with

$$\kappa_{fg} = \frac{\sum_h \eta_{fh} \lambda_{gh}}{\sum_h \eta_{fh} \lambda_{fh}}. \tag{4.40}$$

The weight is large when the investors who control f own large cash-flow stakes in g. Backus et al. (2021a) compute such weights for the ready-to-eat cereal industry and ask whether pricing reflects them.

Joint ventures. Miller and Weinberg (2017) study the 2008 joint venture that combined the US operations of SABMiller and Molson Coors. The Department of Justice approved the transaction on June 5, 2008, on the ground that efficiencies in brewing would outweigh any adverse competitive effect (Asker and Nocke, 2021, p. 241, n. 161). Almost immediately after clearance, the prices of 12-packs of Miller Lite, Bud Light and Coors Light rose by about 8 percent. The imported flagship brands Corona Extra and Heineken show little persistent change (Asker and Nocke, 2021, p. 242). Miller and Weinberg's demand system is a random coefficients nested logit. On the supply side, a weight $\kappa \in [0, 1]$ captures coordination between brands that are not jointly owned. It enters the ownership matrix of the standard first-order conditions and is estimated. A weight of zero is Nash pricing, and a weight of one is joint profit maximization. The estimate rejects unilateral price competition (Asker and Nocke, 2021, p. 242, n. 164). In their specification the weight applies to pairs of products of Anheuser-Busch InBev (ABI) and MillerCoors in the periods after the joint venture (Miller and Weinberg, 2017, Section 5.1, p. 1779). Chapter 11 treats the application.

Remark 4.33 (Profit weights and the conduct parameter). Profit weights give the conduct parameter of Chapter 3 a structural reading. Let N symmetric Cournot firms with constant marginal cost c each maximize $\pi_i + \kappa \sum_{l \neq i} \pi_l$, with $\pi_l = (P(Q) - c) q_l$. The first-order condition of firm i is

$$P(Q) - c + P'(Q)\Big(q_i + \kappa \sum_{l \neq i} q_l \Big) = 0.$$

At a symmetric equilibrium $q_i = \frac{Q}{N}$, so $q_i + \kappa \sum_{l \neq i} q_l = \frac{1 + \kappa(N-1)}{N} Q$ and

$$P(Q) = c - \frac{1 + \kappa(N-1)}{N}\, Q\, P'(Q).$$

This is the supply relation (3.1) with $\theta = \frac{1+\kappa(N-1)}{N}$. Nash behavior ($\kappa = 0$) gives the Cournot value $\theta = \frac{1}{N}$, and full collusion ($\kappa = 1$) gives $\theta = 1$. With differentiated products, however, conduct is a matrix. We therefore compare a short menu of ownership matrices, or estimate a low-dimensional κ, rather than a free parameter for every pair of products.

Testing conduct. Two ownership matrices Ω^A and Ω^B imply two markup vectors and two vectors of recovered costs. There are four main ways to choose between them. First, implied costs may be implausible, as the negative costs of Example 4.29 are. Second, implied margins can be compared with independent measures of margins, as in Nevo (2001) below. Third, nonnested tests compare the fit of the full models, as in the 1955 automobile price war studied by Bresnahan (1987) (Section 6.6). A *nonnested test* compares two models, neither of which is a special case of the other. Fourth, under the true model the implied cost shock is mean independent of excluded instruments, while under a false model it generally is not. Berry and Haile (2014, Section 6, p. 1776) give a formal foundation, in a much more general setting, to the intuition of Bresnahan (1982), discussed in Section 3.5.2. Their results allow product differentiation and do not require rotations of demand. Variation in the number of competing firms, the set of competing goods, or the characteristics or costs of competitors can discriminate between models of conduct (p. 1779).

An application: margins in ready-to-eat cereal. Nevo (2001) estimates a random coefficients demand system for 25 brands of ready-to-eat cereal and uses the pricing equation to decompose margins (Chapter 8 gives the full case study). His supply side writes the first-order conditions as $s(p) - \Omega(p - mc) = 0$, where $\Omega_{jr} = \Omega^*_{jr} S_{jr}$, $S_{jr} = -\frac{\partial s_r}{\partial p_j}$, and Ω^* is the ownership matrix. This is the convention of Berry et al. (1995). The implied markups are (his eq. 1, p. 313)

$$p - mc = \Omega^{-1} s(p). \tag{4.41}$$

Nevo evaluates (4.41) under three structures. With *single-product firms*, each brand is priced by an agent who cares only about that brand, and margins reflect product differentiation alone. With the *current ownership* of the brands by multi-product firms, margins also reflect the internalization of substitution among a firm's brands. With *joint ownership* of all brands, margins are those of a monopolist or of a perfect cartel. The margins of the three structures define a decomposition,

$$m^{\text{joint}} = \underbrace{m^{\text{single}}}_{\text{differentiation}} + \underbrace{\left(m^{\text{current}} - m^{\text{single}}\right)}_{\text{portfolio effect}} + \underbrace{\left(m^{\text{joint}} - m^{\text{current}}\right)}_{\text{collusion effect}}. \tag{4.42}$$

Each term is nonnegative product by product when goods are substitutes (Proposition 8.44).

The three structures imply very different margins. With the full random coefficients model, the median margin $\frac{p-mc}{p}$ over 27,862 brand-city-quarter observations is 35.8 percent with single-product firms. It is 42.2 percent under current ownership and 72.6 percent under joint ownership of the 25 brands (Nevo, 2001, Table VIII). Product differentiation thus accounts for most of the predicted margin, and the portfolio effect adds 6.4 percentage points. Joint profit maximization would add 30.4 points more. Nevo compares these predictions with a gross retail margin of 46.0 percent from accounting sources. The price gap between national brands and private labels gives a lower bound of about 31 percent (p. 333). He rejects joint profit maximization of the 25 brands, whose 95 percent confidence interval runs from 62.2 to 97.2 percent. He cannot reject multi-product Nash pricing, whose interval runs from 29.1 to 55.8 percent (p. 334).

The logit version of the same exercise illustrates why the demand model matters for conduct. With logit demand, the median margins are 33.6, 35.8 and 41.9 percent under the three structures, and 54.0 percent if all brands in the market are priced jointly (Nevo, 2001, Table VIII). The mean price sensitivity of the full model is close to the logit price coefficient. The gap between the models widens from single-product to joint ownership, because the full model captures cross-price substitution better (p. 332). By Proposition 4.7, logit markups depend on ownership only through combined shares. When those shares are small, as they are when the outside good is large, internalizing rival brands changes logit margins little. Nevo notes that with the logit estimates one cannot reject full collusion over all products, and he attributes this to the strong assumptions of the logit rather than to conduct (p. 335). A demand model that hardly distinguishes conduct structures cannot test them. Table 8.26 in Chapter 8 reproduces the full table.

4.5.4 Counterfactual analysis

A counterfactual asks what would happen under conditions never observed: a merger that has not occurred, a product not yet launched, a tax not yet levied. Answering it requires a model whose primitives remain valid under the new conditions.

Definition 4.34 (Structural model and counterfactual)**.** A model is *structural* with respect to a change in the environment if its primitives do not change when the environment changes. Here the primitives are the demand parameters and unobserved qualities ξ, the cost function and cost shocks ω, and the rule of conduct. A *counterfactual* is the equilibrium of the model after one element of the environment is changed, with all other primitives held at their estimated values.

Remark 4.35 (The counterfactual algorithm). A static counterfactual in a differentiated-products market proceeds in five steps.

1. *Estimate demand* from data on the status quo, with instruments for price (Chapters 7 and 8). Recover $\hat{\xi}$ along with $\hat{\theta}_d$.
2. *Recover marginal costs* at the observed prices and quantities from (4.31), using the status quo ownership matrix Ω^0. Optionally estimate the cost equation (4.33) and recover $\hat{\omega}$.
3. *Change the environment.* A merger, a divestiture or collusion changes the ownership matrix to Ω^1 (for instance by setting to one the entries for pairs of products of the merging firms). Entry, exit or a new good changes the product set (Chapter 10). A new product needs characteristics x_{J+1}, an assumed quality ξ_{J+1} (often zero, the mean of ξ) and a marginal cost from the cost equation. A tax, a tariff, an input-price change or a merger efficiency changes marginal costs: $mc_j + t_j$ for a specific tax t_j, and $(1 - E_j)mc_j$ for a proportional efficiency E_j, as in (4.18).
4. *Solve for the new equilibrium*, that is, find p^1 with
$$q(p^1) + \left(\Omega^1 \odot \Delta(p^1)^\top\right)\left(p^1 - mc^1\right) = 0,$$
using the demand model to evaluate $q(\cdot)$ and $\Delta(\cdot)$ at every trial price vector.
5. *Compute outcomes*, namely price and share changes, firms' profits, and consumer surplus from the demand model. With logit demand and market size M, the change in consumer surplus is $\frac{M}{\alpha}\ln\frac{\Phi^1}{\Phi^0}$, where $\Phi = 1 + \sum_k e^{\delta_k}$ (Chapter 7). With random coefficients the log-sum is integrated over consumers, each term divided by that consumer's α_i.

Step 4 is the computational core. Four solution methods are common.

1. *Best-response iteration.* Each firm in turn maximizes its profit given the others' current prices, and the process repeats until prices stop changing. It converges when the best-response map is a contraction, as in the single-product logit (Proposition 4.24). With logit demand each step has the Lambert-W closed form of Section 4.2.6.

2. *Markup iteration.* Iterate $p \leftarrow mc - (\Omega \odot \Delta(p)^\top)^{-1} q(p)$. The update is simple, but nothing guarantees convergence. Damped updates, which move prices only part of the way toward the right side, often help.

3. *Newton's method.* Write the stacked conditions as $G(p) = q(p) + (\Omega \odot \Delta(p)^\top)(p - mc)$ and iterate $p \leftarrow p - [\frac{\partial G}{\partial p^\top}]^{-1} G(p)$. Convergence is quadratic near the solution. The Jacobian involves second derivatives of demand, given in (4.45) below, and the method can wander when it starts far from the solution.

4. *The Morrow-Skerlos iteration.* For random coefficients logit demand with price coefficient $\alpha_i > 0$, split the share Jacobian as $\Delta^s(p) = -\Lambda(p) + \Gamma(p)$, with the diagonal matrix $\Lambda_{jj}(p) = \int \alpha_i s_{ij}(p)\, \mathrm{d}F$ and the symmetric matrix $\Gamma_{jk}(p) = \int \alpha_i s_{ij}(p) s_{ik}(p)\, \mathrm{d}F$. Here s_{ij} is consumer i's choice probability. The first-order conditions are then equivalent to the fixed point (Morrow and Skerlos, 2011)

$$p - mc = \zeta(p) \equiv \Lambda(p)^{-1} \Big[s(p) + \big(\Omega \odot \Gamma(p)\big)(p - mc) \Big], \tag{4.43}$$

   which is iterated as $p \leftarrow mc + \zeta(p)$. The derivation is Proposition 8.38 in Chapter 8. In the plain logit, $\Lambda = \alpha \operatorname{diag}(s)$ and $\Gamma = \alpha s s^\top$, so (4.43) becomes $m_j = \frac{1}{\alpha} + \sum_k \Omega_{jk} s_k m_k$. This is the fixed point of Proposition 4.7.

Whatever the method, convergence must be checked. We stop when the sup-norm change in prices falls below a tight tolerance, such as 10^{-12}, and then verify the first-order conditions directly. A residual in price units, such as $\|\zeta(p) - (p - mc)\|_\infty$, is more informative than a residual in share units, which becomes small at very high prices where every share is small. First-order conditions do not guarantee that each firm is at a global maximum. Where profit may have several local maxima in own price (Example 4.27), we also evaluate each firm's profit over a grid of unilateral deviations.

Equilibrium selection. Section 4.4.5 showed that a counterfactual can have several equilibria even when estimation is unaffected. An iterative solver selects the equilibrium in whose basin of attraction it starts, so the common practice of starting from the status quo prices is itself a selection rule. A careful analysis restarts the solver from many points and reports every equilibrium it finds. With logit demand and constant marginal costs the issue does not arise, because the equilibrium is unique for every ownership structure (Theorem 4.25).

Example 4.36 (A simulated merger)**.** In the 25-product market of Example 4.8, take the multi-product equilibrium (M) as the status quo and let owners 3 and 4 merge. They hold 6 and 7 products with combined shares of 21.40 and 25.36 percent. We hold marginal costs fixed and solve for the post-merger equilibrium with all four methods, starting from the pre-merger prices. Best-response iteration and the Morrow-Skerlos iteration converge in 17 steps, markup iteration needs 91 steps, and Newton's method with the analytic Jacobian (4.45) converges in 6 iterations. All four reach the same prices, within 5×10^{-14}. Five hundred random starting points lead to the same equilibrium, as Theorem 4.25 implies. Table 4.4 reports the results.

Table 4.4: A simulated merger of owners 3 and 4 in the 25-product logit market

		Combined share (%)		Markup		Price	Profit ×100	
Owner	Products	Pre	Post	Pre	Post	change	Pre	Post
Panel A. Owners								
0	3	18.87	21.23	0.616	0.635	0.018	11.632	13.476
1	3	4.67	5.41	0.524	0.529	0.004	2.449	2.857
2	6	13.68	15.56	0.579	0.592	0.013	7.925	9.214
3 (merging)	6	21.40	17.25	0.636	0.821	0.185	13.616	14.167
4 (merging)	7	25.36	21.87	0.670	0.821	0.151	16.989	17.959
Panel B. Market								
Outside share s_0			0.1601	0.1869				
Consumer surplus $\frac{1}{\alpha}\ln\Phi$			0.9159	0.8387				
Total profit			0.5261	0.5767				
Total surplus			1.4421	1.4154				
Share-weighted mean price			1.3553	1.4465				

Notes: Pre is the multi-product equilibrium (M) of Table 4.2. Post is the equilibrium after owners 3 and 4 merge, with marginal costs unchanged. Every product of an owner has the same markup and so the same price change. Market size is one. Computed with `figures/ch04/src/supply_examples.py`.

The merged firm prices all 13 of its products at the common markup 0.821. This equals $\frac{1}{\alpha(1-S)}$ at its post-merger combined share $S = 0.3912$, as Proposition 4.7 requires. The prices of former owner 3 rise by 0.185 and those of former owner 4 by 0.151. Most of the increase is the merged firm's unilateral response. If the merged firm best-responds to the unchanged pre-merger prices of its rivals, its markup is 0.817. Rivals' price increases, between 0.004 and 0.018, add only 0.004 to it through strategic complementarity.

The outsiders gain more than the merging parties. The merging parties' combined profit rises from 30.605 to 32.126 (times 100), while the rivals' combined profit rises from 22.006 to 25.547. The merged firm restricts its own sales to raise price, and the rivals capture the diverted customers at higher prices. This free-riding reappears in merger theory (Chapter 11). Consumer surplus falls by 8.4 percent, the outside share rises from 16.0 to 18.7 percent, and total surplus falls by 0.027.

How large would merger efficiencies need to be to leave consumers unharmed? With logit demand the answer has a closed form. All prices stay at their pre-merger levels if and only if the merged firm's first-order condition holds at the pre-merger prices. At those prices shares are unchanged, so the merged firm's markup must equal $\frac{1}{\alpha(1-S_3-S_4)} = \frac{1}{2(1-0.4676)} = 0.939$. Marginal costs must therefore fall by $0.939 - 0.636 = 0.303$ for the products of owner 3 and by $0.939 - 0.670 = 0.269$ for those of owner 4. Re-solving the equilibrium with these costs returns the pre-merger prices exactly. Such compensating cost reductions (Werden, 1996) are large here: 46 percent of owner 3's average marginal cost and 37 percent of owner 4's.

4.5.5 Comparative statics and pass-through

How do equilibrium prices respond to small changes in costs? The answer gives pass-through of taxes and input prices, and it converts pricing pressure from a merger into price changes. We derive the general formula and then evaluate it for logit demand.

The general formula. Write the stacked first-order conditions as a function of prices and marginal costs,

$$G(p;c) \equiv q(p) + \left(\Omega \odot \Delta(p)^\top\right)(p-c) = 0, \tag{4.44}$$

with c the vector of constant marginal costs. Row j reads $G_j = q_j + \sum_k \Omega_{jk} \frac{\partial q_k}{\partial p_j}(p_k - c_k)$. Differentiating with respect to c_l gives

$$\frac{\partial G_j}{\partial c_l} = -\Omega_{jl} \frac{\partial q_l}{\partial p_j}, \qquad \text{so} \qquad \frac{\partial G}{\partial c^\top} = -\big(\Omega \odot \Delta^\top\big).$$

Differentiating with respect to p_l gives three terms, one from q_j, one from the markup of product l, and one from the dependence of the derivatives on prices:

$$\frac{\partial G_j}{\partial p_l} = \frac{\partial q_j}{\partial p_l} + \Omega_{jl} \frac{\partial q_l}{\partial p_j} + \sum_k \Omega_{jk}(p_k - c_k) \frac{\partial^2 q_k}{\partial p_j \, \partial p_l}.$$

In matrix form,

$$\frac{\partial G}{\partial p^\top} = \Delta + \Omega \odot \Delta^\top + H, \qquad H_{jl} = \sum_k \Omega_{jk} \, m_k \, \frac{\partial^2 q_k}{\partial p_j \, \partial p_l}. \tag{4.45}$$

If $\frac{\partial G}{\partial p^\top}$ is nonsingular at the equilibrium, the implicit function theorem (Appendix B) shows that equilibrium prices are locally a differentiable function of costs, with

$$\frac{\partial p}{\partial c^\top} = -\left[\frac{\partial G}{\partial p^\top}\right]^{-1} \frac{\partial G}{\partial c^\top} = \big[\Delta + \Omega \odot \Delta^\top + H\big]^{-1} \big(\Omega \odot \Delta^\top\big). \tag{4.46}$$

For a single-product monopolist the matrices are scalars, and (4.46) reduces to $\frac{q'}{2q' + (p-c)q''}$. This is the monopoly pass-through formula (2.57) of Chapter 2. The second derivatives in H show that pass-through depends on the curvature of demand as well as on its slope. A specific tax t_j enters exactly like a cost, so (4.46) also gives tax pass-through. The same formula holds with $\Omega(\kappa)$ in place of Ω.

Partial and full pass-through. It helps to separate a firm's own response from the feedback through rivals' prices. For single-product firms, let $BR_j(p_{-j}; c_j)$ be firm j's best response, assumed differentiable. Define the *partial pass-through* $\rho_j^{\mathrm{p}} = \frac{\partial BR_j}{\partial c_j}$, which holds rivals' prices fixed, and the matrix R of best-response slopes, with $R_{jk} = \frac{\partial BR_j}{\partial p_k}$ for $k \neq j$ and $R_{jj} = 0$.

Lemma 4.37 (Equilibrium pass-through from best responses)**.** *If $I - R$ is nonsingular at the equilibrium, then*

$$\frac{\partial p}{\partial c^\top} = (I - R)^{-1} \operatorname{diag}\big(\rho^{\mathrm{p}}\big). \tag{4.47}$$

If moreover $\rho^{\mathrm{p}} > 0$, $R \geq 0$ element by element and every row sum of R is below one, then every element of $(I - R)^{-1} - I$ is nonnegative. Equilibrium own pass-through then weakly exceeds partial pass-through, and a cost increase for one firm weakly raises every rival's price.

Proof. In equilibrium $p_j = BR_j(p_{-j}; c_j)$ for every j. Totally differentiating,

$$dp_j = \sum_{k \neq j} R_{jk} \, dp_k + \rho_j^{\mathrm{p}} \, dc_j, \qquad \text{so} \qquad (I - R)\, dp = \operatorname{diag}\big(\rho^{\mathrm{p}}\big)\, dc.$$

Multiplying by $(I - R)^{-1}$ gives (4.47). If $R \geq 0$ with row sums below one, then $\|R\|_\infty < 1$, so the Neumann series $(I - R)^{-1} = \sum_{n \geq 0} R^n$ converges. Every term is nonnegative, so $(I - R)^{-1} - I = \sum_{n \geq 1} R^n \geq 0$. Since $\rho_j^{\mathrm{p}} > 0$, the diagonal of $\frac{\partial p}{\partial c^\top}$ is at least ρ_j^{p} and the off-diagonal elements are nonnegative. □

Proposition 4.38 (Partial pass-through with logit demand)**.** *Let demand be logit with constant marginal costs, and hold the prices of all other firms fixed.*

(i) A single-product firm passes through the fraction $\frac{\partial p_j}{\partial c_j} = 1 - s_j$ *of a cost increase.*

(ii) If the cost of product j *of a multi-product firm* f *rises, then* $\frac{\partial p_j}{\partial c_j} = 1 - s_j$*, and the price of every other product* $l \in \mathcal{J}_f$ *falls, with* $\frac{\partial p_l}{\partial c_j} = -s_j$*.*

(iii) If the costs of all products of firm f *rise by the same amount* dc*, every price of firm* f *rises by* $(1 - S_f)\, dc$*.*

Proof. By Proposition 4.7, whatever its costs, firm f's optimal prices satisfy $p_l = c_l + m_f$ for all $l \in \mathcal{J}_f$, with a common markup that solves

$$\alpha\, m_f\, (1 - S_f) = 1. \tag{4.48}$$

The firm's best response is the unique solution of this condition (Section 4.2.6). After a change in costs, the price changes are therefore $dp_l = dc_l + dm_f$.

First we compute how S_f responds. By (4.8), for $l \in \mathcal{J}_f$,

$$\frac{\partial S_f}{\partial p_l} = \sum_{k \in \mathcal{J}_f} \frac{\partial s_k}{\partial p_l} = -\alpha s_l (1 - s_l) + \sum_{k \in \mathcal{J}_f, k \neq l} \alpha s_k s_l = -\alpha s_l (1 - S_f).$$

Hence

$$dS_f = -\alpha (1 - S_f) \sum_{l \in \mathcal{J}_f} s_l\, dp_l = -\alpha (1 - S_f) \Big[\sum_{l \in \mathcal{J}_f} s_l\, dc_l + S_f\, dm_f \Big].$$

Next we differentiate (4.48): $(1 - S_f)\, dm_f = m_f\, dS_f$. Substituting dS_f and $\alpha m_f = \frac{1}{1 - S_f}$ from (4.48),

$$(1 - S_f)\, dm_f = -\alpha m_f (1 - S_f) \Big[\sum_{l} s_l\, dc_l + S_f\, dm_f \Big] = -\Big[\sum_{l} s_l\, dc_l + S_f\, dm_f \Big],$$

$$dm_f = -\sum_{l \in \mathcal{J}_f} s_l\, dc_l.$$

The markup falls by the share-weighted cost increase. For part (ii), only $dc_j \neq 0$, so $dm_f = -s_j\, dc_j$. Then $dp_j = (1 - s_j)\, dc_j$ and $dp_l = -s_j\, dc_j$ for $l \neq j$. Part (i) is part (ii) with $\mathcal{J}_f = \{j\}$. For part (iii), $dc_l = dc$ for all $l \in \mathcal{J}_f$, so $dm_f = -S_f\, dc$ and $dp_l = (1 - S_f)\, dc$. □

Part (i) is the residual-demand result of Example 2.73 in Chapter 2. Logit residual demand is log-concave, so pass-through is below one (Corollary 2.71). Part (ii) is less familiar. A cost increase on one product lowers the firm's combined share, and with it the firm's market power. The firm's common markup falls, so it cuts the prices of its other products. Part (iii) shows that a multi-product firm with a large combined share absorbs a large fraction of firm-wide cost shocks.

Corollary 4.39 (Equilibrium pass-through with single-product logit firms)**.** *With single-product logit firms and constant marginal costs,*

$$\frac{\partial p}{\partial c^\top} = (I - R)^{-1} \operatorname{diag}(1 - s), \qquad R_{jk} = \frac{s_j s_k}{1 - s_j}\ (k \neq j). \tag{4.49}$$

Own equilibrium pass-through exceeds $1 - s_j$*, and every rival's price rises. In a symmetric market with* J *products of share* s *each and outside share* $s_0 = 1 - Js > 0$*, an industry-wide cost increase is passed through at the rate* $\frac{(1-s)^2}{1-s-(J-1)s^2} < 1$*.*

Proof. The slopes $R_{jk} = \frac{s_j s_k}{1-s_j}$ are the logit best-response slopes of Proposition 4.24, and $\rho_j^{\mathrm{p}} = 1 - s_j$ by Proposition 4.38. Formula (4.47) gives (4.49). Let $S = \sum_k s_k = 1 - s_0 < 1$. Row j of R sums to

$$\sum_{k \neq j} \frac{s_j s_k}{1 - s_j} = \frac{s_j(S - s_j)}{1 - s_j} < \frac{s_j(1 - s_j)}{1 - s_j} = s_j < 1,$$

so Lemma 4.37 applies. In the symmetric case every off-diagonal element of R equals $\bar{R} = \frac{s^2}{1-s}$, so every row of R sums to $(J-1)\bar{R}$. With an equal cost increase for all products the equilibrium is symmetric, $dp = \bar{\rho}\, dc\, \mathbf{1}$ for a scalar $\bar{\rho}$, and $(I - R)\, dp = (1 - s)\, dc\, \mathbf{1}$ gives

$$\bar{\rho} = \frac{1 - s}{1 - (J-1)\bar{R}} = \frac{(1-s)^2}{1 - s - (J-1)s^2}.$$

This is below one if and only if $(1-s)^2 < 1 - s - (J-1)s^2$, that is $Js^2 < s$, that is $Js < 1$, which holds because $s_0 > 0$. □

The strategic feedback is usually small. In a symmetric duopoly with $s = 0.3$, $\bar{R} = \frac{0.09}{0.7} = 0.129$. Own equilibrium pass-through is $\frac{1-s}{1-\bar{R}^2} = 0.712$, against the partial value 0.700. The rival raises its price by $\frac{\bar{R}(1-s)}{1-\bar{R}^2} = 0.092$ per unit of cost. An industry-wide cost increase is passed through at the rate $\frac{1-s}{1-\bar{R}} = 0.803$. Higher prices push consumers to the outside good, shares and markups fall, and part of the cost increase is absorbed even though every firm faces it.

The multi-product market of Example 4.8 tells the same story. We compute (4.46) at the equilibrium (M) and confirm it by re-solving the equilibrium after small cost changes, with agreement to 2×10^{-9}. A firm-wide cost increase for owner 4, whose combined share is 25.36 percent, has partial pass-through $1 - S_4 = 0.746$. In equilibrium, owner 4's prices rise by 0.755 and rivals' prices by 0.011 to 0.056 per unit of cost. A cost increase for product 20 alone, owner 4's largest product with share 11.09 percent, has partial pass-through 0.889 on its own price and −0.111 on owner 4's other prices. The equilibrium values are 0.893 and −0.107. An industry-wide cost increase is passed through at rates between 0.937 and 0.990. These rates are below one, as in the symmetric single-product case of Corollary 4.39.

These formulas connect to other parts of the book. Pass-through below one under log-concave residual demand, and its dependence on curvature, are developed in Chapter 2. The tax pass-through tests of Chapter 3 interpret estimated pass-through through the joint lens of conduct and curvature, and (4.46) shows how conduct enters through Ω with differentiated products. First-order approximations to merger price effects multiply upward pricing pressure (Section 4.3) by a pass-through matrix of this kind (Chapter 11).

4.6 Product space versus characteristics space

Everything so far took the demand system as given. We now turn to the choice of demand system. The first decision is the space in which demand is written. This section compares the two answers, develops a result on how the dimension of characteristics space shapes competition, and surveys the classical product-space systems.

4.6.1 Two ways to write demand

Definition 4.40 (Product space and characteristics space)**.**

(i) A demand system is written in *product space* when the demand for each product is a function of all prices and other demand shifters z,

$$q_j = f_j(p_1, \ldots, p_J, z; \theta_d), \qquad j = 1, \ldots, J, \tag{4.50}$$

with parameters θ_d indexed by products. Consumers have preferences over the products themselves.

(ii) A demand system is written in *characteristics space* when each product is a vector of characteristics (x_j, ξ_j) with a price p_j, and consumers have preferences over these vectors. Consumer i with taste vector ν_i obtains utility $U(x_j, \xi_j, p_j, \nu_i; \theta_d)$ from product j. The market share of product j is the mass of consumers for whom j is the best option,

$$s_j = \mathbb{P}\{\nu_i : U(x_j, \xi_j, p_j, \nu_i; \theta_d) \geq U(x_k, \xi_k, p_k, \nu_i; \theta_d) \text{ for all } k\}. \tag{4.51}$$

The parameters θ_d describe the distribution of tastes for characteristics and carry no product index.

Linear demand $q = a + Ap$ and log-linear demand $\ln q = a + E \ln p$ are product-space systems, with a $J \times J$ matrix of price slopes A or of elasticities E. The characteristics approach goes back to Lancaster (1966) and Gorman (1980), who viewed products as bundles of characteristics. McFadden (1974) supplied its econometric form, the discrete choice model. Its empirical workhorse is the random coefficients logit,

$$u_{ij} = x_j \beta_i - \alpha_i p_j + \xi_j + \epsilon_{ij}, \tag{4.52}$$

in which the distribution of (β_i, α_i) is the object of estimation (Chapters 6 and 8).

The two approaches are linked. Every characteristics model implies product-space demand functions $s_j(p)$. Conversely, a product-space model can be read as a characteristics model whose characteristics are J product indicators, each valued by its own taste. Berry and Pakes (2007, p. 5) note that Caplin and Nalebuff (1991) suggest reading the i.i.d. shock ϵ_{ij} of (4.52) in exactly this way. The real difference between the approaches is therefore the dimension of the space of characteristics, and whether it grows with the number of products. This observation organizes the section.

4.6.2 Advantages of characteristics space

Dimension. In product space the number of parameters grows with the square of the number of products. A linear system has J intercepts and J^2 price slopes. In characteristics space it grows with the number of characteristics K and with the dimension of consumer heterogeneity. If each of K characteristics and price has a mean taste and a standard deviation, the model has $2(K + 1)$ taste parameters. For $J = 50$ products and $K = 5$ characteristics,

$$J + J^2 = 2{,}550 \qquad \text{versus} \qquad 2(K + 1) = 12.$$

Berry and Pakes (2007, fn. 1) make the same point: a (log) linear system for J products needs a number of parameters that grows like J^2.

The few parameters still generate rich substitution. With random coefficients, the cross-price derivative is

$$\frac{\partial s_k}{\partial p_j} = \int \alpha_i \, s_{ij} \, s_{ik} \, \mathrm{d}F(\beta_i, \alpha_i), \tag{4.53}$$

where s_{ij} is consumer i's probability of choosing j (Chapter 8). The integrand is large for consumers who are likely to buy both j and k, and those are consumers whose tastes favor characteristics that j and k share. Products close in characteristics space are therefore close substitutes. The distribution of tastes governs all J^2 cross effects. In the plain logit, by contrast, $\frac{\partial s_k}{\partial p_j} = \alpha s_j s_k$ whatever the distance between the products.

New goods. A product that combines existing characteristics in a new way can be placed in the estimated model before it is launched. In the random coefficients logit its predicted share is

$$s_{J+1} = \int \frac{e^{x_{J+1}\beta_i - \alpha_i p_{J+1} + \xi_{J+1}}}{1 + \sum_{k=1}^{J+1} e^{x_k \beta_i - \alpha_i p_k + \xi_k}} \, \mathrm{d}F(\beta_i, \alpha_i). \tag{4.54}$$

The prediction needs the new product's characteristics x_{J+1}, a value for its unobserved quality ξ_{J+1}, and its price. The price comes from solving the post-entry equilibrium with a marginal cost taken from the cost equation (Remark 4.35). Berry and Pakes (2007, p. 1) stress these two requirements. The researcher must specify the characteristics of the new product and the form of equilibrium in the product market. Product-space systems cannot make the prediction at all, because the new product has no parameters.

The power of the prediction depends on where the new product lies (Figure 4.6). A product inside the convex hull of existing products' characteristics is an interpolation. The tastes that value it were estimated from products with similar characteristics. A product outside the hull, within the same space, is an extrapolation that rests on functional form, such as the linearity of $x_j\beta_i$. A product with a new characteristic is a different matter. The first electric cars offered battery range, charging time and freedom from fuel costs. No existing car varied in these dimensions, so the data contain no information on the corresponding taste coefficients, and the model cannot predict demand.

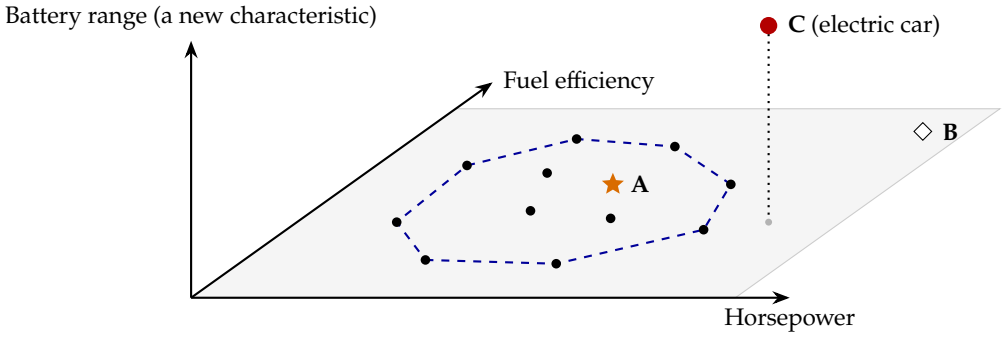

Figure 4.6: Characteristics space and new goods. Dots are existing products in the plane of two observed characteristics, and the dashed polygon is their convex hull. Tastes estimated from these products predict demand for a new combination inside the hull (A, an interpolation). A product outside the hull but in the same plane (B) is predicted only by extrapolating the functional form. An electric car (C) sits off the plane: it has a characteristic that no existing product has, so the data are silent about how consumers value it.

4.6.3 Drawbacks of characteristics space

The characteristics approach has six drawbacks. The first two are practical. The approach needs more data, namely the relevant characteristics of every product and often information on consumers. Estimation is harder, because market shares are integrals over the taste distribution that must be inverted and simulated (Chapter 8). The other four drawbacks are conceptual.

Too many characteristics. Models with an i.i.d. taste shock ϵ_{ij} for every product can have odd implications, known as the *too many characteristics* problem. The shock is a taste for the product itself, so it acts as one more characteristic for each product. Adding a product adds a dimension to the space. Three consequences follow in the logit, with $\Phi = 1 + \sum_{k=1}^{J} e^{\delta_k}$. Proposition 6.55 proves them in detail.

1. *Clones attract buyers.* Let product $J+1$ be an exact copy of product 1, with the same δ_1. The copy's share and the original's share are both $\frac{e^{\delta_1}}{\Phi+e^{\delta_1}}$, so together the two identical products sell
$$\frac{2e^{\delta_1}}{\Phi + e^{\delta_1}} > \frac{e^{\delta_1}}{\Phi},$$
where the inequality is $2\Phi > \Phi + e^{\delta_1}$, true because $\Phi > e^{\delta_1}$. A physical duplicate draws new customers from the outside good.

2. *Markups never vanish.* A single-product logit firm sets
$$p_j - mc_j = \frac{1}{\alpha(1-s_j)} > \frac{1}{\alpha}$$
however many products crowd the market (Proposition 4.7). With J symmetric firms the markup converges to $\frac{1}{\alpha}$ as J grows, so it stays bounded away from zero.

3. *Every product adds welfare.* At fixed prices, adding product $J+1$ raises consumer surplus by
$$\Delta CS = \frac{1}{\alpha} \ln\left(1 + \frac{e^{\delta_{J+1}}}{\Phi}\right) > 0,$$
even if the product duplicates an existing one. With J identical products of mean utility δ, consumer surplus is $\frac{1}{\alpha}\ln(1 + Je^{\delta})$, which grows like $\frac{1}{\alpha}\ln J$ without bound.

The *pure characteristics model* of Berry and Pakes (2007) removes the product-specific shock, so the space has a fixed dimension. As products fill the space, neighbors become close substitutes, markups are driven toward marginal cost, and the gain from one more product declines to zero (pp. 6–7). Section 6.7 develops the comparison, and Chapter 10 shows how much it matters for the value of new goods.

No complementarity. In a model where each consumer buys one unit of one product, all products are substitutes. Raising p_j lowers only the utility of product j. Every consumer who bought $k \neq j$ still prefers k, and some former buyers of j switch to k, so $\frac{\partial s_k}{\partial p_j} \geq 0$ (Corollary 6.8). Complements such as a printer and its cartridges, or a print and an online newspaper, need other structures. Gentzkow (2007) treats bundles of products as choice alternatives. A utility term lets the value of a bundle exceed or fall short of the sum of its parts (Chapter 10). Hendel (1999) develops a model of multiple discrete choices (Chapter 7).

Unmeasurable attributes. For books, films or recipes, the attributes that matter (plot, style, taste) cannot be coded as a short vector x_j. The unobserved quality ξ_j then carries most of

the variation, and the dimension advantage disappears. Hausman (1997, sec. 5.5) makes this objection for breakfast cereals and models each brand with its own parameters (Chapter 10).

Exogenous characteristics. Empirical characteristics models treat x_j as fixed and uncorrelated with ξ_j. This is the assumption behind characteristics-based instruments, and it fails if firms choose characteristics knowing ξ_j (Section 6.1.4). It also leaves out product choice, which the location models of Section 4.8 study.

4.6.4 The dimension of characteristics space shapes competition

The dimension of characteristics space is a modeling choice with first-order consequences. In a low-dimensional space each product competes with a few neighbors. In a logit-type model every product competes with every other. Caplin and Nalebuff (1991, Section 7) make the role of dimension precise. They measure dimension by the number of taste parameters. Consumers may evaluate many product attributes through a few indices, so the count of attributes can overstate the dimension that matters.

We work with Assumption A1 of Assumption 4.17. Consumer types $\nu \in \mathbb{R}^L$ have density ψ on a support B. The utility of type ν from product j, bought out of income y, is

$$U_j(\nu) = \sum_{l=1}^{L} \nu_l \, t_l(x_j) + g(y - p_j)\, t_{L+1}(x_j) + t_{L+2}(x_j) = \nu \cdot \boldsymbol{t}_j + a_j, \tag{4.55}$$

where $\boldsymbol{t}_j = (t_1(x_j), \dots, t_L(x_j))$ and $a_j = g(y - p_j)t_{L+1}(x_j) + t_{L+2}(x_j)$. At fixed prices, utility is affine in the type. Type ν prefers j to k when $\nu \cdot (\boldsymbol{t}_j - \boldsymbol{t}_k) > a_k - a_j$, which defines a half-space of types. Following Caplin and Nalebuff, product k is a *competitor* of product j if a small cut in p_j reduces the demand for k. As in Section 4.4, each of the J products is sold by a separate firm.

Proposition 4.41 (Dimension restricts preferences, after Caplin and Nalebuff, 1991, Proposition 8)**.** *Let utility satisfy* (4.55) *with L-dimensional types, and fix the prices of J products.*

(a) If $J \le L + 1$ and the vectors $\boldsymbol{t}_1, \dots, \boldsymbol{t}_J$ are affinely independent, then each of the $J!$ strict preference orderings of the products is held by a set of types in $\mathbb{R}^L$ of positive volume.

(b) If $J > L + 1$, some of the $J!$ orderings are held by no type.

Proof. (a) Fix an ordering $\iota(1) \succ \iota(2) \succ \cdots \succ \iota(J)$, where ι is a permutation of the products. By transitivity it suffices that each product beats the next one, that is,

$$\nu \cdot d_r > a_{\iota(r+1)} - a_{\iota(r)}, \qquad d_r = \boldsymbol{t}_{\iota(r)} - \boldsymbol{t}_{\iota(r+1)}, \qquad r = 1, \dots, J-1.$$

The vectors $d_1, \dots, d_{J-1}$ telescope, so they span the same space as the vectors $\boldsymbol{t}_k - \boldsymbol{t}_{\iota(J)}$, $k \neq \iota(J)$. That space has dimension $J - 1$ because the $\boldsymbol{t}_j$ are affinely independent. The $J - 1 \le L$ vectors d_r are therefore linearly independent, and the linear map $\nu \mapsto (\nu \cdot d_1, \dots, \nu \cdot d_{J-1})$ from $\mathbb{R}^L$ to $\mathbb{R}^{J-1}$ is onto. Some type ν^* therefore attains any target, for instance $\nu^* \cdot d_r = a_{\iota(r+1)} - a_{\iota(r)} + 1$ for every r. By continuity every type near ν^* satisfies the strict inequalities, which gives a set of positive volume.

(b) Caplin and Nalebuff (1991) derive the general case from a theorem of Greenberg (1979) on majority rule. That theorem implies that some product wins at least the fraction $\frac{1}{L+1}$ of the market in a pairwise contest with each of the other products. Suppose all orderings were possible. Then we could form a population of J equally weighted types holding the J cyclic orderings $1 \succ 2 \succ \cdots \succ J$, then $J \succ 1 \succ \cdots \succ J - 1$, and so on. In this population product j

beats product $j-1$ only in one of the J orderings, where product 0 is read as product J. Every product thus wins only the fraction $\frac{1}{J} < \frac{1}{L+1}$ of some pairwise contest, a contradiction.

The one-dimensional case has an elementary proof. With $L = 1$, each $U_j(v) = v\boldsymbol{t}_j + a_j$ is a line in v. Two lines cross at most once, so the ranking of the products changes only at crossing points, and there are at most $\frac{J(J-1)}{2}$ of them. These points cut the real line into at most $\frac{J(J-1)}{2}+1$ intervals, each with a single ranking. For $J = 3$ at most $4 < 3! = 6$ orderings occur, and $\frac{J(J-1)}{2}+1 < J!$ for every $J \geq 3$. The restriction has a sharp form. Label three products so that $\boldsymbol{t}_1 < \boldsymbol{t}_2 < \boldsymbol{t}_3$, and let v_{jk} be the type indifferent between j and k. Product 2 is ranked first by the types in (v_{12}, v_{23}) and last by the types in (v_{23}, v_{12}). At most one of these intervals is nonempty, so the middle product is never both some type's favorite and another type's worst. □

In one dimension consumers behave like voters on a left-right spectrum. Each product competes with at most two neighbors, whatever the number of products. In two dimensions a single product can compete with all others, but the average number of competitors is bounded.

Proposition 4.42 (Six competitors in two dimensions, after Caplin and Nalebuff, 1991, Proposition 9)**.** *Let utility satisfy* (4.55) *with* $L = 2$*, and let the type density satisfy Assumption A2 (Assumption 4.18), so that in particular its support* B *is convex. At any prices, let* $J' \geq 3$ *be the number of firms with positive demand and* C_j *the number of competitors of firm* j*. Then*

$$\frac{1}{J'}\sum_j C_j \leq 6.$$

Proof. Market areas. The types who buy j form the intersection of B with the half-planes in which j beats each rival. The intersection of convex sets is convex, so every market area is convex. The areas partition B, up to indifferent types, who have measure zero. Two convex areas meet along at most one segment, because their common boundary lies on the line of types indifferent between the two products. Product k is a competitor of j exactly when the areas share a segment of positive length. A cut in p_j then shifts that segment into k's area, and the consumers it passes over switch from k to j.

Polygons. Following Caplin and Nalebuff, replace B by the convex hull of the points on its boundary at which some consumer is indifferent between two products. This changes no neighbor relation, because each cut-off piece of B lies inside a single market area. Now B is a convex polygon, every market area is a convex polygon with n_j sides, and $C_j \leq n_j$. Sides on the boundary of B separate no two firms, and each other side is shared with exactly one competitor.

Angles. The interior angles of a convex polygon with n_j sides sum to $180°(n_j - 2)$. Summing over all market areas, the angles total

$$\sum_j 180°(n_j - 2) = 180°\Big(\sum_j n_j - 2J'\Big).$$

We bound the same total vertex by vertex. A corner of a market area in the interior of B is a point where at least three areas meet. (Where only two convex areas meet, their boundary is straight.) The angles at such a vertex sum to 360°, so their average is at most 120°. A vertex on the boundary of B is a point where at least two areas meet, with angles summing to at most 180°, so their average is at most 90°. There are $\sum_j n_j$ angles in all, so their total is at most $120° \sum_j n_j$. Combining the two expressions,

$$180\Big(\sum_j n_j - 2J'\Big) \leq 120\sum_j n_j \quad\Longrightarrow\quad 60\sum_j n_j \leq 360\,J' \quad\Longrightarrow\quad \frac{1}{J'}\sum_j n_j \leq 6.$$

Since $C_j \le n_j$, the average number of competitors is at most six. □

The bound is attained in the limit by a regular hexagonal tiling of the plane, as in the location theory of Lösch (1954). Caplin and Nalebuff (1991) add that, for generic product locations and prices, the average converges to six as the number of firms grows. They also note that no regular polygon with more than six sides tiles the plane. In three dimensions space can be tiled with 14-faced solids (truncated octahedra), and in higher dimensions the general bound is not known. Stiglitz (1986) studied a model in which market areas are L-dimensional cubes. In the summary of Caplin and Nalebuff (1991), the markup there is inversely proportional to the ratio of a market area's surface to its volume. Markets therefore become more competitive as the dimension rises.

Caplin and Nalebuff (1991, n. 17) compare the bound with a result of Archibald and Rosenbluth (1975) for the Lancaster model, in which goods are freely divisible and can be combined. When goods are represented in a three-dimensional space of characteristics, the average number of competitors per firm there is at most six as well. The parallel breaks down in higher dimensions. With four characteristics Archibald and Rosenbluth find no bound on the number of neighbors, while the three-dimensional version of the Caplin-Nalebuff model has one. Tirole (1988, Section 7.1.2, n. 6) reports that with four characteristics an average brand may have $\frac{J}{2}$ direct competitors. Caplin and Nalebuff give a geometric reason. In the Lancaster model with L characteristics, the count is the average number of sides in a partition of an $(L-1)$-dimensional surface into polygons, which need not be convex. That count is at least as large as the Caplin-Nalebuff bound in $L-1$ dimensions, whose market areas are convex. The two numbers agree for partitions of the plane only because convexity makes no difference there.

Figure 4.7 illustrates the proposition. Consumers' ideal points v are uniform on the unit square, and a consumer buys from the product j that minimizes $p_j + \tau\|v - x_j\|^2$, with x_j the product's location and τ a mismatch cost. Expanding the square shows that this preference satisfies (4.55): the terms $\tau\|v\|^2$ are common to all products and cancel from every comparison. Type v prefers j to k when

$$2\tau\, v \cdot (x_k - x_j) < p_k - p_j + \tau\big(\|x_k\|^2 - \|x_j\|^2\big),$$

a half-plane. With equal prices the market areas are the *Voronoi cells* of the locations, the sets of points closer to one location than to any other. With unequal prices they form a *power diagram*, in which a high-priced product's area shrinks and can vanish.

The averages in the figure lie below six, as the proposition requires. Firms at the edge of the market have few competitors, which pulls the overall average down. As the number of firms grows, the boundary matters less and the average approaches six from below. Over random draws of uniform locations with equal prices, the average number of competitors is 3.72 with 10 firms, 4.87 with 40, 5.43 with 160, 5.72 with 640 and 5.80 with 1,280. For firms away from the boundary the averages are 5.16, 5.71, 5.87, 5.94 and 5.96.

The result matters for empirical work in two ways. A low-dimensional pure characteristics model implies a sparse matrix of cross-price effects, in which each product's diversion goes to a handful of neighbors. A logit-type model spreads every product's diversion over all products. These are very different predictions for a merger between two products, and the choice between them is made when the researcher picks the dimension of the model. The result also shows that the location models of Section 4.8, with one dimension, impose strong restrictions on preferences, and that richer competition requires more dimensions.

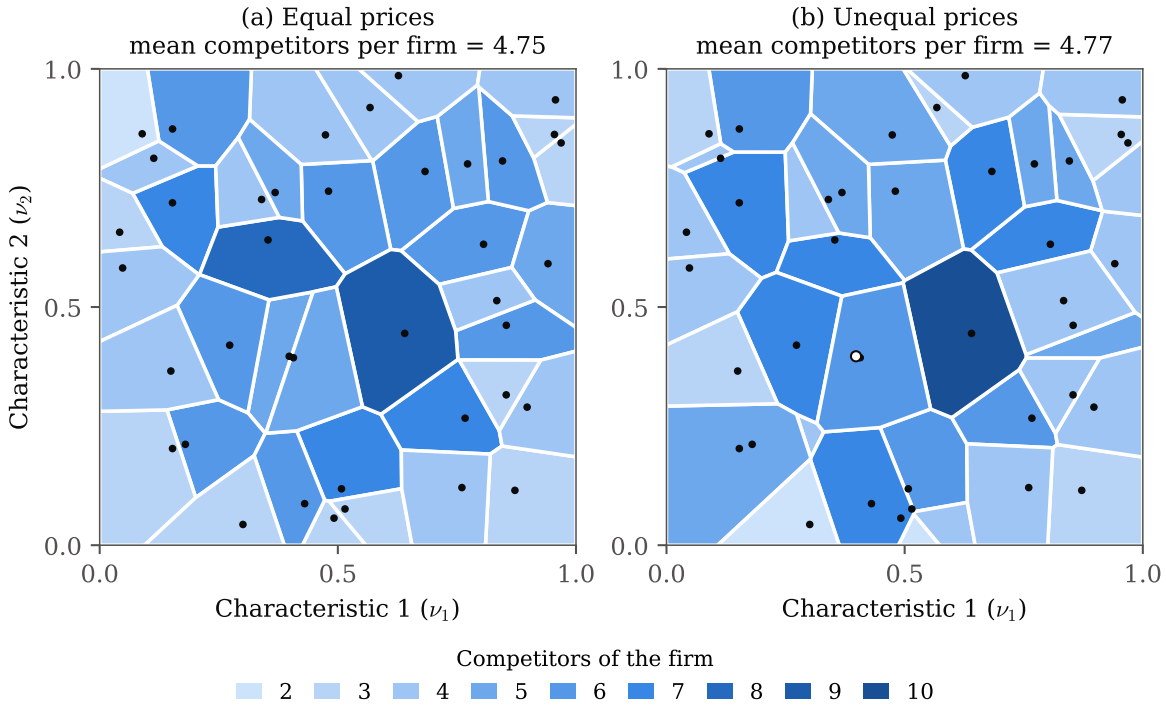

Figure 4.7: Market areas of 40 products in a two-dimensional characteristics space. Consumers' ideal points are uniform on the unit square, mismatch costs are quadratic, and dots mark product locations. Shading gives each firm's number of competitors. (a) Equal prices: Voronoi cells. The average number of competitors is 4.75 over all 40 firms and 5.83 over the 18 firms whose areas do not touch the boundary. (b) Prices drawn between 1.000 and 1.012: power diagram. One product (open circle) has no buyers. The average is 4.77 over the 39 active firms and 5.72 over the 18 interior firms. Computed with `figures/ch04/src/voronoi.py`.

4.6.5 Demand systems in product space

The goal of product-space demand analysis is to estimate $q = f(p, z)$ in a form that is flexible and consistent with consumer theory. Aggregation is the main theoretical issue. Market demand behaves like the demand of a single utility-maximizing consumer only under restrictions on individual preferences. Two such restrictions are the Gorman polar form and the price-independent generalized logarithmic (PIGLOG) class (Chapter 5). Table 4.5 summarizes the four classical systems. In the table and in this subsection goods are indexed by i and k, as in Chapter 5. Total expenditure is y, and $w_i = \frac{p_i q_i}{y}$ is the budget share of good i.

Table 4.5: Classical demand systems in product space

System and source	Demand equation	Price parameters	Restrictions of theory	Main limitation
Linear expenditure system (Stone, 1954)	$p_i q_i = p_i \gamma_i + \beta_i \left(y - \sum_k p_k \gamma_k\right)$, from Stone-Geary utility $\sum_i \beta_i \ln(q_i - \gamma_i)$ with $\sum_i \beta_i = 1$	None beyond the $2J - 1$ parameters (γ, β)	Adding up, homogeneity and symmetry hold by construction	Too few parameters to be flexible. All goods are Hicksian substitutes, and no good is inferior.
Rotterdam model (Theil, 1965; Barten, 1966)	$w_i \, \mathrm{d} \ln q_i = \theta_i \, \mathrm{d} \ln \bar{Q} + \sum_k \pi_{ik} \, \mathrm{d} \ln p_k$, with $\mathrm{d} \ln \bar{Q} = \sum_k w_k \, \mathrm{d} \ln q_k$	$\frac{J(J-1)}{2}$ free π_{ik}	Adding up, homogeneity and symmetry are linear restrictions on (θ, π). Negativity needs $[\pi_{ik}]$ negative semidefinite	A local approximation in differentials, with constant coefficients, not derived from a utility function.
Indirect translog (Christensen et al., 1975)	$w_i = \frac{\alpha_i + \sum_k \beta_{ik} \ln \frac{p_k}{y}}{\sum_l \alpha_l + \sum_l \sum_k \beta_{lk} \ln \frac{p_k}{y}}$, by Roy's identity from a quadratic $\ln V$ in $\ln \frac{p}{y}$	$\frac{J(J+1)}{2}$ symmetric β_{ik}, less a normalization	Homogeneity and adding up built in. Symmetry imposed by $\beta_{ik} = \beta_{ki}$	Shares nonlinear in parameters. Aggregates only under extra restrictions.
Almost Ideal Demand System (Deaton and Muellbauer, 1980a)	$w_i = \alpha_i + \sum_k \gamma_{ik} \ln p_k + \beta_i \ln \frac{y}{P}$, with translog price index $\ln P$	$\frac{J(J-1)}{2}$ free γ_{ik}	Linear and testable: adding up, homogeneity, symmetry	Still of order J^2 parameters. Negativity not imposed globally.

Notes: Goods are indexed by i and k, y is total expenditure and $w_i = \frac{p_i q_i}{y}$ is a budget share. Parameter symbols are specific to each row. For the AIDS, $\ln P = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2} \sum_k \sum_l \gamma_{kl} \ln p_k \ln p_l$, and the restrictions are $\sum_i \alpha_i = 1$, $\sum_i \gamma_{ik} = 0$, $\sum_i \beta_i = 0$ (adding up), $\sum_k \gamma_{ik} = 0$ (homogeneity) and $\gamma_{ik} = \gamma_{ki}$ (symmetry) (Deaton and Muellbauer, 1980a, eqs. 8–12). In the Rotterdam model $\mathrm{d} \ln \bar{Q}$ is the Divisia volume index. Price-parameter counts are after the restrictions of theory.

The linear expenditure system was the first system estimated from an explicit utility function (Deaton and Muellbauer, 1980a, p. 312). Consumers buy subsistence quantities γ_i first and split the remaining income in the fixed proportions β_i. Its cross-price effects are $\frac{\partial q_i}{\partial p_k} = -\frac{\beta_i \gamma_k}{p_i}$ for $k \neq i$, so the J^2 price effects are pinned down by $2J - 1$ parameters. The Rotterdam model approximates the demand functions themselves in differential form. The translog approximates the indirect utility function to second order. The Almost Ideal Demand System starts from a class of preferences that aggregates across consumers and yields shares that are nearly linear in

the parameters. Chapter 5 develops the AIDS in full, and Remark 5.29 states when the translog aggregates.

Three problems in practice. The first problem is dimensionality. A linear system $q = a + Ap$ has J intercepts and J^2 price coefficients. With $J = 50$ brands, as in a cereal aisle, that is 2,500 price coefficients. Symmetry reduces the count to $\frac{J(J+1)}{2} = 1{,}275$, and the full set of AIDS restrictions to $\frac{J(J-1)}{2} = 1{,}225$. These numbers exceed what typical market-level data can estimate.

The second problem is instruments. Each demand equation contains all J prices, and every price is endogenous. Write the equation for good i in market t as $q_{it} = a_i + \sum_k A_{ik} p_{kt} + e_{it}$, and let z_t be a vector of excluded instruments. The order condition requires at least J instruments. The rank condition requires that $\mathbb{E}[z_t p_t^\top]$ have rank J, so the instruments must move the J prices independently of one another. A single market-wide cost shifter fails this test. If z_t is a scalar, the first-stage fitted prices $\hat{p}_{kt} = \hat{\pi}_k z_t$ are proportional to one another, and only one linear combination of the row $A_{i\cdot}$ is identified. Identification needs product-specific shifters, such as ingredient costs that differ across products, or prices of the same product in other markets (Chapter 5).

The third problem is consumer heterogeneity. A representative consumer cannot say who gains and who loses from a price change or a new product. Distributional questions, and substitution patterns that depend on who buys which product, require explicit heterogeneity. Characteristics models build it in through the taste distribution and demographics.

Four ways forward. Applied work responds to these problems in four ways. Each buys tractability with an assumption.

1. *Aggregate, or study one product.* Group products into a few aggregates, or estimate the residual demand of a single firm, as Baker and Bresnahan (1988) do (Chapter 3). This sacrifices the cross-effects among products within each aggregate.

2. *Impose symmetry.* Representative-consumer systems such as CES and logit treat products symmetrically up to one or two parameters (Section 4.7). They suit questions about variety and poorly serve questions about which products are close substitutes.

3. *Impose separability.* Multi-stage budgeting splits goods into groups and estimates a small system within each group (Section 5.5). Hausman et al. (1994) and Hausman (1997) follow this route with the AIDS at the lowest level.

4. *Move to characteristics space.* Discrete choice models replace product-indexed parameters with tastes for characteristics (Chapters 6 to 8), at the costs described in Section 4.6.3.

The rest of this chapter develops the second route, together with the location models that underlie the fourth. Chapter 5 takes the third route, and Chapters 6 to 8 take the fourth.

4.7 Representative-consumer demand systems: linear, CES and logit

Section 4.6 showed that an unrestricted demand system in product space has far too many parameters. One remedy imposes symmetry. A *representative consumer* is a single fictitious agent whose demands equal market demands. If she also treats all products symmetrically, a handful of parameters governs every own and cross effect. This section develops the three systems of this kind that appear most often in applied work: linear demand from quadratic utility, constant elasticity of substitution (CES) demand, and the logit. For each we derive demand, elasticities, diversion and Bertrand markups. We then show that the CES and the

logit are also discrete choice models, which ties this section to the random utility models of Chapter 6. A two-sector version of the CES model, the model of monopolistic competition of Spence (1976) and Dixit and Stiglitz (1977), asks whether markets supply the right number of products. The section closes with the questions these systems answer well and a table that compares them.

4.7.1 Linear demand from quadratic utility

The linear demand of Example 4.6 has a utility foundation. A representative consumer with income y buys quantities $q_1, \dots, q_J$ of J differentiated products and an amount z of a numeraire good with price one. Her utility is quasi-linear in the numeraire,

$$U(q, z) = z + \bar{a} \sum_{j=1}^{J} q_j - \frac{1}{2}\Big[\bar{b} \sum_{j=1}^{J} q_j^2 + 2\bar{g} \sum_{j<k} q_j q_k\Big], \qquad \bar{b} > \bar{g} \geq 0 \tag{4.56}$$

(Singh and Vives, 1984; Vives, 1999). The parameter $\bar{a}$ is the marginal utility of the first unit of any product. The parameter $\bar{b}$ measures how fast marginal utility falls with own consumption, and $\bar{g}$ measures how much consuming one product lowers the marginal utility of another. The products are substitutes when $\bar{g} > 0$ and independent when $\bar{g} = 0$. As $\bar{g}$ approaches $\bar{b}$, utility depends only on total consumption and the products become perfect substitutes.

Proposition 4.43 (Linear demand from quadratic utility)**.** *Let the consumer maximize* (4.56) *subject to* $z + \sum_j p_j q_j = y$*, and suppose the solution has* $q_j > 0$ *for every* j *and* $z > 0$*. Then:*

(i) Inverse demand is $p_j = \bar{a} - \bar{b} q_j - \bar{g} \sum_{k \neq j} q_k$*.*

(ii) With two products, demand is $q_j = a - b p_j + d p_k$ *with*

$$a = \frac{\bar{a}}{\bar{b} + \bar{g}}, \qquad b = \frac{\bar{b}}{\bar{b}^2 - \bar{g}^2}, \qquad d = \frac{\bar{g}}{\bar{b}^2 - \bar{g}^2},$$

so that $b > d \geq 0$ *and the diversion ratio is* $D_{jk} = \frac{d}{b} = \frac{\bar{g}}{\bar{b}}$*.*

(iii) With J *products, for every* $k \neq j$*,*

$$\frac{\partial q_j}{\partial p_j} = -\frac{\bar{b} + (J-2)\bar{g}}{(\bar{b} - \bar{g})[\bar{b} + (J-1)\bar{g}]}, \qquad \frac{\partial q_k}{\partial p_j} = \frac{\bar{g}}{(\bar{b} - \bar{g})[\bar{b} + (J-1)\bar{g}]}, \qquad D_{jk} = \frac{\bar{g}}{\bar{b} + (J-2)\bar{g}}.$$

A fraction $1 - (J-1)D_{jk} = \frac{\bar{b} - \bar{g}}{\bar{b} + (J-2)\bar{g}}$ *of the sales that product* j *loses leaves the group of products.*

Proof. For (i), substitute the budget constraint $z = y - \sum_j p_j q_j$ into utility:

$$y + \sum_{j=1}^{J} (\bar{a} - p_j) q_j - \frac{1}{2}\Big[\bar{b} \sum_{j} q_j^2 + 2\bar{g} \sum_{j<k} q_j q_k\Big].$$

The derivative with respect to q_j is $\bar{a} - p_j - \bar{b} q_j - \bar{g} \sum_{k \neq j} q_k$. Setting it to zero gives (i). The Hessian of the objective is $-B$, where B has $\bar{b}$ on the diagonal and $\bar{g}$ off it. In matrix form $B = (\bar{b} - \bar{g}) I_J + \bar{g} \mathbf{1}\mathbf{1}^\top$. Its eigenvalues are $\bar{b} - \bar{g} > 0$ (on vectors orthogonal to $\mathbf{1}$) and $\bar{b} + (J-1)\bar{g} > 0$ (on $\mathbf{1}$). The objective is therefore strictly concave, and the first-order conditions characterize the maximum.

For (ii) and (iii), stack (i) as $p = \bar{a}\mathbf{1} - Bq$, so that $q = B^{-1}(\bar{a}\mathbf{1} - p)$ and $\frac{\partial q}{\partial p^\top} = -B^{-1}$. We claim that

$$B^{-1} = \frac{1}{\bar{b} - \bar{g}}\Big[I_J - \frac{\bar{g}}{\bar{b} + (J-1)\bar{g}}\mathbf{1}\mathbf{1}^\top\Big].$$

To check it, multiply by B and use $\mathbf{1}^\top\mathbf{1}^\top = J\mathbf{1}^\top$:

$$\begin{aligned}\big[(\bar{b} - \bar{g})I_J + \bar{g}\mathbf{1}\mathbf{1}^\top\big]\Big[I_J - \frac{\bar{g}}{\bar{b} + (J-1)\bar{g}}\mathbf{1}\mathbf{1}^\top\Big] &= (\bar{b} - \bar{g})I_J + \Big[\bar{g} - \frac{\bar{g}(\bar{b} - \bar{g}) + J\bar{g}^2}{\bar{b} + (J-1)\bar{g}}\Big]\mathbf{1}\mathbf{1}^\top \\ &= (\bar{b} - \bar{g})I_J + \Big[\bar{g} - \frac{\bar{g}\,[\bar{b} + (J-1)\bar{g}]}{\bar{b} + (J-1)\bar{g}}\Big]\mathbf{1}\mathbf{1}^\top = (\bar{b} - \bar{g})I_J.\end{aligned}$$

The diagonal element of $-B^{-1}$ is $-\frac{1}{\bar{b}-\bar{g}}\big[1 - \frac{\bar{g}}{\bar{b}+(J-1)\bar{g}}\big] = -\frac{\bar{b}+(J-2)\bar{g}}{(\bar{b}-\bar{g})[\bar{b}+(J-1)\bar{g}]}$, and the off-diagonal element is $\frac{\bar{g}}{(\bar{b}-\bar{g})[\bar{b}+(J-1)\bar{g}]}$. This proves the derivatives in (iii). The diversion ratio (4.11) is minus their ratio. The fraction that leaves the group is $1 - \frac{(J-1)\bar{g}}{\bar{b}+(J-2)\bar{g}} = \frac{\bar{b}-\bar{g}}{\bar{b}+(J-2)\bar{g}}$, which is positive because $\bar{b} > \bar{g}$. Setting $J = 2$ gives $b = \frac{\bar{b}}{(\bar{b}-\bar{g})(\bar{b}+\bar{g})}$ and $d = \frac{\bar{g}}{(\bar{b}-\bar{g})(\bar{b}+\bar{g})}$. The intercept is $\frac{\bar{a}(\bar{b}-\bar{g})}{\bar{b}^2-\bar{g}^2} = \frac{\bar{a}}{\bar{b}+\bar{g}}$, which proves (ii). □

Three features of this system matter below. First, cross derivatives are symmetric, $\frac{\partial q_k}{\partial p_j} = \frac{\partial q_j}{\partial p_k}$, because the Jacobian $-B^{-1}$ is symmetric. This is the quasi-linear case (i) of Remark 4.4. Second, the values $\bar{a} = 10$, $\bar{b} = \frac{2}{3}$ and $\bar{g} = \frac{1}{3}$ give $a = 10$, $b = 2$ and $d = 1$, the numbers of Example 4.6. Third, the linear form holds only on the set of prices at which every product is bought. If p_2 is so high that $q_2 = 0$, product 1 faces $q_1 = \frac{\bar{a}-p_1}{\bar{b}}$, with slope $\frac{1}{\bar{b}}$. This is smaller in absolute value than $b = \frac{\bar{b}}{\bar{b}^2-\bar{g}^2}$, so demand is continuous but kinked where the rival drops out.

The system has three parameters only because of symmetry. A general quadratic utility $z + \bar{a}^\top q - \frac{1}{2}q^\top Bq$ with any symmetric positive definite B gives the linear system $q = B^{-1}(\bar{a} - p)$, with $\frac{J(J+1)}{2}$ slope parameters. That is the linear product-space system of Section 4.6 with symmetry imposed. The symmetric version replaces it by $\bar{b}$ and $\bar{g}$.

Crowded markets. The symmetric system has a strong implication for markets with many products. Suppose N single-product firms (here $N = F = J$) sell the N products at a common marginal cost c. At symmetric prices p, part (i) gives each firm the quantity $q = \frac{\bar{a}-p}{\bar{b}+(N-1)\bar{g}}$. By the inverse semi-elasticity rule of Section 4.2.4, a single-product firm sets $p - c = -q\big(\frac{\partial q_j}{\partial p_j}\big)^{-1}$. Substituting q and the own slope from part (iii),

$$p - c = \frac{\bar{a} - p}{\bar{b} + (N-1)\bar{g}} \cdot \frac{(\bar{b} - \bar{g})[\bar{b} + (N-1)\bar{g}]}{\bar{b} + (N-2)\bar{g}} = \frac{(\bar{a} - p)(\bar{b} - \bar{g})}{\bar{b} + (N-2)\bar{g}}.$$

Write $\bar{a} - p = (\bar{a} - c) - (p - c)$ and collect the terms in $p - c$:

$$(p - c)\big[\bar{b} + (N-2)\bar{g} + \bar{b} - \bar{g}\big] = (\bar{a} - c)(\bar{b} - \bar{g}) \quad\Longrightarrow\quad p - c = \frac{(\bar{a} - c)(\bar{b} - \bar{g})}{2\bar{b} + (N-3)\bar{g}}. \tag{4.57}$$

With $N = 2$ and the numbers above, $p - c = \frac{9 \cdot \frac{1}{3}}{1} = 3$, so $p = 4$ as in Example 4.6. When $\bar{g} > 0$, the markup falls to zero as N grows. Every new product is a substitute for every existing one,

and a crowded market approaches marginal-cost pricing. The same symmetric products give consumers bounded gains from variety. At a common price p, consumer surplus is utility minus expenditure, $Nq(\bar{a}-p) - \frac{1}{2}Nq^2[\bar{b}+(N-1)\bar{g}]$. Substituting q gives

$$CS(N) = Nq(\bar{a}-p) - \frac{1}{2}Nq(\bar{a}-p) = \frac{N(\bar{a}-p)^2}{2[\bar{b}+(N-1)\bar{g}]} \longrightarrow \frac{(\bar{a}-p)^2}{2\bar{g}} \quad \text{as } N \to \infty.$$

The CES and logit systems behave very differently on both counts, as we show next.

4.7.2 CES demand

The CES system is the workhorse of models of monopolistic competition and international trade. A representative consumer spends income y on J products and has utility

$$u(q) = \Big(\sum_{j=1}^{J} q_j^{\frac{\sigma-1}{\sigma}} \Big)^{\frac{\sigma}{\sigma-1}}, \qquad \sigma > 1. \tag{4.58}$$

The parameter σ is the *elasticity of substitution*. We show below that $\frac{q_j}{q_k} = (\frac{p_j}{p_k})^{-\sigma}$, so a one percent rise in the relative price $\frac{p_j}{p_k}$ lowers the relative quantity $\frac{q_j}{q_k}$ by σ percent. In this section σ always denotes the CES elasticity, as in Chapter 5. It is a different object from the nesting parameter of the nested logit, which other chapters also write as σ. Two other conventions appear in the literature. Some authors write the inner exponent as $\varsigma = \frac{\sigma-1}{\sigma} \in (0,1)$, so that $\sigma = \frac{1}{1-\varsigma}$. Others use a different outer exponent, such as $(\sum_j q_j^{\varsigma})^{1-\varsigma}$. Any strictly increasing transformation of u represents the same preferences, so all of these forms give the same demand.

Proposition 4.44 (CES demand and Bertrand pricing)**.** *Let the consumer maximize* (4.58) *subject to* $\sum_j p_j q_j = y$. *Define the* CES price index $P^{CES} = \big(\sum_{k=1}^{J} p_k^{1-\sigma}\big)^{\frac{1}{1-\sigma}}$ *and the expenditure shares* $s_j = \frac{p_j q_j}{y}$. *Then:*

(i) Demand is

$$q_j = \frac{p_j^{-\sigma}}{\sum_k p_k^{1-\sigma}}\, y = \Big(\frac{p_j}{P^{CES}}\Big)^{-\sigma} \frac{y}{P^{CES}}, \qquad s_j = \Big(\frac{p_j}{P^{CES}}\Big)^{1-\sigma}, \tag{4.59}$$

and indirect utility is $\frac{y}{P^{CES}}$.

(ii) The own elasticity is $\varepsilon_j = \sigma - (\sigma-1)s_j = \sigma(1-s_j) + s_j$, *the cross elasticity is* $\varepsilon_{jk} = (\sigma-1)s_k$ *for* $k \neq j$, *and the income elasticity is one.*

(iii) The diversion ratio is $D_{jk} = \frac{(\sigma-1)p_j q_k}{y[\sigma-(\sigma-1)s_j]}$. *Measured in expenditure, the fraction of the revenue lost by* j *that goes to* k *is* $-\frac{\partial(p_k q_k)}{\partial p_j}\big(\frac{\partial(p_j q_j)}{\partial p_j}\big)^{-1} = \frac{s_k}{1-s_j}$.

(iv) Suppose each product has constant marginal cost mc_j *and firms set prices as in Section 4.2. A single-product firm sets*

$$\frac{p_j - mc_j}{p_j} = \frac{1}{\sigma - (\sigma-1)s_j}. \tag{4.60}$$

A firm that sells the products $\mathcal{J}_f$ *gives all of them the same Lerner index,* $\frac{p_j - mc_j}{p_j} = \frac{1}{\sigma-(\sigma-1)S_f}$, *where* $S_f = \sum_{k\in\mathcal{J}_f} s_k$.

Proof. (i) Let $\varsigma = \frac{\sigma-1}{\sigma} \in (0,1)$ and $V(q) = \sum_j q_j^{\varsigma}$. Since $u = V^{\frac{1}{\varsigma}}$ is a strictly increasing function of V, we may maximize V. It is strictly concave, and its marginal utilities are infinite at zero, so the solution is interior and unique. The first-order condition of the Lagrangian is $\varsigma q_j^{\varsigma-1} = \lambda p_j$. Since $\varsigma - 1 = -\frac{1}{\sigma}$, it gives

$$q_j = \left(\frac{\lambda}{\varsigma}\right)^{-\sigma} p_j^{-\sigma} \equiv C p_j^{-\sigma},$$

with C the same for all products. The budget constraint gives $\sum_j p_j C p_j^{-\sigma} = C \sum_j p_j^{1-\sigma} = y$, so $C = \frac{y}{\sum_k p_k^{1-\sigma}}$. By definition $\sum_k p_k^{1-\sigma} = (P^{CES})^{1-\sigma}$, hence $q_j = p_j^{-\sigma}(P^{CES})^{\sigma-1} y$, which is (4.59). Multiplying by $\frac{p_j}{y}$ gives the share. For indirect utility, note that $\sigma\varsigma = \sigma - 1$, so

$$q_j^{\varsigma} = \left(\frac{p_j}{P^{CES}}\right)^{-\sigma\varsigma}\left(\frac{y}{P^{CES}}\right)^{\varsigma} = \left(\frac{p_j}{P^{CES}}\right)^{1-\sigma}\left(\frac{y}{P^{CES}}\right)^{\varsigma} = s_j\left(\frac{y}{P^{CES}}\right)^{\varsigma}.$$

Summing over j gives $V = (\frac{y}{P^{CES}})^{\varsigma}$, so $u = \frac{y}{P^{CES}}$. Proposition 5.2 derives the expenditure function and the other duality relations.

(ii) Take logs of (4.59): $\ln q_j = -\sigma \ln p_j + (\sigma-1)\ln P^{CES} + \ln y$. From $\ln P^{CES} = \frac{1}{1-\sigma}\ln \sum_k p_k^{1-\sigma}$,

$$\frac{\partial \ln P^{CES}}{\partial \ln p_k} = \frac{1}{1-\sigma} \cdot \frac{(1-\sigma)p_k^{1-\sigma}}{\sum_l p_l^{1-\sigma}} = s_k.$$

Hence $\frac{\partial \ln q_j}{\partial \ln p_j} = -\sigma + (\sigma-1)s_j$, $\frac{\partial \ln q_j}{\partial \ln p_k} = (\sigma-1)s_k$ and $\frac{\partial \ln q_j}{\partial \ln y} = 1$. The own elasticity, written as a positive number, is $\varepsilon_j = \sigma - (\sigma-1)s_j$.

(iii) By (ii), $\frac{\partial q_k}{\partial p_j} = (\sigma-1)s_j\frac{q_k}{p_j}$ and $\frac{\partial q_j}{\partial p_j} = -\varepsilon_j\frac{q_j}{p_j}$. Their ratio is

$$D_{jk} = \frac{(\sigma-1)s_j q_k}{\varepsilon_j q_j} = \frac{(\sigma-1)p_j q_k}{y[\sigma-(\sigma-1)s_j]},$$

because $\frac{s_j}{q_j} = \frac{p_j}{y}$. For revenues, $\frac{\partial(p_j q_j)}{\partial p_j} = q_j(1-\varepsilon_j) = -(\sigma-1)(1-s_j)q_j$ and $\frac{\partial(p_k q_k)}{\partial p_j} = p_k\frac{\partial q_k}{\partial p_j} = (\sigma-1)\frac{s_j s_k y}{p_j}$. Their ratio, with a minus sign, is $\frac{s_j s_k y}{p_j q_j(1-s_j)} = \frac{s_k}{1-s_j}$, since $p_j q_j = s_j y$.

(iv) For a single-product firm, the inverse elasticity rule of Section 4.2.4 gives $\frac{p_j - mc_j}{p_j} = \frac{1}{\varepsilon_j}$, and $\varepsilon_j - 1 = (\sigma-1)(1-s_j) > 0$. For a multi-product firm, write the first-order condition (4.2) for $j \in \mathcal{J}_f$ and substitute the derivatives from (iii):

$$q_j - (p_j - mc_j)\varepsilon_j\frac{q_j}{p_j} + \sum_{k\in\mathcal{J}_f\setminus\{j\}}(p_k - mc_k)(\sigma-1)s_j\frac{q_k}{p_j} = 0.$$

Let $L_k = \frac{p_k - mc_k}{p_k}$, so that $(p_k - mc_k)q_k = L_k s_k y$. Divide by q_j and use $\frac{s_j y}{p_j q_j} = 1$:

$$1 - L_j\varepsilon_j + (\sigma-1)\sum_{k\in\mathcal{J}_f\setminus\{j\}} L_k s_k = 0.$$

Substitute $\varepsilon_j = \sigma - (\sigma-1)s_j$ and move the term $(\sigma-1)L_j s_j$ into the sum:

$$\sigma L_j = 1 + (\sigma-1)\sum_{k\in\mathcal{J}_f} L_k s_k.$$

The right side is the same for every $j \in \mathcal{J}_f$, so the firm's products share one Lerner index L_f. Then $\sigma L_f = 1 + (\sigma-1)S_f L_f$, and solving gives $L_f = \frac{1}{\sigma-(\sigma-1)S_f}$. □

Part (ii) shows how little freedom the system has. One parameter governs all substitution. The own elasticity is a weighted average of σ and one, with weight s_j on the unit elasticity of total spending. When p_k rises, every other product gains demand in the same proportion, $(\sigma - 1)s_k$, however close it is to k. With many small products every own elasticity is close to σ. Part (iii) restates this in the language of Section 4.3. Quantity diversion is proportional to q_k, and expenditure diversion is exactly the logit formula $\frac{s_k}{1-s_j}$. The quantity ratios do not sum to one, because total spending is fixed while total units are not.

Symmetric firms and the large-group limit. Let N single-product firms ($N = F = J$) share a common marginal cost. In the symmetric equilibrium $s_j = \frac{1}{N}$, and (4.60) becomes

$$\frac{p - mc}{p} = \frac{1}{\sigma - \frac{\sigma - 1}{N}} = \frac{N}{\sigma N - \sigma + 1}. \tag{4.61}$$

The Lerner index equals $\frac{2}{\sigma+1}$ with two firms and falls toward $\frac{1}{\sigma}$ as N grows. In the limit $p = \frac{\sigma}{\sigma-1} mc$, the constant markup of monopolistic competition in the model of Dixit and Stiglitz (1977). There each firm is too small to affect P^{CES}, so it perceives the elasticity σ. Caplin and Nalebuff (1991) note (footnote 19) that an early version of the Dixit-Stiglitz paper worked with a continuum of firms, for which this own effect is exactly zero. With finitely many firms it is positive, and with few firms ignoring it is inappropriate. The exact formula measures the error. With $\sigma = 3$ and $N = 10$ the Lerner index is $\frac{1}{2.8} = 0.357$, against $\frac{1}{3} = 0.333$ in the large-group approximation.

The case $N = 1$ shows why at least two firms are needed. A single seller has $s = 1$ and faces unit-elastic demand $q = \frac{y}{p}$. Its revenue is fixed at y. With $mc > 0$, its profit $y - mc\,\frac{y}{p}$ rises with p toward the supremum y, which no finite price attains, so no finite price is optimal. With $mc = 0$ every price earns y, so the price is indeterminate. With $N \geq 2$ each firm's demand is log-concave in the logarithm of its own price. By part (ii), the elasticity $\sigma - (\sigma - 1)s_j$ rises with p_j because s_j falls. The log-log condition of Section 4.4.2 then makes profit quasi-concave in own price. Caplin and Nalebuff (1991) prove that a pure-strategy equilibrium exists with at least two firms and positive costs, and that it is unique in the duopoly (Section 4.7.4).

Why CES misleads for mergers. Part (iv) says that a CES firm's markup depends only on its combined expenditure share. A merger of products j and k raises both Lerner indices to $\frac{1}{\sigma-(\sigma-1)(s_j+s_k)}$ at given shares. Nothing in this formula refers to how close j and k are. Two near-identical brands and two unrelated products with the same shares produce the same predicted price increase. A numerical illustration makes the point. Take ten single-product firms with $mc = 1$ and $\sigma = 3$. In the symmetric equilibrium each has share 0.1, Lerner index 0.357 and price 1.556. Now let firms 1 and 2 merge. We solve the post-merger first-order conditions of part (iv) by iterating on the Lerner formulas. The merged firm raises both prices by 3.9 percent, to 1.616, and each of its products' shares falls to 0.094. Each rival raises its price by 0.06 percent. These predictions hold for every pair of firms, whether the merging products are close or distant substitutes. The model has no parameter that could tell the two cases apart. For the same reason CES markups are nearly equal across products whenever shares are small, whatever the pattern of competition.

Remark 4.45 (Taste weights and an outside good). Chapter 5 writes CES utility with weights, $u(q) = \left(\sum_j a_j^{\frac{1}{\sigma}} q_j^{\frac{\sigma-1}{\sigma}}\right)^{\frac{\sigma}{\sigma-1}}$ with $a_j > 0$ (Proposition 5.2). The weights act as quality shifters. They change the price index to $P^{CES} = \left(\sum_k a_k p_k^{1-\sigma}\right)^{\frac{1}{1-\sigma}}$ and the shares to $s_j = a_j \left(\frac{p_j}{P^{CES}}\right)^{1-\sigma}$. Parts (ii) to (iv) of Proposition 4.44 hold unchanged when written in terms of these shares. An outside

good can be added through a Cobb-Douglas upper tier in $u(q)$ and a numeraire. The consumer then spends a fixed fraction of income on the differentiated products, and every result holds with y replaced by that expenditure (Caplin and Nalebuff, 1991, Section 8).

4.7.3 The logit as the demand of a representative consumer

The logit is usually derived from a population of consumers with random utility (Chapter 6). Anderson et al. (1988a) show that the same shares solve the problem of a single consumer with a taste for variety. Write mean utility as $\delta_j = \tilde{\delta}_j - \alpha p_j$, where $\tilde{\delta}_j = x_j\beta + \xi_j$ is the quality of product j before price is taken into account. The outside good has $\tilde{\delta}_0 = p_0 = 0$. The consumer allocates one unit of consumption across the $J+1$ alternatives, so q_j is the fraction of the unit that goes to alternative j. With a market of size one, q_j is also the market share.

Proposition 4.46 (Logit demand from an entropy representative consumer)**.** *Consider the program, with the convention* $0 \ln 0 = 0$*,*

$$\max_{q_0,\dots,q_J \geq 0} \sum_{j=0}^{J} (\tilde{\delta}_j - \alpha p_j) q_j - \sum_{j=0}^{J} q_j \ln q_j \qquad \textit{subject to} \qquad \sum_{j=0}^{J} q_j = 1. \tag{4.62}$$

(i) The program has a unique solution. It is interior and equals the logit shares $q_j = \frac{e^{\delta_j}}{\Phi}$*, with* $\Phi = 1 + \sum_{k=1}^{J} e^{\delta_k}$*.*

(ii) The maximized value is $\ln \Phi$*.*

(iii) The same demands solve the quasi-linear program $\max\ y - \sum_j p_j q_j + \frac{1}{\alpha}\big[\sum_j \tilde{\delta}_j q_j - \sum_j q_j \ln q_j\big]$ *subject to* $\sum_j q_j = 1$*. Its maximized value is* $y + \frac{1}{\alpha}\ln\Phi$*, and the derivative of this value with respect to* p_j *equals* $-q_j$*.*

Proof. (i) The objective is continuous on the simplex, which is compact, so a maximum exists. The function $-q \ln q$ is strictly concave and the other terms are linear, so the objective is strictly concave and the maximum is unique. The derivative of $-q \ln q$ is $-\ln q - 1$, which tends to $+\infty$ as $q \to 0$. Moving a little mass from any alternative with positive consumption to one with zero consumption therefore raises the objective. The maximum is interior, and it solves the first-order conditions of the Lagrangian $\sum_j \delta_j q_j - \sum_j q_j \ln q_j - \lambda(\sum_j q_j - 1)$:

$$\delta_j - \ln q_j - 1 - \lambda = 0 \quad \Longrightarrow \quad q_j = e^{\delta_j} e^{-(1+\lambda)}.$$

The constraint gives $e^{-(1+\lambda)} \sum_{k=0}^{J} e^{\delta_k} = 1$. Since $\delta_0 = 0$, the sum equals Φ, and $q_j = \frac{e^{\delta_j}}{\Phi}$.

(ii) At the solution $\ln q_j = \delta_j - \ln \Phi$. The value is $\sum_j \delta_j q_j - \sum_j q_j(\delta_j - \ln\Phi) = \ln\Phi \sum_j q_j = \ln\Phi$.

(iii) Since $-\sum_j p_j q_j = \frac{1}{\alpha}\sum_j (-\alpha p_j) q_j$, the quasi-linear objective equals y plus $\frac{1}{\alpha}$ times the objective in (4.62). It has the same maximizer and the value $y + \frac{1}{\alpha}\ln\Phi$. Finally, $\frac{\partial}{\partial p_j}\frac{1}{\alpha}\ln\Phi = \frac{1}{\alpha}\cdot\frac{-\alpha e^{\delta_j}}{\Phi} = -q_j$. □

The adding-up constraint does the work of substitution. Without it, the first-order conditions read $\delta_j - \ln q_j - 1 = 0$ and give $q_j = e^{\delta_j - 1}$. Each demand would then depend only on its own price, and no product would gain when a rival raised its price. The constraint ties the demands together through the multiplier λ, which equals the inclusive value $\ln\Phi$ minus one.

The term $-\sum_j q_j \ln q_j$ is the *entropy* of the consumption profile. It is largest when consumption is spread evenly, so it represents a taste for variety. In the quasi-linear form of part (iii) the entropy carries the weight $\frac{1}{\alpha}$, and $\frac{\tilde{\delta}_j}{\alpha}$ is the dollar value of product j's quality. As α grows, the taste for variety vanishes relative to money. The consumer then concentrates on the alternative with the largest net value $\frac{\tilde{\delta}_j}{\alpha} - p_j$, as buyers of a homogeneous good would. As α falls, variety dominates and consumption spreads out.

The proposition gives the logit two foundations with the same aggregate demand. In the population view, consumer i has utility $u_{ij} = \delta_j + \epsilon_{ij}$ with i.i.d. type-I extreme value shocks and buys one unit of her best alternative (McFadden, 1974). Her expected maximum utility is $\ln \Phi$ plus Euler's constant (Chapter 6). Part (ii) shows that the representative consumer's value has the same form. The log-sum measure of consumer surplus used in Chapter 7 therefore has a representative-consumer reading as well. Part (iii) is a version of Roy's identity: the derivative of the value with respect to a price is minus the demand.

Remark 4.47 (Perturbed utility and random utility). The equivalence extends beyond the logit. Take any additive random utility model with a strictly positive joint density of shocks and continuously differentiable choice probabilities. Its choice probabilities maximize $\sum_j \delta_j q_j - C(q)$ over the interior of the simplex for some function $C(q)$ (Hofbauer and Sandholm, 2002, Theorem 2.1, p. 2269). This C is strictly convex on the interior of the simplex, and its gradient grows without bound near the boundary. For the logit, C is the negative entropy $\sum_j q_j \ln q_j$. The converse fails. With four or more alternatives, no additive random utility model generates the demands that maximize $\sum_j \delta_j q_j + \sum_j \ln q_j$ (Hofbauer and Sandholm, 2002, Proposition 2.2, p. 2271).

IIA, elasticities and diversion. At the solution, $\frac{q_j}{q_k} = e^{\delta_j - \delta_k}$ depends only on products j and k. This is the independence of irrelevant alternatives (IIA). The derivatives (4.8) give $\varepsilon_j = \alpha p_j (1 - s_j)$, $\varepsilon_{kj} = \alpha p_j s_j$ for every $k \neq j$, and $D_{jk} = \frac{s_k}{1 - s_j}$ (Section 4.3.4). The classic illustration is the red bus and the blue bus. A commuter chooses between a car and a red bus, each with share $\frac{1}{2}$. Now add a blue bus that is identical to the red one. Intuition says the car keeps $\frac{1}{2}$ and the buses split the other half. The logit gives each option $\frac{1}{3}$, because it treats the blue bus as a new product with its own taste shock (Chapter 7). The entropy view tells the same story. The representative consumer gains $\ln 3 - \ln 2$ utils from the duplicate, because the entropy term rewards variety itself. This is the "too many characteristics" problem of Section 4.6.3.

Logit and CES share the same proportional substitution, and both allow quality differences ($\tilde{\delta}_j$ in the logit, the weights a_j of Remark 4.45 in the CES). They differ in what is held fixed and in how price enters. In the logit, total quantity is fixed and price enters utility in levels. In the CES, total spending is fixed and price enters through its logarithm, as the next subsection shows. As a result, logit markups are constant in dollars for a given share, $\frac{1}{\alpha(1 - s_j)}$. CES markups are constant as a fraction of price, $\frac{1}{\sigma - (\sigma - 1)s_j}$.

4.7.4 CES as a discrete choice model

The CES demand of a representative consumer can also be generated by a population in which each consumer buys only one product (Anderson et al., 1987). Let a mass M of consumers each have income y. Consumer i picks one product and spends all of her income on it, so she buys $\frac{y}{p_j}$ units if she picks j. Her utility from q units of product j is $\ln q + \frac{1}{\sigma - 1}\epsilon_{ij}$, so her indirect

utility from choosing j is

$$u_{ij} = \ln y - \ln p_j + \frac{1}{\sigma - 1}\epsilon_{ij}, \tag{4.63}$$

with ϵ_{ij} i.i.d. type-I extreme value across consumers and products.

Proposition 4.48 (CES as a discrete choice model)**.** *Under* (4.63)*, with* $\sigma > 1$*:*

(i) The probability that a consumer chooses j *is* $\frac{p_j^{1-\sigma}}{\sum_k p_k^{1-\sigma}}$*. This is a logit in* $-\ln p_j$ *with coefficient* $\sigma - 1$*, and it equals the CES expenditure share of* (4.59)*.*

(ii) Expected demand for product j *is* $\frac{My\, p_j^{-\sigma}}{\sum_k p_k^{1-\sigma}}$*, the CES demand of a representative consumer with income* My *and elasticity of substitution* σ*.*

(iii) Expected maximum utility is $\mathbb{E}[\max_j u_{ij}] = \ln \frac{y}{P^{CES}} + \frac{\gamma_E}{\sigma-1}$*, where* $\gamma_E \approx 0.5772$ *is Euler's constant. Up to a constant, it is the logarithm of the representative consumer's indirect utility.*

Proof. (i) Multiplying all utilities by $\sigma - 1 > 0$ does not change choices: $(\sigma-1)u_{ij} = (\sigma-1)\ln y - (\sigma-1)\ln p_j + \epsilon_{ij}$. The first term is common to all products and drops out. The logit formula with mean utilities $-(\sigma-1)\ln p_j$ (McFadden, 1984, eqs. 3.14–3.15) gives

$$\mathbb{P}(j) = \frac{e^{-(\sigma-1)\ln p_j}}{\sum_k e^{-(\sigma-1)\ln p_k}} = \frac{p_j^{1-\sigma}}{\sum_k p_k^{1-\sigma}}.$$

(ii) Each of the $M\mathbb{P}(j)$ consumers who choose j buys $\frac{y}{p_j}$ units, so expected demand is $M\frac{y}{p_j} \cdot \frac{p_j^{1-\sigma}}{\sum_k p_k^{1-\sigma}} = \frac{My p_j^{-\sigma}}{\sum_k p_k^{1-\sigma}}$. This is (4.59) with income My. (iii) For i.i.d. type-I extreme value shocks, $\mathbb{E}[\max_j(V_j + \epsilon_{ij})] = \ln \sum_j e^{V_j} + \gamma_E$ (Chapter 6). With $V_j = (\sigma-1)(\ln y - \ln p_j)$,

$$(\sigma-1)\mathbb{E}\big[\max_j u_{ij}\big] = (\sigma-1)\ln y + \ln \sum_k p_k^{1-\sigma} + \gamma_E = (\sigma-1)\ln y + (1-\sigma)\ln P^{CES} + \gamma_E.$$

Dividing by $\sigma - 1$ gives the result. □

Caplin and Nalebuff (1991) use a version of this equivalence with a numeraire, which they attribute to Anderson et al. (1988b). Their representative consumer has a CES aggregate of the differentiated goods and a Cobb-Douglas weight on a numeraire z. In the discrete choice version, a consumer buys q units of a single product j and maximizes qz^η subject to $p_j q + z = y$, where $\eta > 0$ is the Cobb-Douglas exponent of the numeraire. The solution is $q = \frac{y}{(1+\eta)p_j}$ and $z = \frac{\eta y}{1+\eta}$. The logarithm of maximized utility is

$$\ln(qz^\eta) = -\ln p_j + (1+\eta)\ln\frac{y}{1+\eta} + \eta\ln\eta.$$

Adding an i.i.d. extreme value term gives their eq. (8.3). They call the distribution Weibull, following earlier usage for the double exponential. With this representation they prove that the representative-consumer CES model has a pure-strategy Bertrand-Nash equilibrium for any number $N \geq 2$ of firms with positive costs. The equilibrium is unique for $N = 2$ (their Proposition 14). Their proof observes that (8.3) is exactly the indirect utility of their model with Cobb-Douglas preferences and variable demand, for suitably chosen product characteristics.

That model extends Theorem 4.22 beyond unit demand (Section 4.4). The extreme value density is log-concave, so its existence and duopoly uniqueness results carry over to the CES. Their footnote 3 adds that Dixit and Stiglitz (1977) and Spence (1976) worked with the limit of infinitely many firms and did not address existence with finitely many.

The proposition shows that the CES and the logit are two members of one family. Both are logit choice models. In the logit, price enters utility linearly and each consumer buys one unit. In the CES, price enters through its logarithm and each consumer spends a fixed budget, with $\sigma - 1$ the coefficient on $-\ln p_j$. This explains the parallel structure of their elasticities in Table 4.6. It also means that the CES inherits IIA, a point Hausman (1997, p. 230) stresses for the valuation of new goods. He credits Anderson et al. (1992) with the analysis of the similarity between the two models (Hausman, 1997, n. 29).

4.7.5 The discrete-choice program of Anderson, de Palma and Thisse

Anderson et al. (1992) build a theory of product differentiation on discrete choice. Two sources we could check describe parts of it. We saw that Hausman (1997, n. 29) credits the book with the analysis of the similarity between the CES and the logit. Anderson et al. (1995, p. 1282) refer to it for the theory of an approach that starts from a population of consumers with heterogeneous tastes and derives aggregate demand. They also cite its Chapter 3 for CES demand from a discrete choice model with a constant budget share and double-exponential tastes (p. 1296). We reconstruct the program, which connects the classical approaches to differentiation through probabilistic choice, and point to where this book develops each piece. The derivations are ours.

Three approaches to differentiation. The first is Chamberlin's (1933) monopolistic competition. A representative consumer likes variety, and every product competes with every other. The CES models of Spence (1976) and Dixit and Stiglitz (1977) are its modern form. The second is the address approach of Hotelling (1929), in which products and consumers have locations and each product competes with its neighbors (Section 4.8). The third is the characteristics approach of Lancaster (1966) and Gorman (1980), in which products are bundles of characteristics (Section 4.6). Caplin and Nalebuff (1991, p. 3) describe the trade-off among them. The symmetric CES models bypass product design and asymmetries. The multi-dimensional probabilistic choice models of Perloff and Salop (1985), Anderson and de Palma (1988) and Anderson et al. (1988b, 1989) also require symmetric specifications. The characteristics approach suits product design, but existence of equilibrium had been hard to establish there.

Probabilistic choice. Discrete choice theory describes behavior by choice probabilities $\mathbb{P}(j \mid C)$ for each choice set C. Luce's axiom gives the simplest coherent family (Luce, 1959).

Lemma 4.49 (Luce's choice axiom)**.** *Let $\mathcal{T}$ be a finite set of alternatives and let $\mathbb{P}(j \mid C) > 0$ for every $j \in C \subseteq \mathcal{T}$. Suppose*

$$\mathbb{P}(j \mid \mathcal{T}) = \mathbb{P}(j \mid C)\mathbb{P}(C \mid \mathcal{T}) \qquad \text{for all } j \in C \subseteq \mathcal{T}, \tag{4.64}$$

where $\mathbb{P}(C \mid \mathcal{T}) = \sum_{k \in C} \mathbb{P}(k \mid \mathcal{T})$. Then there are positive scale values *w_j with $\mathbb{P}(j \mid C) = \frac{w_j}{\sum_{k \in C} w_k}$ for every C. Moreover, (4.64) holds if and only if $\frac{\mathbb{P}(j|C)}{\mathbb{P}(k|C)}$ is the same for every C that contains j and k.*

Proof. Set $w_j = \mathbb{P}(j \mid \mathcal{T})$. By (4.64), $\mathbb{P}(j \mid C) = \frac{\mathbb{P}(j|\mathcal{T})}{\mathbb{P}(C|\mathcal{T})} = \frac{w_j}{\sum_{k \in C} w_k}$. This formula gives $\frac{\mathbb{P}(j|C)}{\mathbb{P}(k|C)} = \frac{w_j}{w_k}$ for every C. Conversely, suppose the ratio does not depend on C. Then $\frac{\mathbb{P}(k|C)}{\mathbb{P}(j|C)} = \frac{\mathbb{P}(k|\mathcal{T})}{\mathbb{P}(j|\mathcal{T})}$ for all $k \in C$. Summing over $k \in C$ gives $\frac{1}{\mathbb{P}(j|C)} = \frac{\mathbb{P}(C|\mathcal{T})}{\mathbb{P}(j|\mathcal{T})}$, which is (4.64). □

The ratio condition in the lemma is IIA. With $w_j = e^{v_j}$ and v_j linear in characteristics, the Luce model is the multinomial logit. McFadden (1984, p. 1412) notes that psychometrics calls this model the Luce strict utility model. The same formula follows from random utility $u_{ij} = v_j + \epsilon_{ij}$ with i.i.d. type-I extreme value shocks (McFadden, 1974). McFadden adds that the shock may stand for tastes the consumer knows and the analyst does not, or for randomness in the decision itself. Choice data alone cannot tell the two readings apart (McFadden, 1984, p. 1412).

Relaxing IIA. IIA implies that the cross elasticity of the probability of choosing k with respect to an attribute of j is the same for every $k \neq j$. McFadden (1984, p. 1414) calls this property "theoretically implausible in many applications", while noting that the multinomial logit often fits well in practice. The generalized extreme value (GEV) family relaxes it. Let $H(w_1, \ldots, w_J)$ be nonnegative and homogeneous of degree one, tend to infinity as any argument does, and have mixed partial derivatives of alternating sign. Then the choice probabilities are $\frac{\partial \ln H(e^{v_1}, \ldots, e^{v_J})}{\partial v_j}$ (McFadden, 1984, eqs. 3.29–3.31, p. 1421). The logit is the case $H = \sum_j w_j$, and the nested logit is the leading other case (Chapter 7). The probit drops the extreme value assumption altogether (Chapter 6). In each GEV model, $\ln H$ is expected maximum utility up to a constant, so the log-sum welfare measure generalizes.

Representative consumers. Sections 4.7.3 and 4.7.4 give the representative consumers of the logit and the CES. McFadden (1984, p. 1406) cautions that this is special. The expectation of a consumer's indirect utility over unobservables need not have the properties of an indirect utility function. Known sufficient conditions for a choice model to come from a population of utility maximizers are restrictive. The logit and the CES are cases in which both foundations hold exactly, which is part of their appeal for theory.

The characteristics approach. Anderson et al. (1989) relate discrete choice demand to the characteristics approach. Caplin and Nalebuff (1991, p. 23) credit this paper and Anderson et al. (1988b) with illuminating a connection. It links representative-agent models, such as the CES of Dixit, Stiglitz and Spence, to models with heterogeneous consumers. A geometric fact suggests what an address model must do to mimic the logit. With equal shares, the logit makes every product an equally close substitute for every other. In an address model this calls for every pair of products to be equally far apart. Points that are pairwise equidistant form a regular simplex, and J such points need a space of at least $J - 1$ dimensions. An address model with logit substitution among J products therefore needs many characteristics, which is the "too many characteristics" problem of Section 4.6.3 in geometric form.

Oligopoly and variety. With symmetric logit or CES demand, price competition, free entry and the optimal number of products have closed forms. The same questions can be posed for any distribution of i.i.d. tastes, as in the oligopoly model of Anderson et al. (1995). Section 4.7.6 treats the representative-consumer benchmark of monopolistic competition. Section 4.8.4 derives the symmetric logit oligopoly, extends it to general i.i.d. tastes and compares the results with the location models of Section 4.8.

4.7.6 Monopolistic competition and optimal variety

Chamberlin (1933) introduced *monopolistic competition* to describe an industry of single-product firms with three properties (Tirole, 1988, Section 7.2). Each firm faces a downward-sloping demand curve. Each firm earns zero profit. A price change by one firm has a negligible effect on the demand of every other firm. The free-entry equilibrium on Salop's circle (Section 4.8.3)

has the first two properties. The third separates monopolistic competition from oligopoly with free entry, because it says that no product has a close neighbor. Tirole notes that this absence of cross effects has been widely criticized. The model's purpose is to set strategic interaction aside and isolate one question: how many products does a market supply?

The excess capacity argument. An old view held that monopolistic competition produces too many firms, each too small to exhaust economies of scale. At a zero-profit equilibrium the residual demand curve is tangent to the average cost curve. The tangency lies where average cost still falls, so output is below the scale that minimizes average cost. Tirole (1988, Section 7.2) shows that this reasoning is flawed. If no other firm sells the same good, the good may be worth introducing even when its output does not exhaust scale economies. With average cost $c + \frac{\phi}{q}$, as in the location models, the efficient scale is infinite and every product falls short of it. The argument therefore needs a second firm that sells the same good. The first firm's demand curve is then horizontal at the rival's price. Both firms can break even only at the efficient scale, so no excess capacity arises.

Two externalities. The comparison of free entry with the optimum turns on two effects of opposite sign (Tirole, 1988, Section 7.2). The first is the *nonappropriability* of surplus. An entrant cannot capture the whole consumer surplus its product creates, which pushes toward too few products. The second is *business stealing*. An entrant takes customers from rivals whose prices exceed marginal cost, and it ignores the margins they lose. This pushes toward too many products. In general either effect can dominate, and only specific models give a definite answer.

The two-sector model. Spence (1976) and Dixit and Stiglitz (1977) gave the question a tractable form. Tirole (1988, Section 7.5.2) presents the model with a CES sub-utility. Following his footnote 40, we use the more general additive form of Dixit and Stiglitz (1977), and the derivations below are ours. A representative consumer with income y buys a numeraire z and quantities q_j of N differentiated products. Her utility and budget constraint are

$$U\Big(z, \sum_{j=1}^{N} \chi(q_j)\Big), \qquad z + \sum_{j=1}^{N} p_j q_j = y, \tag{4.65}$$

where U is increasing and quasi-concave, and the *sub-utility* χ is increasing and strictly concave with $\chi(0) = 0$. All products enter symmetrically, so entry adds variety but no product has a neighbor. Each producer pays a fixed cost ϕ and a constant marginal cost c, both in units of the numeraire. Free entry drives profits to zero, so profits do not enter the consumer's income. Two functions of q summarize χ. The first is the elasticity of the demand for one product, $\varepsilon(q) = -\frac{\chi'(q)}{q\chi''(q)}$, which we assume exceeds one. The second is the *rate of appropriability*,

$$\mathcal{R}(q) = \frac{q\chi'(q)}{\chi(q)}, \tag{4.66}$$

the ratio of a firm's revenue to the gross surplus its product creates (Tirole, 1988, Section 7.5.2). Strict concavity and $\chi(0) = 0$ give $\chi(q) > q\chi'(q)$, so $\mathcal{R}(q) < 1$. Mankiw and Whinston (1986, p. 54) isolate the same comparison in their model of product diversity. Measured in units of sub-utility, the marginal entrant adds $\chi(q)$ to gross surplus and earns $\chi'(q)q$, and the gap is the diversity effect.

Proposition 4.50 (Free entry and the optimum with a representative consumer)**.** *Let utility be* (4.65)*, and let N be large enough that each firm takes as given the ratio of marginal utilities $\lambda = \frac{U_y}{U_z}$,*

where $V = \sum_j \chi(q_j)$ and subscripts denote partial derivatives. Assume that each firm's profit is strictly concave in its output.

(i) In the symmetric free-entry equilibrium each firm charges $p = \frac{\varepsilon(q)}{\varepsilon(q)-1}\,c$ and sells the quantity q^* that solves

$$\frac{cq}{\varepsilon(q)-1} = \phi. \tag{4.67}$$

(ii) A planner who prices at marginal cost and covers fixed costs with a lump-sum tax chooses the output per product q^o and the number of products N^o. The first-best output per product solves

$$cq\,\frac{1-\mathcal{R}(q)}{\mathcal{R}(q)} = \phi. \tag{4.68}$$

(iii) Firms are too large, $q^* > q^o$, if $\mathcal{R}'(q^*) > 0$. They are too small if $\mathcal{R}'(q^*) < 0$, and of optimal size if $\mathcal{R}'(q^*) = 0$.

(iv) Let $\chi(q) = q^{\varsigma}$ with $\varsigma = \frac{\sigma-1}{\sigma}$ and $\sigma > 1$, and let $U = z^{1-\gamma}\big(\sum_j q_j^{\varsigma}\big)^{\frac{\gamma}{\varsigma}}$ with $\gamma \in (0,1)$. Then

$$p = \frac{\sigma c}{\sigma-1}, \qquad q^* = q^o = \frac{(\sigma-1)\phi}{c}, \qquad N^* = \frac{\gamma y}{\sigma\phi}, \qquad N^o = \frac{\gamma y}{(\sigma-1+\gamma)\phi}, \tag{4.69}$$

so the market supplies too few products, $\frac{N^o}{N^*} = \frac{\sigma}{\sigma-1+\gamma} > 1$.

Proof. (i) Substitute the budget constraint for z. The first-order condition for q_j is $U_V\chi'(q_j) = U_z p_j$, so the inverse demand for product j is $p_j = \lambda\chi'(q_j)$. A firm that takes λ as given maximizes $[\lambda\chi'(q)-c]q - \phi$. Its first-order condition is $\lambda[\chi'(q)+q\chi''(q)] = c$. By the definition of ε, $q\chi''(q) = -\frac{\chi'(q)}{\varepsilon(q)}$, so the condition reads $p\big(1-\frac{1}{\varepsilon}\big) = c$. This gives the price and $p - c = \frac{c}{\varepsilon-1}$. Zero profit, $(p-c)q = \phi$, then gives (4.67).

(ii) With N products of output q each, the consumer gets $z = y - N(\phi + cq)$ and $V = N\chi(q)$. The planner maximizes $U\big(y - N(\phi+cq), N\chi(q)\big)$. The first-order conditions for q and N are

$$-U_z N c + U_V N\chi'(q) = 0, \qquad -U_z(\phi + cq) + U_V\chi(q) = 0.$$

Let $\lambda^o = \frac{U_V}{U_z}$ at the optimum. The first condition gives $\lambda^o\chi'(q) = c$, so the consumer's marginal valuation equals marginal cost. The second gives $\lambda^o\chi(q) = \phi + cq$. Dividing the second by the first,

$$\frac{\chi(q)}{\chi'(q)} = \frac{\phi+cq}{c} \quad\Longrightarrow\quad \frac{cq}{\mathcal{R}(q)} = \phi + cq \quad\Longrightarrow\quad cq\Big(\frac{1}{\mathcal{R}(q)} - 1\Big) = \phi,$$

which is (4.68).

(iii) Let $g(q) = cq\frac{1-\mathcal{R}(q)}{\mathcal{R}(q)} = c\big[\frac{\chi(q)}{\chi'(q)} - q\big]$. Its derivative is $c\frac{\chi'^2 - \chi\chi''}{\chi'^2} - c = -\frac{c\chi\chi''}{\chi'^2} > 0$, so g is strictly increasing and q^o is its unique root. Next, differentiate $\ln\mathcal{R} = \ln q + \ln\chi' - \ln\chi$:

$$\frac{\mathcal{R}'(q)}{\mathcal{R}(q)} = \frac{1}{q} + \frac{\chi''}{\chi'} - \frac{\chi'}{\chi} = \frac{1}{q}\Big[1 - \frac{1}{\varepsilon(q)} - \mathcal{R}(q)\Big].$$

So $\mathcal{R}' > 0$ exactly when $\mathcal{R} < \frac{\varepsilon-1}{\varepsilon}$. Taking reciprocals and subtracting one, this holds exactly when $\frac{1-\mathcal{R}}{\mathcal{R}} > \frac{1}{\varepsilon-1}$. At q^*, (4.67) then gives

$$g(q^*) - \phi = cq^*\Big[\frac{1-\mathcal{R}(q^*)}{\mathcal{R}(q^*)} - \frac{1}{\varepsilon(q^*)-1}\Big],$$

which has the sign of $\mathcal{R}'(q^*)$. If it is positive, $g(q^*) > \phi = g(q^o)$, and $q^* > q^o$ because g is increasing. The other two cases follow in the same way.

(iv) For $\chi(q) = q^\varsigma$, $\chi' = \varsigma q^{\varsigma-1}$ and $q\chi'' = \varsigma(\varsigma-1)q^{\varsigma-1}$, so $\varepsilon = \frac{1}{1-\varsigma} = \sigma$ and $\mathcal{R} = \varsigma$ is constant. Part (i) gives $p = \frac{\sigma c}{\sigma-1}$ and $\frac{cq^*}{\sigma-1} = \phi$. Part (iii) with $\mathcal{R}' = 0$ gives $q^o = q^*$. The upper tier is Cobb-Douglas in z and the CES index $(\sum_j q_j^\varsigma)^{\frac{1}{\varsigma}}$, which is homogeneous of degree one. The consumer therefore spends the share γ of income on the differentiated products, $N^* p q^* = \gamma y$. Since $pq^* = \frac{\sigma c}{\sigma-1} \cdot \frac{(\sigma-1)\phi}{c} = \sigma\phi$, we get $N^* = \frac{\gamma y}{\sigma\phi}$. For the planner, symmetric outputs give the CES index $qN^{\frac{1}{\varsigma}}$, so

$$\ln U = (1-\gamma)\ln\left[y - N(\phi + cq)\right] + \gamma \ln q + \frac{\gamma}{\varsigma}\ln N.$$

At $q = q^o$ we have $\phi + cq^o = \sigma\phi$. The first-order condition for N is $\frac{(1-\gamma)\sigma\phi}{y - N\sigma\phi} = \frac{\gamma}{\varsigma N}$, so $N\sigma\phi[(1-\gamma)\varsigma + \gamma] = \gamma y$. Since $(1-\gamma)\varsigma + \gamma = \frac{\sigma - 1 + \gamma}{\sigma}$, this gives N^o. □

The proposition separates the two margins. Output per product depends only on χ, c and ϕ, and the rate of appropriability decides how it compares with the optimum. When $\mathcal{R}$ rises with q, a firm captures a growing share of the surplus it creates as it expands. It then has a stronger incentive to expand than the planner, as Tirole (1988, Section 7.5.2) explains. When $\mathcal{R}$ falls, firms are too small, which is the case of excess capacity. With CES sub-utility the two forces balance and firm size is optimal. The number of products then carries the whole distortion. In part (iv) the market charges $\frac{\sigma c}{\sigma-1}$ against the planner's c. The planner therefore draws spending from the numeraire into the differentiated sector and finances more products of the same size. The gap closes as $\gamma \to 1$, when there is no numeraire to draw from.

The benchmark matters. The first best of part (ii) needs lump-sum taxes to cover the losses of marginal-cost pricing. Anderson et al. (1995, p. 1293) argue that the relevant benchmark for a market is the optimum subject to zero profits. They also note that a CES example yields too few products relative to the first best, as in part (iv). For the utility $z^{1-\gamma}[\sum_j \chi(q_j)]^\gamma$ they report the comparison of Dixit and Stiglitz (1977) with this constrained optimum (p. 1296). Relative to it, the market supplies too many products when $\mathcal{R}$ falls with q and too few when it rises. With constant $\mathcal{R}$, the CES case, the equilibrium and constrained-optimal numbers of products coincide (p. 1297). The shortfall in part (iv) is relative to the first best. Dixit and Stiglitz regard a rising $\mathcal{R}$ as the plausible case, so that markets underprovide variety. Anderson, de Palma and Nesterov object that a rising $\mathcal{R}$ makes total demand for the differentiated goods fall, at given prices, as products are added. They find a falling $\mathcal{R}$ more plausible, which gives too many products.

Tirole (1988, Section 7.5.2) adds that later work, such as Perloff and Salop (1985), gave monopolistic competition firmer foundations. These models replace the representative consumer by a population whose valuations of the brands are drawn independently from a distribution, and each consumer buys one brand. Section 4.8.4 takes this route. Its model of i.i.d. tastes contains the logit as a special case and gives a sharp answer on variety.

4.7.7 What symmetric systems are good for

Symmetric representative-consumer systems answer some questions well and others badly. They are good for questions about the number of products. Do markets provide too many or too few varieties? How much do consumers gain from new varieties? How should a price

index adjust when varieties enter or exit? They are poor guides to questions that hinge on which products are close substitutes, such as mergers.

The gains from variety have closed forms. Suppose a CES product enters and takes expenditure share s. Before entry $(P^{CES}_{\text{before}})^{1-\sigma} = \sum_{k \text{ old}} p_k^{1-\sigma} = (1-s)(P^{CES}_{\text{after}})^{1-\sigma}$, because the new product's share of $(P^{CES}_{\text{after}})^{1-\sigma}$ is s. Taking logs,

$$\ln \frac{P^{CES}_{\text{before}}}{P^{CES}_{\text{after}}} = -\frac{1}{\sigma - 1} \ln(1-s). \tag{4.70}$$

Real income $\frac{y}{P^{CES}}$ rises by this proportion. With N symmetric products at a common price p, $P^{CES} = pN^{\frac{1}{1-\sigma}}$ and real income is $\frac{y}{p} N^{\frac{1}{\sigma-1}}$, unbounded in N. In the logit, part (iii) of Proposition 4.46 gives the gain from an entrant with share s in a market of size M: $\Delta CS = \frac{M}{\alpha} \ln \frac{\Phi_{\text{after}}}{\Phi_{\text{before}}} = -\frac{M}{\alpha} \ln(1-s)$. With N symmetric products, consumer surplus grows like $\frac{M}{\alpha} \ln N$. The quadratic model of Section 4.7.1 bounds the gains instead. These formulas explain why trade theory relies on the CES. Krugman (1980) combines CES preferences with scale economies to explain trade between similar countries. Melitz (2003) adds productivity differences across firms inside the same CES framework. The CES has also been applied to the introduction of new products (Hausman, 1997, p. 230, n. 30), for example by Feenstra (1994), who adjusts import price indices for new and disappearing varieties. His exact index multiplies the price index of continuing varieties with unchanged taste parameters by the ratio of their current to previous expenditure share, raised to the power $\frac{1}{\sigma-1}$ (Feenstra, 1994, Proposition 1, p. 159). With no exits and unchanged prices of continuing varieties, this is (4.70). Proposition 10.17 states and proves the result.

The same formulas show the danger. Each new product's value depends only on its share and one substitution parameter, never on how similar it is to existing products. Hausman (1997, p. 230) writes that the IIA problem of the logit "typically leads to a vast overestimate of the consumer's surplus from a new good". He argues that the CES shares the problem. He estimates a CES demand for cereal brands by nonlinear two-stage least squares and reports an elasticity of substitution of 2.13 (Hausman, 1997, p. 231). The implied consumer surplus from the introduction of Apple-Cinnamon Cheerios is about three times his estimate of $78.1 million per year from a flexible multilevel demand system (Chapter 10). Table 4.6 collects the properties of the three systems.

4.8 Location models: prices, products and entry in characteristics space

Location models describe differentiation by a position in a space of characteristics. Each consumer has an ideal point, and buying a product away from it costs her a *transport cost*, also called a mismatch cost. The models predate empirical demand analysis by decades. They remain the cleanest setting for three questions that the symmetric systems of Section 4.7 cannot pose. Does a price equilibrium exist when demand has kinks or jumps? How do firms choose products when they anticipate price competition? Does free entry produce too many or too few products? Section 6.4.2 introduces the Hotelling and Salop models as demand models. Here we develop their equilibrium theory, add the vertical model of quality choice and a symmetric oligopoly with logit or other i.i.d. tastes, and compare entry outcomes across models. Throughout, $\tau > 0$ is the transport cost parameter, ϕ is a fixed cost of entry, and the location of product j is a one-dimensional characteristic x_j.

Table 4.6: Linear, CES and logit demand compared

	Linear (quadratic utility)	CES	Logit
Representative utility	$z + \bar{a}\sum_j q_j - \frac{\bar{b}}{2}\sum_j q_j^2 - \bar{g}\sum_{j<k} q_j q_k$	$\left(\sum_j q_j^{\frac{\sigma-1}{\sigma}}\right)^{\frac{\sigma}{\sigma-1}}$ with $\sum_j p_j q_j = y$	$\sum_{j=0}^{J} \delta_j q_j - \sum_{j=0}^{J} q_j \ln q_j$ with $\sum_{j=0}^{J} q_j = 1$
Parameters	$\bar{a}, \bar{b}, \bar{g}$	σ, plus $J-1$ taste weights if qualities differ	α and the qualities $\tilde{\delta}_1, \ldots, \tilde{\delta}_J$
Demand	$q_j = a - bp_j + dp_k$ when $J = 2$	$q_j = \left(\frac{p_j}{P^{CES}}\right)^{-\sigma} \frac{y}{P^{CES}}$	$s_j = \frac{e^{\delta_j}}{\Phi}$
Own elasticity ε_j	$\frac{bp_j}{q_j}$	$\sigma - (\sigma-1)s_j$	$\alpha p_j (1 - s_j)$
Cross elasticity ε_{jk}	$\frac{dp_k}{q_j}$	$(\sigma-1)s_k$	$\alpha p_k s_k$
Diversion D_{jk}	$\frac{\bar{g}}{\bar{b}+(J-2)\bar{g}}$, equal to $\frac{d}{b}$ when $J = 2$	$\frac{(\sigma-1)p_j q_k}{y[\sigma-(\sigma-1)s_j]}$ in units, $\frac{s_k}{1-s_j}$ in expenditure	$\frac{s_k}{1-s_j}$
Single-product markup	$p_j - c = \frac{q_j}{b}$	$\frac{p_j - mc_j}{p_j} = \frac{1}{\sigma-(\sigma-1)s_j}$	$p_j - mc_j = \frac{1}{\alpha(1-s_j)}$
Multi-product firm	joint owner of two products: $p - c = \frac{a-(b-d)c}{2(b-d)}$	common Lerner index $\frac{1}{\sigma-(\sigma-1)S_f}$	common markup $\frac{1}{\alpha(1-S_f)}$
N symmetric firms	$p - c = \frac{(\bar{a}-c)(\bar{b}-\bar{g})}{2\bar{b}+(N-3)\bar{g}} \to 0$	$\frac{p-c}{p} = \frac{N}{\sigma N-\sigma+1} \to \frac{1}{\sigma}$	$p - c = \frac{N}{\alpha(N-1)} \to \frac{1}{\alpha}$
Own-cost pass-through, rivals' prices fixed	$\frac{1}{2}$	$\frac{\sigma}{\sigma-1}$ in the limit $s_j \to 0$	$1 - s_j$
Existence and uniqueness	unique where all products sell (best responses are contractions)	exists for $N \geq 2$ and $mc_j > 0$, unique for $N = 2$	exists and is unique for any ownership (Theorem 4.25)
Gain from variety	bounded: $CS \to \frac{(\bar{a}-p)^2}{2\bar{g}}$ as $N \to \infty$	real income rises by the factor $(1-s)^{-\frac{1}{\sigma-1}}$, unbounded in N	$\Delta CS = -\frac{M}{\alpha}\ln(1-s)$, growing like $\frac{M}{\alpha}\ln N$

Notes: s_j is the expenditure share (CES) or market share (logit) of product j. S_f is the combined share of firm f, and s is the share of an added product after entry. Linear entries for N firms use the symmetric J-product system of Proposition 4.43 with $J = N$. The logit markup for N symmetric firms assumes no outside good, and with an outside good it is $\frac{1}{\alpha(1-s)}$. Linear best responses have slopes summing to $\frac{(J-1)\bar{g}}{2[\bar{b}+(J-2)\bar{g}]} < \frac{1}{2}$. CES existence and uniqueness are due to Caplin and Nalebuff (1991). Sources: Propositions 4.7, 4.43, 4.44 and 4.46, (4.57), (4.61), (4.70) and Section 4.8.4.

4.8.1 Hotelling's line with linear transport costs

Assumption 4.51 (Hotelling duopoly)**.** (i) A mass M of consumers is uniformly distributed on $[0,1]$. A consumer at x buys one unit from the firm that minimizes her delivered price $p_j + T(|x - x_j|)$, where T is the transport cost function. (ii) Her reservation value $\bar{u}$ is high enough that every consumer buys, so the market is *covered*. (iii) Two firms located at $x_1 = a$ and $x_2 = 1 - b$, with $a + b < 1$, produce at constant marginal cost c and set prices simultaneously. (iv) Transport costs are linear, $T(d) = \tau d$, or quadratic, $T(d) = \tau d^2$.

The parameters a and b measure how far each firm sits from its own end of the line. In this section they denote locations and are unrelated to the demand parameters of Example 4.6. Unless stated otherwise we take $a, b \geq 0$. Write $\Delta x = x_2 - x_1 = 1 - a - b$ for the distance between the firms. Firm 1 has a *hinterland* $[0, a]$ of consumers to its left, and firm 2 has the hinterland $[1 - b, 1]$.

Demand with linear costs. A consumer between the firms, $x \in [a, 1 - b]$, prefers firm 1 when $p_1 + \tau(x - a) < p_2 + \tau(1 - b - x)$. The indifferent consumer solves this with equality:

$$2\tau x = p_2 - p_1 + \tau(1 + a - b) \quad \Longrightarrow \quad \tilde{x} = \frac{1 + a - b}{2} + \frac{p_2 - p_1}{2\tau}.$$

Consumers in a hinterland compare two delivered prices that rise at the same rate τ as they move away. A consumer at $x \geq 1 - b$ prefers firm 1 if and only if $p_1 + \tau(x - a) < p_2 + \tau(x - 1 + b)$, that is, if $p_1 < p_2 - \tau\Delta x$. The comparison does not depend on x, so the whole hinterland switches at once. Firm 1's demand is therefore

$$q_1(p_1, p_2) = \begin{cases} M & \text{if } p_1 < p_2 - \tau\Delta x, \\ M\left[\frac{1+a-b}{2} + \frac{p_2 - p_1}{2\tau}\right] & \text{if } |p_1 - p_2| \leq \tau\Delta x, \\ 0 & \text{if } p_1 > p_2 + \tau\Delta x. \end{cases} \tag{4.71}$$

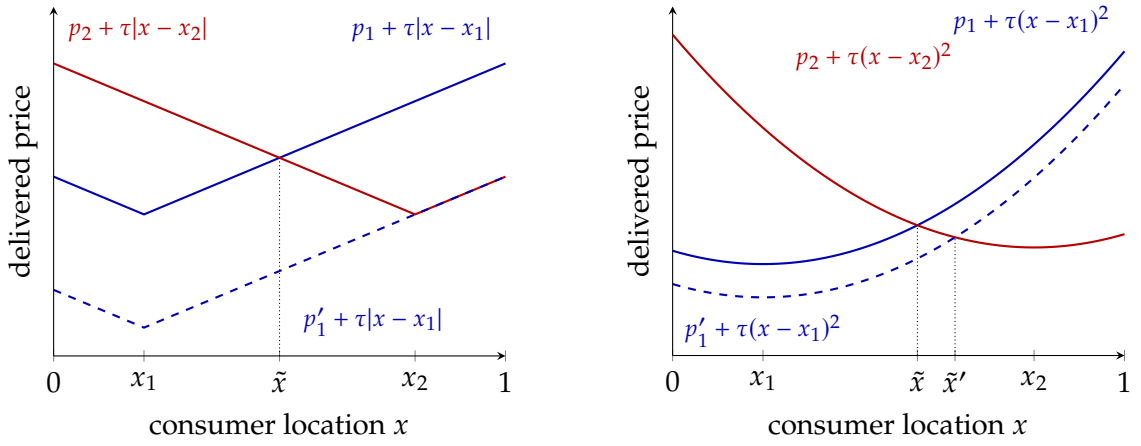
At $p_1 = p_2 - \tau\Delta x$ the middle expression equals $M(1 - b)$, so demand jumps by Mb, the mass of firm 2's hinterland. At $p_1 = p_2 + \tau\Delta x$ it equals Ma and demand jumps to zero. Demand is continuous only when both firms sit at the ends, $a = b = 0$. Panel (a) of Figure 4.8 shows the mechanism. When firm 1 cuts its price to $p_2 - \tau\Delta x$, its delivered-price schedule lies weakly below firm 2's everywhere, and the consumers beyond x_2 switch together.

Firms at the ends. With $a = b = 0$, the middle case of (4.71) holds whenever $|p_1 - p_2| \leq \tau$. Firm 1 maximizes $(p_1 - c)M[\frac{1}{2} + \frac{p_2 - p_1}{2\tau}]$, a concave quadratic. Its first-order condition is $\frac{1}{2} + \frac{p_2 - 2p_1 + c}{2\tau} = 0$, so the best response is $p_1 = \frac{c + \tau + p_2}{2}$. Symmetry gives $p_1 = p_2 = c + \tau$, with $\tilde{x} = \frac{1}{2}$ and profits $\frac{\tau M}{2}$. Undercutting to take the whole market requires $p_1 \leq p_2 - \tau = c$, which earns nothing. The markup equals the transport cost, so it vanishes as the products become perfect substitutes. This is the same outcome as with quadratic costs at the ends (Example 6.22).

Nonexistence when the firms are close. Hotelling (1929) argued that firms would cluster at the center of the market, the *principle of minimum differentiation*. D'Aspremont et al. (1979) showed that the argument breaks down at the pricing stage. With linear costs, firms that are close have no pure-strategy price equilibrium at all.

Proposition 4.52 (Existence with linear transport costs)**.** *Under Assumption 4.51 with linear costs and $a, b \geq 0$, a pure-strategy price equilibrium exists if and only if*

$$\left(1 + \frac{a - b}{3}\right)^2 \geq \frac{4}{3}(a + 2b) \qquad \text{and} \qquad \left(1 + \frac{b - a}{3}\right)^2 \geq \frac{4}{3}(b + 2a). \tag{4.72}$$



(a) Linear transport costs

(b) Quadratic transport costs

Figure 4.8: Delivered prices on Hotelling's line. Solid curves show each firm's price plus transport cost at the initial prices, and the indifferent consumer $\tilde{x}$ is where they cross. In panel (a), with linear costs, firm 1 cuts its price to $p_1' = p_2 - \tau(x_2 - x_1)$ (dashed). Its schedule then coincides with firm 2's beyond x_2, so firm 2's whole hinterland switches at once and demand jumps. In panel (b), with quadratic costs, a price cut (dashed) moves the indifferent consumer continuously from $\tilde{x}$ to $\tilde{x}'$. Both panels use $x_1 = 0.2$ and $x_2 = 0.8$. Panel (a) uses $\tau = 1$, $p_1 = p_2 = 1$ and $p_1' = 0.4$, and panel (b) uses $\tau = 2$, $p_1 = 1$, $p_2 = 1.1$ and $p_1' = 0.8$.

When it exists, it is $p_1 = c + \tau(1 + \frac{a-b}{3})$ *and* $p_2 = c + \tau(1 + \frac{b-a}{3})$. *With symmetric locations,* $a = b$, *an equilibrium exists if and only if* $a \le \frac{1}{4}$, *and then* $p_1 = p_2 = c + \tau$.

Proof. Step 1. Any equilibrium lies in the middle region of (4.71). Suppose firm 1 served the whole market, $p_1 < p_2 - \tau\Delta x$. Its profit is nonnegative only if $p_1 \ge c$. Firm 2 sells nothing, yet it could charge any price in $(c, p_1 + \tau\Delta x)$, win some consumers and earn a positive profit. That is a profitable deviation. The same argument rules out firm 2 serving everyone. At the boundary prices some consumers are indifferent. Whichever way they break ties, one firm can gain by a small price change, so boundary prices are not equilibria either.

Step 2. In the middle region firm 1's profit is $(p_1 - c)M[\frac{1+a-b}{2} + \frac{p_2 - p_1}{2\tau}]$, a concave quadratic in p_1. Its first-order condition, multiplied by 2τ, is $\tau(1 + a - b) + p_2 - 2p_1 + c = 0$. Firm 2's condition is symmetric:

$$2p_1 - p_2 = c + \tau(1 + a - b), \qquad 2p_2 - p_1 = c + \tau(1 + b - a).$$

Adding twice the first equation to the second gives $3p_1 = 3c + \tau(3 + a - b)$, so $p_1 = c + \tau(1 + \frac{a-b}{3})$, and by symmetry $p_2 = c + \tau(1 + \frac{b-a}{3})$. At these prices $\tilde{x} = \frac{1+a-b}{2} + \frac{b-a}{3} = \frac{3+a-b}{6}$, and firm 1 earns

$$\pi_1 = \tau\,\frac{3 + a - b}{3} \cdot M\,\frac{3 + a - b}{6} = \frac{M\tau}{2}\Big(1 + \frac{a - b}{3}\Big)^2.$$

The candidate lies in the middle region if $|p_1 - p_2| = \frac{2\tau|a-b|}{3} < \tau\Delta x$. Take $a \ge b$. The condition fails only if $5a + b \ge 3$, which with $b \le a$ requires $a \ge \frac{1}{2}$. Then the right side of the second inequality in (4.72) is at least $\frac{4}{3}$, while its left side is at most one. So whenever (4.72) holds, the candidate is interior.

Step 3. Within the middle region the candidate is firm 1's best price. Prices that give firm 1 no demand earn zero. The remaining deviation undercuts into the first region. There profit

is $M(p_1 - c)$, which rises with p_1, so the supremum is approached as p_1 rises to $p_2 - \tau\Delta x$. Its value is

$$M\big(p_2 - \tau\Delta x - c\big) = M\tau\Big[1 + \frac{b-a}{3} - (1-a-b)\Big] = \frac{2}{3}M\tau(a+2b).$$

The candidate is a best response for firm 1 if and only if $\frac{M\tau}{2}(1+\frac{a-b}{3})^2 \geq \frac{2}{3}M\tau(a+2b)$, which is the first inequality in (4.72). The second inequality is the same condition for firm 2. By Steps 1 and 2 no other price pair can be an equilibrium. With $a = b$ both inequalities read $1 \geq 4a$. □

The undercutting deviation drives the result. Firm 1's equilibrium profit falls as it moves toward the center, while the gain from stealing firm 2's hinterland rises with b. When the firms are close, each prefers to undercut the other and capture the whole line, and no pair of prices is stable. Mixed-strategy equilibria still exist, but they are of little use for comparative statics (Section 4.4.1). Hotelling's principle of minimum differentiation therefore fails as a result about the location-price game. Caplin and Nalebuff (1991) make the same point from the side of their existence theorem. Hotelling's distance utility is not linear in the consumer's location, and the resulting discontinuity of demand is inconsistent with their assumptions (Theorem 4.22).

4.8.2 Quadratic transport costs and the location-price game

D'Aspremont et al. (1979) restored existence by making transport costs quadratic. A consumer at x then pays $p_j + \tau(x - x_j)^2$. The cost difference between the two firms is linear in x, so the indifferent consumer moves continuously with prices, as panel (b) of Figure 4.8 shows. We now allow any real a and b with $a + b < 1$, so that firms may also locate outside the line.

Proposition 4.53 (Hotelling with quadratic costs)**.** *Let Assumption 4.51 hold with quadratic costs and suppose the indifferent consumer lies in* $[0,1]$.

(i) The unique price equilibrium is

$$p_1 = c + \tau(1-a-b)\Big(1 + \frac{a-b}{3}\Big), \qquad p_2 = c + \tau(1-a-b)\Big(1 + \frac{b-a}{3}\Big), \tag{4.73}$$

with $q_1 = M\frac{3+a-b}{6}$ *and* $\pi_1 = \frac{M\tau}{18}(1-a-b)(3+a-b)^2$.

(ii) In the first stage of a game in which firms choose locations and then prices,

$$\frac{\mathrm{d}\pi_1}{\mathrm{d}a} = -\frac{M\tau}{18}(3+a-b)(1+3a+b) < 0 \qquad \text{for all } a, b \geq 0. \tag{4.74}$$

If locations are restricted to $[0,1]$*, the unique location equilibrium is* $x_1 = 0$, $x_2 = 1$ *(maximal differentiation), with prices* $c + \tau$.

(iii) If locations are unrestricted, the location equilibrium is $x_1 = -\frac{1}{4}$ *and* $x_2 = \frac{5}{4}$.

Proof. (i) Let $\Delta x = 1 - a - b$. The indifferent consumer solves $p_1 + \tau(x-a)^2 = p_2 + \tau(x-1+b)^2$. The quadratic terms τx^2 cancel, leaving

$$2\tau x\,(1-b-a) = p_2 - p_1 + \tau\big[(1-b)^2 - a^2\big] = p_2 - p_1 + \tau(1-a-b)(1-b+a),$$

so that

$$\tilde{x} = \frac{1+a-b}{2} + \frac{p_2 - p_1}{2\tau\Delta x} = a + \frac{\Delta x}{2} + \frac{p_2 - p_1}{2\tau\Delta x}.$$

Consumers to the left of $\tilde{x}$ buy from firm 1, so $q_1 = M\tilde{x}$ when $\tilde{x} \in [0,1]$. Firm 1 maximizes $(p_1 - c)M\tilde{x}$. Its first-order condition, multiplied by $\frac{2\tau\Delta x}{M}$, is $\tau\Delta x(1 + a - b) + p_2 - 2p_1 + c = 0$. Firm 2 sells $M(1 - \tilde{x})$ and has the symmetric condition. The system is

$$2p_1 - p_2 = c + \tau\Delta x(1 + a - b), \qquad 2p_2 - p_1 = c + \tau\Delta x(1 + b - a).$$

Adding twice the first to the second gives $3p_1 = 3c + \tau\Delta x(3 + a - b)$, which is (4.73). Then $p_2 - p_1 = \frac{2}{3}\tau\Delta x(b - a)$, so $\tilde{x} = \frac{1+a-b}{2} + \frac{b-a}{3} = \frac{3+a-b}{6}$. Profit is $(p_1 - c)M\tilde{x} = \tau\Delta x\frac{3+a-b}{3} \cdot M\frac{3+a-b}{6}$. Demand is continuous, and where positive it is the minimum of M and a linear function, hence log-concave. By Lemma 4.14 profit is quasi-concave in own price, so the first-order conditions give best responses. Each best response has slope $\frac{1}{2}$, so the best-response map is a contraction and the equilibrium is unique.

(ii) By the envelope theorem, the effect of a on π_1 at the equilibrium of (i) has two parts. The direct effect holds both prices fixed: $(p_1 - c)M\frac{\partial\tilde{x}}{\partial a}$. The strategic effect works through the rival's price: $(p_1 - c)M\frac{\partial\tilde{x}}{\partial p_2}\frac{\mathrm{d}p_2}{\mathrm{d}a}$. Firm 1's own price response has no first-order effect. At the equilibrium, with $\frac{p_2-p_1}{2\tau\Delta x^2} = \frac{b-a}{3\Delta x}$,

$$\frac{\partial\tilde{x}}{\partial a} = \frac{1}{2} + \frac{p_2 - p_1}{2\tau\Delta x^2} = \frac{3 - 5a - b}{6\Delta x}, \qquad \frac{\partial\tilde{x}}{\partial p_2} = \frac{1}{2\tau\Delta x}, \qquad \frac{\mathrm{d}p_2}{\mathrm{d}a} = -\frac{\tau(4 - 2a)}{3}.$$

The last derivative follows from differentiating $p_2 = c + \frac{\tau}{3}(1 - a - b)(3 + b - a)$, which gives $\frac{\tau}{3}[-(3 + b - a) - (1 - a - b)] = -\frac{\tau}{3}(4 - 2a)$. Adding the two effects,

$$\frac{\mathrm{d}\pi_1}{\mathrm{d}a} = (p_1 - c)M\left[\frac{3 - 5a - b}{6\Delta x} - \frac{4 - 2a}{6\Delta x}\right] = -(p_1 - c)M\frac{1 + 3a + b}{6\Delta x}.$$

Substituting $p_1 - c = \frac{\tau\Delta x(3+a-b)}{3}$ gives (4.74), which is negative for $a, b \geq 0$. Each firm therefore wants to move away from the center for any location of its rival. On $[0,1]$ the unique equilibrium is $a = b = 0$, and (i) gives prices $c + \tau$.

(iii) Without restrictions, the location first-order conditions are $1 + 3a + b = 0$ for firm 1 and $1 + 3b + a = 0$ for firm 2. Their solution is $a = b = -\frac{1}{4}$, so $x_1 = -\frac{1}{4}$ and $x_2 = 1 + \frac{1}{4} = \frac{5}{4}$. Given $b = -\frac{1}{4}$, the derivative (4.74) is positive for $a < -\frac{1}{4}$ and negative above, so $a = -\frac{1}{4}$ is firm 1's best location. □

The two effects in the proof have a clear meaning. The direct effect is positive as long as $5a + b < 3$. Moving toward the center at given prices takes consumers from the rival. The strategic effect is negative, because moving closer makes the products better substitutes and lowers the rival's price. The strategic effect always wins. Shaked and Sutton (1982) call this *relaxing price competition through product differentiation*. Firms give up market share at given prices to soften the price war that would follow. The result is *maximal differentiation*, the opposite of Hotelling's conjecture.

Equilibrium differentiation is excessive from the social point of view. With a covered market and inelastic unit demand, prices are transfers, and welfare depends only on transport costs. A planner who places two products to minimize average transport cost chooses $\frac{1}{4}$ and $\frac{3}{4}$, with average cost $2\int_0^{\frac{1}{2}} \tau(x - \frac{1}{4})^2\mathrm{d}x = \frac{\tau}{48}$. Firms at the ends impose $2\int_0^{\frac{1}{2}} \tau x^2\mathrm{d}x = \frac{\tau}{12}$, four times as much. When firms may locate outside the line, they move even farther apart, to $-\frac{1}{4}$ and $\frac{5}{4}$. Tirole (1988, Section 7.1.1) gives a textbook treatment.

Minimal differentiation with fixed prices. Hotelling's principle does hold when prices cannot compete. Tirole (1988, Section 7.1.3) shows this with Hotelling's own location game at an exogenous price.

Proposition 4.54 (Location choice at a fixed price)**.** *Let consumers be uniform on* $[0,1]$ *with mass* M *and buy one unit each from the nearest firm. Two firms sell at a common exogenous price* $p > c$ *and choose locations* $x_1 = a$ *and* $x_2 = 1 - b$*, splitting demand equally if they locate at the same point. The unique equilibrium places both firms at* $\frac{1}{2}$*.*

Proof. Prices and margins are fixed, so each firm maximizes its demand. Suppose first that $a < 1 - b$. Firm 1 serves its hinterland and half of the consumers between the firms, so its demand is

$$q_1 = M\left[a + \frac{1 - b - a}{2}\right] = M\,\frac{1 + a - b}{2}.$$

It rises with a, so firm 1 gains by moving toward its rival, and the same holds for firm 2. Any equilibrium therefore has $a = 1 - b$. Suppose the common location is $x < \frac{1}{2}$. Each firm sells $\frac{M}{2}$. If firm 2 moves to $x + e$ with small $e > 0$, it serves every consumer to the right of $x + \frac{e}{2}$, which gives $M(1 - x - \frac{e}{2}) > \frac{M}{2}$. So $x < \frac{1}{2}$ is not an equilibrium, and the same argument rules out $x > \frac{1}{2}$. At $x = \frac{1}{2}$, a firm that moves to any $x' \neq \frac{1}{2}$ serves only the consumers on its side of the midpoint between x' and $\frac{1}{2}$. That is less than half of the market, so neither firm deviates. □

The products are socially too close. With linear costs, the average distance is $\frac{1}{4}$ when both firms sit at the center and $\frac{1}{8}$ at the efficient locations $\frac{1}{4}$ and $\frac{3}{4}$. The contrast with Proposition 4.53 isolates the role of prices. Firms differentiate to soften price competition, and without price competition they have no reason to. Tirole (1988, Section 7.1.3) groups the forces that work against maximal differentiation into three categories. The first is the location of demand. Firms want to be where consumers are, and when demand is concentrated around a few poles they cluster there. Tirole's examples are ice cream parlors and bookstores near universities. The second is positive externalities among firms. On the cost side these include shared installations and sources of raw materials. On the demand side, consumer search draws stores together, as with the furniture stores of a single Paris street. The third is the absence of price competition, as in the game above. Airline fares in the United States before deregulation and the prices of gasoline and books in France were once set outside the market. Resale price maintenance has the same effect. Tirole adds that fixed-price location models may explain why political platforms cluster at the center.

Two connections close this subsection. First, quadratic costs satisfy the linearity assumption of Theorem 4.22. Expanding the square gives $-\tau(x - x_j)^2 = -\tau x^2 + 2\tau x\, x_j - \tau x_j^2$. The first term is common to all products and drops out, and the second is linear in the consumer's type x. With uniform types, which have a log-concave density, an equilibrium exists for any locations (Caplin and Nalebuff, 1991). Second, heterogeneity in tastes can bring minimum differentiation back. De Palma et al. (1985) add a logit taste shock to Hotelling's linear transport costs. Demand becomes smooth, and with enough taste heterogeneity relative to τ, both firms locate at the center of the market. Their title states the result: the principle of minimum differentiation holds under sufficient heterogeneity.

4.8.3 Salop's circle, free entry and excess variety

Salop (1979) removed the ends of the line by placing consumers on a circle. Without ends there are no hinterlands, and symmetric configurations with any number of firms are natural. This makes the circle the standard model of entry with differentiated products.

Proposition 4.55 (Salop's circle)**.** *Let a mass M of consumers be uniform on a circle of circumference one, buy one unit each, and have a high enough reservation value that the market is covered. N firms are equally spaced, with marginal cost c, fixed cost ϕ and linear transport cost τ.*

(i) There is a symmetric price equilibrium with $p = c + \frac{\tau}{N}$, in which each firm earns $\frac{\tau M}{N^2} - \phi$.

(ii) Treating N as continuous, free entry yields $N^* = \sqrt{\frac{\tau M}{\phi}}$ firms.

(iii) The number of firms that minimizes fixed plus transport costs is $N^o = \frac{1}{2}\sqrt{\frac{\tau M}{\phi}}$. Hence $N^* = 2N^o$.

Proof. (i) Take a firm that charges p while its two neighbors, each at distance $\frac{1}{N}$, charge $\bar{p}$. A consumer at distance d from the firm, on the arc toward a neighbor, is indifferent when $p + \tau d = \bar{p} + \tau(\frac{1}{N} - d)$, that is, at $d = \frac{1}{2N} + \frac{\bar{p}-p}{2\tau}$. The firm serves the arcs on both sides, so its demand is

$$q = 2Md = M\left[\frac{1}{N} + \frac{\bar{p} - p}{\tau}\right] \qquad \text{for } |\bar{p} - p| \le \frac{\tau}{N}.$$

In this range profit $(p-c)q-\phi$ is a concave quadratic. Its first-order condition is $\frac{1}{N}+\frac{\bar{p}-p}{\tau}-\frac{p-c}{\tau} = 0$. At a symmetric point $p = \bar{p}$, it gives $p = c + \frac{\tau}{N}$. Each firm sells $\frac{M}{N}$ and earns $\frac{\tau}{N} \cdot \frac{M}{N} - \phi$. To take its neighbor's whole market, a firm would have to price at $\bar{p} - \frac{\tau}{N} = c$, which earns no variable profit. A price above $\bar{p} + \frac{\tau}{N}$ sells nothing. So no deviation outside the range is profitable.

(ii) Free entry drives profit to zero: $\frac{\tau M}{N^2} = \phi$, so $N^* = \sqrt{\frac{\tau M}{\phi}}$.

(iii) With N equally spaced firms, each consumer travels to the nearest firm. Distances are uniform on $[0, \frac{1}{2N}]$, so the average distance is $\frac{1}{4N}$ and total transport cost is $\frac{\tau M}{4N}$. Prices are transfers because the market is covered. The planner minimizes $N\phi + \frac{\tau M}{4N}$. The first-order condition $\phi - \frac{\tau M}{4N^2} = 0$ gives $N^o = \frac{1}{2}\sqrt{\frac{\tau M}{\phi}}$. □

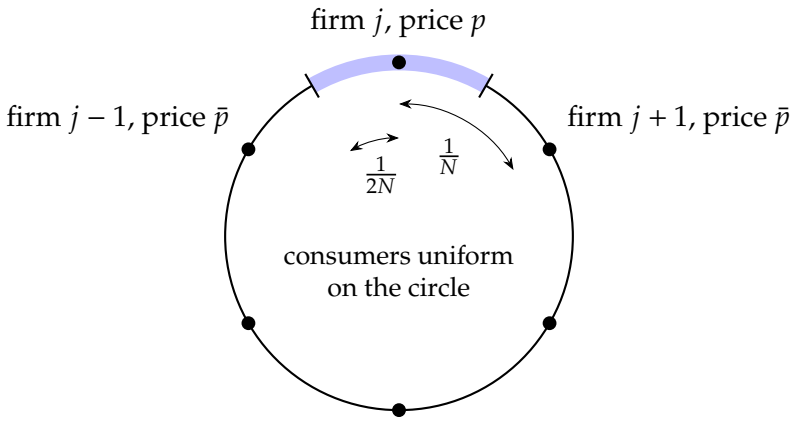


Figure 4.9: Salop's circle with $N = 6$ equally spaced firms. Firm j serves the shaded arc between the two indifferent consumers (tick marks). At symmetric prices each indifferent consumer is at distance $d = \frac{1}{2N}$ from firm j, so the firm's market has length $\frac{1}{N}$. A price cut by firm j moves both tick marks outward and takes customers from its two neighbors only.

Figure 4.9 shows the structure. Each firm competes only with its two neighbors, and its markup $\frac{\tau}{N}$ falls as the circle fills up. The market provides twice the efficient number of products. The reason is the balance of two externalities (Spence, 1976; Dixit and Stiglitz, 1977; Mankiw and Whinston, 1986). An entrant creates variety: consumers near its location travel less. It

does not capture this whole benefit in its profit, which pushes toward too little entry. An entrant also steals business from incumbents, which pushes toward too much entry. On the circle the market is covered, so every unit the entrant sells is taken from a rival. At N^* the entrant's private gain, its variable profit $\frac{\tau M}{N^2} = \phi$, is four times the social gain $\frac{\tau M}{4N^2} = \frac{\phi}{4}$ in saved transport costs. Business stealing dominates. Proposition 2.40 gives the corresponding result for homogeneous goods.

Remark 4.56 (Coverage and touching markets). Proposition 4.55 assumes that every consumer buys. Let $\bar{u}$ be the reservation value. The consumer farthest from a firm is at distance $\frac{1}{2N}$ and pays $c + \frac{\tau}{N} + \frac{\tau}{2N} = c + \frac{3\tau}{2N}$, so the equilibrium requires $\bar{u} \geq c + \frac{3\tau}{2N}$. At free entry $\frac{\tau}{N^*} = \sqrt{\frac{\tau\phi}{M}}$, and the condition becomes

$$\frac{3}{2}\sqrt{\frac{\tau\phi}{M}} \leq \bar{u} - c \quad \Longleftrightarrow \quad \phi \leq \bar{\phi} = \frac{4M(\bar{u}-c)^2}{9\tau}$$

(Tirole, 1988, Section 7.1.2). With larger fixed costs fewer firms enter, and the consumer halfway between two firms would not buy at the price of the proposition. Salop (1979) studies this case. Suppose the neighbors charge $\bar{p} = \bar{u} - \frac{\tau}{2N}$, so that the consumer halfway between two firms is just willing to buy. A firm that raises its price loses customers to the outside good. Its demand is then $\frac{2M(\bar{u}-p)}{\tau}$, with slope $-\frac{2M}{\tau}$. A firm that cuts its price takes customers from its neighbors, with the demand of the proof and slope $-\frac{M}{\tau}$. Demand therefore has a kink at $\bar{p}$. At sales of $\frac{M}{N}$, a price rise does not pay if $\frac{M}{N} \leq \frac{2M}{\tau}(\bar{p} - c)$, and a price cut does not pay if $\frac{M}{N} \geq \frac{M}{\tau}(\bar{p} - c)$. So $\bar{p}$ is an equilibrium price whenever

$$\frac{\tau}{N} \leq \bar{u} - c \leq \frac{3\tau}{2N}.$$

Free entry requires $G(N) \equiv (\bar{u} - c - \frac{\tau}{2N})\frac{M}{N} = \phi$. In this regime $G'(N) = \frac{M}{N^2}\left[\frac{\tau}{N} - (\bar{u} - c)\right] \leq 0$, and G also falls with τ. A higher fixed cost or a higher transport cost therefore lowers the number of firms, and the price $\bar{u} - \frac{\tau}{2N}$ falls with it. In the competitive regime of the proposition both changes raise the price. Tirole (1988, Section 7.1.2, Exercise 7.4) calls such results a priori counterintuitive. The explanation is that the price is pinned by the reservation value of the consumer halfway between two firms. When firms are farther apart, that consumer travels farther and can pay less.

The factor of two depends on linear costs. With quadratic costs τd^2 on the circle, the same steps give the markup $\frac{\tau}{N^2}$ and free-entry number $N^* = (\frac{\tau M}{\phi})^{\frac{1}{3}}$. Average transport cost is $\frac{\tau}{12N^2}$, so the optimum is $N^o = (\frac{\tau M}{6\phi})^{\frac{1}{3}}$ and $\frac{N^*}{N^o} = 6^{\frac{1}{3}} \approx 1.82$. Entry is still excessive. The dimension of the space matters more. Caplin and Nalebuff (1991) discuss Stiglitz (1986), who places firms on a grid in L dimensions with quadratic transport costs, so each firm has $2L$ neighbors. Demand becomes more elastic as L grows, profits fall, and fewer firms can cover the entry cost. Yet consumers have farther to travel in higher dimensions, so the efficient number of firms per unit area rises. Stiglitz concludes that low-dimensional markets have excess diversity and high-dimensional markets too little (Caplin and Nalebuff, 1991, Section 8.3 and n. 21). Caplin and Nalebuff show that, with quadratic costs, the symmetric solution of the first-order conditions in his model is indeed an equilibrium. Figure 4.7 shows the two-dimensional analogue of the circle's market areas.

The circle fixes locations by assumption. Tirole (1988, Section 7.1.2) discusses three extensions. First, equal spacing is a natural guess given maximal differentiation on the line. Economides (1989) justifies it with quadratic costs in a game where firms choose entry, then

locations, then prices, and a symmetric free-entry equilibrium exists. Tirole cites the 1984 working-paper version. Second, firms may enter in sequence, and then an early entrant's location shapes later choices. Prescott and Visscher (1977) studied sequential location on the line. Third, one firm may sell several brands and crowd the product space so that no entrant fits, especially when it can preempt. Anderson et al. (1995, p. 1283, n. 4) add that the known results for the circle all suggest substantial overentry at every level of fixed costs.

The welfare comparison has been taken to data. Berry and Waldfogel (1999) estimate how listening and advertising revenue vary with the number of radio stations in 135 US metropolitan markets and recover fixed costs from a free-entry condition. In the 1996 working-paper version on which we rely, the welfare loss from free entry relative to the social optimum is 40 percent of industry revenue. This calculation leaves out the value of programming to listeners. Advertisers pay 4.5 cents per hour for a marginal listener. The authors compute that free entry would be optimal if programming were worth more than three times that amount to the marginal listener.

4.8.4 Symmetric logit oligopoly and entry

The symmetric logit gives a useful contrast with the circle. Every product competes with every other, and each new product brings a new taste shock and hence new variety.

Proposition 4.57 (Symmetric logit oligopoly and entry)**.** *Let $N \geq 2$ single-product firms sell products with common quality $\tilde{\delta}$ and marginal cost c to a mass M of consumers with logit demand and no outside good. Each firm pays a fixed cost ϕ.*

(i) The symmetric price equilibrium has markup $p - c = \frac{N}{\alpha(N-1)}$, and each firm earns $\frac{M}{\alpha(N-1)} - \phi$. With an outside good, the markup is $\frac{1}{\alpha(1-s)}$, with s each firm's share.

(ii) Treating N as continuous, free entry yields $N^* = 1 + \frac{M}{\alpha\phi}$.

(iii) Total surplus is $TS(N) = \frac{M}{\alpha} \ln N + M\left(\frac{\tilde{\delta}}{\alpha} - c\right) - N\phi$, up to a constant. It is maximized at $N^o = \frac{M}{\alpha\phi}$, so $N^* = N^o + 1$.

Proof. (i) With no outside good, the shares are $\frac{e^{\delta_j}}{\sum_k e^{\delta_k}}$, and at symmetric prices $s = \frac{1}{N}$. The first-order condition of a single-product firm, $\alpha(p-c)(1-s) = 1$, is derived as in Proposition 4.7, which does not use the outside good. With $s = \frac{1}{N}$ it gives $p - c = \frac{1}{\alpha(1-\frac{1}{N})} = \frac{N}{\alpha(N-1)}$. Each firm sells $\frac{M}{N}$ and earns $\frac{N}{\alpha(N-1)} \cdot \frac{M}{N} - \phi$. With an outside good, Proposition 4.7 applies directly. (ii) Setting profit to zero gives $\alpha(N-1)\phi = M$. (iii) By Proposition 4.46, consumer surplus is $\frac{M}{\alpha} \ln \sum_{k=1}^{N} e^{\tilde{\delta} - \alpha p}$ up to a constant. At symmetric prices this equals $\frac{M}{\alpha} \ln N + \frac{M\tilde{\delta}}{\alpha} - Mp$. Total profit is $M(p-c) - N\phi$. In the sum the price cancels, because every consumer buys and payments are transfers. The derivative $TS'(N) = \frac{M}{\alpha N} - \phi$ vanishes at $N^o = \frac{M}{\alpha\phi}$, and TS is concave. Comparing with (ii) gives $N^* = N^o + 1$. □

The logit market also has too many products, but only one too many. The relative excess $\frac{N^* - N^o}{N^o} = \frac{\alpha\phi}{M}$ vanishes as the market grows, whereas on the circle it is always 100 percent. The reason lies in the social value of the marginal product. In the logit it is $\frac{M}{\alpha N}$, which falls slowly with N, because each product brings its own taste shock. On the circle it is $\frac{\tau M}{4N^2}$, which falls fast, because a new product only shortens the trips of nearby consumers. The entrant's private gain, $\frac{M}{\alpha(N-1)}$, exceeds the social gain by only $\frac{M}{\alpha N(N-1)}$. Business stealing is weak because the

logit treats variety itself as valuable. Mankiw and Whinston (1986, p. 49) isolate the two forces at work. Business stealing pushes toward excessive entry, as in homogeneous-good markets. Product diversity pushes the other way, because the entrant creates surplus through variety that it does not capture as profit. With the CES form and equilibrium notion of Spence (1976), the diversity effect always dominates and entry is insufficient. They also give examples in which business stealing always dominates. The symmetric logit of Proposition 4.57 is another such case, with an excess of one firm. For the CES, Dixit and Stiglitz (1977) show that the market can provide too few or too many products, depending on preferences (Section 4.7.6).

General i.i.d. tastes. Anderson et al. (1995) ask how far the logit's verdict extends. They keep the symmetric discrete choice structure, with the demand side of Perloff and Salop (1985), but let the taste shocks have any log-concave density. The following proposition collects the pieces we need, in our notation.

Proposition 4.58 (Symmetric oligopoly with i.i.d. tastes)**.** *A mass M of consumers each buy one unit of the product that maximizes $u_{ij} = y - p_j + \epsilon_{ij}$. The shocks ϵ_{ij} are i.i.d. across consumers and products, with density f_ϵ and distribution function F_ϵ on $(\underline{e}, \bar{e})$ and a finite mean. There are $N \geq 2$ single-product firms with marginal cost c and fixed cost ϕ.*

(i) Demand for product i is

$$q_i = M \int f_\epsilon(x) \prod_{j \neq i} F_\epsilon(p_j - p_i + x)\, \mathrm{d}x. \tag{4.75}$$

(ii) The unique candidate for a symmetric equilibrium has the markup

$$p - c = \frac{1}{\Theta(N)}, \qquad \Theta(N) = N(N-1) \int f_\epsilon(x)^2 F_\epsilon(x)^{N-2}\, \mathrm{d}x. \tag{4.76}$$

(iii) At equal prices, an $(N+1)$th product raises total surplus by $M \int F_\epsilon(x)^N [1 - F_\epsilon(x)]\, \mathrm{d}x - \phi$. Its profit in the symmetric equilibrium with $N+1$ firms is $\frac{M}{(N+1)\Theta(N+1)} - \phi$.

(iv) If ϵ_{ij} is type-I extreme value with scale $\frac{1}{\alpha}$, then $\Theta(N) = \frac{\alpha(N-1)}{N}$, the markup is $\frac{N}{\alpha(N-1)}$, and the surplus gain in (iii) is $\frac{M}{\alpha} \ln \frac{N+1}{N} - \phi$.

(v) If $F_\epsilon(x) = 1 - e^{-\lambda_\epsilon (x - \underline{e})}$ on $[\underline{e}, \infty)$ with $\lambda_\epsilon > 0$, then $\Theta(N) = \lambda_\epsilon$ for every N. The surplus gain and the profit in (iii) are both $\frac{M}{\lambda_\epsilon (N+1)} - \phi$.

Proof. (i) Fix a consumer and write ϵ_k for her shock on product k. She buys i when $y - p_i + \epsilon_i > y - p_j + \epsilon_j$ for every $j \neq i$. Given $\epsilon_i = x$, this requires $\epsilon_j < p_j - p_i + x$ for every $j \neq i$. By independence the conditional probability is $\prod_{j \neq i} F_\epsilon(p_j - p_i + x)$. Integrating over the density of x gives (4.75). Ties have probability zero.

(ii) Differentiate (4.75) with respect to p_i and set all prices equal. Each of the $N-1$ factors contributes $-f_\epsilon(x) F_\epsilon(x)^{N-2}$, so

$$\frac{\partial q_i}{\partial p_i} = -M(N-1) \int f_\epsilon(x)^2 F_\epsilon(x)^{N-2}\, \mathrm{d}x = -\frac{M\,\Theta(N)}{N}.$$

At equal prices $q_i = \frac{M}{N}$. The first-order condition $q_i + (p_i - c)\frac{\partial q_i}{\partial p_i} = 0$ becomes $\frac{M}{N} = (p - c)\frac{M\,\Theta(N)}{N}$, which has the single solution (4.76).

(iii) Every consumer buys and prices are transfers, so at equal prices total surplus is $M(y-c)$ plus $M\mathbb{E}[\max_j \epsilon_{ij}]$ minus total fixed costs. The maximum of N shocks has distribution function F_ϵ^N. Integrating by parts, with boundary terms that vanish because the mean is finite,

$$\mathbb{E}\Big[\max_{j\le N+1}\epsilon_{ij}\Big]-\mathbb{E}\Big[\max_{j\le N}\epsilon_{ij}\Big]=\int x\,\mathrm{d}\big(F_\epsilon^{N+1}-F_\epsilon^N\big)(x)=\int F_\epsilon(x)^N\big[1-F_\epsilon(x)\big]\,\mathrm{d}x.$$

With $N+1$ firms, each sells $\frac{M}{N+1}$ at the markup $\frac{1}{\Theta(N+1)}$, which gives the profit.

(iv) Here $F_\epsilon(x)=\exp(-e^{-\alpha x})$ and $f_\epsilon(x)=\alpha e^{-\alpha x}F_\epsilon(x)$, so $f_\epsilon^2F_\epsilon^{N-2}=\alpha^2e^{-2\alpha x}\exp(-Ne^{-\alpha x})$. Substitute $u=e^{-\alpha x}$, with $\mathrm{d}x=-\frac{\mathrm{d}u}{\alpha u}$:

$$\int f_\epsilon(x)^2F_\epsilon(x)^{N-2}\,\mathrm{d}x=\alpha\int_0^\infty ue^{-Nu}\,\mathrm{d}u=\frac{\alpha}{N^2},\qquad\text{so}\qquad\Theta(N)=\frac{\alpha(N-1)}{N}.$$

For the surplus, $F_\epsilon(x)^N=\exp\big(-e^{-\alpha(x-\frac{\ln N}{\alpha})}\big)$. The maximum of N shocks is therefore extreme value with location $\frac{\ln N}{\alpha}$, and its mean rises by $\frac{1}{\alpha}\ln\frac{N+1}{N}$ when N rises by one.

(v) Let $v=F_\epsilon(x)$, so that $f_\epsilon(x)=\lambda_\epsilon(1-v)$ and $\mathrm{d}v=\lambda_\epsilon(1-v)\,\mathrm{d}x$. Then

$$\int f_\epsilon^2F_\epsilon^{N-2}\,\mathrm{d}x=\lambda_\epsilon\int_0^1(1-v)v^{N-2}\,\mathrm{d}v=\lambda_\epsilon\Big[\frac{1}{N-1}-\frac{1}{N}\Big]=\frac{\lambda_\epsilon}{N(N-1)},$$

so $\Theta(N)=\lambda_\epsilon$. Likewise $\int F_\epsilon^N(1-F_\epsilon)\,\mathrm{d}x=\frac{1}{\lambda_\epsilon}\int_0^1 v^N\,\mathrm{d}v=\frac{1}{\lambda_\epsilon(N+1)}$, and the profit is $\frac{M}{(N+1)\lambda_\epsilon}-\phi$. □

Part (iv) is the integer version of Proposition 4.57. The $(N+1)$th product adds $\frac{M}{\alpha}\ln(1+\frac{1}{N})$ to surplus and earns $\frac{M}{\alpha N}$, and $\ln(1+\frac{1}{N})<\frac{1}{N}$. The general results of Anderson et al. (1995) rest on log-concavity. Utility is linear in the vector of shocks, whose joint density $\prod_j f_\epsilon(\epsilon_{ij})$ is log-concave when f_ϵ is. The theorem of Caplin and Nalebuff (1991) then makes profit quasi-concave, so the candidate in (ii) is an equilibrium (p. 1285, Theorem 4.22). Their Proposition 1 (p. 1285) shows that log-concavity also makes $\Theta(N)$ nondecreasing, so markups do not rise with entry. Revenue per firm then falls with N, and the free-entry number of firms is unique. Their Theorem 1 (p. 1287) is the main result. With log-concave tastes and unit demands, the profit of an extra firm is never below its social value, so the market never provides too little variety. Corollary 1 (p. 1289) shows that equilibrium and optimum coincide for every fixed cost only for the exponential-tail distributions of part (v) and their mirror images. For the densities of their example held fixed, the equilibrium number of firms is about the optimum plus one as fixed costs vanish (p. 1290), as in the logit. For a general fixed density only the ratio of the two numbers tends to one, a result Anderson et al. (1995, p. 1283) credit to Deneckere and Rothschild (1992). Overentry can still be large. For each optimal number of firms they choose a log-concave density, and as fixed costs vanish the ratio of the equilibrium to the optimal number tends to $r^*>1.097$ (p. 1290). That is almost 10 percent excess entry even with very many firms. When individual demand responds to price, entry can fall short of the optimum subject to zero profits, but by at most one firm (their Theorem 2, p. 1294).

The logit's verdict depends on taking the taste shocks literally. If they are a statistical device, the term $\frac{M}{\alpha}\ln N$ overstates the value of variety, and the true optimum may be far below N^o. This is the "too many characteristics" problem of Section 4.6.3 in its welfare form. It is also why models of entry and variety that use logit demand need care before their welfare conclusions are trusted.

4.8.5 Vertical differentiation and quality choice

In the models so far consumers disagree about which product is best at equal prices. In a *vertical* model they agree: at equal prices every consumer ranks products the same way. Consumers differ only in how much they value quality relative to money. Consumer i has utility $v_i x_j - p_j$ from product j with quality x_j. The taste for quality v_i is uniform on $[\underline{v}, \bar{v}]$ with mass M. Dividing utility by v_i gives $x_j - \frac{1}{v_i} p_j$, the vertical model $u_{ij} = \delta_j - \nu_i p_j$ of Chapter 6 with $\delta_j = x_j$ and price sensitivity $\nu_i = \frac{1}{v_i}$.

Proposition 4.59 (Price and quality competition with vertical differentiation)**.** *Two firms with a common marginal cost $c \geq 0$ sell qualities $x_1 < x_2$. Assume $\bar{v} > 2\underline{v}$ and the coverage condition $c + \frac{1}{3}(\bar{v} - 2\underline{v})(\bar{x} - \underline{x}) \leq \underline{v}\,\underline{x}$, where qualities lie in $[\underline{x}, \bar{x}]$.*

(i) The price equilibrium is

$$p_1 = c + \frac{(\bar{v} - 2\underline{v})(x_2 - x_1)}{3}, \qquad p_2 = c + \frac{(2\bar{v} - \underline{v})(x_2 - x_1)}{3}, \tag{4.77}$$

with cutoff type $\hat{v} = \frac{\bar{v}+\underline{v}}{3}$ and profits $\pi_1 = \frac{M(\bar{v}-2\underline{v})^2(x_2-x_1)}{9(\bar{v}-\underline{v})}$ and $\pi_2 = \frac{M(2\bar{v}-\underline{v})^2(x_2-x_1)}{9(\bar{v}-\underline{v})}$.

(ii) If firms first choose qualities in $[\underline{x}, \bar{x}]$ at no cost and then set prices, the equilibrium qualities are $\underline{x}$ and $\bar{x}$.

Proof. (i) Let $\Delta x = x_2 - x_1$. Type v prefers quality 2 when $v x_2 - p_2 > v x_1 - p_1$, that is, when $v > \hat{v} = \frac{p_2 - p_1}{\Delta x}$. Under coverage every type buys, so with density $\frac{M}{\bar{v}-\underline{v}}$,

$$q_1 = M \frac{\hat{v} - \underline{v}}{\bar{v} - \underline{v}}, \qquad q_2 = M \frac{\bar{v} - \hat{v}}{\bar{v} - \underline{v}}.$$

Firm 1 maximizes $(p_1 - c)q_1$. Since $\frac{\partial \hat{v}}{\partial p_1} = -\frac{1}{\Delta x}$, its first-order condition is $\hat{v} - \underline{v} - \frac{p_1 - c}{\Delta x} = 0$, or $p_2 - 2p_1 = \underline{v}\Delta x - c$. Firm 2's condition is $\bar{v} - \hat{v} - \frac{p_2 - c}{\Delta x} = 0$, or $2p_2 - p_1 = \bar{v}\Delta x + c$. The first gives $p_2 = 2p_1 + \underline{v}\Delta x - c$. Substituting into the second gives $3p_1 = 3c + (\bar{v} - 2\underline{v})\Delta x$, and then $p_2 = c + \frac{(2\bar{v} - \underline{v})\Delta x}{3}$. The cutoff is $\hat{v} = \frac{p_2 - p_1}{\Delta x} = \frac{\bar{v}+\underline{v}}{3}$, which lies strictly inside $(\underline{v}, \bar{v})$ because $\bar{v} > 2\underline{v}$. Profits follow from the margins $p_j - c$ and from $\hat{v} - \underline{v} = \frac{\bar{v} - 2\underline{v}}{3}$ and $\bar{v} - \hat{v} = \frac{2\bar{v} - \underline{v}}{3}$. Coverage requires that the lowest type buy, $\underline{v} x_1 \geq p_1$. The left side is smallest and the right side largest at $x_1 = \underline{x}$ and $x_2 = \bar{x}$, where the assumed condition makes it hold. A firm that raised its price enough to lose low types would face demand no larger than the covered formula, so the candidate remains optimal.

(ii) Both profits are proportional to Δx. Given $x_2 = \bar{x}$, the low-quality firm's profit $\propto \bar{x} - x_1$ is largest at $x_1 = \underline{x}$. Choosing $x_1 = \bar{x}$ would make the products identical and drive both prices to marginal cost, and leapfrogging is impossible. Given $x_1 = \underline{x}$, the high-quality firm's profit $\propto x_2 - \underline{x}$ is largest at $\bar{x}$. So $(\underline{x}, \bar{x})$ is an equilibrium. In any configuration with $\underline{x} < x_1$ or $x_2 < \bar{x}$, one firm can raise Δx and its profit, and equal qualities yield zero profits. So the only equilibria assign $\underline{x}$ to one firm and $\bar{x}$ to the other. □

Figure 4.10 shows the segments. The force behind part (ii) is the one we saw on Hotelling's line. Closer qualities mean fiercer price competition, so firms differentiate as much as they can (Gabszewicz and Thisse, 1979; Shaked and Sutton, 1982). The high-quality firm charges more, sells more and earns more. Both markups and profits scale with the quality gap $x_2 - x_1$, and they vanish when the products are identical.

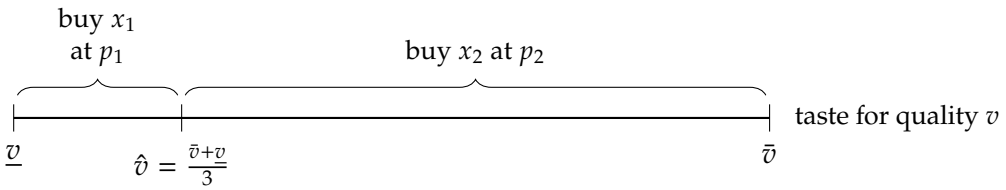

Figure 4.10: Market segments in the vertical duopoly of Proposition 4.59, drawn for $\underline{v} = 1$ and $\bar{v} = 4$. Consumers with a high taste for quality buy the high-quality product. The cutoff $\hat{v} = \frac{\bar{v}+\underline{v}}{3}$ does not depend on the two qualities.

Tirole (1988, Section 7.5.1) draws out two further points. First, part (ii) has two equilibria, which differ only in which firm takes the top quality. If one firm chooses its quality first, it takes $\bar{x}$ and leaves $\underline{x}$ to its rival, so the equilibrium is unique. Since $\pi_2 > \pi_1$, each firm would like to move first. With a cost of introducing a quality and growing demand, this becomes a preemption race, in which firms trade the gain from leadership against the cost of entering too early. Second, maximal differentiation is not robust. If the lowest feasible quality is so low that the coverage condition fails, the low-quality firm loses the bottom of the market and no longer wants the lowest quality. The effect is stronger when marginal costs differ across qualities, which already softens price competition. The principle of differentiation itself survives.

Remark 4.60 (Natural oligopoly). The condition $\bar{v} > 2\underline{v}$ requires enough dispersion in tastes. If $\bar{v} \le 2\underline{v}$, formula (4.77) would give $p_1 \le c$. The equilibrium then has $p_1 = c$ and the high-quality firm serving every consumer at the limit price $p_2 = c + \underline{v}(x_2 - x_1)$, the highest price at which the lowest type still prefers quality 2. To see this, write $m_2 = p_2 - c$. At $p_1 = c$, firm 2's profit for $m_2 > \underline{v}\Delta x$ is $m_2 M \frac{\bar{v}\Delta x - m_2}{(\bar{v}-\underline{v})\Delta x}$. Its slope at $m_2 = \underline{v}\Delta x$ is $M\frac{\bar{v}-2\underline{v}}{\bar{v}-\underline{v}} \le 0$, and it is concave, so firm 2 does not raise its price further. With any positive fixed cost, only one firm enters, however large M is. This is the simplest instance of the finiteness property of Shaked and Sutton (1983), which Tirole (1988, Section 7.5.1) states as follows. Let quality x cost $c(x)$ per unit. Suppose that, if every quality were sold at its unit cost, all consumers would buy the highest quality. Then at most a finite number of firms can have positive market shares, whatever the relative sizes of demand and entry costs. Price competition among the high-quality firms leaves no room for low qualities. The condition requires unit cost to rise slowly with quality. Shaked and Sutton therefore expect finiteness when the burden of quality improvement falls mainly on research and development or other fixed costs, rather than on labor and materials. On the circle, by contrast, the number of firms grows without bound as fixed costs vanish. Chapter 6 estimates the vertical demand model, and Bresnahan (1987) applies it to the 1955 automobile price war.

4.8.6 From address models to discrete choice

Location models are characteristics-space models with one or two characteristics and no idiosyncratic taste shock. Substitution is local. On the line and the circle a product competes only with its neighbors, and in the vertical model only with the products just above and below it in quality. Adding a product close to an existing one adds little value, since the gain on the circle is the saved transport cost of nearby consumers. Logit-type models sit at the opposite extreme. Every product competes with every other, IIA holds, and each new product adds value through its own taste shock (Section 4.6.3). The two classes share a formal structure. Expanding the square in a quadratic ideal-point model turns it into a random coefficients model, as shown in Proposition 6.23. The pure characteristics model of Berry and Pakes

(2007) keeps the local substitution of address models while allowing many characteristics and estimation from market data (Chapter 6). Random coefficient logit models (Chapter 8) sit between the extremes. They generate local substitution through correlated tastes while keeping the logit shock.

Location models also frame empirical work on product choice. In the location and quality games above, firms choose positions in anticipation of price competition. Mergers change these incentives. Sweeting (2010) studies how radio stations reposition their formats after mergers (Chapter 11). The estimation of such product choice models builds on the equilibrium theory of this section.

4.9 Bibliographic notes

Tirole (1988, ch. 7) and Vives (1999) give textbook treatments of price competition with differentiated products, and Anderson et al. (1992) build the theory on discrete choice. Tirole treats the linear city in Section 7.1.1, the circular city in Section 7.1.2 and the forces for and against differentiation in Section 7.1.3. Vertical differentiation is in Section 7.5.1, and monopolistic competition is in Sections 7.2 and 7.5.2. The location tradition starts with Hotelling (1929). d'Aspremont et al. (1979) overturned its conclusion about minimum differentiation, and Salop (1979) moved the model to the circle. Economides (1989) studies location choice on the circle, and Prescott and Visscher (1977) study sequential location on the line. Gabszewicz and Thisse (1979) and Shaked and Sutton (1982, 1983) developed vertical differentiation and the theory of natural oligopoly.

Chamberlin (1933) introduced monopolistic competition. The representative-consumer CES model of Spence (1976) and Dixit and Stiglitz (1977) remains its workhorse and that of trade theory (Krugman, 1980; Melitz, 2003). Mankiw and Whinston (1986) isolate the business-stealing and product-diversity externalities behind excess or insufficient entry, and Berry and Waldfogel (1999) measure them in radio broadcasting. Perloff and Salop (1985) replaced the representative consumer by a population with i.i.d. tastes for the brands. Anderson et al. (1995) use that model to show that log-concave tastes rule out insufficient variety when each consumer buys one unit. With price-sensitive individual demand, the shortfall relative to the zero-profit constrained optimum is at most one product.

Caplin and Nalebuff (1991) remains the reference on existence of price equilibrium with single-product firms, and Dierker (1989) reached related conditions independently. The theory of supermodular games (Milgrom and Roberts, 1990; Vives, 1990) explains why log-supermodular price games are well behaved. Classical sufficient conditions for uniqueness go back to Friedman (1977) and Gale and Nikaidô (1965). Konovalov and Sándor (2010, Theorems 7 and 13) prove existence and uniqueness of price equilibrium with multi-product firms for the simple logit and for CES demand. Nocke and Schutz (2018) develop an aggregative-games approach to multi-product price competition with logit and CES demands. Each firm's profit depends on its rivals' prices only through a one-dimensional aggregator, and firms may differ in their numbers of products (Asker and Nocke, 2021, p. 229, n. 127, and p. 232, n. 140).

The multi-product pricing equation became a standard part of empirical work with Berry (1994) and Berry et al. (1995), who used it to recover costs and to sharpen demand estimates. Bresnahan (1987) and Nevo (2001) used it to compare models of conduct. Berry and Haile (2014) formalize the identification of conduct with differentiated products, and Backus et al. (2021a) and Duarte et al. (2024) develop tests among conduct models. Profit weights from partial ownership go back to O'Brien and Salop (2000), and Miller and Weinberg (2017) estimate

a weight for a joint venture. Farrell and Shapiro (2010) put diversion ratios at the center of merger screening, and Conlon and Mortimer (2021) study how to measure them. Morrow and Skerlos (2011) provide a fixed-point algorithm that computes equilibria reliably with mixed logit demand, and Werden (1996) derives the cost reductions that leave prices unchanged after a merger.

The characteristics approach goes back to Lancaster (1966) and Gorman (1980), and McFadden (1974) gave it its econometric form. McFadden (1984) surveys the qualitative response models that implement it, and Berry and Pakes (2007) analyze the pure characteristics model, which drops the product-specific taste shock. Deaton and Muellbauer (1980a) is the standard reference for demand systems in product space (Chapter 5). Hausman (1997) argues that symmetric systems such as the logit and the CES overstate the value of new goods, a theme that Chapter 10 takes up.

4.10 Exercises

1. *Asymmetric costs, upward pricing pressure and cost-reducing investment.* Let demands be $q_1 = a - bp_1 + dp_2$ and $q_2 = a - bp_2 + dp_1$ with $b > d \geq 0$, as in Example 4.6, but let marginal costs differ, $c_1 \neq c_2$.

   (a) Solve for the Bertrand-Nash prices with separate owners. Show that $p_1 - p_2 = \frac{b(c_1 - c_2)}{2b + d}$.

   (b) Solve for the prices of a joint owner. Show that $p_j = \frac{a}{2(b-d)} + \frac{c_j}{2}$, so the joint owner passes half of each product's cost through to that product's price and none to the other price. Write each merged markup in terms of $\frac{a}{b}$, c_j and $D = \frac{d}{b}$.

   (c) Take $a = 10$, $b = 2$, $d = 1$, $c_1 = 1$ and $c_2 = 2$. Compute UPP_1 and UPP_2 from (4.18) with no efficiencies, at the pre-merger prices. Compare each with the actual price change.

   (d) Which price rises more? Explain the answer with the margins that enter upward pricing pressure, and relate the gap between UPP and the price change to Example 4.13.

   (e) Now let the two firms sit at the ends of Hotelling's line with linear transport cost τ and mass M of consumers (Section 4.8.1). Let c_1 and c_2 be close enough that both firms sell. Show that their demands are the limiting case $a = \frac{M}{2}$ and $b = d = \frac{M}{2\tau}$ of the system above. Derive the reaction functions $p_i = R_i(p_j)$, the equilibrium prices $p_i(c_i, c_j)$ and the reduced-form profits $\Pi_i(c_i, c_j)$. Check that the price gap agrees with part (a).

   (f) Show that $\frac{\partial^2 \Pi_i}{\partial c_i \partial c_j} < 0$, and interpret the sign.

   (g) Before prices are set, each firm chooses its marginal cost c_i at an investment cost $\Gamma(c_i)$ with $\Gamma' < 0$ and $\Gamma'' > 0$. Use the envelope theorem to split the marginal return to a lower c_i into two parts. The direct effect works on the firm's own sales, and the strategic effect works through the rival's price. Find the sign of each, and compare the decomposition with the location game of Proposition 4.53. Tirole (1988, Section 7.1.1, Exercise 7.2) poses this problem.

2. *Best responses of a multi-product logit firm.* Use the notation of Section 4.2.6.

   (a) Starting from $S_f = \frac{E_f e^{-\alpha m_f}}{\Phi_{-f} + E_f e^{-\alpha m_f}}$ and the condition $\alpha m_f (1 - S_f) = 1$, derive (4.10) line by line.

(b) Use $W'(z) = \frac{W(z)}{z(1+W(z))}$ to show that $\frac{\partial BR_k}{\partial p_l} = \frac{S_f s_l}{1-S_f}$ for $k \in \mathcal{J}_f$ and $l \notin \mathcal{J}_f$, with shares evaluated at the best response.

(c) Show that each row of the matrix of best-response slopes sums to less than S_f. Explain why this delivers convergence of best-response iteration from any starting point.

(d) A firm owns two products with $v_1 = v_2 = 1$. The price coefficient is $\alpha = 2$ and the rivals' aggregate is $\Phi_{-f} = 4$. Compute the firm's best-response markup and combined share, and verify Proposition 4.7. How do they change if the firm sells only product 1?

3. *Diversion and merger screening with nests.* Use the four-product market of Figure 4.3.

(a) Nested logit shares are $s_j = s_{j|g} s_g$, with $s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma^{\mathrm{NL}}}}}{\mathcal{S}_g}$, $\mathcal{S}_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma^{\mathrm{NL}}}}$ and $s_g = \frac{\mathcal{S}_g^{1-\sigma^{\mathrm{NL}}}}{1+\sum_h \mathcal{S}_h^{1-\sigma^{\mathrm{NL}}}}$. Derive the share derivatives stated in Section 4.3.4 and then (4.22).

(b) Verify the diversion ratios reported for $\sigma^{\mathrm{NL}} = 0.5$ and check that they sum to one.

(c) All prices are equal and every product earns a margin of 40 percent. Compute the GUPPI of product 1 for a merger of products 1 and 2 and for a merger of products 1 and 3. Do so under the logit and under the nested logit with $\sigma^{\mathrm{NL}} = 0.5$. Which mergers would a screen that flags a GUPPI above 5 percent select?

(d) Both models fit the same market shares exactly. Explain what data could tell them apart, using (4.14) and (4.15).

4. *Pass-through and markups with CES demand.* A single-product firm faces the CES demand of Proposition 4.44 and has constant marginal cost. Rivals' prices are fixed.

(a) Differentiate the Lerner condition (4.60) to show that the pass-through of the firm's own cost is $\rho_j = \frac{[\sigma-(\sigma-1)s_j]^2}{\sigma(\sigma-1)(1-s_j)}$.

(b) Show that $\rho_j \to \frac{\sigma}{\sigma-1}$ as $s_j \to 0$, as in Table 4.6. Evaluate ρ_j for $\sigma = 3$ and $s_j \in \{0, 0.1, 0.5\}$.

(c) Show that residual CES demand is log-convex in own price when s_j is small. Relate pass-through above one to the curvature results of Chapter 2, and contrast it with the logit value $1 - s_j$.

(d) With N symmetric firms, compute the Lerner index (4.61) for $\sigma = 3$ and $N \in \{2, 5, 10\}$, and compare it with the large-group value $\frac{1}{\sigma}$. Explain in one paragraph why no equilibrium exists with $N = 1$.

5. *Concavity of demand and the Caplin-Nalebuff bounds.*

(a) Let $q(p) = (1 - p)^k$ on $[0, 1]$ with $k > 0$. Show that q is $\frac{1}{k}$-concave and not ϱ-concave for any $\varrho > \frac{1}{k}$. Use Lemma 4.15 to show that $(p - c)q(p)$ is quasi-concave for every $c \in [0, 1)$.

(b) Let $L = 1$, reservation prices $R(v) = 1 - v$ and the type density $\psi(v) = 3v^2$ on $[0, 1]$. Compute demand. Find the largest ϱ for which ψ is ϱ-concave, and check that the bound of Theorem 4.19 is attained.

(c) Now let a fraction 0.2 of consumers have reservation prices uniform on $[0.8, 1]$ and a fraction 0.8 have reservation prices uniform on $[0, 0.2]$. With zero cost, compute

demand and profit as functions of price. Show that profit has two local maxima, and find the global one.

(d) Which part of Assumption A2 does the distribution in (c) violate? Relate the two local maxima to the equilibria of Example 4.27.

6. *Salop's circle with quadratic transport costs.* Consumers of mass M are uniform on a circle of circumference one, and a consumer at distance d from a firm pays the transport cost τd^2. There are N equally spaced firms with marginal cost c and fixed cost ϕ.

(a) Show that a firm charging p against neighbors charging $\bar{p}$ sells $M\left[\frac{1}{N} + \frac{N(\bar{p}-p)}{\tau}\right]$.

(b) Derive the symmetric equilibrium price $c + \frac{\tau}{N^2}$ and the free-entry number of firms $N^* = \left(\frac{\tau M}{\phi}\right)^{\frac{1}{3}}$.

(c) Show that average transport cost is $\frac{\tau}{12N^2}$ and that the efficient number of firms is $N^o = \left(\frac{\tau M}{6\phi}\right)^{\frac{1}{3}}$, so $\frac{N^*}{N^o} = 6^{\frac{1}{3}}$.

(d) Compare with Propositions 4.55 and 4.57. In each of the three models, compare the entrant's private gain with the social gain from its product, and explain which externality dominates.

7. *Profit weights and the identification of conduct.* In the linear duopoly of Example 4.6, each firm maximizes its own profit plus κ times its rival's profit, with $\kappa \in [0, 1]$ as in Definition 4.31.

(a) Show that the symmetric equilibrium markup is $m(\kappa) = \frac{a-(b-d)c}{2b-(1+\kappa)d}$, and that it equals m^N at $\kappa = 0$ and m^J at $\kappa = 1$.

(b) Rewrite the first-order condition in the diversion form (4.16). Interpret κD as an effective diversion ratio.

(c) Take $a = 10$, $b = 2$, $d = 1$ and $c = 1$, and suppose the observed price is 5. Infer κ. Then suppose instead that $\kappa = 0$ is known, and find the marginal cost that rationalizes the same price.

(d) Show that the pass-through of a common cost change is $\frac{\mathrm{d}p}{\mathrm{d}c} = \frac{b-\kappa d}{2b-(1+\kappa)d}$. Explain how a cost shifter with known effect on c separates conduct from cost, and relate the argument to Remark 4.33 and to the pass-through tests of Chapter 3.

8. *Computation: a six-product logit market.* Six products have price-free mean utilities $x_j\beta + \xi_j = (2.0, 1.8, 1.6, 2.2, 1.4, 1.2)$ and marginal costs $mc = (1.0, 0.9, 0.8, 1.2, 0.7, 0.6)$. The price coefficient is $\alpha = 1$, the outside good has mean utility zero and market size is one.

(a) Compute the equilibrium prices, shares and markups under three ownership structures: six single-product firms, two firms owning $\{1, 2, 3\}$ and $\{4, 5, 6\}$, and a single owner. Use best-response iteration with (4.10), and check each answer against Proposition 4.7.

(b) At the two-firm equilibrium, compute the diversion matrix and check the adding-up property of Proposition 4.11.

(c) Treat the two-firm equilibrium as data. Recover marginal costs with (4.31) assuming single-product firms and assuming a single owner. Which assumption is rejected by implausible costs?

(d) Run best-response iteration from 100 random starting prices to check uniqueness. Then compute the change in consumer surplus from the single-product to the two-firm structure, and the partial pass-through of a cost increase on all of firm 1's products. Compare the latter with Proposition 4.38.

Part II

Demand Estimation

Chapter 5

Demand in Product Space: The Almost Ideal Demand System

Suppose India begins to enforce foreign patents on antibiotics. The domestic versions of the patented molecules leave the market, and the foreign patent holders no longer face domestic rivals. How much would prices rise? How much would consumers lose, and how much would the patent holders gain? Questions of this kind call for a demand model with three properties. It must describe how consumers substitute among many related products. It must tie the estimated substitution patterns to preferences, so that price changes translate into money measures of welfare. And it must predict demand at prices, and for sets of products, that the data have never shown.

This chapter develops the first of the two approaches to demand estimation in this book. We write demand in *product space*, where each good has its own parameters and the cross-price effects among goods are estimated directly. The workhorse model is the Almost Ideal Demand System (AIDS) of Deaton and Muellbauer (1980a). It is derived from an explicit expenditure function. The restrictions of consumer theory are linear in its parameters, and it aggregates over consumers with different incomes. Its budget-share equations are nearly linear, so standard tools can estimate it. Its main cost is the number of parameters, which grows with the square of the number of goods. Applied work therefore combines it with *multi-stage budgeting*, in which consumers allocate expenditure first across broad groups of goods and then within each group.

The chapter moves from theory to data to applications. Sections 5.1 to 5.3 build the theory. They motivate microfounded demand systems, collect the duality results we need, and derive the AIDS with its restrictions, elasticities, flexibility and limits. Sections 5.4 to 5.6 take the model to data. They ask when market data behave as if one consumer had chosen them, when demand can be estimated group by group, and how the system is estimated, tested and identified. The original British application of Deaton and Muellbauer is the first case study. Section 5.7 turns estimates into welfare measures and counterfactual equilibria. It values products that disappear at their virtual prices, the shadow prices of a zero ration, and it bounds marginal cost when conduct is unknown.

The remaining sections apply the toolkit. Section 5.8 studies the multi-level demand system for beer of Hausman et al. (1994). That paper introduced prices in other cities as instruments and used its estimates for merger analysis. Section 5.9 studies Chaudhuri et al. (2006), who answer the patent question above with a two-level AIDS. Section 5.10 confronts their forecast with the retrospective evidence of Duggan et al. (2016). Section 5.11 closes with an assessment of what product-space demand can and cannot do.

The chapter builds on earlier material. The monopoly pricing condition and the inverse elasticity rule come from Chapter 2. Multiproduct pricing and the distinction between product space and characteristic space come from Chapter 4. We prove the duality results we use. Appendix B restates them with references to these proofs, and adds producer duality, integrability and the envelope-theorem route to Shephard's lemma. Instrumental variables, the generalized method of moments and the bootstrap are developed in Appendix A. The chapter also prepares what follows. Chapters 6 to 8 model demand in characteristic space, where the number of parameters no longer grows with the number of products. Chapter 10 uses the multi-level AIDS and virtual prices to value a new good, and Chapter 11 uses estimated demand systems to simulate mergers. One three-good numerical example, introduced in Example 5.21, runs through the chapter and illustrates the formulas.

5.1 Demand Systems in Product Space

A *demand system* gives the quantity of every good as a function of all prices and of the consumer's budget. This chapter studies demand systems written in *product space*. Each good has its own parameters, and the model states directly how the demand for one good responds to the price of another. The workhorse is the Almost Ideal Demand System of Deaton and Muellbauer (1980a). We follow that literature and index goods by i, j and k, with J goods in total. Elsewhere in the book the letter i indexes consumers. In this chapter households are indexed by $h = 1, \ldots, H$, and Section 5.1.5 collects the remaining conventions.

5.1.1 Questions a demand system answers

Demand systems serve two kinds of questions. *Positive* questions ask what will happen. How do consumers substitute among goods when one price rises? How will prices respond to a merger, a tax or the withdrawal of a product? Will a change in the rules alter the incentives of firms to invest in research and development? *Normative* questions ask whether the change is desirable. Who wins and who loses? Could the winners compensate the losers? How large is the total compensating or equivalent variation, the money measure of welfare change defined in Section 5.2.7?

A second distinction concerns timing. *Prospective* analysis predicts the effects of a policy before it is implemented. Because the policy has not yet generated data, prospective analysis needs a model of demand and supply, and sometimes a model of dynamic investment as well. *Retrospective* analysis measures what happened after a policy was implemented. It relies on causal identification from the variation that the policy created. The two approaches complement each other. Only a model can evaluate a policy that has never been tried, and only retrospective evidence can tell us whether a model predicted well.

One policy question runs through this chapter. The Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) requires members of the World Trade Organization to enforce product patents in all fields of technology, including pharmaceuticals. Countries that excluded pharmaceuticals from product patents were given a transition period to amend their laws. Between April 1972 and March 2005, India recognized only process patents for pharmaceuticals (Chaudhuri et al., 2006), and Indian firms sold their own versions of molecules patented abroad. Enforcing patents would remove these domestic versions from the market. Would consumers then buy the foreign version of the same molecule, a different domestic molecule, or nothing in the segment? How much would prices rise, and how would the loss to

consumers compare with the gain to patent holders? Section 5.9 studies the prospective answer of Chaudhuri et al. (2006), which is built on the demand system of this chapter. Section 5.10 confronts it with the retrospective evidence of Duggan et al. (2016).

5.1.2 Why microfoundations

A *microfounded* demand system is derived from an explicit model of optimizing consumers. It has three advantages over a purely statistical description of demand. The first is internal consistency. The budget constraint holds, demands do not change when all prices and income scale up together, and the cross-price effects obey the symmetry restrictions derived in Section 5.2. The second is that the model rests on *primitives*, preferences and technology, which we can treat as invariant to the policy under study. Reduced-form coefficients estimated under one policy regime need not survive a change of regime. The third is that the model links observed behavior to the primitives through an assumption about behavior, here utility maximization. Observed choices then reveal preferences.

These properties deliver the two products we want from a demand model. Policy-invariant primitives permit prospective analysis, because we can solve the model again under the new policy. The link to preferences permits normative statements, because the expenditure function converts a change in prices into a money measure of welfare.

A statistical demand system can fit the data well and still fail these tests. Consider the *double-log* system, in which every log quantity is linear in log prices and log income with constant elasticities. It is a natural first regression, and it imposes no theory at all. The next proposition shows how little of it survives the budget constraint.

Proposition 5.1 (Double-log demand and the budget constraint)**.** *Suppose that for every good i and every $(p, I) \in \mathbb{R}^J_{++} \times \mathbb{R}_{++}$,*

$$\ln q_i = a_i + \sum_{j=1}^{J} e_{ij} \ln p_j + \eta_i \ln I, \tag{5.1}$$

with constant coefficients a_i, e_{ij} and η_i, and that the budget identity $\sum_i p_i q_i = I$ holds everywhere. Then $\eta_i = 1$, $e_{ii} = -1$, $e_{ij} = 0$ for $j \neq i$, and $\sum_i e^{a_i} = 1$. The only double-log system that satisfies the budget constraint at all prices and incomes is the Cobb-Douglas demand system.

Proof. Divide the budget identity by I and substitute (5.1):

$$\sum_{i=1}^{J} \exp\left(a_i + \sum_{j=1}^{J} \big(e_{ij} + \mathbf{1}(i=j)\big) \ln p_j + (\eta_i - 1) \ln I \right) = 1.$$

Write $x = (\ln p_1, \ldots, \ln p_J, \ln I)^\top$, which ranges over all of $\mathbb{R}^{J+1}$. Term i equals $e^{a_i} \exp(\ell_i^\top x)$ for a coefficient vector ℓ_i. Collect the terms that share the same vector, and move the constant 1 to the left side as the term $-\exp(0^\top x)$. Exponentials of distinct linear forms are linearly independent functions on $\mathbb{R}^{J+1}$. To see this, restrict them to a line on which the distinct forms have distinct slopes, and use the independence of $e^{\lambda_1 t}, \ldots, e^{\lambda_m t}$ for distinct λ's. Every coefficient of the collected sum must therefore vanish. The coefficient of a group with $\ell \neq 0$ is a sum of positive numbers e^{a_i}, so no such group can exist. Hence $\ell_i = 0$ for every i, and the coefficient of the zero form gives $\sum_i e^{a_i} = 1$. The condition $\ell_i = 0$ reads $e_{ij} + \mathbf{1}(i = j) = 0$ and $\eta_i = 1$. □

The double-log system remains useful as a local approximation, and we meet it again at the upper levels of multi-level demand systems in Section 5.8. As a global model it cannot satisfy the budget constraint, its elasticities need not obey the restrictions of consumer theory, and it delivers no welfare measure. The systems in the rest of this chapter are built so that they do all three.

5.1.3 Product space and characteristic space

Chapter 4 introduced the two ways of modeling demand for differentiated products. In *product space*, preferences are defined over the goods themselves, and demand is written as

$$q_i = f_i(p_1, \ldots, p_J, I), \qquad i = 1, \ldots, J, \tag{5.2}$$

with parameters indexed by goods. In *characteristic space*, goods are bundles of characteristics and preferences are defined over the characteristics. The number of parameters then grows with the number of characteristics and with the dimension of consumer heterogeneity, rather than with the number of goods.

Product space is the more natural starting point. Substitution patterns are estimated from the data instead of being imposed by the location of goods in a space of attributes. Goods can be complements as well as substitutes. No data on characteristics are needed, which helps when the relevant attributes are hard to measure, as for books or films.

Its central problem is dimensionality. Even a linear system $q = a + Ap$ has J^2 price coefficients in the matrix A, which is 10,000 coefficients for $J = 100$ goods. Theory helps but not enough. In the Almost Ideal Demand System, symmetry, homogeneity and adding up leave $\frac{J(J-1)}{2}$ free price coefficients (Section 5.3.9), which is still 4,950 for $J = 100$. Dimensionality has two further costs. Each of the J prices is a potentially endogenous regressor in every equation, so estimation requires instruments that move the prices independently of one another (Section 5.6). And because every parameter belongs to a particular good, the model cannot predict demand for a good that has never been sold.

There are two remedies. The first aggregates goods into a few groups and assumes that consumers budget in stages, so that each stage involves only a few goods. The theory of separability that justifies this procedure is developed in Section 5.5, and the applications of Hausman et al. (1994) and Chaudhuri et al. (2006) take this route. The second remedy moves to characteristic space, as in Chapters 6 to 8. Its costs are data on characteristics, more complex estimation, and restrictions on substitution that come from the structure of the random utility model.

5.1.4 Three product-space systems

We now compare three systems that are all derived from a model of consumer behavior. The logit and the constant elasticity of substitution (CES) systems place all substitution in a single parameter. The Almost Ideal Demand System frees the cross effects. Chapters 4 and 7 develop the first two in depth, so the derivations here are brief.

Logit. A population of M consumers, indexed by h, each buys one unit of one of the goods $i = 1, \ldots, J$ or of an outside good $i = 0$. Consumer h obtains utility

$$u_{hi} = \delta_i - \alpha p_i + \epsilon_{hi}, \qquad u_{h0} = \epsilon_{h0},$$

where the ϵ_{hi} are independent type-I extreme value draws. In this subsection only, δ_i is a taste shifter that excludes price, and $\alpha > 0$ is the logit price coefficient. (Elsewhere in the book δ denotes mean utility including price, and in the Almost Ideal Demand System α_i is an intercept.) The share of consumers who choose good i and the share who choose the outside good are

$$s_i = \frac{e^{\delta_i - \alpha p_i}}{1 + \sum_{k=1}^{J} e^{\delta_k - \alpha p_k}}, \qquad s_0 = \frac{1}{1 + \sum_{k=1}^{J} e^{\delta_k - \alpha p_k}},$$

as Chapter 6 derives from the extreme value distribution. The ratio of the two is $\frac{s_i}{s_0} = e^{\delta_i - \alpha p_i}$. Quantities are $q_i = M s_i$, so the market size M cancels from the ratio $\frac{q_i}{q_0}$. Taking logs gives the market-level logit,

$$\ln q_i - \ln q_0 = \delta_i - \alpha p_i. \tag{5.3}$$

The left side is computed from data, and the right side is linear in the parameters. Once we add an error term to δ_i, the logit can be estimated by linear regression (Berry, 1994), as Chapter 7 explains. Differentiating the shares gives $\frac{\partial s_i}{\partial p_i} = -\alpha s_i(1 - s_i)$ and $\frac{\partial s_i}{\partial p_k} = \alpha s_i s_k$ for $k \neq i$. The elasticities are therefore

$$\varepsilon_{ii} = -\alpha p_i (1 - s_i), \qquad \varepsilon_{ik} = \alpha p_k s_k \quad (k \neq i). \tag{5.4}$$

The cross elasticity with respect to p_k is the same for every good i. When good k raises its price, all other goods gain demand in the same proportion, however close or distant they are to k. This is the independence of irrelevant alternatives, studied in Chapter 7.

Constant elasticity of substitution. A single consumer with budget I has CES utility. The next proposition collects the facts we use. In this chapter σ denotes the elasticity of substitution. Elsewhere in the book it denotes the nesting parameter of the nested logit.

Proposition 5.2 (CES demand)**.** *Let $U(q) = \left(\sum_{j=1}^{J} a_j^{\frac{1}{\sigma}} q_j^{\frac{\sigma-1}{\sigma}} \right)^{\frac{\sigma}{\sigma-1}}$ with $a_j > 0$, $\sigma > 0$ and $\sigma \neq 1$, and let the consumer maximize U subject to $\sum_j p_j q_j = I$. Define the CES price index $P^{CES} = \left(\sum_{j=1}^{J} a_j p_j^{1-\sigma} \right)^{\frac{1}{1-\sigma}}$. Then:*

(i) Demand is $q_i = a_i \left(\frac{p_i}{P^{CES}} \right)^{-\sigma} \frac{I}{P^{CES}}$, and the budget share is $w_i = \frac{p_i q_i}{I} = a_i \left(\frac{p_i}{P^{CES}} \right)^{1-\sigma}$.

(ii) Indirect utility is $v(p, I) = \frac{I}{P^{CES}}$ and the expenditure function is $e(p, u) = P^{CES} u$, so preferences are homothetic.

(iii) The Marshallian elasticities are $\varepsilon_{ii} = -\sigma + (\sigma - 1) w_i$, $\varepsilon_{ik} = (\sigma - 1) w_k$ for $k \neq i$, and the expenditure elasticity is $\eta_i = 1$.

Proof. Write $U = S^{\frac{\sigma}{\sigma-1}}$ with $S = \sum_j a_j^{\frac{1}{\sigma}} q_j^{\frac{\sigma-1}{\sigma}}$. By the chain rule,

$$\frac{\partial U}{\partial q_i} = \frac{\sigma}{\sigma - 1} S^{\frac{1}{\sigma-1}} \cdot \frac{\sigma - 1}{\sigma} a_i^{\frac{1}{\sigma}} q_i^{-\frac{1}{\sigma}} = U^{\frac{1}{\sigma}} a_i^{\frac{1}{\sigma}} q_i^{-\frac{1}{\sigma}},$$

because $S^{\frac{1}{\sigma-1}} = U^{\frac{1}{\sigma}}$. The first-order condition $\frac{\partial U}{\partial q_i} = \lambda p_i$ gives $q_i = a_i U (\lambda p_i)^{-\sigma}$. Substitute into the budget constraint:

$$I = \sum_j p_j q_j = U \lambda^{-\sigma} \sum_j a_j p_j^{1-\sigma} = U \lambda^{-\sigma} (P^{CES})^{1-\sigma}.$$

Hence $U\lambda^{-\sigma} = I(P^{CES})^{\sigma-1}$, and $q_i = a_i p_i^{-\sigma} I(P^{CES})^{\sigma-1} = a_i\left(\frac{p_i}{P^{CES}}\right)^{-\sigma}\frac{I}{P^{CES}}$. Multiplying by $\frac{p_i}{I}$ gives the share. For (ii), substitute the demands into S:

$$S = \sum_j a_j^{\frac{1}{\sigma}} a_j^{\frac{\sigma-1}{\sigma}}\left(\frac{p_j}{P^{CES}}\right)^{1-\sigma}\left(\frac{I}{P^{CES}}\right)^{\frac{\sigma-1}{\sigma}} = \left(\frac{I}{P^{CES}}\right)^{\frac{\sigma-1}{\sigma}}\sum_j a_j\left(\frac{p_j}{P^{CES}}\right)^{1-\sigma} = \left(\frac{I}{P^{CES}}\right)^{\frac{\sigma-1}{\sigma}},$$

since the last sum equals one by the definition of P^{CES}. Then $v = S^{\frac{\sigma}{\sigma-1}} = \frac{I}{P^{CES}}$, and inverting $u = \frac{e}{P^{CES}}$ gives $e(p,u) = P^{CES}u$. For (iii), take logs of the demand function, $\ln q_i = \ln a_i - \sigma \ln p_i + (\sigma-1)\ln P^{CES} + \ln I$. Differentiating $\ln P^{CES} = \frac{1}{1-\sigma}\ln\sum_k a_k p_k^{1-\sigma}$ gives $\frac{\partial \ln P^{CES}}{\partial \ln p_j} = \frac{a_j p_j^{1-\sigma}}{\sum_k a_k p_k^{1-\sigma}} = w_j$. Hence $\varepsilon_{ij} = -\sigma\mathbf{1}(i=j) + (\sigma-1)w_j$ and $\eta_i = 1$. □

Writing $a_j = e^{\sigma\delta_j}$, with δ_j a taste shifter, the log of the demand function takes the form

$$\ln q_i = \sigma\left(\delta_i - \ln\frac{p_i}{P^{CES}}\right) + \ln\frac{I}{P^{CES}}. \tag{5.5}$$

The normalization $\sum_j e^{\sigma\delta_j} = 1$ makes $P^{CES} = \left(\sum_j a_j\right)^{\frac{1}{1-\sigma}} = 1$ when all prices equal one. The parameter σ is the elasticity of substitution. From part (i), $\ln\frac{q_i}{q_k} = \ln\frac{a_i}{a_k} - \sigma\ln\frac{p_i}{p_k}$, so a one percent rise in the relative price $\frac{p_k}{p_i}$ raises the relative quantity $\frac{q_i}{q_k}$ by σ percent. Goods are gross substitutes when $\sigma > 1$. The cross elasticity $(\sigma-1)w_k$ does not depend on i, so the CES has the same proportional substitution as the logit. The compensated cross elasticity, obtained from the Slutsky equation of Section 5.2.6, is σw_k.

The Almost Ideal Demand System. The third system expresses the budget share of each good as

$$w_i = \alpha_i + \sum_{j=1}^{J}\gamma_{ij}\ln p_j + \beta_i \ln\frac{I}{\mathbf{P}}, \tag{5.6}$$

where $w_i = \frac{p_i q_i}{I}$ and $\mathbf{P}$ is a price index defined in Section 5.3. Shares respond to every log price through a separate coefficient γ_{ij}, and to log real expenditure $\ln\frac{I}{\mathbf{P}}$ through β_i. Section 5.3 derives the system from an expenditure function.

Table 5.1 sets the three systems side by side. The logit and the CES buy parsimony with restrictive substitution, because one parameter governs every cross effect. Consumers who leave a product spread over the other products in proportion to their sizes, whatever the attributes of those products. The AIDS frees the cross effects at the cost of many parameters.

The row on choke prices matters for welfare. A *choke price*, or *virtual price*, is the price at which the demand for a good falls to zero (Hicks, 1940; Rothbarth, 1941). Removing a good from the market is equivalent, for consumers, to raising its price to the virtual price. Under CES and logit the demand for a good stays positive at every finite price, because $p_i^{-\sigma}$ and $e^{-\alpha p_i}$ never reach zero. The virtual price is infinite, and the welfare loss from removing a good depends only on its share and on the single substitution parameter. The value of variety is then built into the functional form. Under the AIDS the share is linear in $\ln p_i$ when $\beta_i = 0$ and quadratic otherwise. When it falls with the own price, it reaches zero at a finite price, so the loss depends on the estimated own and cross effects. Section 5.7.2 develops this comparison.

Table 5.1: Three product-space demand systems compared

	Logit (market level)	CES	AIDS
Dependent variable	$\ln q_i - \ln q_0$	$\ln q_i$ (or share w_i)	budget share w_i
Substitution parameters	one (α)	one (σ)	$\frac{J(J-1)}{2}$ free γ_{ij}
Level parameters	J taste shifters δ_i	$J-1$ free δ_i	$2(J-1)$ free α_i, β_i, and α_0
Own elasticity ε_{ii}	$-\alpha p_i(1-s_i)$	$-\sigma+(\sigma-1)w_i$	$-1+\frac{1}{w_i}\frac{\partial w_i}{\partial \ln p_i}$, (5.38)
Cross elasticity ε_{ik}	$\alpha p_k s_k$, the same for all i	$(\sigma-1)w_k$, the same for all i	$\frac{1}{w_i}\frac{\partial w_i}{\partial \ln p_k}$, any sign
Engel curves	no income effects (each consumer buys one unit)	homothetic, $\eta_i = 1$	shares linear in $\ln I$, luxuries and necessities
Choke (virtual) price	infinite	infinite	finite if the own share falls with price ($\gamma_{ii} < 0$ when $\beta_i = 0$)
Aggregation	exact: shares add up individual discrete choices	representative consumer with homothetic preferences	almost exact: representative budget level I_0
Typical data	shares of many products, with an outside good	expenditure on many varieties	budget shares of a few goods or groups over time or markets

Notes: Elasticities are signed. In the logit column s_i is the market share including the outside good. In the CES and AIDS columns w_i is the budget share. The AIDS count of free γ_{ij} imposes adding up, homogeneity and symmetry (Section 5.3.9). Aggregation for AIDS is developed in Section 5.4.

5.1.5 Conventions for this chapter

Goods are indexed by $i, j, k = 1, \dots, J$, and in this chapter the J goods exhaust the budget under study. Households are indexed by $h = 1, \dots, H$ and appear as subscripts, as in I_h and w_{ih}. The Hicksian demand $h_i(p, u)$ (defined in Section 5.2.1) is always written with its arguments, so it cannot be confused with a household index. Total expenditure, which we also call income, is I, and the budget share of good i is $w_i = \frac{p_i q_i}{I}$. Logarithms are natural logarithms.

Elasticities are signed throughout this chapter, as in the tables of the papers we study. The Marshallian price elasticity is $\varepsilon_{ij} = \frac{\partial \ln q_i}{\partial \ln p_j}$, so own-price elasticities are negative. This departs from the convention elsewhere in the book, where the own-price elasticity is reported as a positive number. The Hicksian elasticity is ε^h_{ij} and the expenditure elasticity is η_i. The Slutsky matrix is $S = [S_{ij}]$ (Section 5.2.5), and we reserve s for market shares. We write the indicator $\mathbf{1}(i = j)$ instead of a Kronecker delta, because δ denotes mean utility elsewhere in the book. Additive errors in share equations are written ξ, while the papers often write ε, which here denotes an elasticity.

5.2 Consumer Duality: The Toolkit

This section collects the results of consumer theory that we need to derive, restrict and use the AIDS. We keep the argument self-contained and prove every result we use. Appendix B restates these results for reference and adds producer duality and integrability. The treatment parallels Deaton and Muellbauer (1980b, ch. 2). They develop the cost function in §2.3 (pp. 37–42), the properties of demands in §2.4 (pp. 43–46) and duality in §2.5 (pp. 47–50). Their $c(u, p)$ is our $e(p, u)$, and their x is our total expenditure I.

5.2.1 Utility maximization and expenditure minimization

Assumption 5.3 (Preferences)**.** The consumer's preferences over bundles $q \in \mathbb{R}^J_+$ are represented by a utility function U that is continuous, strictly increasing and strictly quasi-concave. Prices satisfy $p \in \mathbb{R}^J_{++}$ and income satisfies $I > 0$. Whenever derivatives appear, the functions defined below are twice continuously differentiable.

The *utility maximization problem* (UMP) and the *expenditure minimization problem* (EMP) are

$$v(p, I) = \max_{q \geq 0} \{U(q) : p^\top q \leq I\}, \qquad e(p, u) = \min_{q \geq 0} \{p^\top q : U(q) \geq u\}. \tag{5.7}$$

The maximizer of the UMP is the *Marshallian* (uncompensated) demand $q(p, I)$, and v is the *indirect utility function*. The minimizer of the EMP is the *Hicksian* (compensated) demand $h(p, u)$, and e is the *expenditure function*. Under Assumption 5.3 both problems have unique solutions, by strict quasi-concavity, and both constraints bind, by continuity and strict monotonicity. The indirect utility function is homogeneous of degree zero in (p, I), because scaling all prices and income leaves the budget set unchanged. It is strictly increasing in I and nonincreasing in p, because a higher income or a lower price enlarges the budget set.

Lemma 5.4 (Duality identities)**.** *Under Assumption 5.3, for all $p \gg 0$, $I > 0$ and attainable utility levels u:*

(i) $e(p, v(p, I)) = I$ *and* $v(p, e(p, u)) = u$.

(ii) $q_i(p, I) = h_i(p, v(p, I))$ *and* $h_i(p, u) = q_i(p, e(p, u))$.

Proof. Let $u = v(p, I)$ and $q^* = q(p, I)$. The bundle q^* attains u at cost I, so $e(p, u) \le I$. Suppose $e(p, u) < I$, and let $q' = h(p, u)$. Then $p^\top q' < I$, so a slightly larger bundle $q' + \epsilon \mathbf{1}$ is affordable for small $\epsilon > 0$. By strict monotonicity it yields utility above $u = v(p, I)$, a contradiction. Hence $e(p, v(p, I)) = I$. The bundle q^* then solves the EMP, and uniqueness gives $q^* = h(p, u)$. For the second pair, let $I = e(p, u) > 0$ and $q' = h(p, u)$. The bundle q' is affordable at income I, so $v(p, I) \ge u$. Suppose $v(p, I) > u$. By continuity, the bundle $t\, q(p, I)$ with $t < 1$ close to one still yields utility above u, and it costs less than $I = e(p, u)$. This contradicts the definition of e. Hence $v(p, e(p, u)) = u$, the bundle q' solves the UMP, and uniqueness gives $h(p, u) = q(p, e(p, u))$. □

5.2.2 Properties of the expenditure function

Proposition 5.5 (Expenditure function)**.** *Under Assumption 5.3, the expenditure function* $e(p, u)$ *has four properties.*

(i) It is homogeneous of degree one in p.

(ii) It is nondecreasing in p *and strictly increasing in* u.

(iii) It is concave in p.

(iv) It is continuous in (p, u).

Proof. (i) For $\lambda > 0$, the constraint set $\{q : U(q) \ge u\}$ does not depend on prices, and $\lambda p^\top q$ is minimized by the same bundle as $p^\top q$. Hence $e(\lambda p, u) = \lambda e(p, u)$.

(ii) Let $p' \ge p$ and $q' = h(p', u)$. Then

$$e(p', u) = p'^\top q' \ge p^\top q' \ge e(p, u),$$

where the last inequality holds because q' is feasible in the EMP at prices p. For u, let $u' > u$ and $q' = h(p, u')$, and suppose $e(p, u') \le e(p, u)$. By continuity, tq' with $t < 1$ close to one still yields utility above u. It costs $t\, e(p, u') < e(p, u)$, which contradicts minimality at u.

(iii) Let $p'' = \lambda p + (1 - \lambda)p'$ with $\lambda \in [0, 1]$, and let $q'' = h(p'', u)$. Since q'' is feasible at every price vector,

$$e(p'', u) = \lambda p^\top q'' + (1 - \lambda) p'^\top q'' \ge \lambda e(p, u) + (1 - \lambda) e(p', u).$$

The expenditure function is the minimum of a family of linear functions of p, one for each feasible bundle, and such a minimum is concave.

(iv) Continuity follows from the theorem of the maximum, since the objective is continuous and the constraint correspondence is continuous under Assumption 5.3. We omit the details, which are standard. □

5.2.3 Shephard's lemma

Proposition 5.6 (Shephard's lemma)**.** *If* $e(\cdot, u)$ *is differentiable at* p*, then* $\frac{\partial e(p,u)}{\partial p_i} = h_i(p, u)$ *for every* i.

Proof. Fix u and p^0, and let $q^0 = h(p^0, u)$. For every price vector p, the bundle q^0 is feasible in the EMP, so $e(p, u) \le p^\top q^0$, with equality at $p = p^0$. The function $g(p) = e(p, u) - p^\top q^0$ therefore attains its maximum, zero, at p^0. Its gradient vanishes there, so $\frac{\partial e(p^0,u)}{\partial p_i} = q_i^0 = h_i(p^0, u)$. The same conclusion follows from the envelope theorem applied to the EMP (Appendix B). □

The lemma is most useful in share form. Differentiate the log of the expenditure function with respect to a log price, applying the chain rule one factor at a time:

$$\frac{\partial \ln e(p,u)}{\partial \ln p_i} = \frac{\partial \ln e}{\partial e} \cdot \frac{\partial e}{\partial p_i} \cdot \frac{\partial p_i}{\partial \ln p_i} = \frac{1}{e} \cdot h_i(p,u) \cdot p_i = \frac{p_i h_i(p,u)}{e(p,u)}.$$

Evaluate at $u = v(p,I)$. By Lemma 5.4, $e = I$ and $h_i = q_i(p,I)$, so the right side is the budget share:

$$w_i = \frac{\partial \ln e(p,u)}{\partial \ln p_i}. \tag{5.8}$$

Budget shares are the log-price derivatives of the log expenditure function. This is the route from an expenditure function to share equations that we take in Section 5.3.

5.2.4 Roy's identity

Proposition 5.7 (Roy's identity)**.** *If v is differentiable at (p,I) with $\frac{\partial v}{\partial I} > 0$, then*

$$q_i(p,I) = -\frac{\partial v(p,I)}{\partial p_i}\left[\frac{\partial v(p,I)}{\partial I}\right]^{-1}, \qquad \textit{equivalently} \qquad w_i = -\frac{\partial v(p,I)}{\partial \ln p_i}\left[\frac{\partial v(p,I)}{\partial \ln I}\right]^{-1}. \tag{5.9}$$

Proof. By Lemma 5.4, $v(p, e(p,u)) = u$ for all p. Differentiate with respect to p_i:

$$\frac{\partial v}{\partial p_i} + \frac{\partial v}{\partial I} \cdot \frac{\partial e(p,u)}{\partial p_i} = 0.$$

By Shephard's lemma, $\frac{\partial e}{\partial p_i} = h_i(p,u)$. Evaluate at $u = v(p,I)$, where $e(p,u) = I$ and $h_i(p,u) = q_i(p,I)$, and solve for q_i. For the share form, multiply the numerator by p_i and the denominator by I, and divide both sides by $\frac{I}{p_i}$. □

Roy's identity holds for any increasing transformation of v, because the transformation multiplies both derivatives in (5.9) by the same positive factor. We use this freedom when we derive the quadratic AIDS in Section 5.3.8.

5.2.5 The Slutsky equation

Proposition 5.8 (Slutsky equation)**.** *Define the* Slutsky matrix *$S(p,u)$ by $S_{ij} = \frac{\partial h_i(p,u)}{\partial p_j}$. Then:*

(i) At $u = v(p,I)$, $\frac{\partial q_i(p,I)}{\partial p_j} = S_{ij} - q_j \frac{\partial q_i(p,I)}{\partial I}$.

(ii) S is symmetric.

(iii) S is negative semidefinite, and in particular $S_{ii} \le 0$.

(iv) $Sp = 0$.

Proof. (i) By Lemma 5.4, $h_i(p,u) = q_i(p, e(p,u))$ for all p. Differentiate with respect to p_j:

$$\frac{\partial h_i}{\partial p_j} = \frac{\partial q_i}{\partial p_j} + \frac{\partial q_i}{\partial I} \cdot \frac{\partial e}{\partial p_j} = \frac{\partial q_i}{\partial p_j} + \frac{\partial q_i}{\partial I}\, h_j(p,u).$$

At $u = v(p,I)$ we have $h_j = q_j$, and rearranging gives (i). (ii) By Shephard's lemma, $S_{ij} = \frac{\partial^2 e}{\partial p_j \partial p_i}$, and Young's theorem makes the matrix of second derivatives symmetric. (iii) The Hessian

of a concave function is negative semidefinite, and e is concave in p by Proposition 5.5. (iv) The gradient of a function homogeneous of degree one is homogeneous of degree zero, so $h_i(\lambda p, u) = h_i(p, u)$. Euler's theorem then gives $\sum_j p_j \frac{\partial h_i}{\partial p_j} = 0$. □

Part (i) splits the effect of a price change into a *substitution effect* S_{ij}, which holds utility constant, and an *income effect* $-q_j \frac{\partial q_i}{\partial I}$, which reflects the loss of purchasing power. Part (iii) is the compensated law of demand. It is the only sign restriction that consumer theory places on demand.

5.2.6 Elasticity forms of the restrictions

Applied work reports elasticities, so we restate the restrictions in elasticity form. Define the signed Marshallian elasticity $\varepsilon_{ij} = \frac{\partial \ln q_i(p,I)}{\partial \ln p_j}$, the Hicksian elasticity $\varepsilon^h_{ij} = \frac{\partial \ln h_i(p,u)}{\partial \ln p_j}$ and the expenditure elasticity $\eta_i = \frac{\partial \ln q_i(p,I)}{\partial \ln I}$. A good is a *luxury* if $\eta_i > 1$ and a *necessity* if $\eta_i < 1$. It is *normal* if $\eta_i > 0$ and *inferior* if $\eta_i < 0$. All elasticities below are evaluated at $u = v(p, I)$.

Proposition 5.9 (Restrictions in elasticity and share form)**.** *Under Assumption 5.3:*

(a) (Slutsky equation) $\varepsilon^h_{ij} = \varepsilon_{ij} + \eta_i w_j$.

(b) (Engel aggregation) $\sum_i w_i \eta_i = 1$.

(c) (Cournot aggregation) $\sum_i w_i \varepsilon_{ij} = -w_j$ *for every* j.

(d) (Homogeneity) $\sum_j \varepsilon_{ij} + \eta_i = 0$ *and* $\sum_j \varepsilon^h_{ij} = 0$ *for every* i.

(e) (Symmetry) $w_i \varepsilon^h_{ij} = w_j \varepsilon^h_{ji}$.

(f) (Negativity in share form) The matrix $K = [k_{ij}]$ *with* $k_{ij} = \frac{p_i p_j S_{ij}}{I} = w_i \varepsilon^h_{ij}$ *satisfies*

$$k_{ij} = \frac{\partial w_i}{\partial \ln p_j} + w_j \frac{\partial w_i}{\partial \ln I} + w_i w_j - \mathbf{1}(i = j) w_i, \tag{5.10}$$

where w_i *is viewed as a function of* (p, I)*, and* K *is symmetric and negative semidefinite.*

Proof. (a) Multiply the Slutsky equation of Proposition 5.8 by $\frac{p_j}{q_i}$:

$$\frac{p_j}{q_i} S_{ij} = \frac{p_j}{q_i} \frac{\partial q_i}{\partial p_j} + \frac{p_j q_j}{I} \cdot \frac{I}{q_i} \frac{\partial q_i}{\partial I},$$

which reads $\varepsilon^h_{ij} = \varepsilon_{ij} + w_j \eta_i$.

(b) Differentiate the budget identity $\sum_i p_i q_i(p, I) = I$ with respect to I to get $\sum_i p_i \frac{\partial q_i}{\partial I} = 1$. Write each term as $\frac{p_i q_i}{I} \cdot \frac{I}{q_i} \frac{\partial q_i}{\partial I} = w_i \eta_i$.

(c) Differentiate the budget identity with respect to p_j to get $q_j + \sum_i p_i \frac{\partial q_i}{\partial p_j} = 0$. Multiply by $\frac{p_j}{I}$ and write each term of the sum as $\frac{p_i q_i}{I} \cdot \frac{p_j}{q_i} \frac{\partial q_i}{\partial p_j} = w_i \varepsilon_{ij}$.

(d) Marshallian demand is homogeneous of degree zero in (p, I), because scaling prices and income leaves the budget set unchanged. Euler's theorem gives $\sum_j p_j \frac{\partial q_i}{\partial p_j} + I \frac{\partial q_i}{\partial I} = 0$. Divide by q_i. The Hicksian version follows from $Sp = 0$ in the same way.

(e) Multiply $S_{ij} = S_{ji}$ by $\frac{p_i p_j}{I}$. The left side becomes $\frac{p_i q_i}{I} \cdot \frac{p_j}{q_i} S_{ij} = w_i \varepsilon^h_{ij}$, and the right side becomes $w_j \varepsilon^h_{ji}$.

(f) The equality $k_{ij} = w_i \varepsilon^h_{ij}$ is the computation in (e). For (5.10), write $q_i = \frac{w_i I}{p_i}$ and differentiate:

$$\frac{\partial q_i}{\partial p_j} = \frac{I}{p_i p_j}\left[\frac{\partial w_i}{\partial \ln p_j} - \mathbf{1}(i=j) w_i\right], \qquad \frac{\partial q_i}{\partial I} = \frac{1}{p_i}\left[w_i + \frac{\partial w_i}{\partial \ln I}\right].$$

Substitute into $S_{ij} = \frac{\partial q_i}{\partial p_j} + q_j \frac{\partial q_i}{\partial I}$ with $q_j = \frac{w_j I}{p_j}$:

$$S_{ij} = \frac{I}{p_i p_j}\left[\frac{\partial w_i}{\partial \ln p_j} - \mathbf{1}(i=j) w_i + w_j w_i + w_j \frac{\partial w_i}{\partial \ln I}\right].$$

Multiply by $\frac{p_i p_j}{I}$. Finally, $K = \frac{1}{I} D S D$ with $D = \operatorname{diag}(p_1, \ldots, p_J)$. For any vector z, $z^\top K z = \frac{1}{I}(Dz)^\top S (Dz) \le 0$, and K inherits symmetry from S. □

These identities serve two purposes. They are the restrictions we impose on, or test against, an estimated demand system. They also give quick consistency checks on published elasticity matrices. For instance, the share-weighted column sums of the Marshallian matrix must equal minus the budget shares. The matrix K of part (f) is the share-space version of the Slutsky matrix, and it plays a central part in Section 5.3.

Remark 5.10 (Integrability). The restrictions are also sufficient. Consider a continuously differentiable demand system that satisfies the budget identity and has a symmetric, negative semidefinite Slutsky matrix everywhere. Hurwicz and Uzawa (1971) show, under regularity conditions, that some utility function generates it. This is the precise sense in which a demand system is "consistent with utility maximization." For the AIDS we do not need the theorem, because we start from an expenditure function. That function is a valid expenditure function only where it is increasing and concave in prices. For the AIDS this means the region where all shares are nonnegative and the matrix K is negative semidefinite (Section 5.3.9).

5.2.7 Welfare measures

Let prices change from p to p' while income stays at I. Write $u^0 = v(p, I)$ for the initial utility and $u' = v(p', I)$ for the final utility.

Definition 5.11 (Compensating and equivalent variation)**.** The *compensating variation* is the income the consumer would need at the new prices to reach the initial utility, minus the actual income:

$$CV = e(p', u^0) - e(p, u^0) = e(p', u^0) - I. \tag{5.11}$$

The *equivalent variation* is the income reduction at the old prices that would leave the consumer as well off as the price change does:

$$EV = e(p, u^0) - e(p, u') = I - e(p, u'). \tag{5.12}$$

With these sign conventions, both measures are positive for a welfare loss.

The second equality in each line uses $e(p, u^0) = I = e(p', u')$ from Lemma 5.4. The ratio $\frac{e(p', u^0)}{e(p, u^0)}$ is the *exact cost-of-living index* at the initial utility. It measures how much more income the consumer needs at the new prices to be as well off as before. Deaton and Muellbauer (1980b, §7.1, eqs. 1.1–1.2, pp. 170–171) call it the true index of the cost of living with reference utility u^0. Using u' as the reference gives a second true index, $\frac{e(p', u')}{e(p, u')}$. The fixed-basket Laspeyres index $\frac{p'^{\top} q^0}{p^{\top} q^0}$ is an upper bound on the first true index, because q^0 is one way, not necessarily the cheapest, to reach u^0 at prices p'. For the same reason the Paasche index $\frac{p'^{\top} q'}{p^{\top} q'}$ is a lower bound on the second (p. 171). The CV and EV are the money counterparts of these two true indices.

When only the price of good i changes, Shephard's lemma and the fundamental theorem of calculus give

$$CV = \int_{p_i}^{p_i'} h_i(s, p_{-i}, u^0)\, \mathrm{d}s, \qquad EV = \int_{p_i}^{p_i'} h_i(s, p_{-i}, u')\, \mathrm{d}s, \tag{5.13}$$

where p_{-i} collects the other prices. The CV is the area to the left of the Hicksian demand curve at the initial utility, between the two prices. The EV is the corresponding area for the Hicksian demand at the final utility. When several prices change, let $p(t)$, $t \in [0, 1]$, be any smooth path from p to p'. The chain rule and Shephard's lemma give

$$CV = \int_0^1 \sum_{i=1}^{J} h_i(p(t), u^0)\, \dot{p}_i(t)\, \mathrm{d}t. \tag{5.14}$$

The integral does not depend on the path, because the Hicksian demands form the gradient of $e(\cdot, u^0)$. Path independence is equivalent to Slutsky symmetry. The analogous line integral of Marshallian demands generally depends on the path, which is one reason to prefer the exact measures.

The familiar *Marshallian consumer surplus* uses the ordinary demand curve. For a change in the price of good i alone, its loss is $\Delta CS = \int_{p_i}^{p_i'} q_i(s, p_{-i}, I)\, \mathrm{d}s$. The next proposition locates it between the two exact measures.

Proposition 5.12 (Ordering of the welfare measures)**.** *Suppose only p_i changes, from p_i to $p_i' > p_i$, and good i is normal at all prices in between. Then $EV \le \Delta CS \le CV$. For an inferior good the inequalities reverse.*

Proof. Differentiate $h_i(p, u) = q_i(p, e(p, u))$ with respect to u: $\frac{\partial h_i}{\partial u} = \frac{\partial q_i}{\partial I} \cdot \frac{\partial e}{\partial u}$. The second factor is positive by Proposition 5.5, so h_i increases with u when good i is normal. For s between p_i and p_i', indirect utility $v(s, p_{-i}, I)$ lies between u' and u^0, since v is nonincreasing in prices. Hence

$$h_i(s, p_{-i}, u') \le h_i\big(s, p_{-i}, v(s, p_{-i}, I)\big) = q_i(s, p_{-i}, I) \le h_i(s, p_{-i}, u^0).$$

Integrating over s from p_i to p_i' and using (5.13) gives the result. For an inferior good h_i decreases with u and every inequality flips. □

Willig (1976) shows that the Marshallian surplus is close to the exact measures when the income elasticity of the good is small and the surplus is a small fraction of income. Deaton and Muellbauer (1980b, §7.4, pp. 184–188) add three points. First, when several prices change, the Marshallian area depends in general on the path of integration. It is a well-defined welfare

measure only under restrictions on income effects (p. 185). Homotheticity is not required. If the goods whose prices change have no income effect, as under quasilinear preferences, the area equals both the CV and the EV. With $U = \ln q_1 + q_2$ and p_1 rising from 1 to 2, for example, $CV = EV = \int_1^2 \frac{1}{p_1}\,dp_1 = \ln 2$. When income effects are present, the area differs from the exact measures, and for a normal good the CV and the EV bracket it by Proposition 5.12. Second, expanding $e(p', u^0)$ around p and $e(p, u')$ around p' gives the first-order approximations

$$CV \approx q^{0\top}(p' - p), \qquad EV \approx q'^{\top}(p' - p)$$

(their eq. 4.3, p. 187), the money counterparts of the Laspeyres and Paasche indices. Third, once the demand system is known, the exact measures need no more information than the Marshallian area (p. 188). The welfare calculations in this chapter use the exact measures, which the AIDS delivers in closed form (Section 5.7). The CV in (5.11) is the CV of one consumer. Interpreting a market-level CV requires a representative consumer, which is the subject of Section 5.4.

Example 5.13 (Cobb-Douglas)**.** Let $U = q_1^{\frac{1}{2}} q_2^{\frac{1}{2}}$, $p_2 = 1$ and $I = 10$. Marshallian demand is $q_1 = \frac{I}{2p_1}$, indirect utility is $v = \frac{I}{2\sqrt{p_1 p_2}}$, and inverting $u = v(p, e)$ gives $e(p, u) = 2u\sqrt{p_1 p_2}$. Shephard's lemma gives $h_1(p, u) = u\sqrt{\frac{p_2}{p_1}}$. Let p_1 rise from 1 to 2. Initial utility is $u^0 = 5$ and final utility is $u' = \frac{5}{\sqrt{2}} \approx 3.54$. Then

$$\begin{aligned} CV &= e(2, u^0) - 10 = 10\sqrt{2} - 10 \approx 4.14, \\ \Delta CS &= \int_1^2 \frac{5}{s}\,\mathrm{d}s = 5\ln 2 \approx 3.47, \\ EV &= 10 - e(1, u') = 10 - 5\sqrt{2} \approx 2.93. \end{aligned}$$

Integrating the Hicksian demand directly confirms the first line, $\int_1^2 5s^{-\frac{1}{2}}\,\mathrm{d}s = 10(\sqrt{2} - 1)$. Figure 5.1 draws the three areas.

5.2.8 Flexible functional forms

An empirical demand system must take a parametric form. We want a form general enough not to prejudge the answers, yet tied to preferences so that it satisfies the restrictions above. The concept that formalizes "general enough" is flexibility.

Definition 5.14 (Flexible functional form)**.** A parametric expenditure function $e(p, u; \theta)$ is a *flexible functional form* if it can match any expenditure function to second order at any point (Diewert, 1974). Formally, let (p^0, u^0) be any point and let $\tilde{e}$ be any twice continuously differentiable expenditure function with the properties of Proposition 5.5. Then there is a parameter value θ such that e and $\tilde{e}$ have the same value and the same first and second partial derivatives with respect to (p, u) at (p^0, u^0).

A flexible expenditure function is a second-order approximation to any expenditure function at a point. By Shephard's lemma its first price derivatives are the Hicksian demands, and its second price derivatives are the Slutsky terms. The cross derivatives in p and u determine the income effects, because $\frac{\partial h_i}{\partial u} = \frac{\partial q_i}{\partial I}\frac{\partial e}{\partial u}$. A flexible expenditure function therefore generates

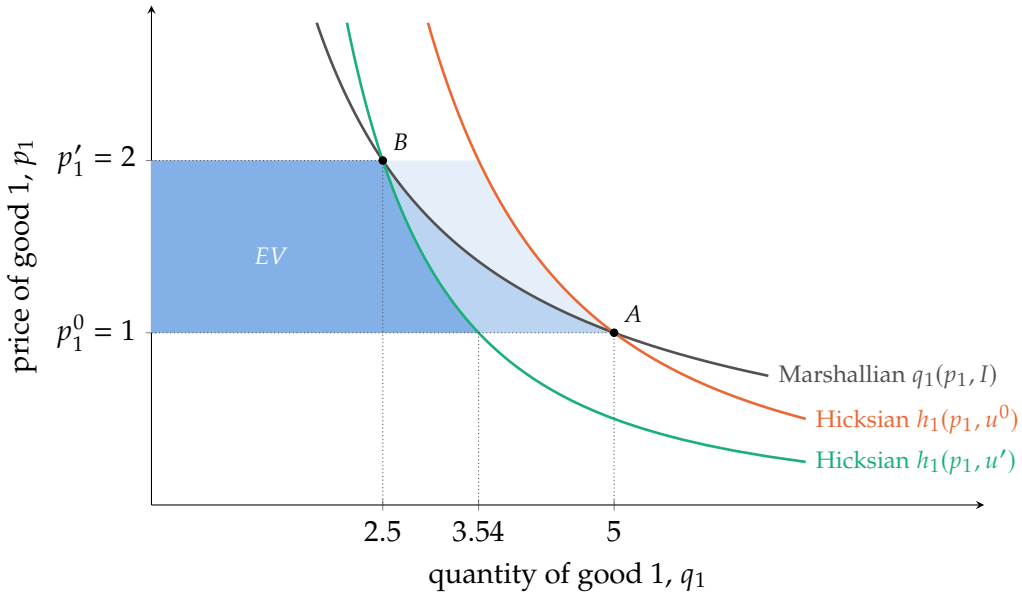

Figure 5.1: Compensating variation, equivalent variation and Marshallian surplus for a rise in p_1 from 1 to 2 (Example 5.13: $U = q_1^{\frac{1}{2}} q_2^{\frac{1}{2}}$, $p_2 = 1$, $I = 10$). The consumer moves from A to B along the Marshallian demand. The Hicksian demand at the initial utility u^0 passes through A, and the Hicksian demand at the final utility u' passes through B. The darkest region is the EV (2.93). Adding the middle band gives the Marshallian surplus loss (3.47). Adding the lightest band gives the CV (4.14).

demands whose levels and first derivatives in prices and income can match those of any demand system at a point. In this sense it is a first-order approximation to demand.

The search for such forms has a long history, which Deaton and Muellbauer (1980a, p. 312) summarize. The *linear expenditure system* of Stone (1954) was the first system estimated from an explicit utility function. Its additive utility function leaves only $2J - 1$ free parameters, too few for flexibility, and it rules out inferior goods and Hicksian complements. The *Rotterdam model* of Theil (1965) and Barten (1969) approximates the demand functions themselves in differential form, with constant coefficients on which the restrictions of theory are linear. The *translog model* of Christensen et al. (1975) takes a second-order approximation to the indirect utility function, $\ln v = \alpha_0 + \sum_i \alpha_i \ln \frac{p_i}{I} + \frac{1}{2} \sum_i \sum_j b_{ij} \ln \frac{p_i}{I} \ln \frac{p_j}{I}$. By Roy's identity its shares are ratios of linear functions of the log normalized prices, which makes estimation nonlinear. The AIDS was designed to combine the virtues of these models. It starts from a class of preferences that permits aggregation over consumers, and it yields shares that are nearly linear in the parameters.

5.3 The Almost Ideal Demand System

Deaton and Muellbauer (1980a) derive the AIDS from a specific expenditure function. We follow their derivation step by step, then establish the restrictions, the elasticities, the flexibility of the system and its Engel curves, and we close with its limits.

5.3.1 The PIGLOG class

Definition 5.15 (PIGLOG preferences)**.** Preferences belong to the *price-independent generalized logarithmic* (PIGLOG) class if the expenditure function can be written as

$$\ln e(p,u) = (1-u)\ln a(p) + u \ln b(p), \tag{5.15}$$

where $a(p)$ and $b(p)$ are positive, linearly homogeneous and concave functions of prices.

Equation (5.15) is equation (1) of Deaton and Muellbauer (1980a, p. 313), who write the expenditure function as $c(u,p)$. With some exceptions that they discuss in their appendix, utility lies between 0 and 1. At $u = 0$ expenditure equals $a(p)$, and at $u = 1$ it equals $b(p)$. The two functions can therefore be regarded as the costs of *subsistence* and of *bliss* (Deaton and Muellbauer, 1980a, p. 313). The class is due to Muellbauer (1975, 1976), who showed that these preferences permit aggregation over consumers. Market demands can then be represented as if they were the decisions of one rational representative consumer, with a representative budget level that does not depend on prices. Section 5.4 develops this property.

Two consequences of (5.15) are useful at once. First, the expenditure function equals $e = a(p)^{1-u} b(p)^u$, a weighted geometric mean of a and b. The geometric mean is concave and increasing in its arguments, so e is concave in p whenever a and b are concave and $0 \le u \le 1$. Deaton and Muellbauer (1980a, p. 324) note that this condition is sufficient for concavity but by no means necessary. Second, Shephard's lemma in share form gives

$$w_i = (1-u)\frac{\partial \ln a(p)}{\partial \ln p_i} + u\frac{\partial \ln b(p)}{\partial \ln p_i}. \tag{5.16}$$

Budget shares are weighted averages of the subsistence shares and the bliss shares, with weights given by utility (Deaton and Muellbauer, 1980a, p. 324). Luxuries are the goods whose bliss share exceeds their subsistence share. Inverting $\ln I = \ln a + u(\ln b - \ln a)$ gives $u = \frac{\ln I - \ln a(p)}{\ln b(p) - \ln a(p)}$. Substituting into (5.16) shows that every PIGLOG share is linear in $\ln I$, with intercept and slope that depend on prices:

$$w_i = \frac{\partial \ln a(p)}{\partial \ln p_i} + \frac{\partial \ln \frac{b(p)}{a(p)}}{\partial \ln p_i} \cdot \frac{\ln I - \ln a(p)}{\ln \frac{b(p)}{a(p)}}. \tag{5.17}$$

5.3.2 The AIDS cost function

Deaton and Muellbauer (1980a, p. 313) choose specific forms for $a(p)$ and $b(p)$:

$$\ln a(p) = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2}\sum_k \sum_j \gamma^*_{kj} \ln p_k \ln p_j, \tag{5.18}$$

$$\ln b(p) = \ln a(p) + \beta_0 \prod_k p_k^{\beta_k}. \tag{5.19}$$

Substituting into (5.15) gives the *AIDS cost function*

$$\ln e(p,u) = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2}\sum_k \sum_j \gamma^*_{kj} \ln p_k \ln p_j + u\beta_0 \prod_k p_k^{\beta_k}, \tag{5.20}$$

where α_0, α_k, β_0, β_k and γ^*_{kj} are parameters. The subsistence cost $\ln a(p)$ is a translog function of prices, and the gap between bliss and subsistence, $\ln b - \ln a$, is a Cobb-Douglas function of prices. According to Deaton and Muellbauer (1980a, p. 313), the choice is governed partly by the need for flexibility, and mainly by the desirable properties of the demand functions it generates. At unit prices and $u = 0$ expenditure is e^{α_0}, so e^{α_0} is the outlay needed for subsistence when all prices equal one.

Proposition 5.16 (Homogeneity of the AIDS cost function)**.** *Let* $\gamma_{kj} = \frac{1}{2}(\gamma^*_{kj} + \gamma^*_{jk})$. *The function* (5.20) *is homogeneous of degree one in* p *for all* u *if and only if*

$$\sum_k \alpha_k = 1, \qquad \sum_j \gamma_{kj} = 0 \ \text{for every } k, \qquad \sum_k \beta_k = 0. \tag{5.21}$$

In particular, the conditions $\sum_j \gamma^*_{kj} = \sum_k \gamma^*_{kj} = 0$ *stated by Deaton and Muellbauer (1980a, p. 313), together with* $\sum_k \alpha_k = 1$ *and* $\sum_k \beta_k = 0$, *are sufficient.*

Proof. The quadratic form depends on γ^* only through its symmetric part, because for any vector x

$$\sum_k \sum_j \gamma^*_{kj} x_k x_j = \sum_k \sum_j \gamma_{kj} x_k x_j.$$

Write $\ell = \ln \lambda$ and $R_k = \sum_j \gamma_{kj}$. Replace $\ln p_k$ by $\ln p_k + \ell$ in (5.20) and subtract $\ln e(p,u) + \ell$. The linear part contributes $\big(\sum_k \alpha_k - 1\big)\ell$. The quadratic part contributes

$$\frac{1}{2}\sum_k \sum_j \gamma_{kj}\big[(\ln p_k + \ell)(\ln p_j + \ell) - \ln p_k \ln p_j\big] = \ell \sum_k R_k \ln p_k + \frac{1}{2}\ell^2 \sum_k R_k,$$

where we used the symmetry of γ to combine the two cross terms. The last term contributes $u\beta_0 \prod_k p_k^{\beta_k}\big(\lambda^{\sum_k \beta_k} - 1\big)$. Under (5.21) every contribution vanishes, which proves sufficiency. For necessity, the total must vanish for all λ, p and u. At $u = 0$ and unit prices it equals $\big(\sum_k \alpha_k - 1\big)\ell + \frac{1}{2}\ell^2 \sum_k R_k$, so $\sum_k \alpha_k = 1$ and $\sum_k R_k = 0$. At $u = 0$ and arbitrary prices it then equals $\ell \sum_k R_k \ln p_k$, so every $R_k = 0$. At $u > 0$ the remaining term forces $\lambda^{\sum_k \beta_k} = 1$ for all λ, that is, $\sum_k \beta_k = 0$. The stated conditions on γ^* imply $R_k = \frac{1}{2}\big(\sum_j \gamma^*_{kj} + \sum_j \gamma^*_{jk}\big) = 0$. □

Remark 5.17 (Two normalizations). The expenditure function depends on u and β_0 only through their product $u\beta_0$. Replacing u by $\frac{u}{c}$ and β_0 by $c\beta_0$ for any $c > 0$ changes nothing observable, because it only rescales utility. Since utility is ordinal, we may set $\beta_0 = 1$, and we do so in numerical work. The expenditure function increases in u only if $\beta_0 > 0$. The second normalization concerns curvature in utility. Because $\ln e$ is linear in u, the AIDS sets $\frac{\partial^2 \ln e}{\partial u^2} = 0$ everywhere. Deaton and Muellbauer (1980a, p. 313) point out that this costs no generality, because an ordinal normalization of utility can always set this derivative to zero at a point.

A parameter count shows that the AIDS cost function has just enough parameters to be flexible. Consider an arbitrary expenditure function and a point (p^0, u^0). Its value, its J price derivatives and its derivative in u make $J + 2$ numbers. Its second derivatives add $\frac{J(J+1)}{2}$ distinct price terms, J cross terms in p and u, and one term in u, for a total of $\frac{J(J+1)}{2} + 2J + 3$. Homogeneity of degree one imposes Euler's equation on the value, on the first price derivatives and on the derivative in u, which removes $J + 2$ of them. That leaves $\frac{(J+1)(J+2)}{2}$ free numbers. The AIDS has α_0, $J - 1$ free α_k, $\frac{J(J-1)}{2}$ free γ_{kj}, $J - 1$ free β_k and β_0, which is $\frac{J(J+3)}{2}$ parameters. The difference

is exactly one, the second derivative in u, which the ordinal normalization of Remark 5.17 absorbs. A count is necessary but not sufficient for flexibility. Proposition 5.23 proves the corresponding property for demands by construction.

5.3.3 Deriving the share equations

We derive the budget shares in six steps.

Step 1. Shephard's lemma in share form gives the shares. By (5.8), the budget share of good i is the derivative of (5.20) with respect to $\ln p_i$ (Deaton and Muellbauer, 1980a, eq. 5):

$$w_i = \frac{\partial \ln e(p,u)}{\partial \ln p_i}.$$

Step 2. We differentiate the translog part. The linear term contributes α_i. In the quadratic term, $\ln p_i$ appears once as $\ln p_k$ (when $k=i$) and once as $\ln p_j$ (when $j=i$):

$$\frac{\partial}{\partial \ln p_i}\Big[\frac{1}{2}\sum_k\sum_j \gamma^*_{kj}\ln p_k \ln p_j\Big] = \frac{1}{2}\sum_j \gamma^*_{ij}\ln p_j + \frac{1}{2}\sum_k \gamma^*_{ki}\ln p_k = \sum_j \gamma_{ij}\ln p_j,$$

where

$$\gamma_{ij} = \frac{1}{2}\big(\gamma^*_{ij} + \gamma^*_{ji}\big) \tag{5.22}$$

is equation (7) of Deaton and Muellbauer (1980a). The coefficients γ_{ij} that enter the share equations are symmetric by construction when the system is derived from the cost function.

Step 3. We differentiate the Cobb-Douglas part. Write the product as an exponential and differentiate:

$$\frac{\partial}{\partial \ln p_i}\prod_k p_k^{\beta_k} = \frac{\partial}{\partial \ln p_i}\exp\Big(\sum_k \beta_k \ln p_k\Big) = \beta_i \prod_k p_k^{\beta_k}.$$

Step 4. Collecting the three pieces gives the shares as functions of prices and utility (Deaton and Muellbauer, 1980a, eq. 6):

$$w_i(p,u) = \alpha_i + \sum_j \gamma_{ij}\ln p_j + \beta_i u \beta_0 \prod_k p_k^{\beta_k}. \tag{5.23}$$

Step 5. We now solve for indirect utility. Define the *translog price index*

$$\ln \mathbf{P}(p) = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2}\sum_k\sum_j \gamma_{kj}\ln p_k \ln p_j, \tag{5.24}$$

which is equation (9) of Deaton and Muellbauer (1980a). By the first step of the proof of Proposition 5.16, $\ln \mathbf{P}(p) = \ln a(p)$, so the price index is the subsistence cost. Write

$$B(p) = \beta_0 \prod_k p_k^{\beta_k} = \ln b(p) - \ln a(p) \tag{5.25}$$

for the Cobb-Douglas part of the cost function. The cost function becomes $\ln e(p,u) = \ln \mathbf{P}(p) + u\,B(p)$. A utility-maximizing consumer spends $e(p,u) = I$. Solving for u gives the indirect utility function

$$v(p,I) = \frac{\ln I - \ln \mathbf{P}(p)}{B(p)}. \tag{5.26}$$

Step 6. We obtain the Marshallian shares. At $u = v(p, I)$, the last term of (5.23) equals $\beta_i u B(p) = \beta_i\big(\ln I - \ln \mathbf{P}\big)$. The AIDS demand functions in budget share form are therefore

$$w_i = \alpha_i + \sum_{j=1}^{J} \gamma_{ij} \ln p_j + \beta_i \ln \frac{I}{\mathbf{P}}, \qquad i = 1, \ldots, J, \tag{5.27}$$

which is equation (8) of Deaton and Muellbauer (1980a).

Roy's identity gives the same result from (5.26), which is a useful check. By Step 3, $\frac{\partial B}{\partial \ln p_i} = \beta_i B$. Then $\frac{\partial v}{\partial \ln I} = \frac{1}{B}$ and

$$\frac{\partial v}{\partial \ln p_i} = -\frac{1}{B}\frac{\partial \ln \mathbf{P}}{\partial \ln p_i} - \frac{\ln I - \ln \mathbf{P}}{B}\beta_i.$$

The share form of (5.9) gives $w_i = \frac{\partial \ln \mathbf{P}}{\partial \ln p_i} + \beta_i \ln \frac{I}{\mathbf{P}}$. Step 2 applied to (5.24) gives $\frac{\partial \ln \mathbf{P}}{\partial \ln p_i} = \alpha_i + \sum_j \gamma_{ij} \ln p_j$, which reproduces (5.27).

The parameters have simple interpretations (Deaton and Muellbauer, 1980a, p. 314). When relative prices and real expenditure $\frac{I}{\mathbf{P}}$ do not change, the budget shares are constant. This is the natural starting point for predictions with the model. Changes in relative prices work through the γ_{ij}. Each γ_{ij} is 100 times the change in the budget share of good i caused by a one percent rise in p_j with $\frac{I}{\mathbf{P}}$ held constant. The factor 100 appears because such a rise increases $\ln p_j$ by about 0.01. Changes in real expenditure work through the β_i, which sum to zero. They are positive for luxuries and negative for necessities, as (5.37) below confirms. Real expenditure is measured relative to the subsistence cost $\mathbf{P}(p) = a(p)$. The price index depends on the parameters α_0, α_k and γ_{kj}, which makes the system nonlinear in its parameters. Section 5.6 discusses how to estimate it, including the common approximation of $\mathbf{P}$ by a price index computed from data.

Remark 5.18 (From Engel curves to the AIDS). Deaton and Muellbauer (1980b, §3.4, pp. 75–77) reach the AIDS from the data side. Budget studies support the *Working-Leser* Engel curve, in which the budget share is linear in the log budget, $w_i = \tilde{\alpha}_i + \tilde{\beta}_i \ln I$ at fixed prices (their eq. 4.1, Working, 1943; Leser, 1963). To use it on time series, the coefficients must become functions of prices in a way consistent with preferences. Any expenditure function of the form

$$\ln e(p, u) = A(p) + u\, B(p)$$

does this (their eq. 4.2). Write $A_i = \frac{\partial A}{\partial \ln p_i}$ and $B_i = \frac{\partial B}{\partial \ln p_i}$. Shephard's lemma in share form gives $w_i = A_i(p) + u\, B_i(p)$. Inverting $\ln I = A(p) + uB(p)$ gives $u = \frac{\ln I - A(p)}{B(p)}$. Substituting,

$$w_i = \left[A_i(p) - \frac{B_i(p)}{B(p)} A(p)\right] + \frac{B_i(p)}{B(p)} \ln I,$$

which has the Working-Leser form at every price vector. The AIDS chooses $A(p)$ translog and $B(p) = \beta_0 \prod_k p_k^{\beta_k}$, as in their eqs. (4.3)–(4.4). Then $\frac{B_i}{B} = \beta_i$ is constant, $A_i = \alpha_i + \sum_j \gamma_{ij} \ln p_j$, and the display becomes (5.27). The book's $A(p)$ is the article's $\ln a(p)$, and its $B(p)$ is the article's $\ln b(p) - \ln a(p)$, which is (5.25). The two derivations therefore describe the same model. The book also states the negativity condition with a matrix C, its eq. (4.12), which is our K of (5.32). It stresses that the matrix $[\gamma_{ij}]$ itself need not be negative semidefinite (p. 76).

5.3.4 Restrictions from consumer theory

Suppose we take the share equations (5.27) with the index (5.24) as a maintained hypothesis, with unrestricted coefficients γ_{ij}, as Deaton and Muellbauer (1980a, p. 316) do. The next proposition states which linear restrictions make the system consistent with demand theory.

Proposition 5.19 (Adding up, homogeneity and symmetry)**.** *Consider* (5.27) *and* (5.24).

(i) The shares sum to one at all (p, I) *if and only if*

$$\sum_i \alpha_i = 1, \qquad \sum_i \gamma_{ij} = 0 \ \text{for every } j, \qquad \sum_i \beta_i = 0. \tag{5.28}$$

(ii) Given (5.28)*, demands are homogeneous of degree zero in* (p, I) *if and only if*

$$\sum_j \gamma_{ij} = 0 \ \text{for every } i. \tag{5.29}$$

(iii) Given (5.28) *and* (5.29)*, the Slutsky matrix is symmetric at all* (p, I) *if and only if*

$$\gamma_{ij} = \gamma_{ji} \ \text{for all } i, j. \tag{5.30}$$

Proof. (i) Sum (5.27) over i:

$$\sum_i w_i = \sum_i \alpha_i + \sum_j \Big(\sum_i \gamma_{ij} \Big) \ln p_j + \Big(\sum_i \beta_i \Big) \ln \frac{I}{\mathbf{P}}.$$

Given p, the term $\ln I$ varies freely, so the sum equals one for all I only if $\sum_i \beta_i = 0$. Then $\sum_j \big(\sum_i \gamma_{ij} \big) \ln p_j = 1 - \sum_i \alpha_i$ for all log prices, which requires every coefficient to vanish and the constant to be zero. The converse is immediate.

(ii) Write $\ell = \ln \lambda$ and $R_i = \sum_j \gamma_{ij}$. Because (5.28) makes the column sums of γ zero and $\sum_k \alpha_k = 1$, the computation in the proof of Proposition 5.16 gives $\ln \mathbf{P}(\lambda p) = \ln \mathbf{P}(p) + \ell + \frac{1}{2}\ell \sum_k R_k \ln p_k + \frac{1}{2}\ell^2 \sum_k R_k$. Hence

$$w_i(\lambda p, \lambda I) - w_i(p, I) = \ell R_i - \beta_i \Big[\frac{1}{2} \ell \sum_k R_k \ln p_k + \frac{1}{2} \ell^2 \sum_k R_k \Big].$$

If every $R_k = 0$, the difference vanishes. Conversely, at unit prices the difference is $\ell R_i - \frac{1}{2}\beta_i \ell^2 \sum_k R_k$, and it vanishes for all λ only if $R_i = 0$.

(iii) Let $\gamma^s_{jk} = \frac{1}{2}(\gamma_{jk} + \gamma_{kj})$ and $r = \ln \frac{I}{\mathbf{P}}$. Then $\frac{\partial w_i}{\partial \ln I} = \beta_i$, $\frac{\partial \ln \mathbf{P}}{\partial \ln p_j} = \alpha_j + \sum_k \gamma^s_{jk} \ln p_k$, and $\frac{\partial w_i}{\partial \ln p_j} = \gamma_{ij} - \beta_i \frac{\partial \ln \mathbf{P}}{\partial \ln p_j}$. Using $w_j = \alpha_j + \sum_k \gamma_{jk} \ln p_k + \beta_j r$, the first two terms of (5.10) are

$$\frac{\partial w_i}{\partial \ln p_j} + w_j \frac{\partial w_i}{\partial \ln I} = \gamma_{ij} + \beta_i \beta_j r + \beta_i \sum_k \big(\gamma_{jk} - \gamma^s_{jk} \big) \ln p_k.$$

The remaining terms of (5.10), $w_i w_j - \mathbf{1}(i = j) w_i$, are symmetric in (i, j). Under (5.30) the last sum vanishes and $k_{ij} = \gamma_{ij} + \beta_i \beta_j r + w_i w_j - \mathbf{1}(i = j) w_i$ is symmetric, so $S_{ij} = \frac{I\, k_{ij}}{p_i p_j}$ is symmetric. Conversely, at unit prices the expression reduces to $\gamma_{ij} + \beta_i \beta_j r$, which is symmetric only if $\gamma_{ij} = \gamma_{ji}$. □

These are equations (10) to (12) of Deaton and Muellbauer (1980a, p. 314). All three sets are linear in the parameters and do not involve the data, so they can be imposed globally by standard methods. They differ in how they can be tested (Deaton and Muellbauer, 1980a, p. 316). Adding up cannot be tested on share data, because observed shares add up to one by construction and the estimated parameters satisfy (5.28) automatically. Homogeneity involves the parameters of a single equation and can be tested equation by equation. Symmetry links the parameters of two equations and can only be tested in a system. Section 5.6.6 carries out these tests.

5.3.5 Negativity

Concavity of the expenditure function is the fourth restriction, and it is of a different kind.

Proposition 5.20 (Negativity of the AIDS)**.** *Under* (5.28), (5.29) *and* (5.30), *the Slutsky terms of the AIDS satisfy*

$$\frac{\partial h_i(p,u)}{\partial p_j} = \frac{e(p,u)}{p_i p_j}\left[\frac{\partial w_i(p,u)}{\partial \ln p_j} + w_i w_j - \mathbf{1}(i=j)w_i\right], \tag{5.31}$$

where $w_i(p,u)$ *is the Hicksian share* (5.23). *The matrix* $K = [k_{ij}]$ *with* $k_{ij} = \frac{p_i p_j S_{ij}}{I}$ *equals*

$$k_{ij} = \gamma_{ij} + \beta_i\beta_j \ln\frac{I}{\mathbf{P}} - \mathbf{1}(i=j)w_i + w_i w_j, \tag{5.32}$$

and its eigenvalues have the same signs as those of S. *The AIDS satisfies negativity at* (p, I) *if and only if* K *is negative semidefinite there.*

Proof. By Shephard's lemma and (5.8), $h_i = \frac{w_i(p,u)e(p,u)}{p_i}$. Differentiate with respect to p_j by the product rule:

$$\frac{\partial h_i}{\partial p_j} = \frac{e}{p_i}\frac{\partial w_i}{\partial p_j} + \frac{w_i}{p_i}\frac{\partial e}{\partial p_j} - \mathbf{1}(i=j)\frac{w_i e}{p_i^2}.$$

Substitute $\frac{\partial w_i}{\partial p_j} = \frac{1}{p_j}\frac{\partial w_i}{\partial \ln p_j}$ and $\frac{\partial e}{\partial p_j} = h_j = \frac{w_j e}{p_j}$, and factor out $\frac{e}{p_i p_j}$ to obtain (5.31). For the AIDS, differentiating (5.23) and using Step 3 gives

$$\frac{\partial w_i(p,u)}{\partial \ln p_j} = \gamma_{ij} + \beta_i\beta_j u\beta_0 \prod_k p_k^{\beta_k} = \gamma_{ij} + \beta_i\beta_j \ln\frac{I}{\mathbf{P}},$$

where the second equality evaluates at $u = v(p, I)$. Multiplying (5.31) by $\frac{p_i p_j}{I}$ with $e = I$ gives (5.32). Finally, $K = \frac{1}{I}DSD$ with $D = \operatorname{diag}(p_1, \ldots, p_J)$ nonsingular. By Sylvester's law of inertia, congruent symmetric matrices have the same numbers of positive, negative and zero eigenvalues. □

Equation (5.32) is equation (14) of Deaton and Muellbauer (1980a, p. 316). It agrees with the general formula (5.10), as the proof of Proposition 5.19 showed. Three features matter in practice. First, the rows of K sum to zero: $\sum_j k_{ij} = \sum_j \gamma_{ij} + \beta_i \ln\frac{I}{\mathbf{P}}\sum_j \beta_j - w_i + w_i\sum_j w_j = 0$. This is the share-form counterpart of $Sp = 0$. One eigenvalue of K is therefore identically zero, and negativity requires the other $J-1$ eigenvalues to be nonpositive. Second, K depends on the data point through the shares and through $\ln\frac{I}{\mathbf{P}}$. As with other flexible forms, no restriction on the parameters alone can guarantee negativity (Deaton and Muellbauer, 1980a, p. 316). Negativity can be checked observation by observation by computing the eigenvalues of K at

the estimates. It can also be imposed at a single point. We write K at that point as $-LL^\top$, with L lower triangular, and estimate the elements of L in place of the γ_{ij} (Lau, 1978; Moschini, 1999). Third, part (f) of Proposition 5.9 gives $\varepsilon^h_{ij} = \frac{k_{ij}}{w_i}$, so that for $i \neq j$

$$\varepsilon^h_{ij} = \frac{\gamma_{ij} + \beta_i \beta_j \ln \frac{I}{\mathbf{P}}}{w_i} + w_j. \tag{5.33}$$

When $\beta_i \beta_j \ln \frac{I}{\mathbf{P}} + w_i w_j$ is small relative to γ_{ij}, the coefficient γ_{ij} has the sign of the compensated cross-price elasticity. This is the approximation that Deaton and Muellbauer (1980a, p. 315) invoke when they suggest using prior beliefs about substitutes and complements to restrict individual γ_{ij}.

5.3.6 Elasticities

The elasticities follow from three derivatives of the Marshallian shares. Throughout, write $r = \ln \frac{I}{\mathbf{P}}$ and impose (5.28), (5.29) and (5.30). The derivative with respect to log income is

$$\frac{\partial w_i}{\partial \ln I} = \beta_i. \tag{5.34}$$

Differentiating the translog index as in Step 2 and using the share equation for good j gives

$$\frac{\partial \ln \mathbf{P}}{\partial \ln p_j} = \alpha_j + \sum_k \gamma_{jk} \ln p_k = w_j - \beta_j r. \tag{5.35}$$

The derivative with respect to a log price therefore has two equivalent forms:

$$\frac{\partial w_i}{\partial \ln p_j} = \gamma_{ij} - \beta_i \Big(\alpha_j + \sum_k \gamma_{jk} \ln p_k \Big) = \gamma_{ij} - \beta_i \big(w_j - \beta_j r \big). \tag{5.36}$$

To convert share derivatives into elasticities, write $q_i = \frac{w_i I}{p_i}$, so that $\ln q_i = \ln w_i + \ln I - \ln p_i$. Differentiating with respect to $\ln I$ gives the expenditure elasticity

$$\eta_i = 1 + \frac{1}{w_i} \frac{\partial w_i}{\partial \ln I} = 1 + \frac{\beta_i}{w_i}. \tag{5.37}$$

A good is a luxury ($\eta_i > 1$) if and only if $\beta_i > 0$, and a necessity if and only if $\beta_i < 0$. Differentiating with respect to $\ln p_j$ gives the Marshallian price elasticity

$$\varepsilon_{ij} = -\mathbf{1}(i = j) + \frac{1}{w_i} \frac{\partial w_i}{\partial \ln p_j} = -\mathbf{1}(i = j) + \frac{\gamma_{ij} - \beta_i \big(w_j - \beta_j \ln \frac{I}{\mathbf{P}} \big)}{w_i}. \tag{5.38}$$

The Slutsky equation of Proposition 5.9(a) gives the Hicksian elasticity. Adding $\eta_i w_j = w_j + \frac{\beta_i w_j}{w_i}$ to (5.38), the terms in $\beta_i w_j$ cancel:

$$\varepsilon^h_{ij} = \varepsilon_{ij} + \eta_i w_j = -\mathbf{1}(i = j) + w_j + \frac{\gamma_{ij} + \beta_i \beta_j \ln \frac{I}{\mathbf{P}}}{w_i}. \tag{5.39}$$

This agrees with $\varepsilon^h_{ij} = \frac{k_{ij}}{w_i}$ from (5.32). Note that (5.38) uses the derivative of the exact index (5.35). Approximating that derivative by w_j, as is common when $\mathbf{P}$ is replaced by a data index, changes the formula. We return to this point in Section 5.6.4.

The elasticities satisfy the identities of Proposition 5.9 under the restrictions. Engel aggregation holds because $\sum_i w_i\eta_i = \sum_i w_i + \sum_i \beta_i = 1$. Cournot aggregation holds because

$$\sum_i w_i\varepsilon_{ij} = -w_j + \sum_i \gamma_{ij} - \big(w_j - \beta_j r\big)\sum_i \beta_i = -w_j,$$

using the adding-up restrictions on γ and β. Homogeneity holds because

$$\sum_j \varepsilon_{ij} + \eta_i = -1 + \frac{1}{w_i}\Big[\sum_j \gamma_{ij} - \beta_i \sum_j \alpha_j - \beta_i \sum_k \Big(\sum_j \gamma_{jk}\Big)\ln p_k\Big] + 1 + \frac{\beta_i}{w_i} = 0,$$

where $\sum_j \gamma_{ij} = 0$ by homogeneity, and $\sum_j \alpha_j = 1$ and $\sum_j \gamma_{jk} = 0$ by adding up. Symmetry holds because $w_i\varepsilon^h_{ij} = k_{ij}$ and K is symmetric.

Example 5.21 (The running example)**.** We use one numerical AIDS throughout the chapter. There are three goods, with $\alpha_0 = 0$, $\alpha = (0.5, 0.3, 0.2)$, $\beta = (-0.10, 0.04, 0.06)$ and

$$\Gamma = [\gamma_{ij}] = \begin{pmatrix} -0.20 & 0.12 & 0.08 \\ 0.12 & -0.22 & 0.10 \\ 0.08 & 0.10 & -0.18 \end{pmatrix}.$$

The parameters satisfy adding up, homogeneity and symmetry, since $\sum_i \alpha_i = 1$, $\sum_i \beta_i = 0$, and Γ is symmetric with zero row and column sums. Evaluate the system at $p = (1, 1, 1)$ and $\ln I = 1$. All log prices are zero, so $\ln \mathbf{P} = \alpha_0 = 0$ and $\ln \frac{I}{\mathbf{P}} = 1$. The shares are $w_i = \alpha_i + \beta_i$, that is, $w = (0.40, 0.34, 0.26)$. Good 1 is a necessity, with $\eta_1 = 1 - \frac{0.10}{0.40} = 0.75$, and goods 2 and 3 are luxuries. For the own-price elasticity of good 1, (5.38) gives

$$\varepsilon_{11} = -1 + \frac{-0.20 - (-0.10)\big(0.40 - (-0.10)(1)\big)}{0.40} = -1 + \frac{-0.15}{0.40} = -1.375,$$

and the Hicksian elasticity is $\varepsilon^h_{11} = -1.375 + 0.75 \times 0.40 = -1.075$. The diagonal element of K is $k_{11} = -0.20 + 0.01 - 0.40 + 0.16 = -0.43$, and indeed $\frac{k_{11}}{w_1} = -1.075$. Table 5.2 reports the full matrices, computed with the script `figures/ch05/src/aids_example.py`. The identities hold to rounding. For the first column, Cournot aggregation gives $0.40(-1.375) + 0.34(0.294) + 0.26(0.192) = -0.40 = -w_1$. For the first row, homogeneity gives $-1.375+0.375+0.250+0.750 = 0$. Symmetry gives $w_1\varepsilon^h_{12} = 0.40 \times 0.630 = 0.252 = 0.34 \times 0.741 = w_2\varepsilon^h_{21}$. The nonzero eigenvalues of K are -0.689 and -0.552, so the cost function is concave at this point.

5.3.7 Flexibility

Deaton and Muellbauer (1980a, p. 315) claim that the AIDS demand functions are first-order approximations to any demand system, whether or not that system comes from utility maximization. We make the claim precise and prove it by construction. A preliminary fact lets us work at unit prices.

Lemma 5.22 (Units of measurement)**.** *Let Γ be symmetric, and measure good k in new units, so that $\ln p_k = \ln \tilde{p}_k + c_k$ for constants c_k. The AIDS in the new prices has the same γ_{ij} and β_i, and the parameters*

$$\tilde{\alpha}_k = \alpha_k + \sum_j \gamma_{kj}c_j, \qquad \tilde{\alpha}_0 = \alpha_0 + \sum_k \alpha_k c_k + \frac{1}{2}\sum_k\sum_j \gamma_{kj}c_k c_j.$$

These parameters satisfy (5.28), (5.29) and (5.30) whenever the original ones do.

Table 5.2: The running example at $p = (1, 1, 1)$ and $\ln I = 1$

A. Parameters, budget shares and expenditure elasticities ($\alpha_0 = 0$)

Good i	α_i	β_i	γ_{i1}	γ_{i2}	γ_{i3}	w_i	η_i
1	0.50	−0.10	−0.20	0.12	0.08	0.400	0.750
2	0.30	0.04	0.12	−0.22	0.10	0.340	1.118
3	0.20	0.06	0.08	0.10	−0.18	0.260	1.231

B. Price elasticities and the negativity matrix (row i, price j)

	Marshallian ε_{ij}			Hicksian ε^h_{ij}			k_{ij}, equation (5.32)		
Good i	$j=1$	$j=2$	$j=3$	$j=1$	$j=2$	$j=3$	$j=1$	$j=2$	$j=3$
1	−1.375	0.375	0.250	−1.075	0.630	0.445	−0.430	0.252	0.178
2	0.294	−1.682	0.271	0.741	−1.302	0.561	0.252	−0.443	0.191
3	0.192	0.315	−1.738	0.685	0.734	−1.418	0.178	0.191	−0.369
Eigenvalues of K							−0.689	−0.552	0.000

Notes: Elasticities are signed and computed from (5.37), (5.38) and (5.39). The script `figures/ch05/src/aids_example.py` also checks every analytic elasticity against numerical derivatives of the demand functions, with a maximum discrepancy below 10^{-9}.

Proof. Substitute $\ln p_k = \ln \tilde{p}_k + c_k$ into (5.24) and expand the quadratic term, using the symmetry of Γ to combine the two cross terms:

$$\ln \mathbf{P} = \left[\alpha_0 + \sum_k \alpha_k c_k + \frac{1}{2}\sum_k \sum_j \gamma_{kj} c_k c_j\right] + \sum_k \left(\alpha_k + \sum_j \gamma_{kj} c_j\right) \ln \tilde{p}_k + \frac{1}{2}\sum_k \sum_j \gamma_{kj} \ln \tilde{p}_k \ln \tilde{p}_j.$$

This is the translog index in the new prices with parameters $\tilde{\alpha}_0$ and $\tilde{\alpha}_k$. In the share equation, $\alpha_i + \sum_j \gamma_{ij} \ln p_j = \tilde{\alpha}_i + \sum_j \gamma_{ij} \ln \tilde{p}_j$, and income is unaffected. Hence every share is the same function of the data in either set of units. Finally, $\sum_k \tilde{\alpha}_k = \sum_k \alpha_k + \sum_j c_j \sum_k \gamma_{kj} = 1$ under adding up, and Γ is unchanged. □

Fitted shares and elasticities therefore do not depend on the units in which goods are measured. Given any point (p^0, I^0), we can choose units so that $p^0 = (1, \ldots, 1)$. We state the flexibility result at such a point.

Proposition 5.23 (First-order flexibility)**.** *Fix a point (p^0, I^0) with $p^0 = (1, \ldots, 1)$. Let w^0 be any vector of positive budget shares that sum to one, let b_i be any numbers with $\sum_i b_i = 0$, and let c_{ij} be any numbers with $\sum_i c_{ij} = 0$ for every j.*

(i) There are AIDS parameters satisfying (5.28) such that, at (p^0, I^0), $w_i = w_i^0$, $\frac{\partial w_i}{\partial \ln I} = b_i$ and $\frac{\partial w_i}{\partial \ln p_j} = c_{ij}$.

(ii) If in addition $\sum_j c_{ij} + b_i = 0$ for every i (homogeneity) and $c_{ij} + b_i w_j^0$ is symmetric in (i, j) (Slutsky symmetry), the parameters also satisfy (5.29) and (5.30).

Proof. At unit prices all log prices are zero, so $\ln \mathbf{P}(p^0) = \alpha_0$ and $\frac{\partial \ln \mathbf{P}}{\partial \ln p_j} = \alpha_j$ there, whether or not Γ is symmetric. Choose any real number r^0, which will be the value of $\ln \frac{I^0}{\mathbf{P}(p^0)}$. Set

$$\beta_i = b_i, \qquad \alpha_j = w_j^0 - b_j r^0, \qquad \gamma_{ij} = c_{ij} + b_i \alpha_j = c_{ij} + b_i w_j^0 - b_i b_j r^0, \qquad \alpha_0 = \ln I^0 - r^0.$$

At (p^0, I^0), the share of good i is $\alpha_i + \beta_i r^0 = w_i^0$ and its income derivative is $\beta_i = b_i$. Its price derivative is $\gamma_{ij} - \beta_i \frac{\partial \ln \mathbf{P}}{\partial \ln p_j} = \gamma_{ij} - b_i \alpha_j = c_{ij}$.

For the restrictions in (i), $\sum_i \beta_i = \sum_i b_i = 0$, $\sum_i \gamma_{ij} = \sum_i c_{ij} + \alpha_j \sum_i b_i = 0$, and $\sum_j \alpha_j = \sum_j w_j^0 - r^0 \sum_j b_j = 1$. For (ii), $\sum_j \gamma_{ij} = \sum_j c_{ij} + b_i \sum_j w_j^0 - b_i r^0 \sum_j b_j = \sum_j c_{ij} + b_i = 0$. The term $b_i b_j r^0$ is symmetric, so γ_{ij} is symmetric whenever $c_{ij} + b_i w_j^0$ is. □

The conditions on (w^0, b, c) are exactly the restrictions that any demand system consistent with utility maximization satisfies at a point. Adding up implies $\sum_i w_i = 1$, $\sum_i b_i = 0$ and $\sum_i c_{ij} = 0$. Homogeneity of degree zero implies $\sum_j c_{ij} + b_i = 0$. By (5.10), Slutsky symmetry is the symmetry of $c_{ij} + b_i w_j$, since the other terms of k_{ij} are symmetric. Part (ii) therefore says that the restricted AIDS can match the shares and the first derivatives of any utility-consistent demand system at a point. Part (i) says that the AIDS without homogeneity and symmetry can match any demand system, derived from theory or not. This second property matters for testing. Tests of homogeneity and symmetry are then "set within a maintained hypothesis which makes sense and would be widely accepted in its own right" (Deaton and Muellbauer, 1980a, p. 315). The construction also shows that one parameter, r^0 or equivalently α_0, is left free. This foreshadows the difficulty of identifying α_0 in practice (Section 5.6).

The count behind the proposition is worth stating. A utility-consistent demand system has $J-1$ free shares, $J-1$ free income derivatives and $\frac{J(J-1)}{2}$ free Slutsky terms at a point. The restricted AIDS has $J-1$ free α_i, $J-1$ free β_i and $\frac{J(J-1)}{2}$ free γ_{ij}. The two counts coincide, so the theoretical restrictions remove as many free derivatives as free parameters.

5.3.8 Engel curves and rank

An *Engel curve* gives the budget share, or the expenditure, on a good as a function of total expenditure at fixed prices. For the AIDS, collect the price terms in $\zeta_i(p) = \alpha_i + \sum_j \gamma_{ij} \ln p_j - \beta_i \ln \mathbf{P}(p)$. Then

$$w_i = \zeta_i(p) + \beta_i \ln I, \qquad p_i q_i = \zeta_i(p)\, I + \beta_i\, I \ln I. \tag{5.40}$$

Deaton and Muellbauer (1980a, p. 317) give the expenditure form in their discussion of budget studies. Expenditure on good i is linear in I only when $\beta_i = 0$. Its second derivative is $\frac{\beta_i}{I}$, so spending is convex in income for luxuries and concave for necessities. The share form is the Engel curve of Working (1943). Leser (1963) recommended it as an excellent fit to cross-section data in a wide range of circumstances (Deaton and Muellbauer, 1980a, p. 317). Before the AIDS, aggregation in time-series models seemed to require linear Engel curves, while cross-section studies typically found them nonlinear. The AIDS reconciles the two, because it aggregates with Engel curves of the Working-Leser form.

The flexibility of Engel curves is measured by the rank of the demand system.

Definition 5.24 (Rank)**.** The *rank* of a demand system is the largest dimension, over price vectors p, of the space of functions of income spanned by its Engel curves $w_1(p, \cdot), \ldots, w_J(p, \cdot)$ (Lewbel, 1991).

Homothetic demand, such as the CES, has rank one, because shares do not depend on income. By (5.40), every AIDS share lies in the span of the functions 1 and $\ln I$, so the AIDS has rank two whenever some $\beta_i \neq 0$. The general PIGLOG share (5.17) is also rank two. Gorman (1981) proved a ceiling for a broad class of systems. If every share is a linear

combination $w_i = \sum_r c_{ir}(p) g_r(I)$ of functions of income and the system is consistent with utility maximization, then the rank is at most three.

Banks et al. (1997) use the third dimension. Their quadratic AIDS (QUAIDS) adds a term in $\big(\ln \frac{I}{\mathbf{P}}\big)^2$ to each share equation, motivated by evidence from household surveys that the Engel curves of some goods bend in log expenditure.

Proposition 5.25 (Quadratic AIDS)**.** *Let* $\ln \mathbf{P}(p)$ *be the translog index* (5.24)*, let* $\lambda(p) = \sum_i \lambda_i \ln p_i$*, and let indirect utility be*

$$\ln V(p, I) = \left\{ \left[\frac{\ln I - \ln \mathbf{P}(p)}{\prod_k p_k^{\beta_k}} \right]^{-1} + \lambda(p) \right\}^{-1}. \tag{5.41}$$

Then the budget shares are

$$w_i = \alpha_i + \sum_j \gamma_{ij} \ln p_j + \beta_i \ln \frac{I}{\mathbf{P}} + \frac{\lambda_i}{\prod_k p_k^{\beta_k}} \Big[\ln \frac{I}{\mathbf{P}} \Big]^2, \tag{5.42}$$

and the expenditure elasticities are $\eta_i = 1 + \frac{1}{w_i}\Big[\beta_i + \frac{2\lambda_i}{\prod_k p_k^{\beta_k}} \ln \frac{I}{\mathbf{P}}\Big]$.

Proof. Write $\Pi(p) = \prod_k p_k^{\beta_k}$, $z = \frac{\ln I - \ln \mathbf{P}}{\Pi}$ and $\phi = \ln V = \big(z^{-1} + \lambda\big)^{-1}$. As noted after Proposition 5.7, we can apply Roy's identity to ϕ. Its derivatives are

$$\frac{\partial \phi}{\partial \ln p_i} = -\phi^2 \Big(- z^{-2} \frac{\partial z}{\partial \ln p_i} + \lambda_i \Big), \qquad \frac{\partial \phi}{\partial \ln I} = -\phi^2 \Big(- z^{-2} \frac{\partial z}{\partial \ln I} \Big).$$

The share form of Roy's identity gives, after cancelling $-\phi^2$ and multiplying through by z^2,

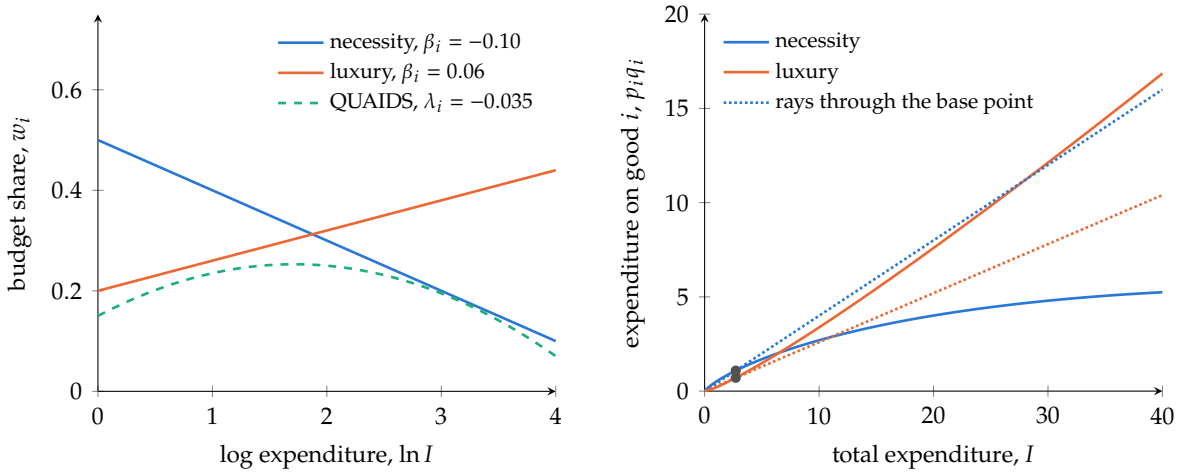
$$w_i = -\frac{\partial \phi}{\partial \ln p_i} \Big[\frac{\partial \phi}{\partial \ln I} \Big]^{-1} = \Big(- \frac{\partial z}{\partial \ln p_i} + \lambda_i z^2 \Big) \Big[\frac{\partial z}{\partial \ln I} \Big]^{-1}.$$

Now $\frac{\partial z}{\partial \ln I} = \frac{1}{\Pi}$. Using Step 2 and Step 3 of Section 5.3.3,

$$\frac{\partial z}{\partial \ln p_i} = -\frac{1}{\Pi} \Big(\alpha_i + \sum_j \gamma_{ij} \ln p_j \Big) - z \beta_i.$$

Substituting, the first term becomes $\alpha_i + \sum_j \gamma_{ij} \ln p_j + \beta_i \Pi z$, and the second term becomes $\lambda_i \Pi z^2$. Since $\Pi z = \ln \frac{I}{\mathbf{P}}$, this is (5.42). The elasticity follows from $\eta_i = 1 + \frac{1}{w_i} \frac{\partial w_i}{\partial \ln I}$. □

When every $\lambda_i = 0$, (5.41) reduces to the AIDS indirect utility (5.26) with $\beta_0 = 1$. Adding up and homogeneity now also require $\sum_i \lambda_i = 0$, so that the quadratic terms sum to zero across goods and $\lambda(p)$ is homogeneous of degree zero. At fixed prices, each QUAIDS share lies in the span of 1, $\ln I$ and $(\ln I)^2$, so the system has rank three, the maximum allowed by Gorman's theorem. A good with $\beta_i > 0$ and $\lambda_i < 0$ is a luxury at low expenditure and a necessity at high expenditure. Figure 5.2 draws the three cases.



(a) Budget shares

(b) Expenditure

Figure 5.2: Engel curves at unit prices. Panel (a) plots budget shares against $\ln I$ for good 1 of the running example (a necessity, $w_1 = 0.5 - 0.10 \ln I$), good 3 (a luxury, $w_3 = 0.2 + 0.06 \ln I$), and an illustrative QUAIDS good with $w = 0.15 + 0.12 \ln I - 0.035(\ln I)^2$. The QUAIDS share rises until $\ln I = \frac{0.12}{0.07} \approx 1.71$ and falls afterwards. Panel (b) plots the corresponding expenditures $p_i q_i = w_i I$ for the two AIDS goods. The dotted rays are the homothetic Engel curves through the base point $\ln I = 1$ (dots), where $w_1 = 0.40$ and $w_3 = 0.26$.

5.3.9 Why only almost ideal

Deaton and Muellbauer (1980a, p. 312) list six properties that together recommend the AIDS. It gives an arbitrary first-order approximation to any demand system (Proposition 5.23). It satisfies the axioms of choice exactly, given the restrictions (Proposition 5.19). It aggregates over consumers without invoking parallel linear Engel curves (Section 5.4). Its functional form is consistent with household budget data (Section 5.3.8). It is simple to estimate and largely avoids nonlinear estimation (Section 5.6.4). Finally, homogeneity and symmetry can be tested through linear restrictions on fixed parameters (Section 5.6.6). The Rotterdam and translog models each possess some of these properties, but neither possesses all of them at once. The authors themselves add that the system, particularly in its simple static form, is not to be regarded as "a fully satisfactory explanation of consumers' behavior" (Deaton and Muellbauer, 1980a, p. 312).

The system falls short of the ideal in five ways.

Concavity is not guaranteed. By Proposition 5.20, negativity depends on the data point and cannot be imposed by linear restrictions. Estimated systems often violate it at some observations. At unit prices the running example is concave over the whole range of $\ln I$ in which all its shares lie in $[0, 1]$, but this must be checked for every estimate.

Fitted shares can leave the unit interval. Shares are linear in $\ln I$ and quadratic in $\ln p$, and these variables are unbounded. For extreme prices or incomes the fitted shares become negative or exceed one, and the cost function then ceases to be a valid expenditure function. In the running example at unit prices, the share of good 1 is $0.5 - 0.10 \ln I$, which turns negative above $\ln I = 5$. The share of good 3 turns negative below $\ln I = -\frac{0.2}{0.06} \approx -3.33$. The appendix of Deaton and Muellbauer (1980a, p. 324) derives the corresponding restrictions on the admissible region of incomes and prices for the PIGLOG class.

There are many parameters. The matrix Γ has J^2 elements. Symmetry leaves $\frac{J(J+1)}{2}$, and

homogeneity removes J more, leaving

$$\frac{J(J+1)}{2} - J = \frac{J(J-1)}{2} \tag{5.43}$$

free price coefficients, about $\frac{1}{2}J^2$. Adding up then determines the last row of Γ from the others, and the α_i and β_i add $2(J-1)$ free parameters, plus α_0. With $J = 8$ groups the count gives 28 free γ_{ij} and 14 free α_i and β_i, the numbers that Deaton and Muellbauer (1980a, p. 318) report for their British application (Section 5.6.7). With $J = 100$ products the count of γ's is 4,950. Deaton and Muellbauer (1980a, p. 315) suggest setting individual γ_{ij} to zero when theory or evidence supports it. The share of each good in such a pair is then independent of the other's price at constant real expenditure. Setting every γ_{ij} to zero is too strong. The resulting model, $w_i = \alpha_i + \beta_i \ln \frac{I}{\mathbf{P}}$, was tested and rejected by Deaton (1978). The restrictions of Chaudhuri et al. (2006) in Section 5.9 follow the middle path.

Engel curves have rank two. Shares are linear in $\ln I$, so a good cannot switch from luxury to necessity as income grows. QUAIDS (Proposition 5.25) relaxes this.

The choke price can be finite. When the own share falls with $\ln p_i$, the demand for the good reaches zero at a finite price. This is not automatic. With $\beta_i = 0$ it requires $\gamma_{ii} < 0$. The food equation of Table 5.5 has $\gamma_{11} = 0.186$, and there the food share rises with the food price. In the running example, holding the other prices at one and income at $\ln I = 1$, the share of good 3 falls to zero at $p_3 \approx 4.10$. A finite virtual price lets the estimated own and cross effects determine the value of a good, instead of the functional form alone (Section 5.1.4). It also means that welfare calculations extrapolate the estimated demand curve well beyond the observed prices. Section 5.7.2 develops both sides of this feature.

Most of these limits are the price of a system that is linear enough to estimate and flexible enough to test. The rest of the chapter shows how applied work lives with them: by aggregating goods into groups and budgeting in stages, by instrumenting prices, and by checking curvature and extrapolation explicitly.

5.4 Aggregation across consumers

The AIDS of Section 5.3 describes the choices of a single consumer. Most data in industrial organization are aggregates: the sales of a product in a city and a month, or national spending on a group of goods in a year. This section asks when such aggregates behave as if one consumer had chosen them. The answer decides two things. It decides whether the share equations of (5.27) can be fitted to market data, and whether the welfare measures of Section 5.2.7, computed from the fitted system, describe anyone's welfare.

We index households by $h = 1, \ldots, H$. Household h has total expenditure I_h, demands q_{ih} and budget shares $w_{ih} = \frac{p_i q_{ih}}{I_h}$. All households face the same price vector p. Mean expenditure is $\bar{I} = \frac{1}{H}\sum_h I_h$. Hicksian demands keep the notation $h_i(p, u)$ of Section 5.2, always written with their arguments, so they cannot be confused with the household index.

5.4.1 The aggregation problem

Aggregate demand for good i is the sum of household demands,

$$Q_i(p, I_1, \ldots, I_H) = \sum_{h=1}^{H} q_{ih}(p, I_h). \tag{5.44}$$

In general it depends on the whole distribution of expenditure. To see why, transfer a small amount $\mathrm{d}t$ of expenditure from household h' to household h, holding total expenditure fixed. Aggregate demand changes by

$$\mathrm{d}Q_i = \left(\frac{\partial q_{ih}}{\partial I_h} - \frac{\partial q_{ih'}}{\partial I_{h'}} \right) \mathrm{d}t .$$

The change is zero only if the two households have the same marginal propensity to spend on good i at their current budgets. Rich and poor households usually differ in this respect, so redistribution moves market demand even when total spending does not change.

We want two things at once. Households should be allowed to differ in income and in demographics, because they do. Yet we would like market data to look as if one consumer had generated them. A *representative consumer* is a fictional utility-maximizing consumer whose demand, evaluated at current prices and at a scalar summary of the expenditure distribution, equals aggregate demand. We call the representative consumer *normative* when, in addition, its expenditure function measures the welfare of the population, for example as the sum of household compensating variations. The positive property licenses estimating a demand system on aggregate data. The normative property licenses welfare analysis with the estimated system. The next subsections show how far each property can be pushed.

5.4.2 The Gorman polar form and exact aggregation

Definition 5.26 (Gorman polar form)**.** Households' preferences have the *Gorman polar form* if their expenditure functions can be written as

$$e_h(p, u_h) = a_h(p) + b(p)\, u_h , \qquad h = 1, \dots, H. \tag{5.45}$$

Here each $a_h(p)$ and the common function $b(p) > 0$ are homogeneous of degree one in p. On the maintained domain of prices and utilities, each e_h is increasing and concave in p. Preferences of this form are called *quasi-homothetic*.

The function a_h may differ across households, for example with family size or age. The function b must be common. Under these conditions each e_h is a valid expenditure function on the maintained domain, and it is increasing in u_h because $b > 0$. A convenient sufficient condition is that each a_h and b is positive, increasing and concave, with $u_h \geq 0$. Then e_h inherits monotonicity and concavity in p from a_h and b. This subclass has $\frac{\partial \ln b}{\partial p_i} \geq 0$, which by (5.47) below rules out inferior goods. The general form allows them on a local domain. The name reflects the relation to homotheticity. A homothetic expenditure function has the form $b(p)u$, so budget shares do not depend on the budget. Adding the fixed cost $a_h(p)$ keeps Engel curves straight but lets them miss the origin. The fixed cost is subsistence expenditure, the cost of living at $u_h = 0$ (Deaton and Muellbauer, 1980b, §5.4, pp. 142–144, and §6.1, eqs. 1.4–1.7, pp. 150–151).

Proposition 5.27 (Exact aggregation, Gorman, 1953, 1961)**.** *Suppose every household has an interior optimum.*

(i) If every household's expenditure function has the Gorman polar form (5.45) with a common $b(p)$, aggregate demand depends on the distribution of expenditure only through $\sum_h I_h$. It is the demand of a representative consumer with expenditure function

$$e(p, U) = \sum_{h=1}^{H} a_h(p) + b(p)\, U , \tag{5.46}$$

and the compensating variation of this consumer for any price change equals the sum of the households' compensating variations.

(ii) Conversely, suppose aggregate demand depends only on p and $\sum_h I_h$ for all distributions of expenditure in an open set. Then on that set household Engel curves are straight lines with slopes common to all households, and preferences have the Gorman polar form with a common $b(p)$. This b need not be increasing or concave.

Proof. (i) Inverting $I_h = e_h(p, u_h)$ gives the indirect utility function

$$v_h(p, I_h) = \frac{I_h - a_h(p)}{b(p)}.$$

Roy's identity (Proposition 5.7) uses two partial derivatives:

$$\frac{\partial v_h}{\partial I_h} = \frac{1}{b(p)},$$
$$\frac{\partial v_h}{\partial p_i} = -\frac{1}{b(p)}\frac{\partial a_h}{\partial p_i} - \frac{I_h - a_h(p)}{b(p)^2}\frac{\partial b}{\partial p_i}.$$

Taking minus their ratio,

$$q_{ih}(p, I_h) = -\frac{\partial v_h}{\partial p_i}\left(\frac{\partial v_h}{\partial I_h}\right)^{-1} = \frac{\partial a_h}{\partial p_i} + \frac{\partial \ln b}{\partial p_i}\big(I_h - a_h(p)\big). \tag{5.47}$$

The marginal propensity to spend, $\frac{\partial q_{ih}}{\partial I_h} = \frac{\partial \ln b}{\partial p_i}$, depends on prices alone. It is the same for every household and at every budget. Summing (5.47) over households gives

$$Q_i = \sum_h \frac{\partial a_h}{\partial p_i} + \frac{\partial \ln b}{\partial p_i}\Big(\sum_h I_h - \sum_h a_h(p)\Big),$$

which depends on budgets only through their sum.

Define $A(p) = \sum_h a_h(p)$ and $U = \sum_h u_h$. The function $e(p, U) = A(p) + b(p)U$ equals $\sum_h e_h(p, u_h)$. It is therefore homogeneous of degree one, increasing and concave in p, and increasing in U, so it is an expenditure function. By Shephard's lemma (Proposition 5.6) its Hicksian demand for good i is $\frac{\partial A}{\partial p_i} + \frac{\partial b}{\partial p_i}U$, the sum of the household Hicksian demands. Its indirect utility at the total budget is $\frac{\sum_h I_h - A(p)}{b(p)} = \sum_h v_h(p, I_h)$, and Roy's identity applied to it reproduces Q_i.

For a price change from p^0 to p^1, with initial utilities u_h^0, household h has

$$CV_h = e_h(p^1, u_h^0) - e_h(p^0, u_h^0) = a_h(p^1) - a_h(p^0) + \big[b(p^1) - b(p^0)\big]u_h^0.$$

Summing over households gives

$$\sum_h CV_h = A(p^1) - A(p^0) + \big[b(p^1) - b(p^0)\big]U^0 = e(p^1, U^0) - e(p^0, U^0),$$

the compensating variation of the representative consumer.

(ii) We sketch the argument. If Q_i depends only on $\sum_h I_h$, every transfer between two households leaves it unchanged. By the transfer argument of Section 5.4.1, $\frac{\partial q_{ih}}{\partial I_h} = \frac{\partial q_{ih'}}{\partial I_{h'}}$ for

every pair of households and every pair of budgets in the open set. Fix the budget of h' and vary that of h. The derivative of q_{ih} does not change, so it is a function $c_i(p)$ of prices alone, common to all households. Integrating gives straight Engel curves $q_{ih} = d_{ih}(p) + c_i(p)I_h$. Recovering preferences from these demands, with the symmetry and homogeneity restrictions of Proposition 5.8, yields the Gorman polar form (Gorman, 1961). □

Example 5.28 (The linear expenditure system)**.** The linear expenditure system of Stone (1954) has expenditure function

$$e_h(p, u_h) = \sum_k p_k \underline{q}_{kh} + u_h \prod_k p_k^{m_k}, \qquad m_k > 0, \quad \sum_k m_k = 1,$$

where $\underline{q}_{kh}$ is the subsistence quantity of good k for household h. It has the Gorman polar form with $a_h(p) = \sum_k p_k \underline{q}_{kh}$ and $b(p) = \prod_k p_k^{m_k}$. Since $\frac{\partial \ln b}{\partial p_i} = \frac{m_i}{p_i}$, the demand function (5.47) becomes

$$p_i q_{ih} = p_i \underline{q}_{ih} + m_i \Big(I_h - \sum_k p_k \underline{q}_{kh} \Big).$$

Each household first buys its subsistence bundle and then spends the fraction m_i of its remaining budget on good i. Households differ in subsistence quantities but share the marginal budget shares m_i. Panel (a) of Figure 5.3 draws two such Engel curves.

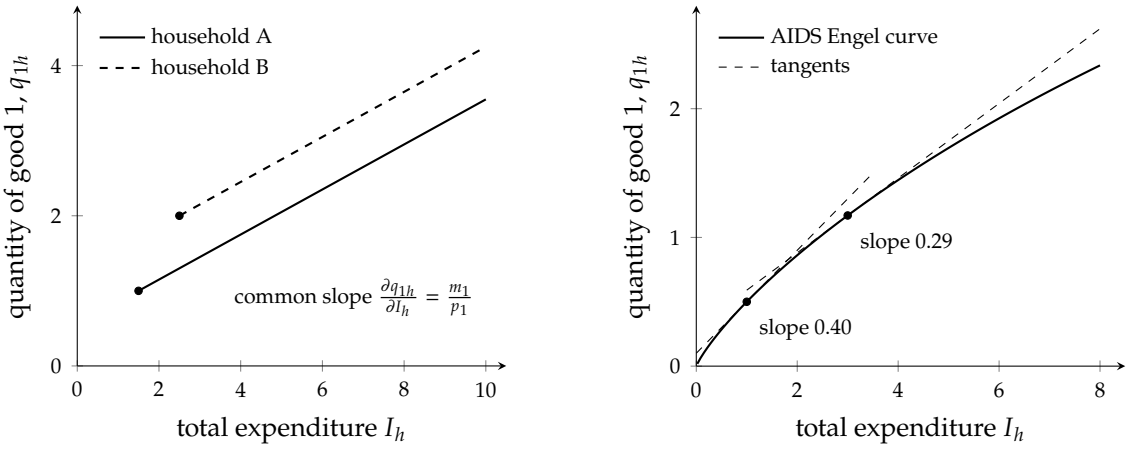
Exact aggregation comes at a price. Engel curves that are straight lines imply budget shares that converge to constants as budgets grow and that leave the unit interval at low budgets. Household budget surveys favor the Working-Leser form instead, in which budget shares are linear in the logarithm of the budget (Section 5.3.8). Under that form the marginal propensity to spend changes with the budget, as panel (b) of Figure 5.3 shows, so a transfer between households moves aggregate demand. We therefore want to relax linear Engel curves while keeping as much of the representative consumer as possible.

Nonnegativity of demand breaks linear aggregation even when every household has quasi-homothetic preferences (Deaton and Muellbauer, 1980b, §6.1, pp. 150–153). Fix prices and write a household's Engel curve for one good as $q_h = d + cI_h$ with $c > 0$. If $d < 0$, the line implies negative demand below the budget $I^* = -\frac{d}{c}$. Actual demand is zero there, so the true Engel curve is the kinked line $q_h = \max\{0, c(I_h - I^*)\}$. A transfer from a household above the kink to one below it lowers market demand, because the two have marginal propensities c and 0. Market demand then depends on how many households sit below the kink. To see the shape, let budgets be uniform on $[\bar{I} - \frac{r}{2}, \bar{I} + \frac{r}{2}]$, with I^* inside this interval. Mean demand is

$$\bar{q} = \frac{1}{r} \int_{I^*}^{\bar{I}+\frac{r}{2}} c\,(I - I^*)\,\mathrm{d}I = \frac{c}{2r} \Big(\bar{I} + \frac{r}{2} - I^* \Big)^2,$$

which is quadratic in mean expenditure. Its slope $\frac{c}{r}(\bar{I} + \frac{r}{2} - I^*)$ rises with $\bar{I}$ as households cross the kink, and it reaches c once all of them buy. This is the quadratic case of Deaton and Muellbauer (1980b, Exercise 6.5), written in our notation.

The argument matters most for narrowly defined goods. Many consumers buy none of a particular brand, so much of the market response to a higher budget comes from new buyers entering the market. Deaton and Muellbauer call this the "extensive" margin, as opposed to the "intensive" margin of buyers who buy more (p. 153). It would be a coincidence if the household Engel curves had just the offsetting nonlinearity that made market demand linear. The discrete-choice models of Chapters 6 and 7 put this extensive margin at the center, since each consumer there buys one product or none.



(a) Gorman polar form (linear expenditure system). **(b)** AIDS at unit prices (running example).

Figure 5.3: Engel curves under exact and almost exact aggregation. Panel (a): two households with the linear expenditure system of Example 5.28, $p = (1, 1)$, $m_1 = 0.3$, subsistence quantities $(\underline{q}_{1h}, \underline{q}_{2h}) = (1, 0.5)$ for household A (solid) and $(2, 0.5)$ for household B (dashed). The lines start at the subsistence budgets (dots) and are parallel. Panel (b): the Engel curve of good 1 in the running example of Example 5.21 at $p = (1, 1, 1)$, $q_1 = I(0.5 - 0.10 \ln I)$. The dashed tangents at the budgets $I = 1$ and $I = 3$ of the two households in Example 5.31 have slopes $0.4 - 0.10 \ln I$, equal to 0.40 and 0.29. These are the households' marginal propensities to spend on good 1. A transfer from the richer to the poorer household therefore raises aggregate demand for good 1. Figure 5.2 draws the same curve together with a luxury.

5.4.3 Muellbauer's generalization: PIGL and PIGLOG

Muellbauer (1975, 1976) weakens the requirement. The aggregate budget share of good i is aggregate spending on i divided by aggregate spending. It equals the expenditure-weighted mean of household shares:

$$\bar{w}_i \equiv \frac{\sum_h p_i q_{ih}}{\sum_h I_h} = \sum_h \frac{I_h}{H\bar{I}}\, w_{ih}(p, I_h). \tag{5.48}$$

Muellbauer's representative consumer exists if there is a scalar I_0, a function of prices and of the distribution $(I_1, \ldots, I_H)$, such that

$$\bar{w}_i = w_i\big(p, I_0(p, I_1, \ldots, I_H)\big) \quad \text{for every good } i. \tag{5.49}$$

Here $w_i(p, \cdot)$ is the share function of a reference household (Deaton and Muellbauer, 1980a, eq. A1). We call I_0 the *representative budget level*. The Gorman case has $I_0 = \bar{I}$. Allowing I_0 to differ from the mean lets features of the distribution other than its mean enter aggregate demand.

Muellbauer shows that (5.49) holds if and only if household shares have the *generalized linear* form

$$w_{ih}(p, I_h) = v_h(p, I_h)\, A_i(p) + B_i(p) + C_{ih}(p), \tag{5.50}$$

with $\sum_i A_i = \sum_i C_{ih} = \sum_h C_{ih} = 0$ and $\sum_i B_i = 1$ (Deaton and Muellbauer, 1980a, eq. A2). We drop the household-specific terms C_{ih} from here on.

The preferences behind (5.50) have a simple structure (Deaton and Muellbauer, 1980b, §6.2, eqs. 2.3–2.6, pp. 154–155). Household expenditure functions take the form $e_h(p, u_h) = \theta_h[u_h, a(p), b(p)] + \phi_h(p)$. Here $a(p)$ and $b(p)$ are linearly homogeneous price indices common

to all households, and each θ_h is linearly homogeneous in (a, b). The terms ϕ_h must sum to zero over households, so the representative expenditure function is $e(p, u_0) = \theta[u_0, a(p), b(p)]$. We can think of a and b as the prices of two intermediate goods. Shephard's lemma in share form and the chain rule give

$$\bar{w}_i = \frac{\partial \ln \theta}{\partial \ln a}\frac{\partial \ln a}{\partial \ln p_i} + \frac{\partial \ln \theta}{\partial \ln b}\frac{\partial \ln b}{\partial \ln p_i}.$$

Euler's theorem for the degree-one function θ gives $\frac{\partial \ln \theta}{\partial \ln a} + \frac{\partial \ln \theta}{\partial \ln b} = 1$. Writing $\varrho(I_0, p) = \frac{\partial \ln \theta}{\partial \ln b}$ after substituting for u_0,

$$\bar{w}_i = \big[1 - \varrho(I_0, p)\big]\frac{\partial \ln a}{\partial \ln p_i} + \varrho(I_0, p)\,\frac{\partial \ln b}{\partial \ln p_i}. \tag{5.51}$$

Every aggregate share is a weighted average of the shares of the two indices, with one weight common to all goods. Matching terms with (5.50) gives $B_i = \frac{\partial \ln a}{\partial \ln p_i}$, $A_i = \frac{\partial \ln b}{\partial \ln p_i} - \frac{\partial \ln a}{\partial \ln p_i}$ and $v(p, I_0) = \varrho(I_0, p)$. Hence at constant prices each aggregate share is a linear function of every other share. With time-series data in which relative prices barely move, this implication can be tested directly (p. 155).

The representative budget level is independent of prices if and only if

$$v_h(p, I_h) = \frac{1 - \left(\frac{I_h}{\kappa_h}\right)^{-\psi}}{\psi}. \tag{5.52}$$

Here ψ is a constant and $\kappa_h > 0$ is a household-specific scale that does not depend on I_h or p.[1] Shares of this form are called *price-independent generalized linear* (PIGL). As $\psi \to 0$, $\frac{1}{\psi}\big[1 - \exp\big(-\psi \ln \frac{I_h}{\kappa_h}\big)\big] \to \ln \frac{I_h}{\kappa_h}$, so

$$v_h(p, I_h) = \ln \frac{I_h}{\kappa_h}. \tag{5.53}$$

This limit is the *price-independent generalized logarithmic* (PIGLOG) case.

The representative budget level under PIGL. With $C_{ih} = 0$, substituting (5.50) into (5.48) gives

$$\bar{w}_i = A_i(p) \sum_h \frac{I_h}{H\bar{I}}\, v_h(p, I_h) + B_i(p).$$

A reference household with $\kappa = 1$ reproduces $\bar{w}_i$ if and only if $v(p, I_0) = \sum_h \frac{I_h}{H\bar{I}} v_h(p, I_h)$. Under (5.52) this condition reads

$$\frac{1 - I_0^{-\psi}}{\psi} = \sum_h \frac{I_h}{H\bar{I}}\,\frac{1 - \left(\frac{I_h}{\kappa_h}\right)^{-\psi}}{\psi}.$$

The weights $\frac{I_h}{H\bar{I}}$ sum to one, so the constant terms cancel and

$$I_0 = \left[\sum_h \frac{I_h}{H\bar{I}}\left(\frac{I_h}{\kappa_h}\right)^{-\psi}\right]^{-\frac{1}{\psi}}. \tag{5.54}$$

[1] Deaton and Muellbauer (1980a, eq. A3) write the PIGL constant as α. We use ψ because α_i denotes the AIDS intercepts, and κ_h for their k_h because k indexes goods. The factor ψ^{-1} appears in their typesetting as a superscript. We read it as a multiplicative factor, which is the reading under which the limit $\psi \to 0$ gives their eq. (A4).

The right-hand side involves budgets only, never prices. This is equation (A5) of Deaton and Muellbauer (1980a).[2] Letting $\psi \to 0$ and expanding $(\frac{I_h}{\kappa_h})^{-\psi} \approx 1 - \psi \ln \frac{I_h}{\kappa_h}$ gives the PIGLOG representative budget,

$$\ln I_0 = \sum_h \frac{I_h}{H\bar{I}} \ln \frac{I_h}{\kappa_h}. \tag{5.55}$$

The curvature parameter ψ fixes how the distribution of budgets enters I_0. Take $\kappa_h = 1$. Then (5.54) says that I_0 is a power mean of order $-\psi$ of the budgets, with expenditure weights $\frac{I_h}{H\bar{I}}$. Power means rise with their order, so I_0 falls as ψ rises. At $\psi = 1$, the case of linear Engel curves, the weighted mean of order -1 is

$$I_0 = \Big[\sum_h \frac{I_h}{H\bar{I}} \cdot \frac{1}{I_h}\Big]^{-1} = \Big[\frac{H}{H\bar{I}}\Big]^{-1} = \bar{I},$$

as in the Gorman case. Hence, when budgets are unequal, $I_0 > \bar{I}$ exactly when $\psi < 1$, the empirically relevant case. Two values of ψ give closed forms (Deaton and Muellbauer, 1980b, §6.2, eqs. 2.14–2.15, p. 157). At $\psi = -1$ the shares (5.58) are linear in the budget, so spending on each good is quadratic in it. Then

$$I_0 = \frac{\sum_h I_h^2}{\sum_h I_h} = \frac{H(\sigma^2 + \bar{I}^2)}{H\bar{I}} = \bar{I}\Big(1 + \frac{\sigma^2}{\bar{I}^2}\Big),$$

where $\sigma^2 = \frac{1}{H}\sum_h (I_h - \bar{I})^2$ is the variance of budgets. The representative budget exceeds the mean by a factor of one plus the squared coefficient of variation. In the PIGLOG limit, Section 5.4.4 shows that $\frac{I_0}{\bar{I}} = \frac{H}{Z}$, where $\ln Z$ is Theil's entropy measure. Deaton and Muellbauer's book writes this ratio as $\kappa_0 = \frac{I_0}{\bar{I}}$. It is the inverse of the index $\kappa = \frac{Z}{H}$ of their article and of Proposition 5.30.

Cost functions and budget shares. If household behavior comes from preferences, the PIGL cost function takes the form

$$\left[\frac{e(p, u_h)}{\kappa_h}\right]^{\psi} = (1 - u_h)\, a(p)^{\psi} + u_h\, b(p)^{\psi}, \tag{5.56}$$

and as $\psi \to 0$ it becomes the PIGLOG form

$$\ln \frac{e(p, u_h)}{\kappa_h} = (1 - u_h) \ln a(p) + u_h \ln b(p) \tag{5.57}$$

(Deaton and Muellbauer, 1980a, eqs. A6–A7). Here $a(p)$ and $b(p)$ are linearly homogeneous and concave, and $0 \le u_h \le 1$ except as discussed below. With $\kappa_h = 1$, (5.57) is the PIGLOG family of Section 5.3.1.

The budget shares follow from Shephard's lemma in share form, $w_i = \frac{\partial \ln e}{\partial \ln p_i}$. Take $\kappa_h = 1$, drop the household subscript, and write $a_i = \frac{\partial \ln a}{\partial \ln p_i}$ and $b_i = \frac{\partial \ln b}{\partial \ln p_i}$. Differentiating (5.56) with respect to $\ln p_i$, and using $\frac{\partial e^{\psi}}{\partial \ln p_i} = \psi e^{\psi} \frac{\partial \ln e}{\partial \ln p_i}$, gives

$$\psi e^{\psi} \frac{\partial \ln e}{\partial \ln p_i} = (1 - u)\, \psi a^{\psi} a_i + u\, \psi b^{\psi} b_i.$$

[2] The version printed in their appendix omits the weight I_h inside the sum. With the weight, I_0 equals the common budget when all budgets are equal and $\kappa_h = 1$, as it must. Their book prints the formula with the weight. For $\kappa_h = 1$ it reads $I_0 = \big[\frac{\sum_h I_h^{1-\psi}}{\sum_h I_h}\big]^{-\frac{1}{\psi}}$ (Deaton and Muellbauer, 1980b, §6.2, eq. 2.13, p. 156), which is (5.54).

At the optimum $e = I$. Dividing by ψI^ψ,

$$w_i = (1-u)\left(\frac{a}{I}\right)^\psi a_i + u\left(\frac{b}{I}\right)^\psi b_i, \qquad u = \frac{I^\psi - a^\psi}{b^\psi - a^\psi}. \tag{5.58}$$

In the PIGLOG limit,

$$w_i = (1-u)\,a_i + u\,b_i, \qquad u = \frac{\ln I - \ln a}{\ln b - \ln a} \tag{5.59}$$

(Deaton and Muellbauer, 1980a, eqs. A8–A10).

These equations have a transparent reading. By (5.56), $(1-u)a^\psi + ub^\psi = I^\psi$, so the weights $(1-u)(\frac{a}{I})^\psi$ and $u(\frac{b}{I})^\psi$ sum to one. Budget shares are weighted averages of a_i and b_i. As utility rises from 0 to 1, cost rises from $a(p)$ to $b(p)$ whenever $b > a$, whatever the sign of ψ, and the shares move from a_i to b_i. Deaton and Muellbauer (1980a) call $a(p)$ "poverty" expenditure, with spending pattern a_i, and $b(p)$ "affluence" expenditure, with pattern b_i. A good is a luxury if and only if $b_i > a_i$, because its share then rises with u. Inferior goods are not excluded.

For the AIDS, (5.20) gives $\ln a(p) = \ln \mathbf{P}(p)$ and $\ln b(p) = \ln a(p) + \beta_0 \prod_k p_k^{\beta_k}$. Because $\frac{\partial}{\partial \ln p_i} \prod_k p_k^{\beta_k} = \beta_i \prod_k p_k^{\beta_k}$,

$$b_i - a_i = \beta_i \beta_0 \prod_k p_k^{\beta_k}.$$

With $\beta_0 > 0$, good i is a luxury exactly when $\beta_i > 0$, as found in Section 5.3.

Where the demands are valid. Shares must lie in $[0,1]$. Under PIGLOG each w_i is linear in u, so the admissible values of u form an interval. Because $a(p)$ and $b(p)$ are increasing and linearly homogeneous, $a_i \geq 0$, $b_i \geq 0$ and $\sum_i a_i = \sum_i b_i = 1$. Hence $a_i, b_i \in [0,1]$, and every $u \in [0,1]$ is admissible. Above $u = 1$, the share of a luxury reaches one at $u = \frac{1-a_i}{b_i - a_i}$, and the share of a necessity reaches zero at $u = \frac{a_i}{a_i - b_i}$. The upper end of the admissible interval is the smallest of these values. Below $u = 0$ the same reasoning, with the roles of zero and one exchanged, gives the lower end. Deaton and Muellbauer (1980a, p. 324) state the corresponding limits for the PIGL case.

In the running example at unit prices, $\ln a = \alpha_0 = 0$ and $\ln b - \ln a = \beta_0 = 1$, so $u = \ln I$. The share vectors are $a = \alpha = (0.5, 0.3, 0.2)$ and $b = \alpha + \beta = (0.40, 0.34, 0.26)$. The necessity, good 1, has its share reach zero at $u = \frac{0.5}{0.1} = 5$. Goods 2 and 3 reach a share of one only at $u = 17.5$ and $u = 13.3$. Below zero, the share of good 3 reaches zero first, at $u = -\frac{0.2}{0.06} = -3.33$. The demands are therefore valid for $\ln I \in [-3.33, 5]$, the range reported for the running example in Section 5.3.9.

Concavity. A sufficient condition for the PIGLOG cost function to be concave in p is that a and b be concave and $0 \leq u \leq 1$. To see this, write (5.57) as $e = a(p)^{1-u}\, b(p)^u$. The weighted geometric mean $g(x,y) = x^{1-u}y^u$ is concave and nondecreasing on the positive orthant for $u \in [0,1]$. A concave nondecreasing function of concave functions is concave. The condition is not necessary. Deaton and Muellbauer (1980a, p. 324) show that the PIGL cost function is concave for *all* $I > 0$ and $p > 0$ only if $a_i = b_i$ for every i, in which case preferences are homothetic. Any nonhomothetic PIGLOG system, the AIDS included, must therefore have its concavity checked where it is used, as in Proposition 5.20.

Two special cases. With $\psi = 1$, (5.56) reads $e_h = \kappa_h a(p) + \kappa_h u_h [b(p) - a(p)]$. Defining $\tilde{u}_h = \kappa_h u_h$ gives $e_h = \kappa_h a(p) + [b(p) - a(p)]\tilde{u}_h$, a Gorman polar form with $a_h = \kappa_h a$ and common slope function $b - a$. So the PIGL family contains every model with linear Engel curves, such as the

linear expenditure system (Deaton and Muellbauer, 1980a, p. 324). The second case is less obvious.

Remark 5.29 (When the indirect translog aggregates). The indirect translog of Christensen et al. (1975) specifies indirect utility as

$$v = \tau_0 + \sum_i \tau_i \ln \frac{p_i}{I} + \frac{1}{2} \sum_i \sum_j \tau_{ij} \ln \frac{p_i}{I} \ln \frac{p_j}{I},$$

with the normalizations $\sum_i \tau_i = -1$ and $\tau_{ij} = \tau_{ji}$. Let $\tau_{Mi} = \sum_k \tau_{ki}$ and $L = \ln I$. Expanding the products and collecting powers of L,

$$v = \tau_0 + \sum_i \tau_i \ln p_i + \frac{1}{2} \sum_i \sum_j \tau_{ij} \ln p_i \ln p_j + L\Big(1 - \sum_i \tau_{Mi} \ln p_i\Big) + \frac{1}{2} L^2 \sum_i \tau_{Mi}.$$

If $\sum_i \tau_{Mi} = 0$, utility is linear in L and can be solved for the log cost function:

$$\ln e(p, v) = \frac{v - \tau_0 - \sum_i \tau_i \ln p_i - \frac{1}{2} \sum_i \sum_j \tau_{ij} \ln p_i \ln p_j}{1 - \sum_i \tau_{Mi} \ln p_i}.$$

This is linear in v, with an intercept and a slope that depend on prices, which is the PIGLOG form (5.57). If $\sum_i \tau_{Mi} \neq 0$, utility is quadratic in L and $\ln e$ is not linear in v. The indirect translog therefore aggregates in Muellbauer's sense under exactly one linear restriction (compare Deaton and Muellbauer, 1980a, eqs. A11–A12). Deaton and Muellbauer add that no such result holds for any interesting special case of the direct translog.

Evidence on the curvature parameter. Deaton and Muellbauer (1980b, §6.2, p. 158) fit the PIGL demand functions to postwar British data for 1954–1974 with eight groups of goods, the same period and number of groups as in Section 5.6.7. They take $a(p) = \sum_k a_k p_k$, the cost of a fixed subsistence bundle, and $b(p) = \beta_0 \prod_k p_k^{\beta_k}$. The estimate of ψ is very close to -1, which implies nearly quadratic Engel curves over time. The hypothesis $\psi = 1$, which gives linear Engel curves, is decisively rejected. The book states these results in words and reports no numerical estimate. A full use of the PIGL class would also measure I_0 from the distribution of budgets. Few countries have data on the distribution of total expenditure of sufficient quality for this, and the authors' own indirect attempts had no notable success. Applied work therefore replaces I_0 by $\bar{I}$. The error is small if the distribution is stable, so that $\frac{I_0}{\bar{I}}$ is roughly constant, which they judge possible for postwar Britain (p. 158). Section 5.4.4 shows what the approximation costs when the distribution moves.

5.4.4 Almost exact aggregation of the AIDS

The AIDS is a PIGLOG system, so it aggregates through a single representative budget. Deaton and Muellbauer (1980a, Section I.A) allow households to differ through a scale κ_h. They interpret it as "a sophisticated measure of household size" that could reflect age composition, other characteristics and economies of household size. Household h deflates its budget by κ_h to a "needs corrected" per capita level.

Proposition 5.30 (Almost exact aggregation)**.** *Suppose every household has the AIDS preferences of* (5.20) *with common parameters, except for a scale* $\kappa_h > 0$ *that deflates its budget, so that*

$$w_{ih} = \alpha_i + \sum_j \gamma_{ij} \ln p_j + \beta_i \ln \frac{I_h}{\kappa_h \mathbf{P}(p)}. \tag{5.60}$$

Define the aggregate index κ by

$$\ln \frac{\bar{I}}{\kappa} = \sum_h \frac{I_h}{H\bar{I}} \ln \frac{I_h}{\kappa_h}. \tag{5.61}$$

Then the aggregate budget shares are

$$\bar{w}_i = \alpha_i + \sum_j \gamma_{ij} \ln p_j + \beta_i \ln \frac{\bar{I}}{\kappa\, \mathbf{P}(p)}, \tag{5.62}$$

the shares of a single AIDS household with budget $\frac{\bar{I}}{\kappa}$. When $\kappa_h = 1$ for all households, $\frac{\bar{I}}{\kappa} = I_0$ with

$$\ln I_0 = \frac{\sum_h I_h \ln I_h}{\sum_h I_h}. \tag{5.63}$$

Proof. Let $A_i(p) = \alpha_i + \sum_j \gamma_{ij} \ln p_j - \beta_i \ln \mathbf{P}(p)$, so that $w_{ih} = A_i(p) + \beta_i \ln \frac{I_h}{\kappa_h}$. Substitute into (5.48):

$$\begin{aligned} \bar{w}_i &= \sum_h \frac{I_h}{H\bar{I}} \left[A_i(p) + \beta_i \ln \frac{I_h}{\kappa_h} \right] \\ &= A_i(p) \sum_h \frac{I_h}{H\bar{I}} + \beta_i \sum_h \frac{I_h}{H\bar{I}} \ln \frac{I_h}{\kappa_h} \\ &= A_i(p) + \beta_i \ln \frac{\bar{I}}{\kappa}. \end{aligned}$$

The last line uses the fact that the weights sum to one and the definition (5.61). Substituting $A_i(p)$ back gives (5.62). With $\kappa_h = 1$, (5.61) reads $\ln \frac{\bar{I}}{\kappa} = \sum_h \frac{I_h}{H\bar{I}} \ln I_h$, which is (5.63). □

The same argument works for any PIGLOG system. From (5.59), $u_h = \frac{\ln I_h - \ln a}{\ln b - \ln a}$, so

$$w_{ih} = a_i + (b_i - a_i) u_h = \left[a_i - \frac{b_i - a_i}{\ln b - \ln a} \ln a \right] + \frac{b_i - a_i}{\ln b - \ln a} \ln I_h.$$

Household shares are linear in $\ln I_h$ with price-dependent coefficients $A_i(p)$ and $B_i(p)$. For the AIDS, $b_i - a_i = \beta_i(\ln b - \ln a)$, so $B_i = \beta_i$ and $A_i = a_i - \beta_i \ln a = \alpha_i + \sum_j \gamma_{ij} \ln p_j - \beta_i \ln \mathbf{P}$, as in the proof. Aggregation is "almost" exact because aggregate demand depends on the distribution of budgets, but only through one scalar index.

What I_0 measures. Write each budget as $I_h = \bar{I} \cdot \frac{I_h}{\bar{I}}$. Then

$$\begin{aligned} \ln I_0 &= \sum_h \frac{I_h}{H\bar{I}} \left[\ln \bar{I} + \ln \frac{I_h}{\bar{I}} \right] = \ln \bar{I} + \mathcal{T}, \\ \mathcal{T} &= \frac{1}{H} \sum_h \frac{I_h}{\bar{I}} \ln \frac{I_h}{\bar{I}}. \end{aligned} \tag{5.64}$$

The quantity $\mathcal{T}$ is the *Theil index* of inequality. The function $f(r) = r \ln r$ is convex and the ratios $r_h = \frac{I_h}{\bar{I}}$ average one. Jensen's inequality therefore gives $\mathcal{T} = \frac{1}{H} \sum_h f(r_h) \geq f(1) = 0$, with equality only when all budgets are equal. The maximum, $\ln H$, is reached when one household does all the spending. Hence

$$I_0 = \bar{I}\, e^{\mathcal{T}} \geq \bar{I}.$$

The representative household is richer than the average household, because expenditure weighting gives rich households more weight.

Deaton and Muellbauer express the same object through an entropy measure. With $\kappa_h = 1$ they write $\kappa = \frac{Z}{H}$, where $\ln Z = -\sum_h \frac{I_h}{H\bar{I}} \ln \frac{I_h}{H\bar{I}}$ is Theil's entropy measure of equality. Since $\ln \frac{I_h}{H\bar{I}} = \ln \frac{I_h}{\bar{I}} - \ln H$,

$$\ln Z = \ln H - \mathcal{T}, \qquad \ln \kappa = \ln Z - \ln H = -\mathcal{T}, \qquad \frac{\bar{I}}{\kappa} = \bar{I} e^{\mathcal{T}} = I_0.$$

Hence $\frac{I_0}{\bar{I}} = \frac{H}{Z}$, which is the ratio κ_0 of Deaton and Muellbauer (1980b, §6.2, eq. 2.15, p. 157). The entropy Z reaches its maximum H under perfect equality. In their words, "as inequality increases, $k = \frac{Z}{H}$ decreases and the representative budget level increases" (Deaton and Muellbauer, 1980a, p. 315). When the scales κ_h differ across households, κ reflects the demographic structure as well as the distribution of budgets.

Consequences for estimation. In a time series of aggregate shares, (5.62) reads

$$\bar{w}_{it} = \alpha_i + \sum_j \gamma_{ij} \ln p_{jt} + \beta_i \ln \frac{\bar{I}_t}{\mathbf{P}_t} - \beta_i \ln \kappa_t. \tag{5.65}$$

Researchers usually observe mean expenditure $\bar{I}_t$ but not κ_t, which requires the joint distribution of budgets and household characteristics. If κ_t is constant, or varies independently of $\bar{I}_t$ and p_t, we can replace $\ln \kappa_t$ by a constant $\ln \kappa^*$, its value or sample mean. The intercepts then become $\alpha_i^* = \alpha_i - \beta_i \ln \kappa^*$ (Deaton and Muellbauer, 1980a, p. 315). The deviation $-\beta_i(\ln \kappa_t - \ln \kappa^*)$ joins the error term and is uncorrelated with the regressors.

If κ_t moves with the regressors, omitting it biases the estimates. Take the case $\kappa_h = 1$, so that $-\ln \kappa_t = \mathcal{T}_t$, and hold prices fixed for simplicity. Let the linear projection of inequality on log mean expenditure be $\mathcal{T}_t = c + \delta_{\mathcal{T}} \ln \bar{I}_t + r_t$, with r_t uncorrelated with $\ln \bar{I}_t$. Substituting into (5.65) and adding an error term ξ_{it},

$$\bar{w}_{it} = \big(\alpha_i - \beta_i \ln \mathbf{P} + \beta_i c\big) + \beta_i(1 + \delta_{\mathcal{T}}) \ln \bar{I}_t + \beta_i r_t + \xi_{it}.$$

A regression of $\bar{w}_{it}$ on $\ln \bar{I}_t$ estimates $\beta_i(1 + \delta_{\mathcal{T}})$. If inequality rises with mean expenditure ($\delta_{\mathcal{T}} > 0$), luxuries look more luxurious and necessities more necessary than they are. With several regressors the same logic applies to the partial correlation of $\mathcal{T}_t$ with each of them. Deaton and Muellbauer list a non-constant κ correlated with $\bar{I}$ and p as one possible reason for the rejection of homogeneity in their data (Section 5.6.7).

The index κ is constant when the distribution of budgets and household characteristics changes only through equiproportional changes in all budgets. Deaton and Muellbauer point out that in this case even α_{ih} and γ_{ijh} may differ across households. The reason is that the weights $\frac{I_h}{H\bar{I}}$ are then constant over time, and each household's $\ln \mathbf{P}_h$ is linear in its own parameters. With a common β_i, the weighted sum of the household equations is an AIDS whose α_i and γ_{ij} are expenditure-weighted averages of the household parameters.

Example 5.31 (Two households)**.** Take the running example of Example 5.21 at $p = (1, 1, 1)$, where $\ln \mathbf{P} = 0$ and $w_{ih} = \alpha_i + \beta_i \ln I_h$. Two households have budgets $I_1 = 1$ and $I_2 = 3$, so $\bar{I} = 2$. The expenditure weights are $\frac{1}{4}$ and $\frac{3}{4}$, and

$$\ln I_0 = \frac{1}{4} \ln 1 + \frac{3}{4} \ln 3 = 0.8240, \qquad I_0 = 2.280.$$

The Theil index is $\mathcal{T} = \ln I_0 - \ln \bar{I} = 0.8240 - 0.6931 = 0.1308$. Equivalently, $\kappa = e^{-\mathcal{T}} = 0.877$ and $Z = H\kappa = 1.755$. Table 5.3 reports the household shares, the aggregate shares computed from (5.48), and the shares of a single consumer at I_0 and at $\bar{I}$. The consumer with budget I_0 reproduces the aggregate shares exactly. The consumer with the mean budget overstates the share of the necessity, good 1, by 1.3 percentage points and understates the share of the luxury, good 3, by 0.8 points.

Table 5.3: Aggregation in the running example at unit prices

	Budget	ln budget	w_1	w_2	w_3
Household 1	1.000	0.0000	0.5000	0.3000	0.2000
Household 2	3.000	1.0986	0.3901	0.3439	0.2659
Aggregate, (5.48)	4.000		0.4176	0.3330	0.2494
Consumer at I_0	2.280	0.8240	0.4176	0.3330	0.2494
Consumer at $\bar{I}$	2.000	0.6931	0.4307	0.3277	0.2416

Notes: parameters of Example 5.21, $w_{ih} = \alpha_i + \beta_i \ln I_h$ at $p = (1,1,1)$. The aggregate row gives total expenditure and expenditure-weighted shares. Computed by `figures/ch05/src/aggregation_example.py`.

Remark 5.32 (Welfare with a representative household). Under the Gorman polar form the representative consumer is normative: its compensating variation is the sum of household compensating variations (Proposition 5.27). Under PIGLOG the household with budget I_0 is a positive construct, and its expenditure function does not aggregate the household expenditure functions. How large is the error if we use it anyway? For the AIDS, the initial utility of household h is $u_h^0 = \frac{\ln I_h - \ln \mathbf{P}(p^0)}{B(p^0)}$ by (5.26), with $B(p) = \beta_0 \prod_k p_k^{\beta_k}$ as in (5.25). Its cost of reaching u_h^0 at new prices p^1 satisfies

$$\ln e(p^1, u_h^0) = \ln \mathbf{P}(p^1) + g\left[\ln I_h - \ln \mathbf{P}(p^0)\right], \qquad g = \frac{B(p^1)}{B(p^0)},$$

so $e(p^1, u_h^0) = \mathbf{P}(p^1)\mathbf{P}(p^0)^{-g} I_h^g$. Summing over households gives $\mathbf{P}(p^1)\mathbf{P}(p^0)^{-g} \sum_h I_h^g$. A natural representative calculation computes the compensating variation of the household with budget I_0 as a fraction of its budget and applies that fraction to aggregate expenditure $H\bar{I}$. This gives $\mathbf{P}(p^1)\mathbf{P}(p^0)^{-g} H\bar{I}\, I_0^{g-1}$ for the aggregate cost at new prices. Since the exponential function is convex, Jensen's inequality gives

$$\sum_h I_h^g = H\bar{I} \sum_h \frac{I_h}{H\bar{I}} e^{(g-1)\ln I_h} \geq H\bar{I}\, e^{(g-1)\sum_h \frac{I_h}{H\bar{I}} \ln I_h} = H\bar{I}\, I_0^{g-1}.$$

The representative calculation therefore understates the sum of household compensating variations. The two coincide when $g = 1$ or when all budgets are equal, and their first-order terms in $g - 1$ agree, so the gap is of second order. In Example 5.31, a 10 percent rise in p_3 gives $g = 1.1^{0.06} = 1.0057$. Household compensating variations are 0.0184 (1.84 percent of the budget) and 0.0745 (2.48 percent). Their sum is 0.09296, against 0.09294 from the representative calculation. For a 50 percent rise the figures are 0.3621 and 0.3618. The aggregate is accurate, but it hides who bears the loss. The richer household loses a larger fraction of its budget because good 3 is a luxury. The welfare numbers of Chaudhuri et al. (2006), studied in Section 5.9,

are representative-household numbers of this kind. The authors state that their framework is not suited to asking how different groups in the population are affected (their Section 3.6).[3] They add that this question would need micro data on purchases (their fn. 30). The same issue arises for price indices. Under PIGLOG the exact cost-of-living index differs across households whenever the prices of luxuries and necessities move apart. Section 5.7.1 derives the household index and reports British estimates in which inflation in 1975–76 ranged from 16.39 percent for a poor couple to 14.05 percent for a rich one (Table 5.9).

5.5 Separability and multi-stage budgeting

A product-space system for J goods has of the order of J^2 price coefficients (Section 5.3.9). With a hundred brands the AIDS has 4,950 free price coefficients even after symmetry and homogeneity, far more than any data set can pin down. The classical remedy is to arrange goods in a tree. The consumer first allocates total expenditure across broad groups and then allocates each group's budget across the goods in the group. This section states the preferences under which such *multi-stage budgeting* is consistent with utility maximization, what they imply for substitution between groups, and how elasticities at different levels of the tree combine.

Throughout, the goods are partitioned into groups $G = 1, \dots, \mathcal{G}$. We write q_G and p_G for the quantities and prices of the goods in group G, $X_G = p_G^\top q_G$ for group expenditure, and $w_{i|G} = \frac{p_i q_i}{X_G}$ for the *within-group share* of good $i \in G$. A second group is denoted G'.

5.5.1 Weak separability and the second stage

Definition 5.33 (Weak separability)**.** Preferences are *weakly separable* in the partition $\{G\}$ if the utility function can be written as

$$U(q) = F\big(U_1(q_1), U_2(q_2), \dots, U_{\mathcal{G}}(q_{\mathcal{G}})\big). \tag{5.66}$$

Here F is strictly increasing in each argument, and each *subutility function* U_G is continuous, increasing and strictly quasi-concave. Preferences are *additively separable* across groups if, in addition, F can be chosen as an increasing function of $\sum_G U_G(q_G)$.

Weak separability says that the marginal rate of substitution between two goods in the same group does not depend on the quantities of goods outside the group. Hence tastes within a group can be described without reference to the rest of the budget.

Proposition 5.34 (The second stage)**.** *Under weak separability, the Marshallian demand for a good $i \in G$ can be written as*

$$q_i(p, I) = q_{i|G}\big(p_G, X_G(p, I)\big), \tag{5.67}$$

where $X_G(p, I)$ is the optimal expenditure on group G and $q_{i|G}(p_G, X_G)$ solves $\max_{q_G} U_G(q_G)$ subject to $p_G^\top q_G = X_G$. The conditional demand *functions $q_{i|G}$ depend only on the prices of the group and on group expenditure.*

Proof. Let q^* be the optimal bundle at (p, I) and let $X_G^* = p_G^\top q_G^*$. Suppose q_G^* did not solve the group problem at budget X_G^*. Then some q_G' with $p_G^\top q_G' \le X_G^*$ would give $U_G(q_G') > U_G(q_G^*)$.

[3] Page, table, equation and footnote numbers for Chaudhuri et al. (2006) refer throughout this chapter to the revised NBER working paper (Working Paper 10159, revised July 2006). Page numbers are those printed in it. Where we cite the published article instead, the text says so.

Replacing q_G^* by q_G' in q^* keeps total spending within I and, because F is strictly increasing, raises U. This contradicts the optimality of q^*. So q_G^* solves the group problem, whose solution is unique by strict quasi-concavity of U_G. Hence $q_G^* = q_G(p_G, X_G^*)$. □

The conditional demands are ordinary demand functions generated by the subutility U_G, with X_G in the role of income. They add up to X_G, are homogeneous of degree zero in (p_G, X_G), and have a symmetric and negative semidefinite conditional Slutsky matrix. Any flexible demand system, the AIDS in particular, can therefore be fitted to within-group shares $w_{i|G}$ with group expenditure as the budget variable. This is the bottom level of both multi-level systems studied in this chapter. It gives the quinolone equations of Chaudhuri et al. (2006) (Section 5.9.4) and the brand equations of Hausman et al. (1994) and Hausman (1997) (Section 5.8). Hausman stresses that the budget variable must be segment expenditure. Using overall expenditure instead "is inconsistent with the economic theory of multistage budgeting, and it can lead to decidedly inferior econometric results" (Hausman, 1997, p. 217).

5.5.2 The first stage

Weak separability alone does not deliver a simple first stage. Group expenditure $X_G(p, I)$ depends, in general, on every individual price in every group. Multi-stage budgeting in the useful sense requires that the allocation of total expenditure depend on group prices only through group price indices $P_G(p_G)$, so that $X_G = X_G(P_1, \ldots, P_{\mathcal{G}}, I)$. Two preference structures deliver this. The second uses the following functional form.

Definition 5.35 (Generalized Gorman polar form)**.** A sub-indirect utility function $V_G(p_G, X_G) = \max\{U_G(q_G) : p_G^\top q_G \le X_G\}$ has the *generalized Gorman polar form* (GGPF) if

$$V_G(p_G, X_G) = F_G\left(\frac{X_G}{\mathcal{P}_G(p_G)}\right) + \mathcal{A}_G(p_G). \tag{5.68}$$

Here F_G is increasing, $\mathcal{P}_G$ is homogeneous of degree one and $\mathcal{A}_G$ is homogeneous of degree zero in p_G.

Proposition 5.36 (Two-stage budgeting, Gorman, 1959)**.** *Suppose preferences are weakly separable.*

(i) If every subutility U_G is homothetic, group expenditures depend on prices only through the group price indices $P_G(p_G) = e_G(p_G, 1)$, the unit costs of the subutilities.

(ii) If preferences are additively separable across groups and every sub-indirect utility function has the GGPF (5.68), group expenditures depend on prices only through the indices $\mathcal{P}_G(p_G)$.

Gorman (1959) showed that, except when there are only two groups, these two structures are also necessary for exact two-stage budgeting under weak separability (Deaton and Muellbauer, 1980b, §5.2, p. 131). Blackorby et al. (1978) give a complete statement.

Proof. (i) Normalize each homothetic U_G to be homogeneous of degree one. Its expenditure function is then $e_G(p_G, u_G) = P_G(p_G)\, u_G$, with $P_G(p_G) = e_G(p_G, 1)$ linearly homogeneous and concave. By Proposition 5.34 the consumer chooses subutility levels to solve

$$\max_{u_1, \ldots, u_{\mathcal{G}}} F(u_1, \ldots, u_{\mathcal{G}}) \quad \text{subject to} \quad \sum_G P_G(p_G)\, u_G \le I.$$

This is a standard consumer problem with "quantities" u_G and "prices" P_G. Its solution u_G^* depends only on $(P_1, \ldots, P_{\mathcal{G}}, I)$, and so does $X_G = P_G u_G^*$.

(ii) Under additive separability the first stage maximizes $\sum_G V_G(p_G, X_G)$ subject to $\sum_G X_G = I$, after an increasing transformation of the objective. At an interior optimum the marginal utilities of group expenditure are equal:

$$\frac{\partial V_G}{\partial X_G} = \frac{1}{\mathcal{P}_G(p_G)} F_G'\left(\frac{X_G}{\mathcal{P}_G(p_G)}\right) = \lambda \quad \text{for every } G.$$

Each equation involves p_G only through $\mathcal{P}_G$. Solving for X_G in terms of λ and $\mathcal{P}_G$, and choosing λ so that the X_G sum to I, gives X_G as a function of $(\mathcal{P}_1, \ldots, \mathcal{P}_\mathcal{G}, I)$. The term $\mathcal{A}_G$ does not affect the allocation. □

Both routes are restrictive, in different places (Deaton and Muellbauer, 1980b, §5.2, pp. 130–131). Route (i) restricts tastes within groups. With $e_G = P_G(p_G)\, u_G$, Shephard's lemma in share form gives the within-group shares

$$w_{i|G} = \frac{\partial \ln e_G(p_G, u_G)}{\partial \ln p_i} = \frac{\partial \ln P_G(p_G)}{\partial \ln p_i},$$

which do not depend on u_G and hence not on X_G. Every good in the group then has an elasticity of one with respect to group expenditure. A group cannot mix necessities and luxuries, so a segment containing both cheap and premium brands violates route (i). Route (ii) permits nonlinear within-group Engel curves. Its price is additivity across groups, which Deaton and Muellbauer call "both severe and, in our view, unrealistic" (p. 131). A reasonably general solution must therefore be approximate, or it must abandon weak separability. The rest of this subsection takes the first path, and Remark 5.37 sketches the second.

The AIDS is a generalized Gorman polar form. Hausman (1997, fn. 17) notes that the AIDS is a GGPF, so Gorman's theorem applies to a top level that is additive across segments. The verification is short. Within group G the AIDS indirect utility is

$$u_G = \frac{\ln X_G - \ln a_G(p_G)}{B_G(p_G)}, \qquad B_G(p_G) = \beta_0 \prod_{k \in G} p_k^{\beta_k}.$$

Here $\ln a_G = \ln \mathbf{P}_G$ is the translog index of the group. The function B_G is homogeneous of degree zero because the β_k of the group sum to zero. Where $X_G > a_G(p_G)$, that is $u_G > 0$, the increasing transformation $\ln u_G$ represents the same preferences and equals

$$\ln u_G = \ln \ln \frac{X_G}{a_G(p_G)} - \ln B_G(p_G).$$

This is (5.68) with $F_G(z) = \ln \ln z$, $\mathcal{P}_G = a_G$ and $\mathcal{A}_G = -\ln B_G$. Under additive separability, the exact group price index of an AIDS group is therefore its translog index $\mathbf{P}_G$, the index that Chaudhuri et al. (2006) use for the quinolone segment.

The first stage in practice. Exact two-stage budgeting requires additivity at the top, which is itself a strong restriction on substitution between groups. Applied work therefore treats the top level as an approximation. The approximation of Deaton and Muellbauer (1980b, §5.2, eqs. 2.18–2.19, pp. 131–132) starts from an identity. Choose base prices p^0 with group subvectors p_G^0, and write each group expenditure function as

$$e_G(p_G, u_G) = e_G(p_G^0, u_G) \cdot \frac{e_G(p_G, u_G)}{e_G(p_G^0, u_G)} \equiv V_G \cdot P_G(p_G, p_G^0; u_G). \tag{5.69}$$

The first factor V_G is the money cost of reaching u_G at base prices, a group quantity index measured in money. The second factor is the exact cost-of-living index of the group at utility u_G, in the sense of Section 5.2.7. Under weak separability the first stage chooses subutilities to maximize $F(u_1, \dots, u_{\mathcal{G}})$ subject to $\sum_G e_G(p_G, u_G) = I$. Since V_G is increasing in u_G, we can invert it and write $u_G = \chi_G(V_G)$, with base prices fixed. The first stage becomes

$$\max_{V_1,\dots,V_{\mathcal{G}}} F\big(\chi_1(V_1), \dots, \chi_{\mathcal{G}}(V_{\mathcal{G}})\big) \quad \text{subject to} \quad \sum_G V_G\, P_G(p_G, p_G^0; u_G) = I. \tag{5.70}$$

This looks like a standard consumer problem with quantities V_G and prices P_G. It is not one, because each P_G depends on u_G, and allowing for this dependence takes us back to the original problem. The dependence reflects within-group Engel curves that are not straight lines through the origin. If homothetic subutilities remove it, (5.70) is exact, which is route (i) of Proposition 5.36. Otherwise the approximation replaces P_G by an index that does not depend on utility. When the variation of P_G with u_G is small, Laspeyres or Paasche indices of group prices approximate it well. These are the indices that national accounts supply, so the construction justifies standard practice, "albeit in an approximate way" (p. 132).

Chaudhuri et al. (2006, p. 13) adopt "an approximate solution" along these lines. It is an AIDS for the shares of sub-segments in total expenditure, with group price indices in place of prices. Hausman et al. (1994) also put group price indices in place of prices at their top and middle levels (Section 5.8.3). Hausman reports that he also estimated a middle level that is not necessarily consistent with exact two-stage budgeting, with "quite similar" results (Hausman, 1997, fn. 17). Group price indices may be the exact translog index of the lower level, or a Stone or Laspeyres-type index of the group's prices (both defined in Section 5.6.4). Hausman finds that this choice "does not typically have much influence on the final model estimates" (Hausman, 1997, p. 218). Representative applications of multi-stage budgeting to differentiated products include Hausman et al. (1994), Ellison et al. (1997) and Hausman and Leonard (2002).

Remark 5.37 (Implicit separability). Weak separability is not the only structure that supports budgeting in stages. Preferences are *implicitly separable* if the expenditure function can be written as

$$e(p, u) = C\big[u, e_1(u, p_1), \dots, e_{\mathcal{G}}(u, p_{\mathcal{G}})\big],$$

where each e_G is increasing in u and linearly homogeneous in p_G (Gorman, 1970). Total utility u enters every e_G, and there are no group subutilities. Shephard's lemma and the chain rule give $q_i = \frac{\partial C}{\partial e_G}\frac{\partial e_G}{\partial p_i}$ for $i \in G$. Summing over the group and using Euler's theorem for e_G,

$$X_G = \sum_{i\in G} p_i q_i = \frac{\partial C}{\partial e_G}\sum_{i\in G} p_i \frac{\partial e_G}{\partial p_i} = \frac{\partial C}{\partial e_G}\, e_G(u, p_G).$$

Dividing by $I = C$ and by X_G gives the two stages:

$$\frac{X_G}{I} = \frac{\partial \ln C}{\partial \ln e_G}, \qquad w_{i|G} = \frac{\partial \ln e_G(u, p_G)}{\partial \ln p_i}.$$

The top stage allocates the budget with the "macro" cost function C and the group price indices $e_G(u, p_G)$. The bottom stage allocates within groups with the same indices. Both stages are exact, at the cost of group price indices that depend on the level of total utility (Deaton and Muellbauer, 1980b, §5.2, eqs. 2.24–2.28, pp. 133–134).

5.5.3 What separability implies for substitution

Separability buys a large reduction in parameters by restricting substitution between groups. The next result makes the restriction precise.

Proposition 5.38 (Goldman and Uzawa, 1964)**.** *Suppose preferences are weakly separable and demands are differentiable, with nonzero income effects* $\frac{\partial X_G}{\partial I}$*. For goods* $i \in G$ *and* $j \in G'$ *in different groups, the Slutsky terms satisfy*

$$S_{ij} = \mu_{GG'}(p, I)\, \frac{\partial q_i}{\partial I}\, \frac{\partial q_j}{\partial I} \tag{5.71}$$

for a function $\mu_{GG'}$ *that depends on the pair of groups but not on the goods within them.*

Proof. We follow the argument of Gorman (1971) as presented by Deaton and Muellbauer (1980b, §5.2, eqs. 2.4–2.9, pp. 128–129). By Proposition 5.34, $q_i(p, I) = q_{i|G}(p_G, X_G(p, I))$. The Hicksian demand is $h_i(p, u) = q_i(p, e(p, u)) = q_{i|G}(p_G, X_G^h(p, u))$, where $X_G^h(p, u) = X_G(p, e(p, u))$ is compensated group expenditure. For $j \notin G$, the price p_j enters h_i only through X_G^h, so

$$S_{ij} = \frac{\partial h_i}{\partial p_j} = \frac{\partial q_{i|G}}{\partial X_G}\, \frac{\partial X_G^h}{\partial p_j}.$$

The income derivative has the same structure, $\frac{\partial q_i}{\partial I} = \frac{\partial q_{i|G}}{\partial X_G}\frac{\partial X_G}{\partial I}$. Eliminating $\frac{\partial q_{i|G}}{\partial X_G}$,

$$S_{ij} = \frac{\partial q_i}{\partial I}\left(\frac{\partial X_G}{\partial I}\right)^{-1} \frac{\partial X_G^h}{\partial p_j}.$$

The same steps with the roles of i and j exchanged give $S_{ji} = \frac{\partial q_j}{\partial I}(\frac{\partial X_{G'}}{\partial I})^{-1}\frac{\partial X_{G'}^h}{\partial p_i}$. Slutsky symmetry, $S_{ij} = S_{ji}$ (Proposition 5.8), and division by $\frac{\partial q_i}{\partial I}\frac{\partial q_j}{\partial I}$ give

$$\left(\frac{\partial q_j}{\partial I}\right)^{-1} \frac{\partial X_G^h}{\partial p_j}\left(\frac{\partial X_G}{\partial I}\right)^{-1} = \left(\frac{\partial q_i}{\partial I}\right)^{-1} \frac{\partial X_{G'}^h}{\partial p_i}\left(\frac{\partial X_{G'}}{\partial I}\right)^{-1}.$$

The left side does not depend on which good $i \in G$ we picked, and the right side does not depend on which good $j \in G'$ we picked. Since the equality holds for all such pairs, both sides equal a common value $\mu_{GG'}(p, I)$. The left side then gives $\frac{\partial X_G^h}{\partial p_j}(\frac{\partial X_G}{\partial I})^{-1} = \mu_{GG'}\frac{\partial q_j}{\partial I}$. Substituting into the expression for S_{ij},

$$S_{ij} = \mu_{GG'}\, \frac{\partial q_i}{\partial I}\, \frac{\partial q_j}{\partial I},$$

which is (5.71). If a good has a zero income effect the formula holds trivially for the pairs that involve it. □

Gorman (1971) shows that the restriction (5.71) is also sufficient for weak separability, so it summarizes the empirical content of separability for substitution (Deaton and Muellbauer, 1980b, p. 129). The factor $\mu_{GG'}$ has an interpretation in terms of the groups themselves. Define

$$\lambda_{GG'} = \mu_{GG'}\, \frac{\partial X_G}{\partial I}\, \frac{\partial X_{G'}}{\partial I}. \tag{5.72}$$

Since $\frac{\partial q_i}{\partial I} = \frac{\partial q_{i|G}}{\partial X_G}\frac{\partial X_G}{\partial I}$, (5.71) becomes $S_{ij} = \lambda_{GG'}\frac{\partial q_{i|G}}{\partial X_G}\frac{\partial q_{j|G'}}{\partial X_{G'}}$. The first display of the proof gives $S_{ij} = \frac{\partial q_{i|G}}{\partial X_G}\frac{\partial X_G^h}{\partial p_j}$. Equating the two expressions,

$$\frac{\partial X_G^h}{\partial p_j} = \lambda_{GG'}\frac{\partial q_{j|G'}}{\partial X_{G'}}, \qquad j \in G',\ G' \neq G. \tag{5.73}$$

Multiply by p_j and sum over $j \in G'$. Conditional demands add up to group expenditure, so $\sum_{j\in G'} p_j \frac{\partial q_{j|G'}}{\partial X_{G'}} = 1$, and

$$\lambda_{GG'} = \sum_{j\in G'} p_j \frac{\partial X_G^h}{\partial p_j} \tag{5.74}$$

(Deaton and Muellbauer, 1980b, §5.2, eq. 2.10, p. 129). The right side is the compensated response of spending on group G to a proportional rise in all prices of group G'. So $\lambda_{GG'}$ is the substitution term between two group aggregates, each defined with fixed relative prices inside the group. Writing $X_G^h = \sum_{i\in G} p_i h_i$ in (5.74) gives $\lambda_{GG'} = \sum_{i\in G}\sum_{j\in G'} p_i p_j S_{ij}$, which is symmetric in (G, G') by Slutsky symmetry. We define λ_{GG} by the same double sum with $G' = G$. Let Π be the $J \times \mathcal{G}$ matrix with elements p_j in the rows of the goods of group G and column G, and zeros elsewhere. Then $\Lambda = [\lambda_{GG'}] = \Pi^\top S\,\Pi$. This matrix is symmetric and negative semidefinite. Its rows sum to zero because $\Pi\iota = p$ for the vector of ones ι, and $Sp = 0$. It is the Slutsky matrix of the group aggregates. Weak separability thus gives two tiers of substitution matrices. Within each group the conditional Slutsky matrix is unrestricted, and between groups substitution runs through Λ alone.

The signs of cross-group substitution are also restricted. If no good is inferior, $\frac{\partial q_i}{\partial I} > 0$ for all i, and (5.71) gives every S_{ij} with $i \in G$ and $j \in G'$ the sign of $\mu_{GG'}$. When two groups are substitutes, every good of one is a Hicksian substitute for every good of the other. When the groups are complements, every cross pair is complementary (Deaton and Muellbauer, 1980b, p. 129).

In elasticity form, with $\frac{\partial q_i}{\partial I} = \eta_i \frac{q_i}{I}$, (5.71) becomes

$$\varepsilon_{ij}^h = \frac{\mu_{GG'}}{I}\,\eta_i\,\eta_j\,w_j, \qquad i \in G,\ j \in G',\ G \neq G'. \tag{5.75}$$

All compensated cross elasticities between two groups are governed by one number per pair of groups, scaled by the goods' expenditure elasticities and the budget share of the good whose price changes. Under additive separability the factor μ is the same for all pairs of groups. Substitution between groups runs entirely through group expenditures.

The restriction is strong when goods in different groups are close substitutes. If a cheap good in one group competes directly with a particular good in another, separability spreads that competition evenly, in proportion to income effects, over all goods of the second group. The sign result adds a second constraint. Two groups that are substitutes on the whole cannot contain a complementary cross pair, such as a camera in one group and its film in the other. The grouping must therefore put close substitutes together and keep complements in the same group. In ready-to-eat cereals the segmentation comes from marketing research and has little ambiguity, but Bresnahan (1997, fn. 5) warns that this is an exception. In many industries "several principles of differentiation, each with a distinct set of close-substitute products, compete for the analyst's attention." In automobiles, size segments, brand names

and even country reputations all shape substitution, and many consumer product markets mix named segments with a private-label versus brand-name split.

Separability can be tested. Under weak separability the individual prices of goods outside a group affect the group's demand only through the group price indices and group expenditure. Adding individual outside prices to a group-level equation and testing their exclusion is therefore a specification test of the grouping. Hausman et al. (1994) implement such a test by adding the prices of individual light beers to the segment equation for premium beer (Section 5.8).

Under weak separability alone, the first stage takes a differential form with two price indices per group. The result goes back to Barten and Turnovsky (1966), and we state it as in Deaton and Muellbauer (1980b, §5.2, eqs. 2.20–2.23, pp. 132–133). Write $w_i = \frac{p_i q_i}{I}$ for the share of good i in total expenditure, $w_G = \frac{X_G}{I}$ for the share of group G, and $b_G = \sum_{i \in G} p_i \frac{\partial q_i}{\partial I}$ for the marginal propensity to spend on the group. Define two differential price indices for each group,

$$\mathrm{d}\ln P^w_G = \sum_{k \in G} w_{k|G}\, \mathrm{d}\ln p_k, \qquad \mathrm{d}\ln P^m_G = \sum_{k \in G} p_k \frac{\partial q_{k|G}}{\partial X_G}\, \mathrm{d}\ln p_k. \tag{5.76}$$

The first weights price changes by within-group budget shares. The second weights them by within-group marginal budget shares. Both sets of weights sum to one.

Proposition 5.39 (Two price indices per group)**.** *Under weak separability, for every group G,*

$$\sum_{i \in G} w_i\, \mathrm{d}\ln q_i = b_G\Big(\mathrm{d}\ln I - \sum_{G'} w_{G'}\, \mathrm{d}\ln P^w_{G'}\Big) + \sum_{G'} \frac{\lambda_{GG'}}{I}\, \mathrm{d}\ln P^m_{G'}, \tag{5.77}$$

where the sums run over all groups, including G, and $\lambda_{GG'}$ is defined in (5.72) and below (5.74).

Proof. Totally differentiate $q_i(p, I)$ and substitute the Slutsky equation $\frac{\partial q_i}{\partial p_j} = S_{ij} - q_j \frac{\partial q_i}{\partial I}$ (Proposition 5.8):

$$\mathrm{d}q_i = \frac{\partial q_i}{\partial I}\Big(\mathrm{d}I - \sum_j q_j\, \mathrm{d}p_j\Big) + \sum_j S_{ij}\, \mathrm{d}p_j.$$

Multiply by $\frac{p_i}{I}$, use $\mathrm{d}p_j = p_j\, \mathrm{d}\ln p_j$, and sum over $i \in G$:

$$\sum_{i \in G} w_i\, \mathrm{d}\ln q_i = b_G\Big(\mathrm{d}\ln I - \sum_j w_j\, \mathrm{d}\ln p_j\Big) + \frac{1}{I}\sum_j \Big(\sum_{i \in G} p_i S_{ij}\Big) p_j\, \mathrm{d}\ln p_j.$$

Since $w_j = w_{G'} w_{j|G'}$ for $j \in G'$, the first bracket equals $\mathrm{d}\ln I - \sum_{G'} w_{G'}\, \mathrm{d}\ln P^w_{G'}$. It remains to show that, for every j in any group G',

$$\sum_{i \in G} p_i S_{ij} = \lambda_{GG'} \frac{\partial q_{j|G'}}{\partial X_{G'}}. \tag{5.78}$$

For $G' \neq G$, the sum equals $\frac{\partial X^h_G}{\partial p_j}$, and (5.73) gives (5.78). For $G' = G$, use Slutsky symmetry and then homogeneity of h_j of degree zero in prices, $\sum_k p_k S_{jk} = 0$:

$$\sum_{i \in G} p_i S_{ij} = \sum_{i \in G} p_i S_{ji} = -\sum_{G'' \neq G} \sum_{k \in G''} p_k S_{kj} = -\frac{\partial q_{j|G}}{\partial X_G} \sum_{G'' \neq G} \lambda_{G''G}.$$

The last step applies (5.73) to group G'' and the price p_j of a good in G. The rows of Λ sum to zero and Λ is symmetric, so $-\sum_{G'' \neq G} \lambda_{G''G} = \lambda_{GG}$, which proves (5.78) for $G' = G$. Substituting (5.78) into the last sum,

$$\frac{1}{I} \sum_{G'} \lambda_{GG'} \sum_{j \in G'} p_j \frac{\partial q_{j|G'}}{\partial X_{G'}} \, \mathrm{d} \ln p_j = \sum_{G'} \frac{\lambda_{GG'}}{I} \, \mathrm{d} \ln P^m_{G'},$$

which completes the proof. □

The left side of (5.77) is the change in a share-weighted quantity index of group G. The right side has the form of a Rotterdam equation for groups (Section 5.6.5). Real income enters through the share-weighted indices P^w, and substitution through the marginally weighted indices P^m. Knowledge of two price indices per group is therefore enough to maintain an optimal allocation across groups, once it is reached. No restriction beyond weak separability is needed. In practice, if prices inside each group move roughly together, the two indices move together and one index may be an adequate proxy for both (p. 133). The result is local. The coefficients b_G and $\lambda_{GG'}$ vary with prices and expenditure, and a Rotterdam-type model treats them as constants.

5.5.4 Conditional and unconditional elasticities

Estimates of a multi-level system yield *conditional* elasticities, which hold group expenditure fixed. Pricing, merger and welfare calculations need *unconditional* elasticities, which let group expenditure respond. As elsewhere in this chapter, elasticities are signed: $\varepsilon_{ij} = \frac{\partial \ln q_i}{\partial \ln p_j}$, so own-price elasticities are negative.

Consider a two-level system. Total expenditure on the upper-level category is X, for example spending on all systemic antibiotics, and plays the role of income. The upper level allocates X to groups with shares $w_G = \frac{X_G}{X}$ that depend on group price indices $P_{G'}$ and on X. The lower level is a conditional demand system $q_{i|G}(p_G, X_G)$ within each group, and $P_G = P_G(p_G)$. For $i \in G$ and a price p_j of the same group, the chain rule with X held fixed gives

$$\varepsilon_{ij} = \varepsilon_{ij}\big|_{X_G} + \frac{\partial \ln q_i}{\partial \ln X_G} \frac{\partial \ln X_G}{\partial \ln P_G} \frac{\partial \ln P_G}{\partial \ln p_j}, \tag{5.79}$$

which is equation (3.10) of Chaudhuri et al. (2006). The first term is the conditional elasticity. The second term traces the effect of p_j on the group price index, of the index on group expenditure, and of group expenditure on q_i.

With an AIDS at both levels, each factor has a closed form. The lower level gives the conditional Marshallian elasticity of (5.38), written with within-group shares,

$$\varepsilon_{ij}\big|_{X_G} = -\mathbf{1}(i = j) + \frac{\gamma_{ij} - \beta_i \left(w_{j|G} - \beta_j \ln \frac{X_G}{P_G} \right)}{w_{i|G}},$$

and the conditional expenditure elasticity $\frac{\partial \ln q_i}{\partial \ln X_G} = 1 + \frac{\beta_i}{w_{i|G}}$. With the translog group index, Shephard's lemma at the lower level gives

$$\frac{\partial \ln P_G}{\partial \ln p_j} = \alpha_j + \sum_{k \in G} \gamma_{jk} \ln p_k = w_{j|G} - \beta_j \ln \frac{X_G}{P_G},$$

which reduces to $w_{j|G}$ for a Stone group index whose weights are held fixed. At the upper level, $X_G = w_G X$ with X fixed, so

$$\frac{\partial \ln X_G}{\partial \ln P_G} = \frac{\partial \ln w_G}{\partial \ln P_G} = \frac{1}{w_G}\frac{\partial w_G}{\partial \ln P_G} = 1 + \varepsilon_{GG}, \tag{5.80}$$

where ε_{GG} is the own-price elasticity of the group quantity index $\frac{X_G}{P_G}$. With an upper-level AIDS deflated by a Stone index, $\ln P = \sum_{G'} w_{G'} \ln P_{G'}$, and the Stone weights held fixed, $\frac{\partial w_G}{\partial \ln P_G} = \gamma_{GG} - \beta_G w_G$. Collecting terms,

$$\varepsilon_{ij} = \varepsilon_{ij}\big|_{X_G} + \left(1 + \frac{\beta_i}{w_{i|G}}\right)\left(\frac{\gamma_{GG}}{w_G} - \beta_G\right)\left(w_{j|G} - \beta_j \ln \frac{X_G}{P_G}\right). \tag{5.81}$$

The middle factor shows when the correction matters. If the group as a whole has unit-elastic demand ($\varepsilon_{GG} = -1$), a higher group price leaves group expenditure unchanged and unconditional and conditional elasticities coincide. If group demand is inelastic, a higher group price draws spending into the group, and the correction is positive. If group demand is elastic, spending leaves the group.

For goods in different groups, $i \in G$ and $j \in G'$ with $G' \neq G$, the conditional term vanishes and only the expenditure channel remains:

$$\varepsilon_{ij} = \frac{\partial \ln q_i}{\partial \ln X_G}\frac{\partial \ln X_G}{\partial \ln P_{G'}}\frac{\partial \ln P_{G'}}{\partial \ln p_j} = \left(1 + \frac{\beta_i}{w_{i|G}}\right)\varepsilon_{GG'}\left(w_{j|G'} - \beta_j \ln \frac{X_{G'}}{P_{G'}}\right), \tag{5.82}$$

where $\varepsilon_{GG'} = \frac{1}{w_G}\frac{\partial w_G}{\partial \ln P_{G'}} = \frac{\gamma_{GG'} - \beta_G w_{G'}}{w_G}$ is the upper-level cross elasticity. This is the elasticity counterpart of Proposition 5.38: cross-group effects are the product of a group-level elasticity and within-group factors. Finally, the unconditional elasticity of q_i with respect to the category budget is the product of the expenditure elasticities at the two levels,

$$\frac{\partial \ln q_i}{\partial \ln X} = \frac{\partial \ln q_i}{\partial \ln X_G}\frac{\partial \ln X_G}{\partial \ln X} = \left(1 + \frac{\beta_i}{w_{i|G}}\right)\left(1 + \frac{\beta_G}{w_G}\right).$$

Three levels. Hausman et al. (1994) and Hausman (1997) use three levels. The bottom level explains brand shares within a segment by an AIDS on segment expenditure. The middle level explains segment quantities by a log-log system in category expenditure and segment price indices. The top level explains category demand by a log-log equation in income and the category price index. Let Π denote the category price index and y income. Group expenditure $X_G(P_1, \ldots, P_{\mathcal{G}}, X)$ now responds to P_G also through the category budget $X(\Pi, y)$. The total effect of the segment index on segment expenditure is

$$\frac{\mathrm{d} \ln X_G}{\mathrm{d} \ln P_G} = \frac{\partial \ln X_G}{\partial \ln P_G}\Big|_X + \frac{\partial \ln X_G}{\partial \ln X}\frac{\partial \ln X}{\partial \ln \Pi}\frac{\partial \ln \Pi}{\partial \ln P_G},$$

and this total replaces $\frac{\partial \ln X_G}{\partial \ln P_G}$ in (5.79). The estimating equations of the three levels are given in Section 5.8.

Figure 5.4 draws the two budgeting trees used in this chapter.

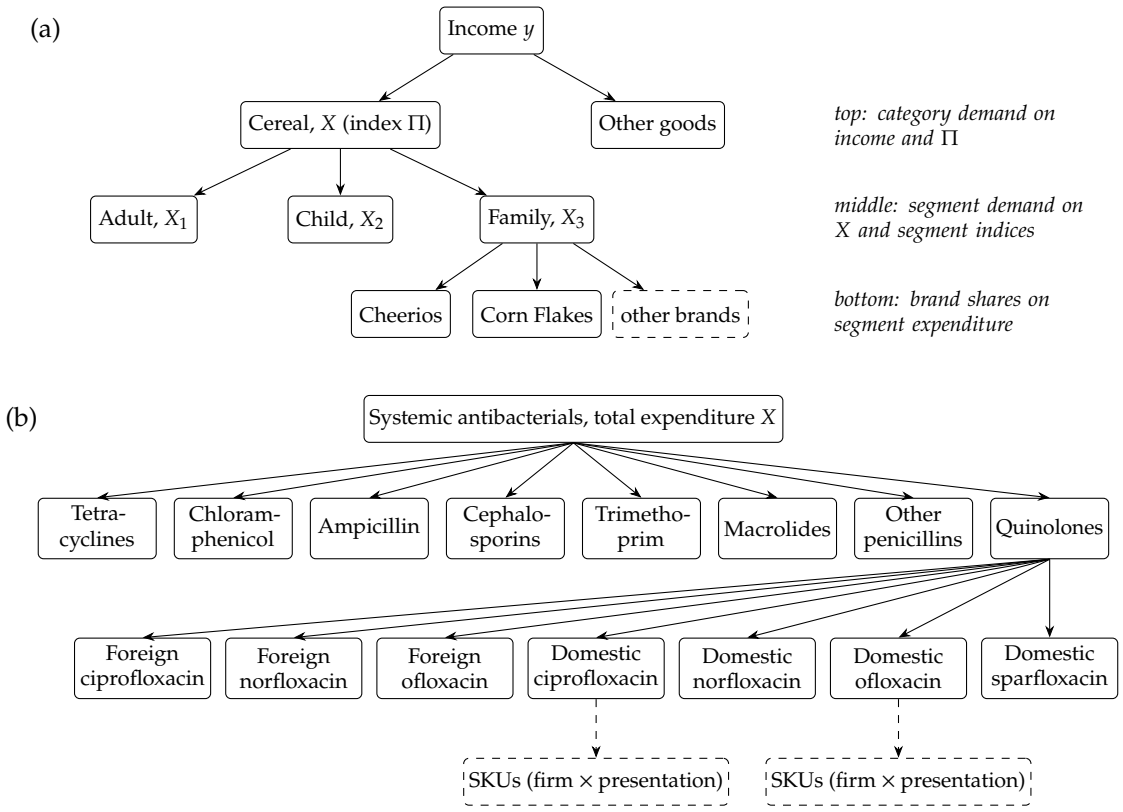


Figure 5.4: Budgeting trees. Panel (a): the three-level structure of Hausman (1997) for ready-to-eat cereal, with the three segments he uses and two of the family-segment brands (his Table 5.1). Panel (b): the two-level structure of Chaudhuri et al. (2006). The upper level allocates systemic antibacterial expenditure across sub-segments, eight of which appear with equations in their upper-level system (their Table A3). The lower level allocates quinolone expenditure across seven molecule-by-status groups. Foreign sparfloxacin, with a minuscule share, is folded into the domestic group. Within-group choice among stock-keeping units (SKUs) is not modeled (dashed).

5.6 Estimation and identification

This section turns the AIDS into an econometric model. We add an error term and ask what it contains, deal with the singular covariance matrix that adding up creates, and compare the exact nonlinear model with its linear approximation. We then show how the theoretical restrictions are tested and work through the original application of Deaton and Muellbauer (1980a) in detail. The section closes with the identification problems that dominate industrial organization applications: endogenous prices, endogenous group expenditure, and group prices measured with error.

5.6.1 Stochastic specification

Observations are indexed by $t = 1, \dots, T$. An observation may be a year of national data, a month in a region, or a week in a city. The estimating equations are

$$w_{it} = \alpha_i + \sum_{j=1}^{J} \gamma_{ij} \ln p_{jt} + \beta_i \ln \frac{I_t}{\mathbf{P}_t} + \xi_{it}, \qquad i = 1, \dots, J, \tag{5.83}$$

with the translog index $\ln \mathbf{P}_t = \alpha_0 + \sum_k \alpha_k \ln p_{kt} + \frac{1}{2} \sum_k \sum_j \gamma_{kj} \ln p_{kt} \ln p_{jt}$ of (5.24). We write the error as ξ_{it}, in place of the ε_{it} used by the original papers, because ε denotes elasticities in this chapter. Its content matters for every later step, so we list the main components.

(a) *Unobserved demand shifters.* Advertising campaigns, epidemics that call for a particular drug, or changes in demographics shift the shares of particular goods. Firms often observe these shocks when they set prices.

(b) *Measurement error.* Shares and prices are measured with error. In multi-level systems the prices of product groups are averages of the prices of many stock-keeping units, which approximate an unobserved exact group price index (Section 5.6.8).

(c) *Aggregation error.* The omitted term $-\beta_i(\ln \kappa_t - \ln \kappa^*)$ of (5.65) enters the error when the distribution of budgets changes.

(d) *Specification error.* Habits, stocks of durables, price expectations and other dynamics that the static model omits.

Component (a) makes prices endogenous when firms set them. Component (b) creates errors in variables. Components (c) and (d) are correlated with the regressors whenever inequality or the omitted dynamics move with prices and real expenditure. We write $\Sigma = \mathbb{E}[\xi_t \xi_t^\top]$ for the $J \times J$ covariance matrix of $\xi_t = (\xi_{1t}, \dots, \xi_{Jt})^\top$.

5.6.2 Adding up and the singular covariance matrix

Budget shares sum to one in the data. Under the adding-up restrictions of Proposition 5.19, the deterministic part of (5.83) also sums to one, because

$$\sum_i \Big(\alpha_i + \sum_j \gamma_{ij} \ln p_{jt} + \beta_i \ln \frac{I_t}{\mathbf{P}_t} \Big) = \sum_i \alpha_i + \sum_j \Big(\sum_i \gamma_{ij} \Big) \ln p_{jt} + \Big(\sum_i \beta_i \Big) \ln \frac{I_t}{\mathbf{P}_t} = 1.$$

Hence $\sum_i \xi_{it} = 0$ for every t. Writing ι for the J-vector of ones, $\iota^\top \xi_t = 0$ implies $\iota^\top \Sigma = 0$, so Σ is singular with rank at most $J - 1$. The Gaussian likelihood of the full system is not defined, because it requires Σ^{-1}.

The standard solution drops one equation, say the J-th, and estimates the remaining $J-1$. The parameters of the dropped equation follow from adding up:

$$\alpha_J = 1 - \sum_{i<J} \alpha_i, \qquad \beta_J = -\sum_{i<J} \beta_i, \qquad \gamma_{Jj} = -\sum_{i<J} \gamma_{ij} \quad (j = 1, \dots, J).$$

Which equation we drop does not matter for maximum likelihood.

Proposition 5.40 (Barten, 1969)**.** *Suppose the errors of any $J-1$ share equations are jointly normal with an unrestricted covariance matrix. Then the maximum likelihood estimates of the parameters are the same whichever equation is dropped.*

Proof. Let $\tilde{\xi}_t(\theta)$ be the residuals of the $J-1$ retained equations at parameter value θ. Concentrating the unrestricted covariance matrix out of the Gaussian log likelihood gives, up to a constant,

$$\ln L^c(\theta) = -\frac{T}{2} \ln \det \hat{\Omega}(\theta), \qquad \hat{\Omega}(\theta) = \frac{1}{T} \sum_t \tilde{\xi}_t(\theta) \tilde{\xi}_t(\theta)^\top.$$

Dropping equation k instead of equation J replaces ξ_{kt} by $\xi_{Jt} = -\sum_{i<J} \xi_{it}$. The new residual vector is $A\tilde{\xi}_t$, where A is the identity matrix with row k replaced by a row of -1's, followed by a reordering of rows. Expanding the determinant along row k shows that $\det A = \pm 1$. The new concentrated likelihood is therefore

$$-\frac{T}{2} \ln \det\big(A \hat{\Omega}(\theta) A^\top\big) = -\frac{T}{2} \ln\big[(\det A)^2 \det \hat{\Omega}(\theta)\big] = \ln L^c(\theta),$$

the same function of θ, with the same maximizer. □

Seemingly unrelated regressions. The standard system estimator is *seemingly unrelated regressions* (SUR) (Zellner, 1962). Write retained equation i as $\mathbf{w}_i = \mathbf{X}_i b_i + \boldsymbol{\xi}_i$, where $\mathbf{w}_i$ stacks the T observed shares, $\mathbf{X}_i$ is the $T \times K_i$ matrix of its regressors and b_i is its coefficient vector. Stacking the $J-1$ equations gives $\mathbf{w} = \mathbf{X} b + \boldsymbol{\xi}$, with $\mathbf{X} = \operatorname{diag}(\mathbf{X}_1, \dots, \mathbf{X}_{J-1})$ block diagonal. The errors of one observation have covariance matrix $\mathbb{E}[\tilde{\xi}_t \tilde{\xi}_t^\top] = \Omega$ and are independent over t, so $\operatorname{Var}(\boldsymbol{\xi}) = \Omega \otimes I_T$. Feasible generalized least squares gives

$$\hat{b} = \big[\mathbf{X}^\top (\hat{\Omega}^{-1} \otimes I_T) \mathbf{X}\big]^{-1} \mathbf{X}^\top (\hat{\Omega}^{-1} \otimes I_T)\, \mathbf{w}, \tag{5.84}$$

where $\hat{\Omega}$ has elements $\hat{\Omega}_{ik} = \frac{1}{T} \hat{\boldsymbol{\xi}}_i^\top \hat{\boldsymbol{\xi}}_k$ computed from equation-by-equation OLS residuals. Homogeneity and symmetry are linear restrictions $R b = r_0$. Minimizing the generalized least squares criterion subject to them gives

$$\hat{b}_R = \hat{b} - V R^\top \big(R V R^\top\big)^{-1} \big(R \hat{b} - r_0\big), \qquad V = \big[\mathbf{X}^\top (\hat{\Omega}^{-1} \otimes I_T) \mathbf{X}\big]^{-1}. \tag{5.85}$$

Section A.2.5 derives this formula from the Lagrangian. Recomputing $\hat{\Omega}$ from the new residuals and iterating until convergence gives the Gaussian maximum likelihood estimator. Iterated SUR therefore shares the invariance of Proposition 5.40. *Three-stage least squares* applies (5.84) after replacing $\mathbf{X}$ by its projection on the instruments, with $\hat{\Omega}$ estimated from two-stage least squares residuals (Section A.3.8).

Two further facts simplify estimation when there are no cross-equation restrictions. First, when every equation has the same regressors, $\mathbf{X}_i = \mathbf{X}_0$ for all i, SUR reduces to ordinary least squares (OLS) equation by equation (Proposition A.13). OLS is then the maximum

likelihood estimator under normality (Deaton and Muellbauer, 1980a, p. 316). Second, OLS automatically satisfies adding up. To see this, stack the T observations of the regressors $(1, \ln p_{1t}, \dots, \ln p_{Jt}, \ln \frac{I_t}{\mathbf{P}_t})$ in the matrix $\mathbf{X}_0$, whose first column is the vector of ones ι_T. The OLS coefficient vectors $b_i = (\mathbf{X}_0^\top \mathbf{X}_0)^{-1} \mathbf{X}_0^\top \mathbf{w}_i$ sum to

$$\sum_i b_i = (\mathbf{X}_0^\top \mathbf{X}_0)^{-1} \mathbf{X}_0^\top \sum_i \mathbf{w}_i = (\mathbf{X}_0^\top \mathbf{X}_0)^{-1} \mathbf{X}_0^\top \iota_T = (1, 0, \dots, 0)^\top,$$

because regressing a column of ones on $\mathbf{X}_0$ returns a coefficient of one on the constant and zero elsewhere. Hence $\sum_i \hat{\alpha}_i = 1$, $\sum_i \hat{\gamma}_{ij} = 0$ and $\sum_i \hat{\beta}_i = 0$.

Short samples. Symmetry is a cross-equation restriction, so the covariance matrix now affects the estimates. With few observations an unrestricted covariance matrix cannot be estimated. Deaton and Muellbauer (1980a, p. 318) had 21 annual observations on eight shares. They note that the likelihood "can be made arbitrarily large by making any one equation fit perfectly." The reason is visible in $\ln L^c(\theta)$. If the parameters can be chosen so that one equation has zero residuals, $\det \hat{\Omega}(\theta) = 0$ and the concentrated likelihood is unbounded. Under symmetry their system has 42 free coefficients, and every equation depends on all of them through $\ln \mathbf{P}_t$. With only 21 observations per equation, the coefficients can typically be chosen to fit one equation exactly. Deaton and Muellbauer therefore impose a structure on the covariance matrix,

$$\Sigma = \sigma^2 \Big(I_J - \frac{1}{J} \iota \iota^\top \Big), \tag{5.86}$$

where I_J is the identity matrix and ι is the J-vector of ones. This matrix satisfies $\Sigma \iota = 0$, as adding up requires. It turns maximum likelihood into least squares on the whole system. To see this, drop equation J. The covariance matrix of the remaining errors is $\sigma^2 (I_{J-1} - \frac{1}{J} \mathbf{1}\mathbf{1}^\top)$, where $\mathbf{1}$ is a $(J-1)$-vector of ones. Its inverse is $\sigma^{-2}(I_{J-1} + \mathbf{1}\mathbf{1}^\top)$, as multiplying the two matrices confirms:

$$\Big(I - \frac{1}{J} \mathbf{1}\mathbf{1}^\top \Big) \big(I + \mathbf{1}\mathbf{1}^\top \big) = I + \mathbf{1}\mathbf{1}^\top - \frac{1}{J} \mathbf{1}\mathbf{1}^\top - \frac{J-1}{J} \mathbf{1}\mathbf{1}^\top = I.$$

The quadratic form in the likelihood is then

$$\tilde{\xi}_t^\top \big(I + \mathbf{1}\mathbf{1}^\top \big) \tilde{\xi}_t = \sum_{i<J} \xi_{it}^2 + \Big(\sum_{i<J} \xi_{it} \Big)^2 = \sum_{i=1}^{J} \xi_{it}^2,$$

using $\xi_{Jt} = -\sum_{i<J} \xi_{it}$. Maximizing the likelihood over the coefficients therefore minimizes the total sum of squared residuals across all J equations, the trace of the residual cross-product matrix rather than its determinant.

5.6.3 The nonlinear AIDS

Substituting the translog index into (5.83) gives the estimating equations of the exact model (Deaton and Muellbauer, 1980a, eq. 15):

$$w_{it} = (\alpha_i - \beta_i \alpha_0) + \sum_j \gamma_{ij} \ln p_{jt} + \beta_i \Big\{ \ln I_t - \sum_k \alpha_k \ln p_{kt} - \frac{1}{2} \sum_k \sum_j \gamma_{kj} \ln p_{kt} \ln p_{jt} \Big\} + \xi_{it}. \tag{5.87}$$

The system is nonlinear in the parameters because β_i multiplies α_k and γ_{kj}. It can be estimated by nonlinear least squares, by maximum likelihood, or by the generalized method of moments

(GMM) when instruments are needed, with or without the homogeneity and symmetry restrictions. The computation is easier than it looks. Given β, the equations are linear in (α, γ). Given (α, γ), the index is known and the equations are linear in β. The first-order conditions can therefore be solved by alternating between two linear problems (Deaton and Muellbauer, 1980a, p. 316).

All parameters of (5.87) are identified given enough variation in prices and expenditure. The constant α_0 is the exception in practice. It is identified only through the appearance of the α_k inside the braces. When individual prices move closely together, $\ln \mathbf{P}_t$ is insensitive to its weights. A change in α_0 can then be offset by changes in the α_i with little effect on the fit. Deaton and Muellbauer recommend fixing α_0 a priori. At unit prices $\ln a(p) = \alpha_0$, so e^{α_0} is the cost of subsistence when all prices equal one. In their words it is "the outlay required for a minimal standard of living," and a plausible value is easy to choose (Deaton and Muellbauer, 1980a, p. 316).

5.6.4 The linear approximate AIDS and the Stone index

The same collinearity suggests a shortcut. If $\mathbf{P}_t$ is approximately proportional to a known index P_t^*, say $\mathbf{P}_t \approx \varphi P_t^*$, then

$$w_{it} = (\alpha_i - \beta_i \ln \varphi) + \sum_j \gamma_{ij} \ln p_{jt} + \beta_i \ln \frac{I_t}{P_t^*} + \xi_{it} \tag{5.88}$$

(Deaton and Muellbauer, 1980a, eq. 16). This *linear approximate AIDS* (LA-AIDS) is linear in the parameters. Without cross-equation restrictions it can be estimated by OLS equation by equation, which is maximum likelihood for the system and satisfies adding up. The intercepts $\alpha_i^* = \alpha_i - \beta_i \ln \varphi$ still sum to one because $\sum_i \beta_i = 0$. The usual choice of P_t^* is the *Stone index*

$$\ln P_t^S = \sum_k w_{kt} \ln p_{kt}. \tag{5.89}$$

It is exact, up to the constant α_0, in one case. If $\gamma_{ij} = 0$ and $\beta_i = 0$ for all i, j, then $w_k = \alpha_k$ and $\ln \mathbf{P} = \alpha_0 + \sum_k \alpha_k \ln p_k = \alpha_0 + \ln P^S$. This is the Cobb-Douglas case. Otherwise the approximation is good when prices move together.

The exact gap between the two models. How good is the approximation, and what goes wrong when it fails? Substituting the share equations into (5.89) and subtracting the translog index gives an exact expression for the gap:

$$\begin{aligned} \ln P_t^S - \ln \mathbf{P}_t &= \sum_k \Big(\alpha_k + \sum_j \gamma_{kj} \ln p_{jt} + \beta_k \ln \frac{I_t}{\mathbf{P}_t} + \xi_{kt} \Big) \ln p_{kt} - \ln \mathbf{P}_t \\ &= -\alpha_0 + \frac{1}{2} \sum_k \sum_j \gamma_{kj} \ln p_{kt} \ln p_{jt} + \ln \frac{I_t}{\mathbf{P}_t} \sum_k \beta_k \ln p_{kt} + \sum_k \xi_{kt} \ln p_{kt}. \end{aligned} \tag{5.90}$$

The true model (5.83) can be written in terms of the Stone index by adding and subtracting $\beta_i \ln P_t^S$:

$$\begin{aligned} w_{it} = (\alpha_i - \beta_i \alpha_0) &+ \sum_j \gamma_{ij} \ln p_{jt} + \beta_i \ln \frac{I_t}{P_t^S} \\ &+ \beta_i \Big[\frac{1}{2} \sum_k \sum_j \gamma_{kj} \ln p_{kt} \ln p_{jt} + \ln \frac{I_t}{\mathbf{P}_t} \sum_k \beta_k \ln p_{kt} + \sum_k \xi_{kt} \ln p_{kt} \Big] + \xi_{it}. \end{aligned} \tag{5.91}$$

The LA-AIDS omits the bracket. Each of its three terms explains one known problem of the Stone index.

Interpretation of the coefficients. The middle term is linear in $\ln p_{kt}$ with coefficient $\beta_i\beta_k \ln \frac{I_t}{\mathbf{P}_t}$. When real expenditure varies around a mean m, this term is absorbed into the price coefficients, and the LA-AIDS estimates $\gamma_{ij}^{LA} \approx \gamma_{ij} + \beta_i\beta_j m$ rather than γ_{ij}. The usual LA-AIDS elasticity formula

$$\varepsilon_{ij} \approx -\mathbf{1}(i=j) + \frac{\gamma_{ij}^{LA} - \beta_i w_j}{w_i} \tag{5.92}$$

then equals $-\mathbf{1}(i=j) + \frac{\gamma_{ij} - \beta_i(w_j - \beta_j m)}{w_i}$, which is the exact AIDS elasticity of (5.38) at $\ln \frac{I}{\mathbf{P}} = m$. Although the LA coefficients differ from the AIDS coefficients, the LA elasticities can be close to the AIDS elasticities near the center of the data.

Simultaneity. The last term contains the errors of all equations. The Stone index is built from current shares, so the regressor $\ln \frac{I_t}{P_t^S}$ is correlated with ξ_{it}. The term is small when log prices are close to zero.

Units of measurement. Moschini (1995) shows that the Stone index is not invariant to the units in which goods are measured. Suppose the unit of good k is changed, so that p_{kt} becomes λp_{kt} ($\lambda > 1$ for a larger unit) and $\ln p_{kt}$ becomes $\ln p_{kt} + c$ with $c = \ln \lambda$. The exact AIDS absorbs the change. Replacing α_j by $\alpha_j - c\gamma_{jk}$ for every j and α_0 by $\alpha_0 - c\alpha_k + \frac{1}{2}c^2\gamma_{kk}$ leaves both the translog index and every share equation unchanged as functions of the new prices. To verify, expand the index in the new log prices $\ln p'_{jt}$:

$$\ln \mathbf{P}_t = \left(\alpha_0 - c\alpha_k + \frac{1}{2}c^2\gamma_{kk}\right) + \sum_j (\alpha_j - c\gamma_{jk}) \ln p'_{jt} + \frac{1}{2}\sum_j \sum_l \gamma_{jl} \ln p'_{jt} \ln p'_{lt},$$

using symmetry, and note that $\gamma_{ik} \ln p_{kt} = \gamma_{ik} \ln p'_{kt} - c\gamma_{ik}$ in each share equation. The new α_j still sum to one because $\sum_j \gamma_{jk} = 0$. Fitted shares and elasticities do not change. The Stone index, by contrast, shifts by $c\, w_{kt}$, which varies over observations. Redoing (5.90) in the new units, the bracket in (5.91) gains the term $c(w_{kt} - \alpha_k)$ plus a constant. The LA-AIDS therefore omits a time-varying term $\beta_i c\, w_{kt}$ that is correlated with its regressors. Its estimates of β_i, γ_{ij} and the elasticities depend on the arbitrary choice of units, and the dependence grows with $|c|$.

Example 5.41 (Units and the Stone index: a simulation)**.** We generate data from the exact AIDS with the running-example parameters and $\alpha_0 = 0$. Log prices are $\ln p_{jt} = \pi_t + s_e e_{jt}$, with a common component $\pi_t \sim N(0, 0.3^2)$ and relative-price noise $e_{jt} \sim N(0,1)$. Log expenditure is $\ln I_t = 1 + \pi_t + 0.3 g_t$ with $g_t \sim N(0,1)$, and share errors sum to zero, with standard deviations of about 0.004. Design A has nearly collinear prices ($s_e = 0.02$) and design B has substantial relative-price variation ($s_e = 0.20$). Each sample has $T = 100$ observations, and we draw 500 samples. Four estimators impose adding up, homogeneity and symmetry, and minimize the total sum of squared residuals. The first is the exact nonlinear AIDS and the second the LA-AIDS with the Stone index. The third is the same LA-AIDS after good 1 is measured in units one hundred times larger (p_1 multiplied by 100, $c = \ln 100 = 4.61$). The fourth is an LA-AIDS deflated by a fixed-weight index with sample-mean shares. Table 5.4 reports the results, with elasticities evaluated at the base point of Example 5.21.

Three lessons emerge. First, with prices normalized to one near the center of the data, the Stone LA-AIDS recovers the elasticities in both designs. It does so even though the gap between the indices in design B is of the order of 0.1 in logs. Its own-price coefficient $\hat{\gamma}_{11}^{LA}$ averages -0.190, while the AIDS coefficient is -0.200. The difference is $\beta_1^2 m = 0.01$, exactly as (5.91)

predicts. Second, merely changing the units of good 1 moves $\hat{\beta}_1$ from -0.100 to about -0.069 and the own-price elasticity of good 1 from -1.38 to -1.26. Third, the fixed-weight index gives the same estimates in either unit, and its elasticities match those of the exact model. In design A the average largest gap between the demeaned Stone and translog indices is 0.008, the same magnitude that Deaton and Muellbauer found in British data (Section 5.6.7).

Table 5.4: Estimating the AIDS with exact and approximate price indices (simulation)

Estimator	$\hat{\beta}_1$	$\hat{\gamma}_{11}$	$\hat{\varepsilon}_{11}$	$\hat{\varepsilon}_{33}$
True values	-0.100	-0.200	-1.375	-1.738
Design A: nearly collinear prices ($s_e = 0.02$)				
Exact AIDS (nonlinear)	-0.100 (0.001)	-0.200 (0.017)	-1.376 (0.042)	-1.739 (0.066)
LA-AIDS, Stone index	-0.100 (0.001)	-0.190 (0.017)	-1.376 (0.042)	-1.740 (0.066)
LA-AIDS, Stone, rescaled p_1	-0.069 (0.001)	-0.130 (0.012)	-1.257 (0.029)	-1.667 (0.060)
LA-AIDS, fixed-weight index	-0.100 (0.001)	-0.190 (0.017)	-1.376 (0.042)	-1.739 (0.066)
Design B: independent relative prices ($s_e = 0.20$)				
Exact AIDS (nonlinear)	-0.100 (0.001)	-0.200 (0.002)	-1.375 (0.004)	-1.738 (0.007)
LA-AIDS, Stone index	-0.100 (0.001)	-0.190 (0.002)	-1.375 (0.005)	-1.737 (0.007)
LA-AIDS, Stone, rescaled p_1	-0.068 (0.001)	-0.130 (0.001)	-1.257 (0.004)	-1.665 (0.007)
LA-AIDS, fixed-weight index	-0.100 (0.001)	-0.190 (0.002)	-1.375 (0.005)	-1.738 (0.007)

Notes: means over 500 simulated samples of $T = 100$, standard deviations across samples in parentheses. Data are generated from the exact AIDS with the parameters of Example 5.21. Elasticities are evaluated at $p = (1, 1, 1)$, $\ln I = 1$, with the true shares $(0.40, 0.34, 0.26)$. The LA-AIDS elasticities use (5.92). The fixed-weight estimates are identical in either unit. Computed by `figures/ch05/src/stone_index_mc.py`.

Elasticities from the LA-AIDS. Applied work often computes LA-AIDS elasticities from (5.92), which treats $\frac{\partial \ln P^S}{\partial \ln p_j}$ as w_j. Green and Alston (1990) point out that the Stone weights themselves respond to prices. Within the LA model,

$$\frac{\partial \ln P^S}{\partial \ln p_j} = w_j + \sum_k \ln p_k \frac{\partial w_k}{\partial \ln p_j}.$$

Let $\mathcal{D}$ be the matrix of share derivatives $\frac{\partial w_i}{\partial \ln p_j}$, ℓ the vector of log prices, β the vector of expenditure coefficients and w the vector of shares. Differentiating (5.88),

$$\mathcal{D} = \Gamma^{LA} - \beta w^\top - \beta \ell^\top \mathcal{D} \quad \Longrightarrow \quad \mathcal{D} = \left(I + \beta \ell^\top\right)^{-1} \left(\Gamma^{LA} - \beta w^\top\right).$$

By the Sherman-Morrison formula, $(I + \beta\ell^\top)^{-1} = I - \frac{\beta \ell^\top}{1 + \ell^\top \beta}$. At a point where all prices equal one, $\ell = 0$ and (5.92) is exact for the LA model. Away from it the correction matters, and it depends on units for the reason just given. Normalizing prices to one at the point of evaluation removes the problem.

Remedies. Several fixes are available. A *Laspeyres-type* index with fixed weights, $\ln P_t^L = \sum_k \bar{w}_k \ln p_{kt}$ (base-period or sample-mean shares), contains no current shares, so it removes the simultaneity. A change of units shifts it by a constant that the intercepts absorb. The *Tornqvist* index $\ln P_t^T = \sum_k \frac{1}{2}(w_{kt} + w_k^0) \ln \frac{p_{kt}}{p_k^0}$ and the log-linear analogue of the Paasche index, $\sum_k w_{kt} \ln \frac{p_{kt}}{p_k^0}$, use prices relative to a base point p^0 and are therefore invariant to units (Moschini, 1995).

The Tornqvist index also has a basis in demand theory (Deaton and Muellbauer, 1980b, §7.1, eqs. 1.8–1.10, pp. 174–175). Along any price path at fixed utility, Shephard's lemma gives $\mathrm{d}\ln e(p,u) = \sum_k w_k(p,u)\,\mathrm{d}\ln p_k$, with Hicksian shares $w_k(p,u)$. Integrating from p^0 to p^1,

$$\ln \frac{e(p^1,u)}{e(p^0,u)} = \int_{p^0}^{p^1} \sum_k w_k(p,u)\,\mathrm{d}\ln p_k,$$

which is the log of the exact cost-of-living index at u. The *Divisia index* replaces the Hicksian shares in this integral by observed shares. Unless preferences are homothetic, observed shares move with utility along the path, so the Divisia index depends on the path. Prices are observed only at discrete dates, so the integral must be approximated. The Tornqvist index is a natural approximation, since it averages the shares at the two ends. Following Diewert (1976), it equals an exact index when the log expenditure function is quadratic in log prices and utility, with reference utility the geometric mean of the two utilities (p. 174). A fixed-weight index shares the units invariance but not this link to the exact index. A Stone index with lagged shares removes the contemporaneous correlation with ξ_t when the errors are serially uncorrelated. Finally, we can iterate toward the exact model, as Deaton and Muellbauer (1980a, p. 321) suggest:

1. Compute P_t^* (for example the Stone index) and estimate (5.88).
2. Compute $\ln \mathbf{P}_t$ from the estimated α and γ and a chosen α_0.
3. Re-estimate the share equations with $\ln \mathbf{P}_t$ in place of $\ln P_t^*$.
4. Repeat steps 2 and 3 until the estimates stop changing.

Deaton and Muellbauer describe this as "a computationally efficient way of obtaining good estimates of the full nonlinear system." They also stress that (5.88) exists only as an approximation. Once the restrictions have been chosen, the full system (5.87) should be re-estimated (Deaton and Muellbauer, 1980a, p. 317).

5.6.5 First differences and the Rotterdam model

Time-series applications often estimate in first differences. Differencing (5.83) gives

$$\Delta w_{it} = \beta_i \Delta \ln \frac{I_t}{\mathbf{P}_t} + \sum_j \gamma_{ij} \Delta \ln p_{jt} + \Delta \xi_{it} \tag{5.93}$$

(Deaton and Muellbauer, 1980a, eq. 17), in which the α_i appear only through $\Delta \ln \mathbf{P}_t$. Written out, $\Delta \ln \mathbf{P}_t$ involves $\sum_k \alpha_k \Delta \ln p_{kt}$ and $\frac{1}{2}\sum_k \sum_j \gamma_{kj} \Delta(\ln p_{kt} \ln p_{jt})$ (their eq. 18). With nearly collinear prices the γ_{ij} and the products $\beta_i \alpha_j$ are hard to separate. In practice $\Delta \ln \mathbf{P}_t$ is replaced by the change in a Stone index or by $\sum_k w_{kt} \Delta \ln p_{kt}$.

With the second choice the right-hand side becomes identical to that of the *Rotterdam model* of Theil (1965) and Barten (1969). The Rotterdam model is a differential demand system. Totally differentiating $q_i(p,I)$ and multiplying by w_i gives $w_i\,\mathrm{d}\ln q_i = w_i \eta_i\,\mathrm{d}\ln I + \sum_j w_i \varepsilon_{ij}\,\mathrm{d}\ln p_j$. Substituting the Slutsky equation in elasticity form, $\varepsilon_{ij} = \varepsilon_{ij}^h - \eta_i w_j$ (Section 5.2.6), gives

$$w_{it} \Delta \ln q_{it} = b_i \Big(\Delta \ln I_t - \sum_k w_{kt} \Delta \ln p_{kt} \Big) + \sum_j c_{ij} \Delta \ln p_{jt}, \tag{5.94}$$

with $b_i = w_i \eta_i = p_i \frac{\partial q_i}{\partial I}$, the marginal budget share, and $c_{ij} = w_i \varepsilon_{ij}^h = \frac{p_i p_j S_{ij}}{I}$. The Rotterdam model treats b_i and c_{ij} as constant parameters (Deaton and Muellbauer, 1980a, eq. 19).

The two models differ in the dependent variable. The AIDS has Δw_i, which is approximately $w_i \Delta \ln w_i = w_i(\Delta \ln q_i + \Delta \ln p_i - \Delta \ln I)$. So the first-difference AIDS replaces the Rotterdam dependent variable $w_i \Delta \ln q_i$ by $w_i \Delta \ln w_i$, adding $w_i \Delta \ln \frac{p_i}{I}$. Both models are linear in constant parameters, and both test homogeneity and symmetry through linear restrictions. Their parameters mean different things. The Rotterdam c_{ij} are compensated price effects, so negativity applies directly to the matrix $[c_{ij}]$. In the AIDS negativity applies to the matrix K of (5.32), which depends on the data. Above all, the AIDS is derived from explicit preferences. For forecasting demand this difference may matter little. For cost-of-living indices, equivalence scales or welfare calculations, the link between estimated parameters and preferences matters a great deal (Deaton and Muellbauer, 1980a, pp. 317–318).

5.6.6 Testing the restrictions of demand theory

The restrictions of Proposition 5.19 have different statistical status.

Adding up cannot be tested with share data. The shares sum to one by construction, and OLS estimates satisfy adding up automatically, as shown in Section 5.6.2.

Homogeneity, $\sum_j \gamma_{ij} = 0$, involves one equation at a time and can be tested equation by equation. Because the Stone index is homogeneous of degree one in prices, homogeneity can be imposed on (5.88) by writing prices relative to the price of good J:

$$w_{it} = \alpha_i^* + \sum_{j=1}^{J-1} \gamma_{ij} \ln \frac{p_{jt}}{p_{Jt}} + \beta_i \ln \frac{I_t}{P_t^*} + \xi_{it} \tag{5.95}$$

(Deaton and Muellbauer, 1980a, eq. 20). The identity $\sum_j \gamma_{ij} \ln p_j = \sum_{j<J} \gamma_{ij} \ln \frac{p_j}{p_J} + (\sum_j \gamma_{ij}) \ln p_J$ shows that (5.95) is the unrestricted equation with the coefficient on $\ln p_J$ set to $\sum_j \gamma_{ij} = 0$. An F test compares the residual sums of squares of the two regressions. Equivalently, it is the square of the t statistic on $\sum_j \hat{\gamma}_{ij}$ in the unrestricted regression.

Symmetry, $\gamma_{ij} = \gamma_{ji}$, links equations and can only be tested on the system, for example by a likelihood-ratio test,

$$LR = 2\big(\ln L_{\mathrm{U}} - \ln L_{\mathrm{R}}\big) \xrightarrow{d} \chi^2_r.$$

Here L_{U} and L_{R} are the maximized likelihoods without and with the restrictions, and r is the number of restrictions. In a J-good system estimated on $J-1$ equations, homogeneity imposes $J-1$ restrictions and symmetry imposes $\frac{(J-1)(J-2)}{2}$ more. For $J = 8$ these numbers are 7 and 21. The test is asymptotic, and allowance must be made for that when samples are short.

Deaton and Muellbauer test symmetry whether or not homogeneity has been rejected. They report an objection by Grayham Mizon, who argued that optimal inference stops testing once a rejection occurs. Their reply is that the choice of maintained hypothesis is partly a matter of judgment. Many economists would treat the absence of money illusion as maintained and regard symmetry as the interesting test. Moreover, "few if any tests in econometrics are carried out within the framework of maintained hypotheses which are even widely accepted" (Deaton and Muellbauer, 1980a, pp. 318–319).

Negativity cannot be imposed by linear restrictions and is checked after estimation. At each observation we compute the matrix K of (5.32) and its eigenvalues. One eigenvalue is identically zero because $K\iota = 0$, and the others should be nonpositive. Negativity can be imposed locally, at one point, by a Cholesky reparameterization of the Slutsky matrix (Lau, 1978; Moschini, 1999).

5.6.7 Case study: the AIDS on British data, 1954–1974

Question. The empirical half of Deaton and Muellbauer (1980a) asks whether aggregate consumer demand obeys the homogeneity, symmetry and negativity restrictions of demand theory. Earlier studies with the Rotterdam and translog models had rejected homogeneity. The AIDS lets the question be posed within a maintained model flexible enough to approximate any demand system to first order (Section 5.2.8). A rejection then speaks against the theory or its static formulation, and an arbitrary functional form cannot take the blame. A second question is practical. Does the linear approximation with the Stone index work well enough to serve as a routine tool?

Data. The data are 21 annual British observations, from 1954 to 1974 inclusive. They cover eight groups of nondurable consumers' expenditure: food, clothing, housing services, fuel, drink and tobacco, transport and communication services, other goods, and other services. For each year and group the data give a budget share and a price index, together with total expenditure on the eight groups. Over the period the price level rose by a factor of about 2.6. In their Table 3 the exact index rises from 0.571 in 1954 to 1.461 in 1974, with 1970 equal to one.

Model. The estimating model is the aggregate AIDS (5.62) of a representative household. Deaton and Muellbauer assume that the aggregation index κ is constant, or that its deviations are independent of mean expenditure and prices. The terms $-\beta_i \ln \kappa$ are then absorbed in the intercepts, as in Section 5.4.4.

Estimating equations and estimator. The procedure has five steps.

1. Estimate the LA-AIDS (5.88) with the Stone index, equation by equation by OLS, with no restrictions beyond adding up, which holds automatically (their Table 1).

2. Impose homogeneity by substitution, (5.95), re-estimate by OLS, and compute an F test for each equation.

3. Impose symmetry, replace P^* by the exact index $\mathbf{P}$ with α_0 fixed a priori, and estimate the nonlinear system (5.87) by maximum likelihood under the covariance structure (5.86). Under symmetry the system has fourteen free intercepts and expenditure coefficients and twenty-eight free price coefficients, the upper triangle, diagonal included, of the γ matrix with its last row and column deleted.

4. Compare P^* with $\mathbf{P}$, re-estimate the unrestricted and homogeneous models with $\mathbf{P}$, and check concavity with the eigenvalues of K in every year.

5. Repeat the analysis in first differences, adding intercepts d_i to (5.93):

$$\Delta w_{it} = d_i + \beta_i \Delta \ln \frac{I_t}{\mathbf{P}_t} + \sum_k \gamma_{ik} \Delta \ln p_{kt} + \Delta \xi_{it} \tag{5.96}$$

   (their eq. 21, where the intercepts are written η_i). Collinearity prevented linking $\mathbf{P}$ to the first-difference estimates, so the index computed from the symmetric levels estimates is used throughout.

Identification. Prices and total expenditure are treated as exogenous. The article does not discuss this assumption, which is common in the analysis of national aggregates. The authors' book does, and doubts both halves of it (Deaton and Muellbauer, 1980b, §3.5, pp. 81–82). On total expenditure it says that "individual expenditures are as much a determinant of the total as

the other way round" (p. 81). On prices it says that demand as a function of prices "only makes sense if prices are set exogenously (say by manufacturers) and quantities supplied elastically to meet whatever demand emerges." That is probably true of most goods, "although food may be a partial exception" (pp. 81–82). The book links this to the difficulty of estimating a "sensible" price elasticity for food. The positive own-price elasticity of food in the unconstrained levels model of Table 5.7 (0.07) fits this warning. The case for treating the regressors as given rests on two premises. Broad group prices are driven largely by costs and by the general price level. Total nondurable expenditure is taken as given at the second stage of an intertemporal budgeting problem. That second premise is the weak intertemporal separability that the authors question in their interpretation. The price coefficients are identified by movements in relative prices, and the expenditure coefficients by movements in real expenditure. Relative prices moved little, which explains both the closeness of P^* and $\mathbf{P}$ and the imprecision of many γ_{ij}.

Unconstrained estimates and homogeneity. Table 5.5 reproduces selected columns of their Table 1. The expenditure coefficients classify food ($\beta = -0.160$) and housing (-0.104) as necessities and the other six groups as luxuries. Twenty-two of the sixty-four price coefficients have t values above two in absolute value. Yet no variable has a detectable effect on the share of fuel, and few affect the shares of other goods and other services. The column $\sum_j \gamma_{ij}$ gives 100 times the effect on each share of a 1 percent rise in all prices and total expenditure. Homogeneity requires it to be zero, and its t value is the square root of the F statistic for the restriction. The authors' book reports these F statistics, with one and eleven degrees of freedom, together with the fit of the free and the homogeneous equations (Deaton and Muellbauer, 1980b, §3.4, Table 3.4, pp. 77–78). Table 5.6 reproduces that table. The rejection thresholds are 4.84 at the 5 percent level and 9.65 at the 1 percent level (p. 77). Homogeneity is rejected at 1 percent for food ($F = 19.4$, $t = -4.4$), clothing (20.3, -4.5), housing (82.8, 9.1) and transport and communication (171.6, 13.1). A proportional increase in all prices and expenditure would lower spending on food and clothing and raise spending on housing and on transport and communication.

The fit is very high in both versions, with R^2 above 0.95 in five of the eight free equations and never below 0.84. Budget shares are harder to predict than quantities or expenditures, so these values are informative. For comparison, the linear expenditure system fitted to the same share data gives $R^2 = -0.16$ for other services (p. 77). A negative R^2 is possible because the restrictions of that system fit the share worse than its sample mean. The *Durbin-Watson statistic* tests for first-order serial correlation in the residuals. Values near 2 indicate none, and values well below 2 indicate positive correlation. In each of the four equations that reject homogeneity, imposing it makes the statistic fall sharply, for example from 2.24 to 1.36 for transport and communication. For the other four groups the statistic barely moves. The imposition of homogeneity thus generates positive serial correlation. Deaton and Muellbauer read this as a sign that the rejection may come from misspecified dynamics (p. 77).

Table 5.7 reproduces their Table 2, the total expenditure and own-price elasticities of all four specifications. In the unconstrained levels model, food has a positive own-price elasticity (0.07), which is insignificant. Demand is generally price inelastic, and only transport and communication is price elastic (-1.21). The elasticities that change most when homogeneity is imposed belong to the four groups that reject it. The expenditure elasticity of housing rises from 0.30 to 0.79, and that of transport and communication from 1.23 to 1.73.

The Stone index versus the exact index. Before imposing symmetry with the exact index, Deaton and Muellbauer compare the two indices year by year (their Table 3, both normalized to one in 1970). The largest absolute difference is 0.008, reached in 1955 (0.587 against 0.595) and

Table 5.5: Unconstrained LA-AIDS estimates and tests of homogeneity, British data, 1954–1974

Group	α_i^*	β_i	γ_{ii}	$\sum_j \gamma_{ij}$
Food	1.221	−0.160	0.186	−0.033
	(7.4)	(−6.1)	(9.8)	(−4.4)
Clothing	−0.482	0.091	0.016	−0.032
	(−3.1)	(3.7)	(1.0)	(−4.5)
Housing	0.793	−0.104	0.088	0.051
	(6.3)	(−5.1)	(7.2)	(9.1)
Fuel	−0.159	0.033	0.037	−0.010
	(−0.8)	(1.0)	(1.6)	(−1.1)
Drink and tobacco	−0.043	0.028	0.056	0.001

Transport and communication	−0.061	0.029	−0.023	0.040
	(−0.9)	(2.6)	(−2.2)	(13.1)
Other goods	−0.038	0.022	0.032	−0.005
	(−0.2)	(0.9)	(1.5)	(0.7)
Other services	−0.231	0.060	0.019	−0.014
	(−1.5)	(2.4)	(0.9)	(−2.0)

Notes: selected columns of Deaton and Muellbauer (1980a, Table 1), with t values in parentheses. OLS estimates of (5.88) with the Stone index, equation by equation. The column γ_{ii} is the own-price coefficient. The original also reports the seven cross-price coefficients of each equation, equation standard errors, R^2 and Durbin-Watson statistics, which Table 5.6 gives. $\sum_j \gamma_{ij}$ is the row sum of the unconstrained price coefficients, and its t value tests homogeneity. The t value for other goods is printed as positive in the original. For drink and tobacco the printed t of 0.0 does not match the book's F of 0.2 in Table 5.6, which implies $|t| \approx 0.45$. Both are far from significance. Each equation uses $T = 21$ annual observations.

Table 5.6: Tests of homogeneity on British data, 1954–1974

	Unrestricted		Homogeneous		Test
Group	R^2	Durbin-Watson	R^2	Durbin-Watson	$F(1, 11)$
Food	0.999	2.33	0.998	1.74	19.4
Clothing	0.984	2.29	0.955	1.55	20.3
Housing	0.999	1.89	0.992	1.29	82.8
Fuel	0.883	2.25	0.870	2.03	1.2
Drink and tobacco	0.969	2.96	0.969	2.93	0.2
Transport and communication	1.000	2.24	0.992	1.36	171.6
Other goods	0.885	1.92	0.880	1.91	0.5
Other services	0.843	2.27	0.788	1.98	4.0

Notes: reproduced from Deaton and Muellbauer (1980b, Table 3.4, p. 78). Equation-by-equation OLS estimates of the LA-AIDS with the Stone index, $T = 21$, the same regressions as Table 5.5. $F(1, 11)$ tests the single homogeneity restriction of each equation. The thresholds are 4.84 at 5 percent and 9.65 at 1 percent. Except for drink and tobacco, each F equals the square of the t value in Table 5.5 up to rounding.

Table 5.7: Total expenditure and own-price elasticities, British data, 1954–1974

	Levels model				First-differences model			
	Unconstrained		Homogeneous		Unconstrained		Homogeneous	
Group	η_i	ε_{ii}	η_i	ε_{ii}	η_i	ε_{ii}	η_i	ε_{ii}
Food	0.21	0.07	0.04	−0.01	0.04	0.22	0.17	−0.00
Clothing	2.00	−0.92	1.51	−0.48	2.83	−0.94	2.92	−0.94
Housing	0.30	−0.31	0.79	−0.16	0.04	−0.31	−0.02	−0.30
Fuel	1.67	−0.28	1.37	0.10	1.00	0.00	0.86	−0.08
Drink and tobacco	1.22	−0.60	1.22	−0.62	1.37	−0.67	1.36	−0.68
Transport and comm.	1.23	−1.21	1.73	−0.92	1.14	−1.23	1.05	−1.17
Other goods	1.21	−0.72	1.15	−0.77	2.03	−0.52	1.92	−0.47
Other services	1.40	−0.93	1.28	−0.78	1.03	−0.78	1.06	−0.74

Notes: reproduced from Deaton and Muellbauer (1980a, Table 2), who write e_i and e_{ii}. η_i is the total expenditure elasticity and ε_{ii} the uncompensated own-price elasticity.

1973 (1.271 against 1.279). At the ends of the sample the indices are 0.566 and 0.571 in 1954 and 1.465 and 1.461 in 1974. Re-estimating the unrestricted and homogeneous models with **P** in place of P^* changes the likelihoods little compared with the effect of the restrictions, as the paired columns of Table 5.8 show. In the authors' words, it "confirmed the empirical unimportance of the difference." They add that this finding is conditional on the kind of relative price movements in their sample.

Symmetry. Table 5.8 reproduces their Table 4 and computes the likelihood-ratio statistics. In levels with the exact index, homogeneity gives $LR = 1723.8 - 1585.1 = 138.7$ on 7 degrees of freedom, far above the 5 percent threshold of 14.07. Symmetry given homogeneity gives $LR = 1585.1 - 1491.0 = 94.1$ on 21 degrees of freedom, against a 5 percent threshold of 32.67. Symmetry is therefore rejected whether or not homogeneity is part of the maintained hypothesis. The authors note that the meaning of this rejection is unclear without an explanation of the failure of homogeneity. For example, habits that are ignored can destroy symmetry even when preferences satisfy it. Their book reads the same evidence more softly. Imposing symmetry led to "a further but less sharp drop in likelihood," especially in first differences (Deaton and Muellbauer, 1980b, §3.4, p. 78). Hence "it is unclear whether we must reject symmetry as a restriction beyond homogeneity" (p. 78). Looking across models and countries, the book concludes that "demand functions fitted to aggregate time series data are not homogeneous and probably not symmetric" (p. 78).

Negativity. The symmetric estimates themselves are not reported. Deaton and Muellbauer evaluate the matrix K of (5.32) in every year. One eigenvalue is identically zero, and concavity requires the others to be negative. They find one positive eigenvalue early in the sample and two by its end. The clearest symptom is a positive compensated own-price elasticity for fuel throughout the period. They argue that the failure matters even though the symmetric model has already been rejected. Price and quantity index numbers and optimal tax formulas require cost functions that are homogeneous and concave. Applied welfare work had therefore relied on the linear expenditure system, whose concavity is virtually guaranteed when no good is inferior, but whose restrictiveness is known to be empirically false.

Robustness: first differences. The first-difference model (5.96) changes the picture. Homogeneity is now rejected only for food and for transport and communication. For clothing and

Table 5.8: Likelihood values and likelihood-ratio tests, British data, 1954–1974

Panel A: values of $2 \ln L$	Levels		First differences	
	Using P^*	Using **P**	Using P^*	Using **P**
Unrestricted	1722.5	1723.8	1560.0	1560.3
Homogeneous	1579.6	1585.1 (7)	1546.6	1547.9 (7)
Symmetric		1491.0 (21)		1508.8 (21)
Panel B: likelihood-ratio tests computed from Panel A, using **P**	LR	df	5% threshold	p-value
Levels				
Homogeneity	138.7	7	14.07	$< 10^{-20}$
Symmetry given homogeneity	94.1	21	32.67	3×10^{-11}
First differences				
Homogeneity	12.4	7	14.07	0.088
Symmetry given homogeneity	39.1	21	32.67	0.010

Notes: Panel A reproduces Deaton and Muellbauer (1980a, Table 4), with numbers of restrictions in parentheses. Values can be compared within columns only. Panel B: LR is the difference in $2 \ln L$ between the less and the more restricted model, compared with the χ^2 distribution with df degrees of freedom. Computed by `figures/ch05/src/dm_lr_tests.py`.

housing the F ratios become insignificant, and in both equations the intercept d_i, insignificant without constraints, becomes significant when homogeneity is imposed. For transport and communication the intercept also becomes significant, but the F ratio stays significant. An intercept in first differences is a time trend in levels, so these results point to trends, stocks or other omitted variables. The first-difference expenditure elasticities are higher than the levels estimates where stock effects are likely (clothing, other goods) and lower where short-run expenditure effects should be limited (food, housing, transport). For the system, homogeneity is no longer rejected at 5 percent ($LR = 12.4$ against 14.07). Symmetry given homogeneity is "only just rejected" ($LR = 39.1$ against 32.67, $p = 0.010$). Concavity tests still reveal several violations.

Interpretation. Deaton and Muellbauer read the rejection of homogeneity, together with the serial correlation it induces, as a sign of dynamic misspecification. They offer several explanations and say that the data cannot discriminate among them.

(i) Spending on some items is inflexible in the short run, housing being the obvious case. Stocks, lagged dependent variables or time trends, which the absolute price level may proxy, are omitted.

(ii) Price expectations are omitted. The frequency with which goods are bought should affect how spending responds to prices when relative or absolute prices change rapidly.

(iii) The aggregation index κ, which reflects the distribution of budgets and the demographic structure, may be correlated with mean expenditure and prices (Section 5.4.4).

(iv) Weak intertemporal separability of nondurables, which the static model requires, may fail.

They conclude that the AIDS explains a high proportion of the variance of budget shares. Without arbitrary time trends, however, it does so "in a way which is inconsistent with

the hypothesis of consumers making decisions according to the model's demand functions" (Deaton and Muellbauer, 1980a, pp. 322–323). With trends, much of the conflict between data and theory disappears.

Limitations and critiques. The application has the weaknesses of its time and data. Twenty-one observations support a system with dozens of parameters, so the covariance matrix has to be restricted to (5.86), and the likelihood-ratio tests rest on asymptotic approximations in a short sample. The article treats prices and expenditure as exogenous without discussion, although the authors' book doubts both (Deaton and Muellbauer, 1980b, §3.5, pp. 81–82). The aggregation index is assumed constant, although the authors themselves list its variation as a possible cause of the rejections. The symmetric estimates violate concavity, and the authors leave the construction of a concave version to future work. Later research took up each point. It added demographic and distributional variables to aggregate demand and built dynamic and habit-forming versions of the AIDS. It also developed richer Engel curves, such as the quadratic AIDS of Banks et al. (1997) (Section 5.3.8).

Contribution. The paper introduced a demand system that is flexible, consistent with utility maximization, aggregable without linear Engel curves, and nearly linear to estimate. Its application established three lasting practices. The first is to estimate the linear approximation and check it against the exact index. The second is to test homogeneity equation by equation and symmetry on the system. The third is to check concavity observation by observation. The application also carries a lesson for industrial organization. A static demand system estimated on time series can reject the restrictions of theory for reasons that have nothing to do with preferences, such as dynamics, aggregation or trends. Applications in industrial organization use panels of markets with market-specific intercepts, partly to absorb such omitted factors. Examples are the product-by-region effects of Chaudhuri et al. (2006) and the city effects of Hausman (1997).

5.6.8 Endogenous prices, endogenous expenditure and measured group prices

The British application treats prices and expenditure as exogenous. In the data that industrial organization uses, brand or product prices in many markets and periods, this assumption usually fails. This subsection explains why, describes the available instruments, and shows how group prices built from many stock-keeping units add a measurement problem of their own.

Why prices are endogenous. Firms set prices knowing at least part of the demand shock. A brand-specific advertising success or a regional epidemic raises ξ_{it} and, through the firm's first-order condition, the price of good i. In the single-product case of Chapter 2, $p_{it} = mc_{it}\left(1 + \frac{1}{\varepsilon_{ii}}\right)^{-1}$, so the price moves with any demand shock that moves marginal cost or the elasticity. Then $\mathrm{Cov}(\ln p_{it}, \xi_{it}) \neq 0$, and OLS estimates of γ_{ii} are biased, typically toward less elastic demand. Regulated prices, as in Indian pharmaceuticals, weaken this channel (Section 5.9.5).

Why group expenditure is endogenous. At the bottom of a multi-level system the budget variable is group expenditure X_G. Within-group share errors sum to zero, so a pure reallocation inside the group does not change X_G. But shocks that raise demand for the whole group, such as an epidemic that calls for one type of drug, usually raise demand for particular goods in it as well. The upper-level shock and the lower-level shock ξ_{it} are then correlated, and so are $\ln \frac{X_{Gt}}{P_{Gt}}$ and ξ_{it}. Hausman (1997, p. 219) notes that instruments "might still be required for the segment-expenditure variable" even when prices are predetermined. Natural instruments are

upper-level expenditure, income and the price indices of other groups. Chaudhuri et al. (2006) include total antibiotic expenditure among their instruments.

Instruments for product-space systems. An unrestricted J-good AIDS with homogeneity imposed has $J-1$ relative prices and real expenditure on the right-hand side of each share equation. Each equation therefore needs at least J excluded instruments, and the requirement grows with the number of goods. Three families of instruments are used.

(a) *Cost shifters*, such as input prices, are the textbook choice. They are often too few, or observed too infrequently, to identify many price coefficients (Hausman, 1997, p. 219).

(b) *Prices of the same product in other markets.* Suppose prices in city n follow $\ln p_{jnt} = \rho_j \ln c_{jt} + \mu_{jn} + \zeta_{jnt}$ (Hausman, 1997, eq. 8). Here c_{jt} is a cost component common to all cities, μ_{jn} a city-brand effect, and ζ_{jnt} a local shock that is independent across cities. Prices of brand j in other cities are then correlated with its price in city n through c_{jt}. They are uncorrelated with the demand error in city n. Section 5.8.4 develops these instruments and Section 5.8.5 presents the critique that national demand shocks invalidate them. Nevo (2001) adopts them in characteristic space (Chapter 8).

(c) *Institutional instruments.* Chaudhuri et al. (2006) use the number of stock-keeping units in each product group, which changes with entry and exit. They also use the prices of the five largest units in each group (Section 5.9.5).

Characteristic-based instruments, which drive identification in Chapter 7 and Chapter 8, help little here. In product space every product has its own intercept and price coefficients, and a product's characteristics are fixed over time and absorbed by its intercept.

A different route treats prices as predetermined. If retailers fix prices for the week under roughly constant marginal cost and do not adjust them to that week's demand, prices are uncorrelated with the week's demand shock. The need for instruments can then be tested with a specification test that compares the IV and OLS estimates (Hausman, 1978, 1997).

Estimators. With instruments z_t, the moment conditions are $\mathbb{E}[z_t \otimes \xi_t(\theta)] = 0$, where $\xi_t(\theta)$ stacks the residuals of the $J-1$ retained equations of (5.87) or (5.88). Equation-by-equation two-stage least squares (2SLS) is consistent but ignores the cross-equation restrictions. Three-stage least squares, defined in Section 5.6.2, and GMM impose symmetry and use the correlation of errors across equations. Two practical points deserve attention. First, consider a two-step estimator that replaces endogenous regressors by their first-stage fitted values and then runs constrained least squares. It is consistent when the second step is linear in the replaced variables, since it is then 2SLS. Its second-step standard errors are wrong, however, because the residual variance is computed with the fitted regressors. Correct 2SLS formulas compute it with the actual regressors, and the bootstrap is an alternative. Chaudhuri et al. (2006, p. 20) use such a two-step procedure. They regress group prices on the instruments, insert the predicted prices in constrained least squares, and compute standard errors by the bootstrap (Section 5.9.5). Second, when an endogenous variable enters nonlinearly, plugging in fitted values is generally inconsistent. The translog index contains products $\ln p_{kt} \ln p_{jt}$. If $\ln p_{kt} = \widehat{\ln p}_{kt} + v_{kt}$ with first-stage errors v_{kt}, then

$$\mathbb{E}\left[\ln p_{kt} \ln p_{jt} \,\middle|\, z_t\right] = \widehat{\ln p}_{kt}\, \widehat{\ln p}_{jt} + \operatorname{Cov}(v_{kt}, v_{jt} \mid z_t),$$

so the plug-in regressor misses a term. The intercepts absorb it only when the conditional covariance is constant, and even then the intercepts, which also enter the index, are distorted.

Nonlinear GMM, which computes residuals from the actual variables and uses instruments only in the moment conditions, avoids the problem.

Group prices as noisy proxies. Multi-level systems face a further problem at the bottom level. The price of a product group is an average of the prices of many stock-keeping units (SKUs), $p_{jt}^A = \sum_{k \in j} \omega_k p_{kt}$ with revenue weights ω_k. The model is written in terms of an exact group price index p_{jt}^T, which is not observed. Following Chaudhuri et al. (2006, pp. 18–19), let ς_{it} be the demand shock of the share equation written in the exact indices, and write $\ln p_{jt}^A = \ln p_{jt}^T + m_{jt}$, where m_{jt} is the proportional approximation error. Substituting $\ln p_{jt}^T = \ln p_{jt}^A - m_{jt}$ into the share equation gives the equation taken to the data,

$$w_{it} = \alpha_i + \sum_j \gamma_{ij} \ln p_{jt}^A + \beta_i \ln \frac{X_t}{P_t} + \xi_{it}, \qquad \xi_{it} = \varsigma_{it} - \sum_j \gamma_{ij} m_{jt}. \tag{5.97}$$

The composite error ξ_{it} has two parts, and each is correlated with the observed group prices. The first, $-\sum_j \gamma_{ij} m_{jt}$, is correlated with $\ln p_{jt}^A$ by construction, as in any errors-in-variables problem. The second, the demand shock ς_{it}, is correlated with $\ln p_{jt}^A$ because the weights ω_k respond to demand.

A one-price version shows how the two channels bias least squares. Suppose $w_t = \alpha + \gamma \ln p_t^T + \varsigma_t$ and we observe $\ln p_t^A = \ln p_t^T + m_t$, with m_t uncorrelated with $\ln p_t^T$. The measured price may still be correlated with the demand shock, for example through the weights. The regression of w_t on $\ln p_t^A$ has error $\varsigma_t - \gamma m_t$. Since $\operatorname{Cov}(\ln p_t^A, m_t) = \operatorname{Var}(m_t)$ and $\operatorname{Var}(\ln p_t^A) = \operatorname{Var}(\ln p_t^T) + \operatorname{Var}(m_t)$, its probability limit is

$$\begin{aligned} \operatorname{plim} \hat{\gamma}_{OLS} &= \gamma + \frac{\operatorname{Cov}(\ln p_t^A, \varsigma_t - \gamma m_t)}{\operatorname{Var}(\ln p_t^A)} \\ &= \gamma \, \frac{\operatorname{Var}(\ln p_t^T)}{\operatorname{Var}(\ln p_t^T) + \operatorname{Var}(m_t)} + \frac{\operatorname{Cov}(\ln p_t^A, \varsigma_t)}{\operatorname{Var}(\ln p_t^T) + \operatorname{Var}(m_t)}. \end{aligned} \tag{5.98}$$

The first term is attenuation toward zero. The second is simultaneity. When positive demand shocks raise the measured price, it also pushes a negative γ toward zero, so both channels make demand look less elastic. Even if every SKU price were exogenous, OLS on (5.97) would be inconsistent, because the measurement error alone biases it. A valid instrument must be correlated with the observed group price and uncorrelated with both the demand shock and the approximation errors m_{jt}. Chaudhuri, Goldberg and Jia point out that the number of SKUs fails this test if the approximation error grows with the number of SKUs in a group (their fn. 22). Section 5.9.5 examines their instruments in detail.

5.7 Welfare, virtual prices and the supply side

An estimated demand system becomes a policy tool once it can do two things. It must translate price changes and product withdrawals into money, and it must predict how firms reprice after a change in the market. This section develops the three ingredients that make this possible. First, the AIDS expenditure function is known in closed form, so compensating and equivalent variations follow directly from the estimated parameters. Second, the loss from removing a product equals the compensating variation of raising its price to the virtual price of Section 5.1.4,

the price at which demand for it vanishes. Third, counterfactual prices require marginal costs, which we recover from first-order conditions or bound when conduct is unknown. Section 5.7.7 combines the three ingredients in a counterfactual equilibrium and decomposes its welfare effect. As in the rest of the chapter, goods are indexed by i, j and k, and elasticities are signed, so own-price elasticities are negative.

5.7.1 Compensating and equivalent variation in closed form

In the notation of Section 5.3.3, the AIDS cost function (5.20) reads

$$\ln e(p,u) = \ln \mathbf{P}(p) + u\, B(p), \tag{5.99}$$

where $\ln \mathbf{P}(p)$ is the translog index (5.24) and $B(p) = \beta_0 \prod_k p_k^{\beta_k}$ is defined in (5.25). The indirect utility function is $v(p,I) = \frac{\ln I - \ln \mathbf{P}(p)}{B(p)}$, as in (5.26). Consider a change in prices from p^0 to p' with total expenditure I held fixed. Following Section 5.2.7, let $u^0 = v(p^0, I)$ and $u' = v(p', I)$, and define

$$CV = e(p', u^0) - I, \qquad EV = I - e(p^0, u').$$

A positive CV is a loss: it is the extra expenditure the consumer needs at the new prices to stay at the initial utility.

Both measures have closed forms. We derive the compensating variation in three steps. First, the initial utility is $u^0 = \frac{\ln I - \ln \mathbf{P}(p^0)}{B(p^0)}$ by (5.26). Second, we substitute u^0 into (5.99) evaluated at p':

$$\ln e(p', u^0) = \ln \mathbf{P}(p') + B(p')\, u^0 = \ln \mathbf{P}(p') + \big[\ln I - \ln \mathbf{P}(p^0)\big] \frac{B(p')}{B(p^0)}.$$

The scale β_0 cancels from the ratio, since $\frac{B(p')}{B(p^0)} = \prod_k \big(\frac{p'_k}{p^0_k}\big)^{\beta_k}$. Third, we subtract $\ln I$ and write $\ln I - \ln \mathbf{P}(p^0) = \ln \frac{I}{\mathbf{P}(p^0)}$. The result is

$$\ln\!\left(1 + \frac{CV}{I}\right) = \underbrace{\ln \mathbf{P}(p') - \ln \mathbf{P}(p^0)}_{\text{translog index change}} + \underbrace{\ln \frac{I}{\mathbf{P}(p^0)} \left[\prod_k \left(\frac{p'_k}{p^0_k} \right)^{\beta_k} - 1 \right]}_{\text{non-homothetic correction}}. \tag{5.100}$$

The same steps applied to u' give $\ln e(p^0, u') = \ln \mathbf{P}(p^0) + [\ln I - \ln \mathbf{P}(p')] \frac{B(p^0)}{B(p')}$, and hence

$$\ln\!\left(1 - \frac{EV}{I}\right) = -\big[\ln \mathbf{P}(p') - \ln \mathbf{P}(p^0)\big] + \ln \frac{I}{\mathbf{P}(p')} \left[\prod_k \left(\frac{p^0_k}{p'_k} \right)^{\beta_k} - 1 \right]. \tag{5.101}$$

The two terms of (5.100) have a clear reading. When all $\beta_k = 0$, preferences are homothetic, the correction vanishes, and $1 + \frac{CV}{I} = \frac{\mathbf{P}(p')}{\mathbf{P}(p^0)}$. The translog index is then the exact cost-of-living index. When some $\beta_k \neq 0$, the cost of reaching u^0 also moves with $B(p)$, and the effect is scaled by real expenditure $\ln \frac{I}{\mathbf{P}(p^0)}$. A rise in the prices of luxuries ($\beta_k > 0$) raises $B(p)$, so richer consumers lose proportionally more from it. The ratio

$$\frac{e(p', u^0)}{e(p^0, u^0)} = 1 + \frac{CV}{I}$$

is the *exact cost-of-living index* at utility u^0, which Deaton and Muellbauer (1980b, §7.1, eq. 1.2, p. 170) call the true index of the cost of living. Under AIDS it depends on u^0, and hence on I. Households with different budgets therefore face different exact price indices. With market data, the relevant household is the representative household with budget I_0 of Section 5.4.

The dependence on the budget is transparent for the whole PIGLOG class (Deaton and Muellbauer, 1980b, §7.1, eqs. 1.11–1.12, pp. 175–176). Evaluate (5.15) at p' and at p^0 with the same utility u^0 and subtract:

$$\ln \frac{e(p', u^0)}{e(p^0, u^0)} = (1 - u^0) \ln \frac{a(p')}{a(p^0)} + u^0 \ln \frac{b(p')}{b(p^0)}, \qquad u^0 = \frac{\ln I - \ln a(p^0)}{\ln b(p^0) - \ln a(p^0)}. \tag{5.102}$$

Across households facing the same prices, u^0 is linear in $\ln I$. The index of a poor household is close to the change in the subsistence cost $a(p)$. The index of a rich household is close to the change in the bliss cost $b(p)$. The two differ whenever the prices of necessities and luxuries move apart. Deaton and Muellbauer estimate such a model on pooled British time-series and cross-section data for four household types, 1965–1976. They take $a(p) = \sum_k a_k p_k$ and $b(p) = \beta_0 \prod_k p_k^{\beta_k}$ and use the 1970 utility level as the base. Table 5.9 reproduces part of their Table 7.1. From 1965 to 1971 inflation was roughly neutral across budgets, and for families with children it was if anything slightly biased against the rich. From 1971, sharply rising food prices gave the indices a strong bias against the poor (p. 176). In 1975–76 a childless couple spending £15 a week faced 16.39 percent inflation, against 14.05 percent at £80. A single representative index hides differences of this size.

Table 5.9: Annual inflation rates of the exact cost-of-living index for British households, 1965–1976 (percent)

	No children				Three children			
Period	£15	£30	£50	£80	£15	£30	£50	£80
1965–71	5.52	5.43	5.36	5.30	5.36	5.41	5.44	5.47
1971–75	14.17	13.82	13.56	13.33	14.45	14.14	13.93	13.70
1974–75	24.66	24.41	24.24	24.06	25.09	24.57	24.18	23.84
1975–76	16.39	15.42	14.69	14.05	16.94	15.85	15.05	14.33

Notes: from Deaton and Muellbauer (1980b, Table 7.1, p. 177). Annual average rates of inflation of the exact index (5.102) for households of two adults, by number of children and by the level of weekly total expenditure in 1970. The 1974–75 row overlaps the 1971–75 period, as in the original. The original also reports one and two children.

Remark 5.42 (Approximations and the substitution bias). Two approximations clarify what the exact formula adds. Differentiating (5.99) in $\ln p$ at fixed u gives the Hicksian share $w_i^h = \alpha_i + \sum_j \gamma_{ij} \ln p_j + \beta_i u\, B(p)$ and the second derivative $\frac{\partial w_i^h}{\partial \ln p_j} = \gamma_{ij} + \beta_i \beta_j u\, B(p)$. At p^0 and u^0 we have $u^0 B(p^0) = \ln \frac{I}{\mathbf{P}(p^0)}$, so a second-order expansion gives

$$\ln\!\left(1 + \frac{CV}{I}\right) \approx \sum_i w_i^0 \,\Delta \ln p_i + \frac{1}{2} \sum_i \sum_j \left[\gamma_{ij} + \beta_i \beta_j \ln \frac{I}{\mathbf{P}(p^0)}\right] \Delta \ln p_i \,\Delta \ln p_j,$$

with $\Delta \ln p_i = \ln p_i' - \ln p_i^0$. The first term is the change in a Stone index with base-period weights. The second term captures substitution. The fixed-basket (Laspeyres) measure is an upper bound on the exact loss. Because $e(\cdot, u^0)$ is concave in p (Proposition 5.5), it lies below

its tangent plane at p^0, and the gradient of that plane is $h(p^0, u^0) = q^0$ by Shephard's lemma. Hence

$$CV = e(p', u^0) - e(p^0, u^0) \le \sum_i q_i^0 (p_i' - p_i^0) = I \sum_i w_i^0 \Big(\frac{p_i'}{p_i^0} - 1 \Big).$$

The gap is the *substitution bias* of a fixed-weight price index.

Example 5.43 (A price rise in the running example)**.** Take the running example of Example 5.21: $p^0 = (1, 1, 1)$, $\ln I = 1$, $\beta_0 = 1$, and let p_1 rise by 10 percent. Then $\Delta \ln p_1 = \ln 1.1 = 0.0953$, and the translog index rises by $\alpha_1 \ln 1.1 + \frac{1}{2}\gamma_{11}(\ln 1.1)^2 = 0.0467$. The correction term equals $1 \times (1.1^{-0.10} - 1) = -0.0095$, because good 1 is a necessity. Hence $\ln(1 + \frac{CV}{I}) = 0.0373$, and the compensating variation is 3.80 percent of income. The equivalent variation is 3.69 percent, and the Marshallian surplus loss is 3.74 percent, between the two as it should be for a normal good. The fixed-basket measure is $w_1^0 \times 10 = 4.00$ percent, which overstates the loss by 0.2 percentage points. The second-order expansion of Remark 5.42 reproduces the exact value to four decimal places (`virtual_price.py`).

5.7.2 Virtual prices

Removing a product from the market is a large, discrete change, and the formulas above need a price to put in its place. Hicks (1940) proposed the answer for new goods and for rationing. In the periods before a good exists, we should value it at the price that would "just make the demands for these commodities (from the whole community) equal to zero." We quote Hicks from Hausman (1997, p. 211). Rothbarth (1941) put the idea on a formal footing and named it the *virtual price* system. Hausman (1997) turned it into an empirical method for new goods, which Chapter 10 develops in detail.

Definition 5.44 (Virtual price)**.** Fix the prices of the other goods p_{-i} and a utility level u. The *virtual price* of good i is the smallest price $p_i^V(p_{-i}, u)$ at which Hicksian demand for good i is zero:

$$h_i\big(p_i^V, p_{-i}, u\big) = 0. \tag{5.103}$$

The virtual price makes the removal of a good equivalent to a price change. Let $e_{-i}(p_{-i}, u) = \min\{p^\top q : U(q) \ge u,\ q_i = 0\}$ be the expenditure function of a consumer who cannot buy good i.

Proposition 5.45 (Removal as a price change)**.** *Suppose the virtual price $p_i^V(p_{-i}, u)$ is finite. Then $e_{-i}(p_{-i}, u) = e\big(p_i^V, p_{-i}, u\big)$, and $e(p_i, p_{-i}, u) \le e_{-i}(p_{-i}, u)$ for every $p_i > 0$.*

Proof. The cost of a bundle with $q_i = 0$ does not depend on p_i. The constrained problem minimizes the same objective over a smaller feasible set, so its value is at least the unconstrained value at any p_i. This proves $e(p_i, p_{-i}, u) \le e_{-i}(p_{-i}, u)$ for every p_i. At $p_i = p_i^V$ the unconstrained minimizer $h(p_i^V, p_{-i}, u)$ has $h_i = 0$ by (5.103). It is therefore feasible in the constrained problem, which gives $e_{-i}(p_{-i}, u) \le e(p_i^V, p_{-i}, u)$. The two inequalities together give equality. □

The compensating variation of losing good i, when the other prices move from p_{-i}^0 to p_{-i}', is therefore

$$CV = e\big(p_i^V, p_{-i}', u^0\big) - e\big(p^0, u^0\big), \qquad p_i^V = p_i^V(p_{-i}', u^0). \tag{5.104}$$

When the other prices do not change, Shephard's lemma (Proposition 5.6) and the fundamental theorem of calculus give

$$CV = \int_{p_i^0}^{p_i^V} h_i\big(s, p_{-i}^0, u^0\big)\,\mathrm{d}s. \tag{5.105}$$

This is the area to the left of the Hicksian demand curve between the observed and the virtual price. The ratio $\frac{e(p_i^V, p_{-i}^0, u^0)}{e(p^0, u^0)}$ is the exact cost-of-living index for the availability of good i. Hausman (1997, p. 212) uses the same ratio, read in the opposite direction, to value a new good. Standard errors for such exact welfare measures can be computed with the method of Hausman and Newey (1995), which Hausman (1997, fn. 24) applies.

Rationing and shadow prices. A missing good is a good rationed at zero, and the theory of rationing explains why virtual prices work (Deaton and Muellbauer, 1980b, §4.3, pp. 109–113). Suppose the consumer must buy exactly z units of good i at price p_i. The *restricted expenditure function* is

$$e^*(p, u, z) = \min_q \big\{p^\top q : U(q) \geq u,\ q_i = z\big\} = p_i z + \min_{q_{-i}} \big\{p_{-i}^\top q_{-i} : U(z, q_{-i}) \geq u\big\} \tag{5.106}$$

(their eq. 3.1). A constraint cannot lower the minimum cost, so $e^*(p, u, z) \geq e(p, u)$, with equality when z is the quantity the consumer would choose freely. Hence $e(p, u) = \min_z e^*(p, u, z)$ (their eq. 3.2), the analogue of long-run cost as the envelope of short-run costs. Define the *shadow price* $p_i^*(p_{-i}, u, z)$ as the price of good i at which the consumer would freely buy z, so that $h_i(p_i^*, p_{-i}, u) = z$. At the prices (p_i^*, p_{-i}) the unrestricted minimizer already has $q_i = z$, so it also solves the restricted problem. The two problems differ only in the price paid for the z units of good i, which gives

$$e^*(p, u, z) = e(p_i^*, p_{-i}, u) + (p_i - p_i^*)\, z. \tag{5.107}$$

Differentiate with respect to z. Shephard's lemma gives $\frac{\partial e}{\partial p_i} = h_i(p_i^*, p_{-i}, u) = z$ at the shadow price, so the terms in $\frac{\partial p_i^*}{\partial z}$ cancel:

$$\frac{\partial e^*(p, u, z)}{\partial z} = z\frac{\partial p_i^*}{\partial z} + p_i - p_i^* - z\frac{\partial p_i^*}{\partial z} = p_i - p_i^* \tag{5.108}$$

(their eq. 3.7). One more unit of the ration costs p_i and saves the consumer p_i^* on everything else at constant utility. Now set $z = 0$. Then $e^*(p, u, 0) = e_{-i}(p_{-i}, u)$, the shadow price is the virtual price $p_i^V(p_{-i}, u)$, and (5.107) reduces to Proposition 5.45. The virtual price of a missing good is thus the shadow price of a zero ration.

Rationing also changes how the other goods respond to prices. Let $h_j^*(p_{-i}, u, z)$ be the restricted Hicksian demand for a good $j \neq i$. It does not depend on p_i, because p_i enters (5.106) only through the fixed outlay $p_i z$. When the ration equals free demand, the two demands coincide:

$$h_j^*\big(p_{-i}, u, h_i(p, u)\big) = h_j(p, u)$$

(their eq. 3.3). Differentiating with respect to p_i gives $\frac{\partial h_j^*}{\partial z} S_{ii} = S_{ji}$, so $\frac{\partial h_j^*}{\partial z} = \frac{S_{ji}}{S_{ii}}$. Differentiating with respect to p_j gives $\frac{\partial h_j^*}{\partial p_j} + \frac{\partial h_j^*}{\partial z} S_{ij} = S_{jj}$. Substituting the first result and using Slutsky symmetry,

$$S_{jj}^* \equiv \frac{\partial h_j^*}{\partial p_j} = S_{jj} - \frac{S_{ji}^2}{S_{ii}} \tag{5.109}$$

(their eq. 3.6). Since $S_{ii} < 0$, the correction is nonnegative, and $S^*_{jj} \geq S_{jj}$. This is the *Le Chatelier principle*. Rationing one good shrinks the compensated own-price response of every other good, and most for its closest substitutes and complements. All derivatives are evaluated where the ration equals free demand, that is, at the shadow price. In elasticity form, dividing by $\frac{h_j}{p_j}$ and rearranging,

$$\varepsilon^{h*}_{jj} = \varepsilon^h_{jj} - \frac{\varepsilon^h_{ji}\,\varepsilon^h_{ij}}{\varepsilon^h_{ii}}. \tag{5.110}$$

For a removed good, $z = 0$ and the derivatives are evaluated at the virtual price. There $h_i = 0$, so the elasticities ε^h_{ij} and ε^h_{ii} are not defined. Their ratio is defined, because the factor $\frac{1}{h_i}$ cancels:

$$\frac{\varepsilon^h_{ij}}{\varepsilon^h_{ii}} = \frac{p_j S_{ij}}{p_i S_{ii}}.$$

For a removed good we therefore use

$$\varepsilon^{h*}_{jj} = \varepsilon^h_{jj} - \varepsilon^h_{ji}\,\frac{p_j S_{ij}}{p_i S_{ii}}, \tag{5.111}$$

with all terms evaluated at the virtual price. The formula describes the compensated demand that a remaining good faces after a withdrawal, once the virtual price adjusts to the prices of the remaining goods. It is less elastic than the unrestricted compensated demand evaluated at the virtual price. The price observed before the withdrawal does not enter this comparison. Markups depend on uncompensated elasticities, which differ from the compensated ones by the income effect. Through the compensated part of demand, the effect pushes the remaining products toward higher markups after a withdrawal (Sections 5.7.7 and 5.9.9).

Hicksian and Marshallian choke prices. Applied work often sets the Marshallian demand to zero instead. The *Marshallian choke price* p^M_i solves $q_i(p^M_i, p_{-i}, I) = 0$ at fixed income. Chaudhuri et al. (2006, eq. 3.14), for example, set the Marshallian share of each withdrawn product to zero at counterfactual expenditure. The two prices differ, and the difference has a known sign.

Lemma 5.46. *If good i is normal and its Hicksian demand decreases in its own price, then $p^M_i \leq p^V_i(p_{-i}, u^0)$. Evaluating the expenditure function at p^M_i therefore understates the compensating variation of removing good i.*

Proof. Let $u^M = v(p^M_i, p_{-i}, I)$. Raising p_i from p^0_i to p^M_i at fixed income lowers utility, so $u^M \leq u^0$. Duality gives $h_i(p^M_i, p_{-i}, u^M) = q_i(p^M_i, p_{-i}, I) = 0$. Normality means that h_i is nondecreasing in u, so $h_i(p^M_i, p_{-i}, u^0) \geq 0$. Because h_i falls with p_i, it reaches zero at utility u^0 only at a price at or above p^M_i. The second claim follows from Proposition 5.45, since $e(p^M_i, p_{-i}, u^0) \leq e_{-i}(p_{-i}, u^0)$. □

Virtual prices under AIDS. AIDS shares are quadratic in the own log price, so the zero-share condition has a simple form. Fix the other prices at p'_{-i}, write $x = \ln p_i$, and define

$$G_i = \sum_{k \neq i} \gamma_{ik} \ln p'_k, \qquad A = \alpha_0 + \sum_{k \neq i} \alpha_k \ln p'_k + \frac{1}{2} \sum_{k \neq i} \sum_{j \neq i} \gamma_{kj} \ln p'_k \ln p'_j.$$

Using the symmetry of Γ, the translog index is quadratic in x:

$$\ln \mathbf{P} = A + (\alpha_i + G_i)\, x + \frac{1}{2}\gamma_{ii}\, x^2.$$

The Marshallian share is $w_i = \alpha_i + G_i + \gamma_{ii}x + \beta_i(\ln X - \ln \mathbf{P})$, with X the relevant expenditure. Substituting the index and collecting powers of x gives

$$w_i(x) = -\frac{1}{2}\beta_i\gamma_{ii}\, x^2 + \big[\gamma_{ii} - \beta_i(\alpha_i + G_i)\big]x + \big[\alpha_i + G_i + \beta_i(\ln X - A)\big]. \tag{5.112}$$

The Marshallian log choke price is the smallest root of $w_i(x) = 0$ above $\ln p_i^0$. When $\beta_i = 0$ the equation is linear, and

$$\ln p_i^V = -\frac{\alpha_i + G_i}{\gamma_{ii}}, \qquad \text{equivalently} \qquad \ln p_i^V - \ln p_i^0 = \frac{w_i^0}{-\gamma_{ii}}. \tag{5.113}$$

The virtual price is finite exactly when $\gamma_{ii} < 0$. The second form uses $w_i^0 = \alpha_i + G_i + \gamma_{ii} \ln p_i^0$. With $\beta_i = 0$ the Marshallian and Hicksian conditions coincide, because the term $\beta_i u\, B(p)$ that separates the two shares is zero.

The Hicksian condition uses the Hicksian share at u^0. Writing $B(p) = B_{-i}\, e^{\beta_i x}$ with $B_{-i} = \beta_0 \prod_{k\neq i}(p_k')^{\beta_k}$, it reads

$$\alpha_i + G_i + \gamma_{ii}\, x + \beta_i u^0 B_{-i}\, e^{\beta_i x} = 0. \tag{5.114}$$

When $\beta_i\gamma_{ii} \neq 0$ this equation has no elementary closed form. Its real roots can be written with branches of the Lambert W function, and a one-dimensional root finder also solves it. Its derivative in x is $\gamma_{ii} + \beta_i^2 u^0 B(p)$, the compensated own share derivative. Negativity does not sign it, because $k_{ii} \leq 0$ only requires $\gamma_{ii} + \beta_i^2 u^0 B(p) \leq w_i(1 - w_i)$. Uniqueness follows from Hicksian demand instead. Where negativity holds, $\frac{\partial h_i}{\partial p_i} \leq 0$, and $h_i = \frac{w_i e}{p_i}$ has the sign of the Hicksian share. The share therefore crosses zero at most once in that region. When several goods are removed together, their zero-share conditions form a system in the vector of log virtual prices, which we solve jointly.

A caveat applies to every AIDS virtual price. The AIDS expenditure function represents preferences only where all Hicksian shares are nonnegative. Beyond p_i^V the formula would imply a negative share, while true demand stays at zero and e stops rising in p_i. We use the AIDS formulas only up to the virtual price.

Example 5.47 (Virtual price of good 3)**.** In the running example, hold $p_1 = p_2 = 1$ and $\ln I = 1$. Then $G_3 = 0$ and $A = 0$, and (5.112) has roots $x = 1.410$ and $x = 34.1$. The Marshallian choke price is therefore $e^{1.410} = 4.10$. The Hicksian condition (5.114) at $u^0 = 1$ gives $\ln p_3^V = 1.475$, so $p_3^V = 4.37$. As Lemma 5.46 predicts for a normal good, the Hicksian virtual price is higher. The compensating variation of removing good 3 is $e(1, 1, 4.37, u^0) - I = 0.574$, which is 21.1 percent of income. Evaluating the expenditure function at the Marshallian choke price instead gives 21.09 percent, a small understatement because Hicksian demand is close to zero between the two prices.

5.7.3 Functional form and the value of variety

The virtual price depends on how demand behaves far from the observed prices. This is where functional forms differ most. CES and logit demands never reach zero, so their virtual prices

are infinite. They still imply finite losses, but those losses are pinned down by one parameter and the product's share. AIDS demand reaches zero at a finite price when the own share falls with price, and the loss depends on own and cross effects. The next proposition puts the three systems side by side.

Proposition 5.48 (The value of variety in three demand systems)**.** *Let good i have budget (or market) share s_i and signed own-price elasticity $\varepsilon_{ii} < -1$, and hold the other prices fixed.*

(a) CES with elasticity of substitution $\sigma > 1$: removing good i costs $\frac{CV}{I} = (1-s_i)^{\frac{1}{1-\sigma}} - 1$, equivalently $\ln\!\left(1 + \frac{CV}{I}\right) = \frac{-(1-s_i)\ln(1-s_i)}{-\varepsilon_{ii}-1}$.

(b) Logit with price coefficient α (used here in its logit meaning): removing good i costs each consumer $-\frac{1}{\alpha}\ln(1-s_i)$ in expectation, which equals $\frac{-p_i(1-s_i)\ln(1-s_i)}{-\varepsilon_{ii}}$.

(c) AIDS with $\beta_i = 0$: the virtual price satisfies $\ln\frac{p_i^V}{p_i^0} = \frac{1}{-\varepsilon_{ii}-1}$, and $\ln\!\left(1 + \frac{CV}{I}\right) = \frac{s_i}{2(-\varepsilon_{ii}-1)}$.

Proof. (a) With CES preferences, $e(p,u) = P^{CES}(p)\,u$ with $(P^{CES})^{1-\sigma} = \sum_j a_j p_j^{1-\sigma}$ and $s_i = a_i\left(\frac{p_i}{P^{CES}}\right)^{1-\sigma}$ (Section 5.1.4). Without good i the index becomes

$$\left(P^{CES}_{-i}\right)^{1-\sigma} = \sum_{j\neq i} a_j p_j^{1-\sigma} = \left(P^{CES}\right)^{1-\sigma} - a_i p_i^{1-\sigma} = \left(P^{CES}\right)^{1-\sigma}(1-s_i).$$

Hence $\frac{CV}{I} = \frac{P^{CES}_{-i}}{P^{CES}} - 1 = (1-s_i)^{\frac{1}{1-\sigma}} - 1$. This is positive because $1-s_i < 1$ and $\frac{1}{1-\sigma} < 0$. For the second form, the CES own elasticity is $\varepsilon_{ii} = -\sigma + (\sigma-1)s_i$, so $\sigma - 1 = \frac{-\varepsilon_{ii}-1}{1-s_i}$. Then $\ln(1+\frac{CV}{I}) = \frac{-\ln(1-s_i)}{\sigma-1}$, which gives the stated expression.

(b) Expected consumer surplus in the logit model is $\frac{1}{\alpha}\ln\sum_{j=0}^{J} e^{\delta_j - \alpha p_j}$ plus a constant (Chapter 7). Removing good i multiplies the sum by $1-s_i$, so surplus changes by $\frac{1}{\alpha}\ln(1-s_i) < 0$. The logit own elasticity is $\varepsilon_{ii} = -\alpha p_i(1-s_i)$, so $\frac{1}{\alpha} = \frac{p_i(1-s_i)}{-\varepsilon_{ii}}$.

(c) With $\beta_i = 0$, the term $u\,B(p)$ does not depend on p_i. Using the notation of (5.112) with $x^0 = \ln p_i^0$ and $x^V = \ln p_i^V$, the log expenditure function changes by

$$\ln e(x^V) - \ln e(x^0) = (\alpha_i + G_i)(x^V - x^0) + \frac{1}{2}\gamma_{ii}\left[(x^V)^2 - (x^0)^2\right].$$

By (5.113), $\alpha_i + G_i = -\gamma_{ii}x^V$. Substituting and factoring $x^V - x^0$,

$$\ln e(x^V) - \ln e(x^0) = \gamma_{ii}(x^V - x^0)\left[-x^V + \frac{1}{2}(x^V + x^0)\right] = -\frac{1}{2}\gamma_{ii}(x^V - x^0)^2.$$

Equation (5.113) also gives $x^V - x^0 = \frac{s_i}{-\gamma_{ii}}$, so the change equals $\frac{s_i^2}{2(-\gamma_{ii})}$. Finally, with $\beta_i = 0$ the Marshallian own elasticity is $\varepsilon_{ii} = -1 + \frac{\gamma_{ii}}{s_i}$ ((5.38)), so $-\gamma_{ii} = s_i(-\varepsilon_{ii} - 1)$. Substituting gives both claims. □

Three lessons follow. First, an AIDS good with $\beta_i = 0$ has a finite virtual price exactly when its demand is price elastic, since $\gamma_{ii} < 0$ is equivalent to $\varepsilon_{ii} < -1$. Second, for a small share the CES loss is $\ln(1+\frac{CV}{I}) \approx \frac{s_i}{-\varepsilon_{ii}-1}$, about twice the AIDS loss at the same share and elasticity. The AIDS share falls linearly in $\ln p_i$ to zero, while CES demand has a thick tail that extends to infinite prices. Third, in the CES and logit cases the loss is fixed once the share and one elasticity are known. The functional form builds in a value of variety that the data never test. Table 5.10 collects the formulas.

Table 5.10: The loss from removing good i in three demand systems

	CES	Logit	AIDS ($\beta_i = 0$)
Virtual price	∞	∞	$p_i^0 \exp\left(\frac{1}{-\varepsilon_{ii} - 1}\right)$
Exact loss	$\frac{-(1 - s_i)\ln(1 - s_i)}{-\varepsilon_{ii} - 1}$	$\frac{-p_i(1 - s_i)\ln(1 - s_i)}{-\varepsilon_{ii}}$	$\frac{s_i}{2(-\varepsilon_{ii} - 1)}$
Loss for small s_i	$\frac{s_i}{-\varepsilon_{ii} - 1}$	$\frac{s_i p_i}{-\varepsilon_{ii}}$	$\frac{s_i}{2(-\varepsilon_{ii} - 1)}$

Notes: s_i is the budget share (CES, AIDS) or market share (logit) of good i, and ε_{ii} is its signed Marshallian own-price elasticity. Other prices are held fixed. For CES and AIDS the loss is $\ln(1 + \frac{CV}{I})$, a fraction of the budget of the demand system. For logit it is the expected loss in money per consumer. Derivations in Proposition 5.48.

Example 5.49 (AIDS versus a calibrated CES)**.** Good 3 in the running example has share 0.26 and own elasticity −1.738. The full AIDS computation of Example 5.47 gives a loss of 21.1 percent of income. The $\beta_i = 0$ formula of Proposition 5.48(c) gives $\ln(1 + \frac{CV}{I}) = \frac{0.26}{2 \times 0.738} = 0.176$, a loss of 19.3 percent, close to the exact value because $\beta_3 = 0.06$ is small. A CES calibrated to the same share and elasticity has $\sigma = \frac{1.738 - 0.26}{1 - 0.26} = 2.00$, and Proposition 5.48(a) gives a loss of 35.2 percent of income. Figure 5.5 shows why. Both Hicksian demand curves pass through the observed point with similar slopes. Their Hicksian own elasticities, −1.42 for AIDS and −1.48 for CES, differ only through the income effect. Far from the observed point the curves part ways, and the CES curve never meets the price axis. Hausman (1997, p. 231) reports the same pattern for a new cereal brand: a CES specification gives a consumer surplus about three times as high as his AIDS estimate.

5.7.4 The extrapolation problem

Remark 5.50 (Virtual prices lie outside the data). Every virtual-price calculation extrapolates. In the running example the virtual price is more than four times the observed price. In Hausman's cereal data, prices vary by about 50 percent, while the estimated virtual price is about twice the average price (Hausman, 1997, p. 228). The answer is then driven by the curvature of the chosen functional form beyond the support of the data. For AIDS the relevant feature is the shape of shares in log prices, linear when $\beta_i = 0$ and quadratic otherwise. Proposition 5.48(c) shows how sensitive the result is near unit elasticity: the log virtual price $\frac{1}{-\varepsilon_{ii} - 1}$ explodes as ε_{ii} approaches −1. Hausman (1997) proposes a lower bound that needs only convexity of demand: the tangent to the demand curve at the observed price meets the price axis below the true virtual price. Chapter 10 develops this bound.

5.7.5 Recovering marginal costs from first-order conditions

Counterfactual prices require marginal costs, which are rarely observed. The standard approach inverts the firms' pricing conditions, as in Chapter 2 and Chapter 4. We state the conditions in elasticity form, which is the natural form for product-space demand.

Single-product pricing. A firm that sets the price of product i with constant marginal cost c_i maximizes $(p_i - c_i)q_i(p)$. The first-order condition is $q_i + (p_i - c_i)\frac{\partial q_i}{\partial p_i} = 0$. Dividing by q_i and

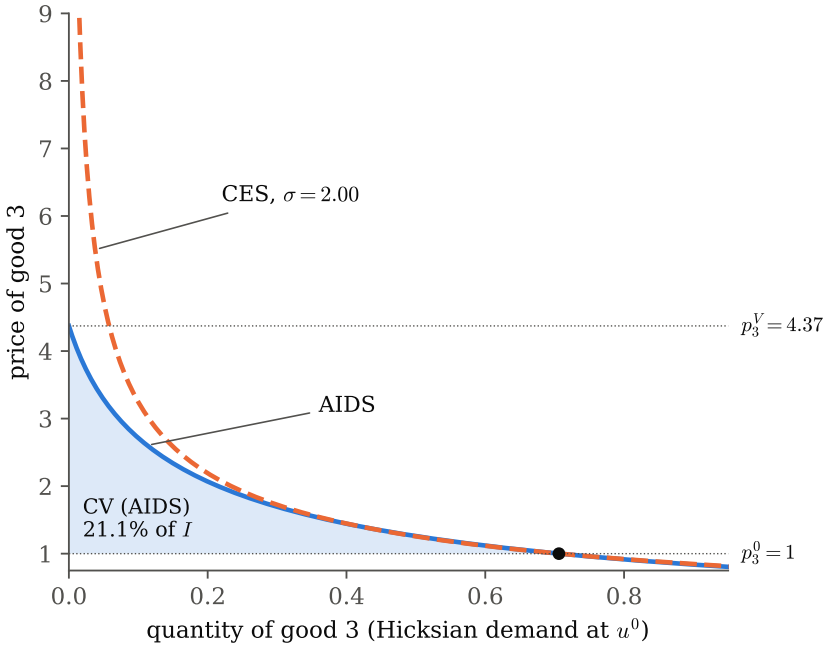

Figure 5.5: Virtual price and the loss from removing a good. The solid curve is the AIDS Hicksian demand for good 3 in the running example at the initial utility u^0, with $p_1 = p_2 = 1$. It reaches zero at the virtual price $p_3^V = 4.37$. The shaded area is the compensating variation of removing good 3, 21.1 percent of income. The dashed curve is the Hicksian demand of a CES system calibrated to the same share (0.26) and own-price elasticity (−1.738) at the observed point. It approaches the price axis only asymptotically, and the area to its left equals 35.2 percent of income. Computed with `figures/ch05/src/virtual_price.py`.

multiplying by $\frac{1}{p_i}$ gives the Lerner condition $\frac{p_i - c_i}{p_i} = -\frac{1}{\varepsilon_{ii}}$, and solving for the cost gives

$$c_i = p_i\Big(1 + \frac{1}{\varepsilon_{ii}}\Big). \tag{5.115}$$

The condition is meaningful only when $\varepsilon_{ii} < -1$. A profit-maximizing firm never prices on the inelastic part of its demand. The same condition holds for a product group whose price is set jointly by perfectly colluding producers, the case used by Chaudhuri et al. (2006).

The elasticity in (5.115) must be *unconditional*. It must include the reallocation of expenditure across segments and between the category and other goods, computed by the chain rule of (5.79). A within-segment elasticity holds segment expenditure fixed. Suppose a segment's own unconditional elasticity is below -1. Raising a brand's price then drains expenditure from the whole segment, so the unconditional own elasticity is larger in magnitude than the conditional one. Markups computed from conditional elasticities are then too high. Table 5.13 shows this pattern for all fifteen beer brands of Section 5.8.

Multiproduct pricing in elasticity form. Firm f owns the products in $\mathcal{J}_f$ and maximizes $\pi_f = \sum_{k \in \mathcal{J}_f} (p_k - c_k) q_k(p)$. The first-order condition for p_j, $j \in \mathcal{J}_f$, is

$$q_j + \sum_{k \in \mathcal{J}_f} (p_k - c_k) \frac{\partial q_k}{\partial p_j} = 0.$$

Let $R_f = \sum_{k \in \mathcal{J}_f} p_k q_k$ be the firm's revenue, $r_k = \frac{p_k q_k}{R_f}$ the revenue share of product k, and $\ell_k = \frac{p_k - c_k}{p_k}$ its Lerner index. Elsewhere the book writes L for the Lerner index. We write ℓ_k in this chapter, where L denotes a likelihood. We multiply the condition by $\frac{p_j}{R_f}$ and rewrite each term of the sum:

$$(p_k - c_k) \frac{\partial q_k}{\partial p_j} \frac{p_j}{R_f} = \frac{p_k - c_k}{p_k} \cdot \frac{p_k q_k}{R_f} \cdot \frac{\partial q_k}{\partial p_j} \frac{p_j}{q_k} = \ell_k \, r_k \, \varepsilon_{kj}.$$

The first-order conditions become

$$r_j + \sum_{k \in \mathcal{J}_f} \ell_k \, r_k \, \varepsilon_{kj} = 0, \quad j \in \mathcal{J}_f, \qquad \text{or} \qquad r_f + E_f^{\top} m_f = 0. \tag{5.116}$$

Here r_f stacks the revenue shares and m_f has elements $m_k = \ell_k r_k$. The matrix E_f collects the elasticities among the firm's products, with (k, j) element ε_{kj}. Solving,

$$m_f = -\big(E_f^{\top}\big)^{-1} r_f, \qquad \ell_k = \frac{m_k}{r_k}. \tag{5.117}$$

This is the form in Hausman et al. (1994, eqs. 7–9 and 14–15) and Hausman (1997, eqs. 12–15), who write s for the revenue shares and w for m_f. The system is homogeneous of degree one in r_f, so the shares can be normalized by any common revenue, such as total market revenue, without changing ℓ. Stacking all firms gives a block-diagonal elasticity matrix, one block per firm (Hausman et al., 1994, eq. 14).

The elasticity form is equivalent to the matrix markup formula of Chapter 4. Let Ω be the ownership matrix and let D have (j, k) element $\frac{\partial q_k}{\partial p_j}$ (note the transposition relative to the Jacobian of demand). Stacking the first-order conditions of all firms gives

$$q + (\Omega \odot D)(p - c) = 0, \qquad \text{so} \qquad p - c = -(\Omega \odot D)^{-1} q.$$

Dividing by market size turns quantities into market shares. Using $\frac{\partial q_k}{\partial p_j} = \varepsilon_{kj}\frac{q_k}{p_j}$, row j reads $q_j + \sum_k \Omega_{jk}\varepsilon_{kj}\frac{q_k}{p_j}(p_k - c_k) = 0$. Multiplying by $\frac{p_j}{R_f}$ returns (5.116).

For a firm with two products, (5.117) gives

$$\ell_1 = \frac{-\varepsilon_{22} + \frac{r_2}{r_1}\varepsilon_{21}}{\varepsilon_{11}\varepsilon_{22} - \varepsilon_{12}\varepsilon_{21}}. \tag{5.118}$$

With $\varepsilon_{21} = \varepsilon_{12} = 0$ this reduces to $-\frac{1}{\varepsilon_{11}}$. When the two products are substitutes, the term $\frac{r_2}{r_1}\varepsilon_{21} > 0$ raises the markup on product 1. Part of the demand lost by raising p_1 is recaptured by product 2. The size of the effect depends on the cross elasticity of the sibling product with respect to p_1 and on its relative revenue.

5.7.6 Partial identification of marginal cost

The first-order condition (5.115) presumes a model of conduct. In many markets conduct is unknown, and in regulated markets prices may not satisfy any unconstrained first-order condition. Chaudhuri et al. (2006) face both problems in the Indian antibiotics market (Section 5.9). Dozens of firms sell each molecule, and many prices are capped by regulation. Their solution is to bound marginal cost instead of point-identifying it.

Assumption 5.51 (Conduct between competition and joint monopoly)**.** For product group i the following hold.

(i) Marginal cost c_i is constant.

(ii) Group demand $q_i(p_i, p_{-i})$ is differentiable, with $\frac{\partial q_i}{\partial p_i} < 0$.

(iii) The group's joint profit $\Pi_i(p_i) = (p_i - c_i)q_i(p_i, p_{-i})$ is strictly quasi-concave in p_i, with maximizer p_i^m.

(iv) The observed price satisfies $c_i \le p_i \le p_i^m$.

Part (iv) is the substantive assumption. Prices are no lower than marginal cost, and no higher than the price a joint monopolist of the group would choose given the other prices. Competition within the group and price caps both move the price into this interval.

Proposition 5.52 (Bounds on marginal cost)**.** *Under Assumption 5.51, $c_i^L \le c_i \le c_i^U$, where*

$$c_i^U = p_i, \qquad c_i^L = p_i\Big(1 + \frac{1}{\varepsilon_{ii}(p)}\Big), \tag{5.119}$$

and $\varepsilon_{ii}(p)$ is the unconditional own-price elasticity at the observed prices. Equivalently, $0 \le \ell_i \le -\frac{1}{\varepsilon_{ii}(p)}$.

Proof. The upper bound is the first inequality in part (iv). For the lower bound, a strictly quasi-concave function increases up to its maximizer. Since $p_i \le p_i^m$, we have $\Pi_i'(p_i) = q_i + (p_i - c_i)\frac{\partial q_i}{\partial p_i} \ge 0$. Rearranging, $(p_i - c_i)\big(-\frac{\partial q_i}{\partial p_i}\big) \le q_i$. Dividing both sides by $p_i\big(-\frac{\partial q_i}{\partial p_i}\big) > 0$ gives

$$\frac{p_i - c_i}{p_i} \le \frac{q_i}{p_i}\Big(-\frac{\partial q_i}{\partial p_i}\Big)^{-1} = -\frac{1}{\varepsilon_{ii}}.$$

Solving for c_i gives $c_i \ge p_i\big(1 + \frac{1}{\varepsilon_{ii}}\big) = c_i^L$. □

These are equations (3.12) and (3.13) of Chaudhuri et al. (2006). Several remarks help in using them. The lower bound is informative only when $\varepsilon_{ii} < -1$. If $-1 < \varepsilon_{ii} < 0$, then $c_i^L < 0$ and the bound adds nothing to $c_i \geq 0$. The observed price then lies where demand is inelastic, which no unconstrained joint monopolist would choose. That pattern is itself evidence of competition or regulation. In the language of Chapter 3, the bounds are the endpoints of the conduct-parameter model $\frac{p_i - c_i}{p_i} = -\frac{\theta}{\varepsilon_{ii}}$ at $\theta = 0$ and $\theta = 1$. The bounds approach avoids estimating θ, which in a regulated market need not be a stable structural parameter. Bounds are transparent, and they often suffice for a policy conclusion. In a counterfactual we simulate the outcome at each bound. The two results bound the counterfactual outcome when that outcome is monotone in marginal cost, which should be checked in each application.

5.7.7 Counterfactual equilibrium after product withdrawal

We now combine virtual prices, cost recovery and the multi-level demand system to simulate the withdrawal of products. The setting is the two-level system of Section 5.5. An upper level allocates total expenditure X across segments G with price indices P_G, and an AIDS allocates segment expenditure X_Q within segment Q. A policy removes the products in $\mathcal{W} \subset Q$, and the products in $\mathcal{R} = Q \setminus \mathcal{W}$ remain.

The equilibrium system. The unknowns are the virtual prices p_i^V of the withdrawn products, the new prices p_k' of the remaining products, and the new segment expenditure and price index X_Q' and P_Q'. They solve three blocks of equations.

(S1) Zero shares for withdrawn products. For each $i \in \mathcal{W}$,

$$0 = \alpha_i + \sum_{j \in \mathcal{W}} \gamma_{ij} \ln p_j^V + \sum_{k \in \mathcal{R}} \gamma_{ik} \ln p_k' + \beta_i \ln \frac{X_Q'}{P_Q'}. \tag{5.120}$$

(S2) Pricing of remaining products. For single-product firms or colluding groups,

$$p_k' = c_k \Big(1 + \frac{1}{\varepsilon_{kk}(p')}\Big)^{-1}, \quad k \in \mathcal{R}, \tag{5.121}$$

and for multiproduct firms the system (5.116) evaluated at the new prices.

(S3) Upper-level adjustment. The new index is $P_Q' = \mathbf{P}_Q(p_{\mathcal{W}}^V, p_{\mathcal{R}}')$, and X_Q' follows from the upper-level share equation of segment Q evaluated at P_Q' and the other segment indices.

Equations (5.120) and (5.121) are equations (3.14) and (3.15) of Chaudhuri et al. (2006), written without their market-specific restrictions on the cross-price terms. The elasticities in (S2) are unconditional and evaluated at the counterfactual prices, including the virtual prices.

One detail of (S2) deserves care. The demand that a remaining firm faces is AIDS demand evaluated at the virtual prices, and by (S1) those prices move when p_k' moves. For a single withdrawn product i, implicit differentiation of $w_i = 0$ gives $\frac{\partial \ln p_i^V}{\partial \ln p_j} = -\big(\frac{\partial w_i}{\partial \ln p_i}\big)^{-1} \frac{\partial w_i}{\partial \ln p_j}$. The elasticity of demand for product k with respect to p_j, once good i has left, is therefore

$$\varepsilon_{kj}^{-i} = \varepsilon_{kj} - \varepsilon_{ki} \Big(\frac{\partial w_i}{\partial \ln p_i}\Big)^{-1} \frac{\partial w_i}{\partial \ln p_j}, \tag{5.122}$$

with all terms evaluated at p_i^V. This is the standard formula for demand under a ration of zero.

Solving the system. A simple algorithm iterates over the blocks. Start at the observed prices and expenditure. Given $p'_{\mathcal{R}}$ and X'_Q, solve (S1) for the virtual prices. Update P'_Q and X'_Q with (S3). Update $p'_{\mathcal{R}}$ with (S2), using elasticities at the current prices. Repeat until the prices stop changing. Newton's method on the stacked system converges faster when a good starting value is available. Existence and uniqueness are not guaranteed, so we solve from several starting values and check the second-order conditions. We also verify that the remaining shares stay positive and that the relevant own elasticities stay below -1.

Welfare and its decomposition. Let $E(u, P)$ be the upper-level expenditure function, with P the vector of segment indices. Let P^0 be the observed indices and P' the counterfactual ones, with P'_Q computed from the virtual and new prices. The compensating variation is (Chaudhuri et al., 2006, eq. 3.16)

$$CV = E(u^0, P') - E(u^0, P^0). \tag{5.123}$$

To see which mechanism drives it, define two intermediate price vectors. P^1 uses virtual prices computed with X_Q and all remaining prices fixed at their observed values. P^2 recomputes the virtual prices letting X_Q respond to the new segment index, still holding the remaining prices fixed. Then

$$CV = \underbrace{E(u^0, P^1) - E(u^0, P^0)}_{\text{pure variety}} + \underbrace{E(u^0, P^2) - E(u^0, P^1)}_{\text{expenditure switching}} + \underbrace{E(u^0, P') - E(u^0, P^2)}_{\text{price adjustment}}. \tag{5.124}$$

This is the general form of the decomposition used by Chaudhuri et al. (2006). The first term values the lost products at fixed prices and fixed segment expenditure. The second term exists because the zero-share condition (S1) is Marshallian. Whenever $\beta_i \neq 0$, the virtual prices depend on segment expenditure, so they shift once X_Q adjusts. The third term records the repricing of the remaining products. The first two terms together describe a regime in which price regulation freezes the remaining prices at their old levels. The decomposition is sequential, so its terms depend on the order in which the changes are introduced.

The welfare of a country adds producer surplus. With $\pi_k = (p_k - c_k)q_k$ computed at the counterfactual and the observed prices, the change in national welfare is $-CV$ plus the change in the profits of domestic firms. Profits of foreign firms are excluded from national welfare. They still measure the private gain that motivates the policy. Section 5.9.8 applies this accounting to patents in India.

Example 5.53 (Withdrawal in the running example)**.** Treat the running example as a segment with fixed expenditure $X_Q = e$, sold by three single-product firms. Equation (5.115) recovers marginal costs $c = (0.273, 0.406, 0.425)$ from the observed prices and elasticities. Suppose good 3 is withdrawn. Firms 1 and 2 reprice, facing the demand of consumers who can no longer buy good 3, with its elasticities given by (5.122). The new equilibrium has $p'_1 = 1.475$ and $p'_2 = 1.365$, increases of 47.5 and 36.5 percent. The own elasticities fall in magnitude from -1.375 and -1.682 to -1.227 and -1.423, because the closest outside option has gone. The total compensating variation is 71.9 percent of segment expenditure. The pure variety effect, with other prices fixed, is 21.1 percent (Example 5.47). The price adjustment adds 50.8 percent. Firms 1 and 2 gain 0.734 in profit, while firm 3 loses 0.407. These effects are large because fixing segment expenditure makes the segment's aggregate demand unit elastic. An upper level with elastic segment demand would add the expenditure-switching channel and dampen the price response. The computation is in `virtual_price.py`.

5.8 Case study: Hausman, Leonard and Zona (1994)

Hausman et al. (1994) (HLZ) built the multi-level AIDS into a tool for antitrust analysis of differentiated products. They estimated a three-level demand system for beer on store-level scanner data and identified it with prices of the same brands in other cities. They then used the estimates to predict the price effects of mergers and to test models of pricing. The paper is short and its data description is thin, but its method shaped two decades of applied work. We treat it in depth.

5.8.1 The economic question

Antitrust questions about consumer goods turn on substitution among brands. Is a set of brands a market? Will two brands owned by merging firms rise in price? Do observed markups match the predictions of a model of competition? Each question needs own and cross elasticities for many brands. HLZ argue that the models then in use restricted these elasticities too much. Representative-consumer models with symmetric preferences and logit-type models share an *independence of irrelevant alternatives* (IIA) property. Consumers of an eliminated good spread over the remaining goods in proportion to their market shares. In terms of elasticities, "all cross price elasticities with respect to a given good are the same" (Hausman et al., 1994, p. 160). HLZ set out to estimate demand without such restrictions.

Store-level scanner data made this possible. Each transaction records units and price paid, by brand and by stock-keeping unit, and weekly promotions generate large price variation. Two econometric problems remain. The first is dimensionality. It is "difficult to conceive of estimating a demand equation with say 135 brands of cereal or say 40 brands of beer" (p. 160). The second is identification: at the brand level, cost shifters that vary across brands and weeks are hard to find. HLZ answer the first problem with multi-stage budgeting and the second with prices in other cities.

A third theme runs through the applications. Firms in these industries sell many brands. HLZ list Miller High Life, Miller Lite, Miller Genuine Draft, Milwaukee's Best and Meisterbrau as Miller brands, and note that Kellogg's produces over 30 cereals (p. 161). A multiproduct firm that raises one brand's price recaptures some of the lost sales on its other brands. HLZ show how this *cannibalization* changes merger predictions and tests of conduct.

5.8.2 Setting and data

Marketing analysts divide the U.S. beer market into segments: premium, light (low-calorie), imported and popular-price beer (p. 162). In estimation HLZ use three segments. The premium segment includes imported beers, which they found belong with premium brands (p. 164). Each segment contains five brands, for fifteen brands in total (Figure 5.6). The brands include national brands such as Budweiser, Miller and Coors, Canadian imports such as Molson and Labatts, and regional brands such as Genesee.

The data are cash-register records from individual stores, aggregated to the metropolitan area (SMSA) level. For each brand they give sales and price per unit, after aggregating over container sizes (p. 160). Most price variation comes from supermarket chains running low-price promotions on a brand in a given week (p. 167). In most cases manufacturers sell at wholesale nationally, with a uniform wholesale price (p. 161), which motivates the identification strategy below. The paper reports little else about the sample. Two graphs show weekly sales of Budweiser and Genesee in Buffalo in February and March 1988 and in March to June 1990. The

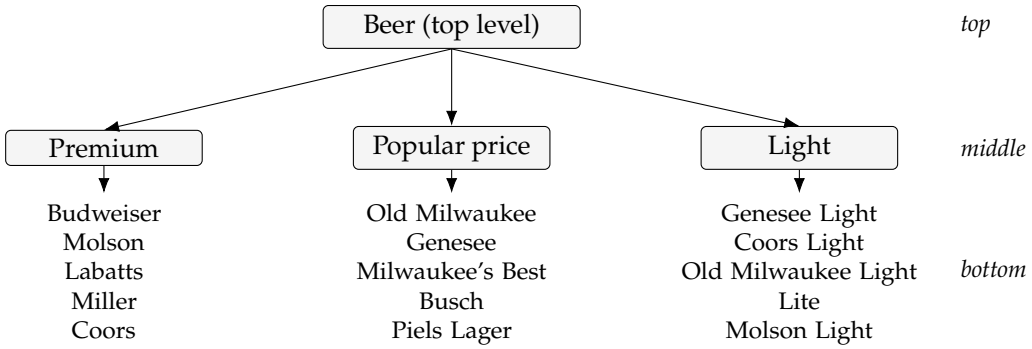

Figure 5.6: The three-level budgeting tree of Hausman et al. (1994). The top level determines beer consumption relative to other goods, the middle level allocates beer expenditure across three segments, and the bottom level allocates each segment's expenditure across five brands. Imported beers are included in the premium segment. Brand lists from HLZ, Tables 2 to 5.

middle-level regressions of Table 1 use 101 observations. HLZ do not report the list of cities, the sample period or the number of stores. The top level uses national monthly data from the Bureau of Labor Statistics covering sixteen years (p. 164). The share equations also include a time trend and the log number of stores.

5.8.3 The three-level demand model

HLZ apply the multi-stage budgeting framework of Section 5.5 with three levels. We write their equations in this chapter's notation. Cities are indexed by $n = 1, \dots, N$ (in this section N counts cities) and weeks by t. Segments are G and H, and brands are i and j.

Bottom level: brands within a segment. For brand i in segment G,

$$w_{int} = \alpha_{in} + \beta_i \ln \frac{X_{Gnt}}{P_{Gnt}} + \sum_{j \in G} \gamma_{ij} \ln p_{jnt} + \xi_{int}. \tag{5.125}$$

This is equation (1) of Hausman et al. (1994). Here w_{int} is the revenue share of brand i in segment expenditure X_{Gnt}, P_{Gnt} is a segment price index and p_{jnt} is the price of brand j. The intercept α_{in} is a brand-city effect. This is an AIDS for the segment, with symmetry $\gamma_{ij} = \gamma_{ji}$ imposed in estimation. The γ_{ij} are free within the segment, so no IIA-type restriction constrains the cross elasticities among the brands that compete most closely. A test of $\beta_i = 0$ is a test of segment homotheticity. HLZ stress that the expenditure variable must be segment expenditure (p. 163), in the words that Hausman (1997) repeats and that we quoted in Section 5.5.1.

Middle level: segments. Given the bottom-level estimates, HLZ construct a price index for each segment. They use either the exact index implied by the bottom-level expenditure function or a weighted-average index of the Laspeyres type, and report that the choice matters little (p. 164). The segment demands are log-log:

$$\ln q_{Gnt} = \alpha_{Gn} + \beta_G \ln X_{Bnt} + \sum_{H} \vartheta_{GH} \ln P_{Hnt} + \xi_{Gnt}, \tag{5.126}$$

where q_{Gnt} is the quantity of segment G and X_{Bnt} is total beer expenditure (HLZ eq. 2, where the price coefficients are written δ_k). Because beer expenditure is held fixed, β_G and ϑ_{GH}

are conditional elasticities. Slutsky restrictions are not imposed at this level (fn. 3). Exact two-stage budgeting under Gorman's results, discussed in Blackorby et al. (1978), requires additive separability at the level above. HLZ note that AIDS is a generalized Gorman polar form, so Gorman's theorem applies, and that a less restrictive middle level, not consistent with exact two-stage budgeting, gives similar results (fn. 2).

Top level: beer. Overall beer consumption Q_{Bt} is

$$\ln Q_{Bt} = \varphi_0 + \varphi_1 \ln y_t + \varphi_2 \ln P_{Bt} + Z_t^{\top}\psi + \xi_{Bt}. \tag{5.127}$$

This is HLZ's equation (3). Here y_t is deflated disposable income and P_{Bt} is the deflated beer price index. The vector Z_t holds demographics, monthly seasonal factors and the minimum legal age for buying beer. The coefficient φ_2 is the overall price elasticity of beer. HLZ estimate it by instrumental variables on the national monthly data, with cost shifters for ingredients, packaging and labor as instruments.

From three levels to unconditional elasticities. Estimation runs bottom-up, and the elasticities that matter for competition combine all three levels. The two-level chain rule of (5.79) extends directly. Take brand i in segment G and brand j in segment H, and drop the city and week subscripts. Let $\varepsilon_{ij}\big|_{X_G}$ be the within-segment elasticity at fixed segment expenditure and $\eta_{i|G} = 1 + \frac{\beta_i}{w_i}$ the elasticity of brand i with respect to segment expenditure. Then

$$\varepsilon_{ij} = \mathbf{1}(G = H)\, \varepsilon_{ij}\big|_{X_G} + \eta_{i|G}\, \frac{\partial \ln X_G}{\partial \ln p_j}.$$

Segment expenditure is $X_G = P_G q_G$, so $\ln X_G = \ln P_G + \ln q_G$. The index P_G responds to p_j only if $H = G$. The quantity q_G responds through the price index P_H and through beer expenditure:

$$\frac{\partial \ln q_G}{\partial \ln p_j} = \left[\vartheta_{GH} + \beta_G \frac{\partial \ln X_B}{\partial \ln P_H}\right] \frac{\partial \ln P_H}{\partial \ln p_j}.$$

Beer expenditure is $X_B = P_B Q_B$, and with income fixed the top level gives $\frac{\partial \ln X_B}{\partial \ln P_B} = 1 + \varphi_2$. If the beer index has segment weights w_H (the shares of the segments in beer expenditure), then $\frac{\partial \ln P_B}{\partial \ln P_H} = w_H$. Collecting terms,

$$\varepsilon_{ij} = \mathbf{1}(G = H)\, \varepsilon_{ij}\big|_{X_G} + \eta_{i|G}\Big[\mathbf{1}(G = H) + \vartheta_{GH} + \beta_G(1 + \varphi_2) w_H\Big] \frac{\partial \ln P_H}{\partial \ln p_j}. \tag{5.128}$$

For a Stone or Laspeyres segment index, $\frac{\partial \ln P_H}{\partial \ln p_j}$ is the weight of brand j in the index. For the exact translog index it equals $w_j - \beta_j \ln \frac{X_H}{P_H}$ (Section 5.3).

Equation (5.128) has two consequences. For the own elasticity ($j = i$), the bracket equals $1 + \vartheta_{GG} + \beta_G(1 + \varphi_2) w_G$. It is negative whenever the segment's own conditional elasticity is well below -1, as it is in the beer data. The unconditional own elasticity is then larger in magnitude than the conditional one. For brands in different segments, ε_{ij} depends on brand j only through its weight in index H, and on brand i only through $\eta_{i|G}$. All brand-pair specific substitution across segments is ruled out. This is the price of the dimension reduction.

The restriction has a compensated counterpart. By the theorem of Goldman and Uzawa (1964) (Proposition 5.38), weak separability implies $S_{ij} = \mu_{GH} \frac{\partial q_i}{\partial I} \frac{\partial q_j}{\partial I}$ for $i \in G$, $j \in H$, $G \neq H$. To

convert to elasticities, we use $\frac{\partial q_i}{\partial I} = \frac{\partial q_i}{\partial X_G}\frac{\partial X_G}{\partial I} = \eta_{i|G}\frac{q_i}{X_G}\frac{\partial X_G}{\partial I}$ and the same expression for good j in segment H. Then

$$\varepsilon^h_{ij} = \frac{p_j}{q_i}S_{ij} = \mu_{GH}\,\eta_{i|G}\,\eta_{j|H}\,\frac{\partial X_G}{\partial I}\frac{\partial X_H}{\partial I}\,\frac{p_j q_j}{X_G X_H},$$

which gives

$$\varepsilon^h_{ij} = \lambda_{GH}\,w_{j|H}\,\eta_{i|G}\,\eta_{j|H}, \qquad \lambda_{GH} = \frac{\mu_{GH}}{X_G}\frac{\partial X_G}{\partial I}\frac{\partial X_H}{\partial I},$$

where $w_{j|H}$ is the share of brand j in segment H and λ_{GH} depends only on the pair of segments. HLZ state the restriction as $\varepsilon^h_{ij} = \lambda_{GH}\eta_{i|G}\eta_{j|H}$ (Hausman et al., 1994, eq. 5). The exact conversion adds the within-segment share of brand j. Either way, a segment-pair constant and brand-level expenditure elasticities determine all compensated substitution across segments.

The dimension reduction is large. A complete AIDS for fifteen brands has $\frac{15\times14}{2} = 105$ free price coefficients after symmetry and homogeneity. Three five-brand segments have $3\times10 = 30$, the middle level adds nine segment price elasticities, and the top level adds one.

5.8.4 Identification with prices in other cities

Prices in (5.125) are endogenous if retailers and manufacturers set them knowing local demand conditions. Cost shifters that vary by brand and week are rarely available. An "insufficient number of input prices may exist or they may not be reported with high enough frequency" (p. 164). HLZ exploit the panel structure of the data instead. They model the price of brand j in city n and week t as

$$\ln p_{jnt} = \rho_j \ln c_{jt} + \mu_{jn} + \zeta_{jnt}. \tag{5.129}$$

This is HLZ's equation (4), with our ρ_j, μ_{jn} and ζ_{jnt} in place of their δ_j, α_{jn} and w_{jnt}. Here c_{jt} is the cost of brand j, assumed to have no city-specific time variation, consistent with national shipments and advertising. The term μ_{jn} is a city-brand differential reflecting transport costs or local wages. The shock ζ_{jnt} has mean zero and captures local promotions.

Assumption 5.54 (Prices in other cities as instruments)**.** In (5.129) the following hold.

(i) The cost component c_{jt} is common to all cities.

(ii) The city-brand effects μ_{jn} are constant over time.

(iii) The local shocks ζ_{jnt} are independent across cities. They may be correlated across brands within a city (Hausman, 1997, fn. 19).

(iv) The demand errors ξ_{int} are uncorrelated with the cost component and with the local price shocks of other cities.

Let a tilde denote the deviation from the city-brand mean, the within transformation that removes μ_{jn} and the fixed effects in (5.125). Under Assumption 5.54 the prices of every brand of the segment in any other city $n' \neq n$ satisfy the moment conditions

$$\mathbb{E}\big[\tilde{\xi}_{int}\,\widetilde{\ln p}_{jn't}\big] = 0, \qquad j \in G,\ n' \neq n. \tag{5.130}$$

Instruments of this kind are now called *Hausman instruments*. Relevance and exclusion follow from (5.129). The price in city n' shares the cost component with the price in city n, while the local shocks are independent, so

$$\operatorname{Cov}\big(\widetilde{\ln p}_{jn't}, \widetilde{\ln p}_{jnt}\big) = \rho_j^2 \operatorname{Var}\big(\widetilde{\ln c}_{jt}\big) > 0$$

whenever national costs vary over time. The covariance with the demand error is

$$\operatorname{Cov}\big(\widetilde{\ln p}_{jn't}, \tilde{\xi}_{int}\big) = \rho_j \operatorname{Cov}\big(\widetilde{\ln c}_{jt}, \tilde{\xi}_{int}\big) + \operatorname{Cov}\big(\tilde{\zeta}_{jn't}, \tilde{\xi}_{int}\big),$$

and both terms are zero by part (iv). In words, "prices in one city (after elimination of city and brand specific effects) are driven by underlying costs" (p. 165).

The first stage regresses $\ln p_{jnt}$ on the brand-city effects, the exogenous regressors and the prices of the segment's brands in other cities, either city by city or averaged. With more than two cities the model is overidentified, and HLZ point to the tests of Hausman and Taylor (1981) for checking the instrument assumptions (fn. 4). The logic is that of Hausman and Taylor (1981): after unit effects are removed, variation shared with other units serves as an instrument. The share equations are estimated as a system, as the residual covariance matrices reported with Tables 2 to 4 suggest, and symmetry is imposed across equations.

HLZ also offer a second interpretation. Suppose supermarkets set weekly prices under constant short-run marginal cost and do not adjust them to clear the market. Prices are then predetermined with respect to the demand errors, and ordinary least squares is consistent. Segment expenditure X_{Gnt} may still need instruments, since it responds to the same demand shocks. The choice between the two views can be tested with the specification test of Hausman (1978). That test compares the IV and OLS estimates through

$$\mathcal{H} = (\hat{b}_{IV} - \hat{b}_{OLS})^{\top} \big[\widehat{\operatorname{Var}}(\hat{b}_{IV}) - \widehat{\operatorname{Var}}(\hat{b}_{OLS})\big]^{-1} (\hat{b}_{IV} - \hat{b}_{OLS}),$$

which is asymptotically chi-squared under exogeneity, with degrees of freedom equal to the number of coefficients tested. HLZ describe the test but do not report its outcome for beer.

Later work adopted these instruments widely. Nevo (2001) uses regional quarterly average prices of the same brand, excluding the city being instrumented, in his study of breakfast cereals. Chapter 7 and Chapter 8 return to them.

5.8.5 Validity: Bresnahan's critique

The identifying assumption rules out demand shocks that are common across cities and reflected in prices. Bresnahan (1997) made this objection in his comment on Hausman (1997), which uses the same strategy for cereals. For the assumption to hold, "there can be no successful nationwide advertising campaigns which shift the demand for individual brands or products" (Bresnahan, 1997, p. 241). There can be no national fads and no slow national acceptance of new brands. Adding advertising to the demand equation does not settle the issue, because the econometrician does not observe which campaigns succeed (fn. 6). The fallback that prices are predetermined requires such shocks to be unforeseen when prices are set, which Bresnahan finds unlikely for national campaigns. If national shocks exist and supply slopes up, prices in other cities move with the demand error. Supply can slope up in the one-week run because inventories cannot adjust or because of market power (fn. 7).

The bias with one product. We derive the bias in the simplest version of Bresnahan's model: one product, linear demand, single-product Bertrand pricing and constant marginal cost. In city n and week t,

$$q_{nt} = d + a\, p_{nt} + \xi_{nt}, \quad a < 0, \qquad\qquad p_{nt} = c_{nt} + \frac{q_{nt}}{-a}.$$

The pricing equation is the first-order condition $q + (p - c)a = 0$. Substituting demand into it gives $p = c - \frac{d}{a} - p - \frac{\xi}{a}$, so

$$p_{nt} = \frac{1}{2} c_{nt} - \frac{d + \xi_{nt}}{2a}.$$

Let the demand error have a national and a local part, $\xi_{nt} = \chi_t + e_{nt}$, and let cost have the same structure, $c_{nt} = \bar{c}_t + v_{nt}$. The national components have variances σ_χ^2 and σ_c^2. All components are mutually independent, and the local ones are independent across cities. The instrument for p_{nt} is $p_{n't}$ with $n' \neq n$. Only the national components survive in the covariances:

$$\operatorname{Cov}(p_{n't}, \xi_{nt}) = -\frac{\sigma_\chi^2}{2a}, \qquad \operatorname{Cov}(p_{n't}, p_{nt}) = \frac{\sigma_c^2}{4} + \frac{\sigma_\chi^2}{4a^2}.$$

The IV estimator therefore converges to

$$\operatorname{plim} \hat{a} = a + \frac{\operatorname{Cov}(p_{n't}, \xi_{nt})}{\operatorname{Cov}(p_{n't}, p_{nt})} = a - \frac{2a\,\sigma_\chi^2}{a^2\sigma_c^2 + \sigma_\chi^2} = a(1 - 2\lambda), \qquad \lambda = \frac{\sigma_\chi^2}{a^2\sigma_c^2 + \sigma_\chi^2}. \tag{5.131}$$

The weight $\lambda \in [0, 1]$ is the share of national demand shocks in the price variation common to all cities. Without national demand shocks ($\lambda = 0$) the estimator is consistent. Otherwise the estimate lies between a and $-a$, biased toward zero, so demand looks too steep. When $\lambda > \frac{1}{2}$ the estimated slope even has the wrong sign. At $\lambda = 1$ the estimator recovers $-a$, the slope of the supply relation $q = -a(p - c)$. In Bresnahan's words, the estimator then behaves "like doing ordinary least squares on a supply and demand system" (p. 242).

The bias with many products. The same logic extends to J products, and the exact bias has a compact form. Let demand be $q_{nt} = d + A\,p_{nt} + \xi_{nt}$, with $A = [a_{jk}]$ and $a_{jk} = \frac{\partial q_j}{\partial p_k}$. Single-product Bertrand pricing gives $p_{jnt} = c_{jnt} + \frac{q_{jnt}}{-a_{jj}}$, or $p = c + \Theta^{-1}q$ with $\Theta = \operatorname{diag}(-a_{11}, \ldots, -a_{JJ})$. Multiplying by Θ and substituting demand,

$$\Theta p_{nt} = \Theta c_{nt} + d + A p_{nt} + \xi_{nt}, \qquad \text{so} \qquad p_{nt} = (\Theta - A)^{-1}\big(d + \Theta c_{nt} + \xi_{nt}\big).$$

This is the price system in the appendix of Bresnahan (1997). Let the national demand and cost components have covariance matrices Σ_χ and Σ_c, and write $M = (\Theta - A)^{-1}$. Equation j is estimated by IV with the vector of other-city prices $p_{n't}$ as instruments. Its coefficient vector, the transpose of row j of A, converges to $A_{j\cdot}^\top + [\mathbb{E}(\tilde{p}_{n't}\tilde{p}_{nt}^\top)]^{-1}\mathbb{E}(\tilde{p}_{n't}\xi_{jnt})$. The two moments are

$$\mathbb{E}(\tilde{p}_{n't}\tilde{p}_{nt}^\top) = M\big(\Theta\Sigma_c\Theta + \Sigma_\chi\big)M^\top, \qquad \mathbb{E}(\tilde{p}_{n't}\xi_{jnt}) = M\Sigma_\chi \mathbf{e}_j,$$

where $\mathbf{e}_j$ is the jth unit vector. The bias of equation j is therefore $(\Theta - A)^\top(\Theta\Sigma_c\Theta + \Sigma_\chi)^{-1}\Sigma_\chi\mathbf{e}_j$. Stacking the equations and using the symmetry of the covariance matrices gives the following result.

Proposition 5.55 (Bias of other-city price instruments)**.** *In the linear model above, IV estimation with other-city prices satisfies*

$$\operatorname{plim} \hat{A} = (I - \Lambda)A + \Lambda\Theta, \qquad \Lambda = \Sigma_\chi\big(\Theta\Sigma_c\Theta + \Sigma_\chi\big)^{-1}. \tag{5.132}$$

The estimate is a matrix-weighted average of the demand slopes A and the supply slopes Θ. With $\Sigma_\chi = 0$ it is consistent, and with $\Sigma_c = 0$ it recovers Θ, which has own slopes $-a_{jj}$ and zero cross slopes.

When the national demand and cost shocks are uncorrelated across products, $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_J)$ with $\lambda_j = \frac{\sigma_{\chi j}^2}{a_{jj}^2\sigma_{cj}^2 + \sigma_{\chi j}^2}$. Then $\operatorname{plim}\hat{a}_{jj} = (1 - 2\lambda_j)a_{jj}$ and $\operatorname{plim}\hat{a}_{jk} = (1 - \lambda_j)a_{jk}$. Own slopes are biased toward zero as in the one-product case, and cross slopes are attenuated toward zero. Correlated national shocks change the cross terms. The bias of a_{12} is

$-\Lambda_{11}a_{12} - 2\Lambda_{12}a_{22}$, and the second term is positive when $\Lambda_{12} > 0$. Cross slopes can then be inflated. `bresnahan_bias_check.py` confirms (5.132) by simulation. For example, with $A = \left[\begin{smallmatrix} -2 & 0.5 \\ 0.5 & -1.5 \end{smallmatrix}\right]$, $\Sigma_c = 0.3I$ and $\Sigma_\chi = 0.4I$, the probability limit is $\left[\begin{smallmatrix} -1.00 & 0.375 \\ 0.314 & -0.384 \end{smallmatrix}\right]$. If the national shocks have correlation 0.8 across the two products, it becomes $\left[\begin{smallmatrix} -1.31 & 1.11 \\ 0.87 & -0.57 \end{smallmatrix}\right]$.

Bresnahan's printed result. Bresnahan states that the sign and magnitude of the bias are governed by $\Sigma_\chi[\mathrm{diag}(-\gamma) - \gamma]^{-1}$, in his notation $\gamma_{jk} = a_{jk}$. This matrix is the covariance between other-city prices and demand errors, $M\Sigma_\chi$ up to transposition. For two products whose national shocks have correlation ϱ, his appendix (pp. 246–247) reports the elements

$$\frac{\sigma}{4\gamma_{11}\gamma_{22} - \gamma_{12}\gamma_{21}} \begin{bmatrix} -2\gamma_{22} + \varrho\gamma_{21} & \gamma_{12} - 2\varrho\gamma_{11} \\ -2\varrho\gamma_{22} + \gamma_{21} & \varrho\gamma_{12} - 2\gamma_{11} \end{bmatrix}.$$

He concludes that the on-diagonal bias has the sign of $-2\gamma_{22} + \varrho\gamma_{12}$ and the off-diagonal bias the sign of $\gamma_{12} - 2\varrho\gamma_{11}$. At $\varrho = 0$ these are positive: own coefficients are biased toward zero and cross coefficients away from zero. The printed algebra has typographical slips. The intermediate inverse has the wrong signs off the diagonal, although the final matrix is correct, and the text writes $\varrho\gamma_{12}$ where the matrix has $\varrho\gamma_{21}$, which coincide under symmetry. The reading of covariance signs as bias signs is exact with one price. With several endogenous prices the bias also involves the inverse of the first-stage covariance matrix, as (5.132) shows. With $\varrho = 0$ the cross coefficients are attenuated, while sufficiently correlated national shocks inflate them. Bresnahan's footnote 9 already hedges the cross-price claim, saying that it "depends on the covariances of the shocks to demand across products." Correlated national shocks can also bias an own slope away from zero. The bias of a_{jj} is the diagonal element $2\Lambda_{jj}|a_{jj}| - \sum_{k\neq j}\Lambda_{jk}a_{kj}$ of $\Lambda(\Theta - A)$, and the second term can dominate. With the matrix A above, $\Sigma_c = \mathrm{diag}(5, 0.01)$ and $\Sigma_\chi = 0.4\left[\begin{smallmatrix} 1 & 0.95 \\ 0.95 & 1 \end{smallmatrix}\right]$ give plim $\hat{a}_{11} = -2.44$, farther from zero than the true -2. The own-price bias toward zero holds when $2\Lambda_{jj}|a_{jj}| > \sum_{k\neq j}\Lambda_{jk}a_{kj}$, for example when national demand and cost shocks are uncorrelated across products.

What the critique implies. National demand shocks typically make estimated own elasticities too small in magnitude. Markups recovered from (5.116) are then too high, simulated merger price increases too large, and the value of new goods too large. Bresnahan's own concern was the last of these. Hausman (1997, fn. 25) anticipates the objection by citing the beer estimates of HLZ, whose own-price elasticities lie "in the range of about -4.0 to -6.2". He concludes that the method does not mechanically produce small elasticities. The reply is incomplete. A bias toward zero is compatible with large estimates if the true elasticities are larger still. The assumption can be probed in the data. Overidentification tests across cities are one check. A more direct symptom of national shocks is correlation between the demand residuals of the same brand in different cities in the same week. Instruments based on observed local cost variation offer a comparison, as in Nevo (2001). Bresnahan himself points to other approaches to estimating substitution, including the then recent method of Berry (1994) (fn. 10). The critique applies to every use of Hausman instruments, including random-coefficient models (Chapter 8).

5.8.6 Results

Top and middle levels. The overall price elasticity of beer is -1.36, with standard error 0.21 (p. 164). Table 5.11 reproduces the segment equations. Each column is a segment demand equation, and because the equations are log-log, the coefficients are conditional elasticities.

Expenditure elasticities are close to one. The own price elasticities are about −2.7 for premium and popular-price beer and −2.4 for light beer. These are large for segment-level elasticities. They imply that a hypothetical attempt to raise all premium prices would not pay if light and popular prices stayed put (p. 166).

Table 5.11: Segment demand equations for beer

	Premium	Popular	Light
Constant	0.501	−4.021	−1.183
	(0.283)	(0.560)	(0.377)
ln beer expenditure	0.978	0.943	1.067
	(0.011)	(0.022)	(0.015)
$\ln P_{\text{premium}}$	−2.671	2.704	0.424
	(0.123)	(0.244)	(0.166)

	(0.016)	(0.034)	(0.023)
Observations		101	

Notes: Dependent variable is the log quantity of the segment, (5.126). Each column is one equation. Coefficients on log prices are elasticities conditional on beer expenditure. Standard errors in parentheses. Source: Hausman et al. (1994, Table 1).

The cross elasticities are large and positive. A 10 percent rise in the premium price index raises light-beer demand by about 4.2 percent, and the popular-price equation has a coefficient of 2.70 on the premium index. HLZ draw an antitrust conclusion. Claims that segments such as light and popular beer form separate markets are contradicted by the data, because enough marginal consumers switch segments in response to price (p. 166).

Bottom level. Table 5.12 reproduces the premium-segment share equations. The AIDS coefficients are not elasticities, so HLZ report the implied conditional own-price elasticities in the last row. Premium brands have conditional own elasticities between −3.5 and −5.0. The conditional cross elasticities of Budweiser lie between 0.4 and 1.0, and Coors has a conditional cross elasticity of 1.0 with respect to Labatts (p. 166). The coefficients on $\ln \frac{X}{P}$ are small. HLZ describe income effects at the bottom level as very small (p. 169).

Example 5.56 (Reading an AIDS table)**.** The AIDS formulas of Section 5.3 let us recover more from Table 5.12 than HLZ report. Ignoring the small expenditure terms, the conditional elasticities are $\varepsilon_{ij} \approx -\mathbf{1}(i=j) + \frac{\gamma_{ij}}{w_i}$. Inverting the own elasticity gives the within-segment share implied by the table, $w_i = \frac{\gamma_{ii}}{\varepsilon_{ii}+1}$. For Budweiser, $w_1 = \frac{-0.936}{-2.527} = 0.370$. The same calculation gives 0.199 for Molson, 0.179 for Labatts and 0.118 for Miller, which leaves 0.134 for Coors. The omitted Coors price can be recovered from homogeneity, $\gamma_{i5} = -\sum_{j\le 4}\gamma_{ij}$, which gives $(0.171, 0.119, 0.134, 0.069)$. Adding up then gives $\gamma_{55} = -0.493$. The implied Coors own elasticity is $-1 + \frac{-0.493}{0.134} = -4.68$, close to the reported −4.641. The cross elasticities of Coors

Table 5.12: Brand share equations, premium segment

	(0.113)	(0.152)	(0.245)	(0.147)	(0.203)

Notes: Each column is the share equation (5.125) of one brand. Symmetry is imposed in estimation. The Coors equation and the coefficients on the Coors price are not reported. The residual covariance matrix reported by HLZ is omitted. Standard errors in parentheses. The coefficient linking the Budweiser and Molson prices is reported with standard error 0.231 in both places. HLZ do not report the number of observations for the brand equations. Source: Hausman et al. (1994, Table 2).

with respect to Budweiser, Molson, Labatts and Miller are $\frac{\gamma_{5j}}{w_5}$ = 1.28, 0.89, 1.00 and 0.52. HLZ report 1.25, 0.86, 1.0 and 0.52 in the text (pp. 166 and 168). The Budweiser row gives cross elasticities from 0.40 to 1.00, matching the range HLZ quote. These are our calculations (`hlz_table2_check.py`). They suggest that homogeneity was imposed with the Coors price as the omitted one, and they show how much an AIDS table reveals once the shares are known.

Table 5.13 collects the conditional own elasticities of all fifteen brands from HLZ's Tables 2 to 4 and the unconditional (overall) own elasticities of their Table 5. HLZ find somewhat higher own elasticities for popular-price brands than for premium or light brands, which they read as lower brand loyalty (pp. 167 and 169). Every unconditional elasticity exceeds the conditional one in magnitude, as (5.128) predicts when segment demand is elastic. The overall elasticities range from −3.76 for Genesee Light to −6.21 for Milwaukee's Best and are precisely estimated despite the three levels. Budweiser and Miller have similar elasticities, while Coors is more elastic, which HLZ attribute to its weaker perceived brand loyalty. Coors Light and Miller Lite have about the same elasticity (p. 169).

Table 5.13: Conditional and overall own-price elasticities of fifteen beer brands

Segment	Brand	Conditional (Tables 2–4)	Overall (Table 5)
Premium	Budweiser	−3.527 (0.113)	−4.196 (0.127)
	Molson	−5.049 (0.152)	−5.390 (0.154)
	Labatts	−4.277 (0.245)	−4.592 (0.247)
	Miller	−4.201 (0.147)	−4.446 (0.149)
	Coors	−4.641 (0.203)	−4.897 (0.205)
Popular price	Old Milwaukee	−4.789 (0.109)	−5.277 (0.118)
	Genesee	−3.832 (0.120)	−4.236 (0.129)
	Milwaukee's Best	−5.813 (0.164)	−6.205 (0.170)
	Busch	−5.704 (0.329)	−6.051 (0.332)
	Piels Lager	−3.956 (0.465)	−4.117 (0.469)
Light	Genesee Light	−3.225 (0.062)	−3.763 (0.072)
	Coors Light	−4.180 (0.109)	−4.598 (0.115)
	Old Milwaukee Light	−5.923 (0.140)	−6.097 (0.140)
	Lite	−4.783 (0.138)	−5.039 (0.141)
	Molson Light	−5.682 (0.147)	−5.841 (0.148)

Notes: Conditional elasticities hold segment expenditure fixed. Overall elasticities combine the three levels of the demand system. Standard errors in parentheses. Source: Hausman et al. (1994, Tables 2, 3, 4 and 5).

Table 5.14 reproduces the full matrix of overall elasticities within the light segment. We read rows as the brand whose quantity responds and columns as the brand whose price changes, the usual convention, which HLZ do not state. The cross elasticities are large, from 0.20 to 1.23. HLZ single out the value of 0.74 between Coors Light and Miller Lite as evidence of close competition (p. 169).

Brand switching versus stockpiling. Because most price variation comes from weekly promotions, a skeptic may ask whether the estimates measure brand switching or households stocking up when prices are low. HLZ argue that pure inventory behavior would produce large own elasticities with cross elasticities near zero. The estimated cross effects are instead large relative

Table 5.14: Overall own and cross elasticities in the light segment

	Genesee Light	Coors Light	Old Milwaukee Light	Lite	Molson Light
Genesee Light	−3.763	0.464	0.397	0.254	0.201
	(0.072)	(0.060)	(0.039)	(0.043)	(0.037)
Coors Light	0.569	−4.598	0.407	0.452	0.482
	(0.085)	(0.115)	(0.058)	(0.075)	(0.061)
Old Milwaukee Light	1.233	0.956	−6.097	0.841	0.565
	(0.121)	(0.132)	(0.140)	(0.112)	(0.087)
Lite	0.509	0.737	0.587	−5.039	0.577
	(0.095)	(0.122)	(0.079)	(0.141)	(0.083)
Molson Light	0.683	1.213	0.611	0.893	−5.841
	(0.124)	(0.149)	(0.093)	(0.125)	(0.148)

Notes: Overall (unconditional) elasticities. Standard errors in parentheses. Source: Hausman et al. (1994, Table 5, lower panel).

to the own effects (p. 168). Their two graphs of Budweiser and Genesee sales in Buffalo show sharp negative co-movement that tracks the relative price, which they read as switching. The argument does not settle the question. Households that stock up on a promoted brand also buy less of the other brands in the following weeks. Stockpiling combined with switching among promoted brands therefore also generates large short-run cross responses. Short-run elasticities estimated from promotions can then exceed the long-run elasticities that matter for a permanent price change after a merger.

Testing the segments. The separability restriction implies that individual brand prices from another segment should not enter a segment's demand once the segment indices are included. HLZ re-estimate the premium equation of (5.126) with the five individual light-beer prices added. None of the prices of Genesee Light, Coors Light, Old Milwaukee Light and Molson Light is significant, and the Miller Lite price is marginally significant. The premium segment's elasticities do not change. HLZ conclude "tentatively" that the segment structure is adequate (p. 172). They also note that adding brands to a segment moves the model toward an unrestricted system. The order of such tests must therefore rely on prior knowledge of which brands are close (fn. 5).

5.8.7 From elasticities to competitive analysis

HLZ emphasize that their estimates are "primitive" in one sense. They do not assume a form of competition, a technology or a pattern of interaction over time (p. 172). Different models of competition can therefore be simulated or tested with the same demand estimates. They give two applications.

Merger price effects. Before the merger, firm 1 sells one product and sets its price by the inverse-elasticity rule $\frac{p_1 - mc_1}{p_1} = -\frac{1}{\varepsilon_{11}}$ (HLZ eq. 6). After the merger, the combined firm sets the prices of its products $1, \dots, m$ by the multiproduct conditions (5.116) (HLZ eqs. 7 to 9). Recall that $\ell_j = \frac{p_j - mc_j}{p_j}$ is the Lerner index of product j, and let ℓ_j^{post} be its post-merger value, obtained from (5.117) with the merged ownership. HLZ derive the price ratio in two steps. The definition of the Lerner index gives $p_j^{\text{post}}\left(1 - \ell_j^{\text{post}}\right) = mc_j^{\text{post}}$ after the merger, and we can

always write $p_j = mc_j \frac{p_j}{mc_j}$ before it. Dividing,

$$\frac{p_j^{\text{post}}}{p_j} = \frac{mc_j^{\text{post}}}{mc_j} \cdot \frac{mc_j}{p_j} \cdot \frac{1}{1 - \ell_j^{\text{post}}} \tag{5.133}$$

(HLZ eq. 11). The first factor carries merger-induced cost savings one for one into prices. The last factor carries the loss of competitive constraint, since $1 - \ell_j^{\text{post}}$ falls as post-merger market power rises. Pre-merger single-product pricing gives $\frac{mc_j}{p_j} = \frac{1+\varepsilon_{jj}}{\varepsilon_{jj}}$, so the percentage change is

$$\frac{p_j^{\text{post}} - p_j}{p_j} = \frac{mc_j^{\text{post}}}{mc_j} \cdot \frac{1 + \varepsilon_{jj}}{\varepsilon_{jj}} \cdot \frac{1}{1 - \ell_j^{\text{post}}} - 1 \tag{5.134}$$

(HLZ eq. 12). HLZ compute ℓ^{post} from the pre-merger elasticity matrix. The calculation therefore holds elasticities and the prices of non-merging firms at their pre-merger values. It is a linearized prediction. HLZ never solve for the post-merger equilibrium.

The same formula measures how much other brands constrain the merging brands. Suppose a hypothetical firm controlled a larger set of brands, and let ℓ_j^* be the Lerner index of product j computed with that larger block in (5.117). The implied price increase (HLZ eq. 13) is

$$\frac{1 + \varepsilon_{jj}}{\varepsilon_{jj}} \cdot \frac{1}{1 - \ell_j^*} - 1.$$

If the added brands have small cross elasticities with the merging brands, ℓ^* is close to ℓ^{post} and they impose little constraint. A large increase reveals a strong constraint. The exercise resembles the hypothetical monopolist test of market definition (Chapter 11).

HLZ apply the method to a hypothetical merger of Coors and Labatts, two premium brands. Table 5.15 reports the results. Without efficiencies, Coors would rise by 4.4 percent and Labatts by 3.3 percent. Coors is constrained mostly by Budweiser and Miller, and Labatts by Molson, another Canadian import. Cost savings of 5 percent would turn both predictions into price decreases. A firm controlling all premium brands would raise Coors and Labatts by 23.1 and 21.0 percent. Adding the popular-price brands to that firm raises the predicted increases to 108.3 and 104.8 percent. Adding the light brands instead gives 29.8 and 27.6 percent. Popular-price beer therefore constrains premium prices more than light beer does (p. 177). A hypothetical cross-segment merger of Labatts and Genesee would raise their prices by 2.2 and 1.0 percent (fn. 13), only slightly less for Labatts than the within-segment merger with Coors.

HLZ claim that their analysis does not require Nash-Bertrand behavior. They add that, to the extent pricing constraints relax after a merger, it "provides a lower bound on expected price changes" (p. 174). The claim needs qualification. Bresnahan objected to the analogous claim in Hausman (1997), where holding rivals' prices fixed after a new product's entry is not an equilibrium calculation (Bresnahan, 1997, pp. 244–245). Entry typically lowers rivals' prices, so holding them fixed overstates the price increases of the entrant's other brands. In a merger the direction differs. When prices are strategic complements, rivals raise their prices in response to the merging firms' increases, and holding them fixed understates the equilibrium effect. Holding the elasticities fixed is a separate approximation whose error can go either way. Example 5.57 shows both errors.

Table 5.15: Predicted price increases from hypothetical beer mergers (percent)

A. Coors and Labatts merge, by assumed efficiency gain	0%	5%	10%
Coors	4.4 (1.2)	−0.8 (1.2)	−6.1 (1.1)
Labatts	3.3 (1.0)	−1.9 (1.0)	−7.0 (0.9)

B. Brands controlled by the hypothetical firm (no efficiencies)	Coors	Labatts
Coors and Labatts	4.4	3.3
All premium brands	23.1	21.0
All premium and popular-price brands	108.3	104.8
All premium and light brands	29.8	27.6

C. Labatts and Genesee merge (no efficiencies)	Labatts	Genesee
Price increase	2.2 (0.3)	1.0 (0.3)

Notes: Computed by HLZ from (5.117) and (5.134) with pre-merger elasticities, holding the prices of other firms fixed. Standard errors in parentheses where reported. Sources: Hausman et al. (1994, table on p. 176, text on p. 177 and fn. 13).

Testing conduct with multiproduct firms. The second application tests models of pricing. A test of Nash-Bertrand pricing that uses only a brand's own elasticity ignores that a price rise sends some customers to the firm's other brands. It therefore understates the predicted markup (p. 178). With M firms producing $K_1, \dots, K_M$ products, the elasticity matrix is block diagonal by firm (HLZ eq. 14). The predicted Lerner indices are $\ell = -\operatorname{diag}(s)^{-1}(E^{\top})^{-1}s$, with s the vector of shares (HLZ eq. 15). This is (5.117) applied to every firm at once. For Miller Lite, the largest low-calorie beer, the single-product rule gives a markup of 19.9 percent. With Miller's other brands taken into account, the Nash-Bertrand markup is 23.2 percent, about 17 percent higher. (The text bases the 19.9 percent on an own elasticity of −5.13, while Table 5 reports −5.039 for Lite. The inverse of 5.13 is 19.5 percent. The inverse of 5.039 is 19.85 percent, which matches the 19.9 percent in the text. The elasticity of −5.13 therefore appears to be a misprint for the Table 5 value.) HLZ note that beer firms typically sell only one beer per segment, so the multi-brand effect should be larger in cereal or cigarettes (p. 179). Earlier tests that found prices inconsistent with Nash behavior may have failed because they ignored multiproduct ownership. With data on marginal cost, the predicted markups could be compared with observed ones.

Example 5.57 (A computed merger simulation)**.** This hypothetical example uses the running AIDS as a segment of three brands, each sold by a single-product firm with constant marginal cost. Marginal costs come from (5.115) at the observed prices $p = (1, 1, 1)$. Firms 1 and 2 merge, and we solve the post-merger Nash equilibrium exactly, with optional cost savings of 5 or 10 percent on the merging brands. We consider two treatments of segment expenditure. In treatment A it is fixed at $X_G = e$. In treatment B it follows a constant-elasticity upper level, $\ln X_G = 1 + (1 + \varphi_2) \ln \mathbf{P}(p)$, with $\varphi_2 = -1.36$, the beer elasticity of HLZ. The pre-merger own elasticities are $(-1.375, -1.682, -1.738)$ in A and $(-1.510, -1.803, -1.827)$ in B. Lerner indices are therefore between 0.55 and 0.73, much higher than in beer. Table 5.16 also reports the linearized prediction of (5.134).

Four lessons emerge. First, the segment's expenditure response dominates the answer.

With fixed expenditure the segment is unit elastic, and merging two brands with 74 percent of segment revenue doubles their prices. With an elastic upper level the increases are 19 and 37 percent. Second, the linearization errs in both directions. It overstates both increases in A, while in B it understates the increase for brand 1 and overstates it for brand 2. Third, the non-merging firm raises its price, by 12.9 percent in A, because prices are strategic complements here. Fourth, cost savings of 5 and 10 percent shrink the price increases without reversing them, because pass-through is incomplete and markups are high. In treatment A the merger costs consumers 67.2 percent of segment expenditure without efficiencies. In treatment B a rise in p_1 lowers the quantity of brand 3 (its unconditional cross elasticity is -0.029), because the drain on segment expenditure outweighs within-segment substitution. The equilibria are unique from four starting values, and the second-order conditions hold (`aids_merger_sim.py`). Functional form also matters. Crooke et al. (1999) show that AIDS tends to predict larger merger price effects than logit or linear demand calibrated to the same elasticities, because of its curvature.

Table 5.16: Simulated merger of firms 1 and 2 in the running example (percent price changes)

	Linearized	Equilibrium		
Efficiency gain	0%	0%	5%	10%
A. Segment expenditure fixed				
Good 1 (merging)	122.0	104.0	95.0	85.9
Good 2 (merging)	131.0	94.3	86.6	78.7
Good 3 (rival)	held fixed	12.9	12.1	11.3
CV (percent of X_G)		67.2	62.3	57.1
B. Upper level with $\varphi_2 = -1.36$				
Good 1 (merging)	11.9	18.6	11.9	5.2
Good 2 (merging)	43.0	36.7	30.4	24.1
Good 3 (rival)	held fixed	2.9	2.4	1.8

Notes: Hypothetical illustration with the running AIDS parameters, observed prices $(1, 1, 1)$ and $\ln X_G = 1$ before the merger. Marginal costs are recovered from single-product first-order conditions. The linearized column applies (5.134) with post-merger Lerner indices computed from pre-merger elasticities and the rival's price held fixed. Efficiency gains reduce the marginal costs of goods 1 and 2. Computed with `figures/ch05/src/aids_merger_sim.py`.

5.8.8 Limitations and contribution

Several limitations qualify the beer results. The segments come from marketing practice, and only one specification test checks them. Separability then removes all brand-pair specific substitution across segments, which matters for cross-segment mergers such as Labatts and Genesee. The Hausman instruments rest on the absence of national brand-specific demand shocks, a strong assumption in an industry with heavy national advertising. The demand model is static, while the price variation comes from temporary promotions that invite stockpiling. The model has a representative consumer, so it is silent on who gains and who loses. The merger predictions hold elasticities and rival prices fixed and assume Nash-Bertrand pricing

with constant marginal cost. The paper reports little about its data, which makes replication and assessment difficult.

The contribution is lasting nonetheless. HLZ showed that flexible product-space demand can be estimated for a realistic number of brands by combining multi-stage budgeting with scanner panels. They introduced the use of prices in other markets as instruments, which Nevo (2001) and much later work adopted. They made merger simulation from estimated demand a practical alternative to inference from concentration indices, and they showed that multiproduct ownership changes both merger predictions and tests of conduct. Hausman (1997) uses the same three-level framework to value a new cereal brand (Chapter 10). Hausman and Leonard (2002) apply it to the competitive effects of a new product introduction, and Ellison et al. (1997) estimate a multi-stage AIDS for four cephalosporin antibiotics. Section 5.9 applies the same machinery, with cost bounds and virtual prices, to patent policy. Chapter 11 develops merger simulation in full.

5.9 Case study: Chaudhuri, Goldberg and Jia (2006), patents and antibiotics in India

This section applies the whole toolkit of the chapter to one policy question. Chaudhuri et al. (2006) (CGJ henceforth) ask what would have happened to prices, profits and welfare in India had foreign patents on four antibiotic molecules been enforced there. The answer needs every piece developed so far. It needs a demand system consistent with utility maximization (Section 5.3) and multi-stage budgeting to keep the number of parameters manageable (Section 5.5). It needs instruments for prices (Section 5.6.8) and virtual prices for the products that disappear (Section 5.7.2). And it needs bounds on marginal cost from first-order conditions (Proposition 5.52). We follow the paper from its question to its welfare numbers, reproduce its key tables, and check several of its numbers against one another.[4] Throughout the section elasticities are signed, as in the paper, so own-price elasticities are negative.

5.9.1 The question and the policy debate

The TRIPS agreement, introduced in Section 5.1.1, was concluded in the Uruguay Round of trade negotiations and took effect in 1995. It requires every member of the World Trade Organization to recognize and enforce product patents in all fields of technology, pharmaceuticals included. Many low and middle-income countries had exempted pharmaceuticals from product patents, because they treated cheap access to essential medicines as a policy priority. Under TRIPS these countries had to amend their patent laws, and transition and least-developed economies had until 2005 to do so.

India is the leading example. Its Patents Act of 1970, effective from April 1972, excluded product patents for pharmaceuticals. It admitted only *process patents*, which protect a method of making a drug and leave the drug itself unprotected. A domestic firm could therefore sell a molecule patented abroad, as long as it made the molecule by a different process. India recognized pharmaceutical product patents only with the third amendment of the Patents Act, passed by parliament in March 2005. Some Indian firms already produced drugs whose patent

[4] As throughout the chapter, table, equation, page and footnote numbers refer to the working-paper version of Chaudhuri et al. (2006) (NBER Working Paper 10159, revised July 2006). Where we cite the published article instead, the text says so. The working paper labels the elasticity tables 6(a) and 6(b), which we call Tables 6A and 6B. Tables 2, 6A and 8 coincide with the published tables.

applications were filed between 1995 and January 1, 2005. Under the amendment they may continue to produce them if they pay a royalty to the patent holder (CGJ, fn. 6).

The debate over pharmaceutical patents in poor countries has two sides. Governments of many developing economies argued that product patents would raise the prices of medicines substantially, with adverse consequences for health. Research-based multinational firms answered that prices would hardly rise, because most patented drugs have many therapeutic substitutes. They added that the absence of patents discourages research on diseases that mainly afflict poor countries. In the language of Section 5.1.1, the first argument is about the static costs of patents, namely higher prices and fewer products. The second combines a claim about demand (close substitutes exist) with a claim about dynamic incentives. Poor-country markets are small, so their contribution to global research incentives may be modest.

CGJ turn the substitutes claim into questions that demand estimation can answer. Suppose the domestic versions of a patented molecule disappear. Do consumers switch to the foreign version of the same molecule, to domestic versions of other molecules, or out of the therapeutic segment altogether? How much do the remaining firms raise their prices? How large are the losses of consumers and domestic firms, and how large are the gains of the foreign patent holders? The last number speaks indirectly to the dynamic argument. If foreign profits in India rise only a little, patents in India are unlikely to redirect research toward the diseases of poor countries.

The paper studies the *fluoroquinolones*, the latest generation of quinolone antibiotics, called quinolones from here on. Three features make the segment suitable. Quinolones are the drug of choice for many bacterial infections that older antibiotics also treat (CGJ's Table A1 lists the spectrum of activity of each family of drugs). If any patented product has close therapeutic substitutes, a quinolone should. Quinolones are also a large segment, with about 20 percent of the sales of systemic antibacterials, and several quinolone molecules were still under patent in the United States during the sample. Finally, antibiotics matter for public health in a way that lifestyle drugs do not.

5.9.2 The setting

The Indian pharmaceutical market differs from those of rich countries in ways that shape demand. Health insurance is almost absent, so households pay for medicines out of pocket. Anti-infectives are the second-largest therapeutic segment in India, with 23 percent of pharmaceutical sales, while worldwide they rank fifth with 9.0 percent. Within anti-infectives, the systemic antibiotics and antibacterials segment earns more than three-quarters of revenue (CGJ, pp. 7–8).

The 1970 Act aimed to build a domestic industry and to give consumers cheap medicines. It came with price controls, limits on capacity expansion and caps on multinational equity shares. Many of these restrictions were eased from the mid-1980s, and liberalization accelerated in the 1990s. Prices of many drugs remained subject to the Drug Price Control Order of 1995 during the sample period. The industry grew into the world's largest producer of formulations by volume, and by 2002 it was the largest producer of generic drugs by volume. Multinational subsidiaries dominated the industry in 1970, whereas by 2001 Indian-owned firms led it and many exported.

Two institutional facts matter for the results. First, foreign subsidiaries also sell molecules patented abroad by other multinationals. CGJ put the word "infringe" in quotation marks for this practice, because Indian law offered no product patent to infringe (fn. 10). Second, drugs reach patients through a layered distribution chain. Firms sell to carrying-and-forwarding agents, often organized by region, who supply stockists (wholesalers). Stockists supply retail

pharmacists, of whom there are about 300,000 in India, and each stockist deals with about 75 retailers on average (fn. 35). Firms also employ medical representatives who promote their products to the doctors who write prescriptions.

5.9.3 Data

The data come from the retail pharmaceutical audit of ORG-MARG, India's main market research firm. The audit covers all products sold by about 300 of the largest firms, which account for roughly 90 percent of retail pharmaceutical sales. It reaches a representative panel of thousands of retail chemists in more than 350 cities and towns. For each product it reports monthly retail sales in each of four zones (North, East, West and South), price, dosage form, launch date, brand, molecule and therapeutic class. The sample runs monthly from January 1999 to December 2000.

The unit of sale is the *stock-keeping unit* (SKU), a presentation of a product. A presentation combines a dosage form (capsule, tablet, syrup), a strength (100 or 500 milligrams) and a pack size. A 100-capsule bottle and a 50-capsule bottle of the same branded drug are two SKUs. CGJ aggregate SKUs into seven *product groups*, defined by molecule and by the domestic or foreign status of the producer. The four molecules are ciprofloxacin, norfloxacin, ofloxacin and sparfloxacin. Sparfloxacin is sold by one foreign subsidiary with a minuscule share, so it is treated as domestic only (fn. 24). The seven groups are foreign and domestic ciprofloxacin, norfloxacin and ofloxacin, and domestic sparfloxacin. Each group has $24 \times 4 = 96$ month-region observations. Foreign norfloxacin is missing in four month-region cells, where its share is set to zero (fn. 16).

The dependent variable is a revenue share. CGJ choose shares because physical quantities are hard to compare across molecules. A systemic antibiotic treats many infections, and the dose depends on the infection, so milligrams of active ingredient do not measure quantity consistently. This is one reason for adopting the multi-stage AIDS framework, which models revenue shares directly.

Table 5.17 shows the structure of the quinolone segment. Domestic ciprofloxacin alone has 53 percent of quinolone sales. The four studied molecules account for 92.6 percent of quinolone sales, with domestic firms selling 86.6 percent and foreign subsidiaries 6.0 percent. CGJ do not report total quinolone sales. The molecules listed in their Table 1 sold Rs. 5.53 billion in 2000, which is 96.8 percent of quinolone sales. The segment total was therefore near Rs. 5.7 billion (our computation). We use this figure below to gauge the size of the welfare estimates.

Table 5.17: The quinolone sub-segment in India, 2000

	Share of quinolone sales (%)		Sales, 2000 (Rs. million)	
Molecule	Domestic firms	Foreign subsidiaries	Domestic firms	Foreign subsidiaries
Ciprofloxacin	53.0	2.7	3,030	156
Norfloxacin	11.2	0.1	640	3
Ofloxacin	11.6	3.1	665	177
Sparfloxacin	10.8	0.1	620	4

Notes: Reproduced from CGJ, Table 1. The table also lists four excluded molecules with small shares: lomefloxacin (1.5 percent, domestic), pefloxacin (1.3 percent domestic, 0.1 percent foreign), levofloxacin (0.0) and nalidixic acid (1.3, domestic).

Table 5.18 reproduces CGJ's Table 2. Three facts stand out. First, many firms sell each molecule: 75 domestic firms and 8 foreign subsidiaries sell ciprofloxacin. Second, Indian

firms launched the molecules within zero to two years of approval by the U.S. Food and Drug Administration (FDA). Third, domestic products often sell at a *premium* over foreign products with the same molecule. Ofloxacin is the exception. Domestic ciprofloxacin is about 10 percent dearer than foreign ciprofloxacin and still holds 53 percent of quinolone sales (CGJ, p. 9). This first look suggests that Indian consumers do not pay extra for the brand reputation of multinationals.

Table 5.18: Basic information about the four quinolone molecules, 2000

	Ciprofloxacin	Norfloxacin	Ofloxacin	Sparfloxacin
U.S. or European patent holder	Bayer	Merck	Ortho-McNeil	Rhone-Poulenc
Year of U.S. patent expiry	2003	1998	2003	2010
Year of U.S. FDA approval	1987	1986	1990	1996
Year first introduced in India	1989	1988	1990	1996
Number of domestic Indian firms	75	40	17	25
Number of foreign subsidiaries	8	2	2	1
Sales-weighted average price per unit of active ingredient (Rs.), products of:				
Domestic Indian firms	11.24	9.05	90.08	78.84
Foreign subsidiaries	10.35	5.28	108.47	n.a.

Notes: Reproduced from CGJ, Table 2 (identical to the published table). The active ingredient is the molecule.

Table 5.19 reports regional averages. Households in the North and West spend more on quinolones and on antibiotics. These regions include richer, more urban states. Domestic groups offer far more SKUs than foreign groups, and the number of SKUs changes over time as presentations enter and leave. SKU prices are fixed by regulation most of the time. They change only occasionally, for example when exchange rates move the cost of imported ingredients. Group prices nevertheless vary over time, because the SKU mix of each group changes.

How much of the price variation is over time, and how much across regions? CGJ answer with an analysis of variance, run separately for each group, that regresses prices on region and time dummies. Table 5.20 reports the shares of the total sum of squares explained by each set of dummies. The demand equations include a full set of group-by-region effects. The price coefficients are therefore identified only from variation over time within a group and region. The table shows that this variation is large for most groups. Domestic ciprofloxacin is the exception: only 5.0 percent of its price variation is over time, and 84.1 percent is regional.

The time variation in group prices comes mostly from changes in composition. SKU revenue shares shift from month to month, and SKUs enter and leave the sample. Could the exits be an artifact of sampling? CGJ compare the revenue shares of exiting SKUs with those of other SKUs (Table 5). Exiting SKUs average a revenue share of 1.0 percent, against 3.4 percent for the comparison group.[5] Exiting SKUs are smaller, but not by orders of magnitude, so exit appears to be real. The audit also excludes the smallest firms, which limits sampling noise of this kind.

5.9.4 The demand model

CGJ use two-stage budgeting with an AIDS at both levels. At the upper level, the representative consumer allocates total spending on systemic antibacterials X across sub-segments, such

[5]The heading of CGJ's Table 5 calls the comparison group "all SKUs", and the text (p. 10) describes it as the SKUs present throughout the sample. The regional figures are 0.8 against 3.3 (North), 1.2 against 3.6 (East), 1.0 against 3.4 (West) and 1.2 against 3.3 (South).

Table 5.19: Summary statistics by region, 1999–2000 (means)

	North	East	West	South
Annual quinolone expenditure per household (Rs.)	31.25	19.75	27.64	23.59
Annual antibiotic expenditure per household (Rs.)	119.88	84.24	110.52	96.24
Number of SKUs				
Foreign ciprofloxacin	12.38	11.29	13.08	12.46
Foreign norfloxacin	1.83	1.71	2.00	1.58
Foreign ofloxacin	3.04	2.96	2.96	3.00
Domestic ciprofloxacin	106.21	97.63	103.42	105.50
Domestic norfloxacin	38.96	34.96	36.17	39.42
Domestic ofloxacin	18.46	16.00	17.25	17.25
Domestic sparfloxacin	29.83	28.29	31.21	29.29
Price per unit of active ingredient (Rs.)				
Foreign ciprofloxacin	9.58	10.90	10.85	10.07
Foreign norfloxacin	5.63	5.09	6.05	4.35
Foreign ofloxacin	109.46	109.43	108.86	106.12
Domestic ciprofloxacin	11.43	10.67	11.31	11.52
Domestic norfloxacin	9.51	9.07	8.88	8.73
Domestic ofloxacin	91.63	89.64	85.65	93.41
Domestic sparfloxacin	79.72	78.49	76.88	80.28
Annual sales (Rs. million)				
Foreign ciprofloxacin	41.79	24.31	45.20	29.47
Foreign norfloxacin	1.28	1.00	0.58	0.73
Foreign ofloxacin	54.46	31.84	35.22	31.11
Domestic ciprofloxacin	962.29	585.91	678.74	703.81
Domestic norfloxacin	222.55	119.71	149.18	158.29
Domestic ofloxacin	125.02	96.21	149.36	112.05
Domestic sparfloxacin	156.17	121.75	161.30	98.11

Notes: Reproduced from CGJ, Table 3, which also reports standard deviations. Two of them are informative here. The price of domestic ciprofloxacin has a standard deviation of only 0.13 to 0.17 rupees across months, while the price of domestic ofloxacin has a standard deviation of 14 to 16 rupees.

Table 5.20: Analysis of product-group price variance

Product group	Explained by time (%)	Explained by region (%)
Foreign ciprofloxacin	28.3	29.2
Foreign norfloxacin	24.8	24.0
Foreign ofloxacin	75.2	3.6
Domestic ciprofloxacin	5.0	84.1
Domestic norfloxacin	29.6	49.4
Domestic ofloxacin	93.5	3.4
Domestic sparfloxacin	94.3	1.7

Notes: Reproduced from CGJ, Table 4 (last two columns). Separate regressions of the group price on time and region dummies for each group. Entries are partial sums of squares as percentages of the total sum of squares.

as tetracyclines, cephalosporins, macrolides and quinolones. At the lower level, quinolone spending X_Q is allocated across the seven product groups. Figure 5.4 draws this tree. CGJ's Table A1 lists nine families of antibacterial drugs. Their Table A3 reports upper-level equations for eight sub-segments: tetracyclines, chloramphenicol, ampicillin, cephalosporins, trimethoprim, macrolides, other penicillins and quinolones. As discussed in Section 5.5, the upper level is an approximation to exact two-stage budgeting (Deaton and Muellbauer, 1980b, pp. 131–132).

From SKUs to product groups. Index an SKU k by its molecule M, its domestic or foreign status DF, its presentation s and its producer f. Product group i collects all SKUs with the same (M, DF). Group revenue and the group price are

$$R_i = \sum_{f,s} R_k, \qquad p_i = \sum_{f,s} \omega_k \, p_k, \qquad \omega_k = \frac{R_k}{R_i}, \tag{5.135}$$

where ω_k is the revenue share of SKU k within its group (CGJ, eq. 3.1). The weights are current revenue shares. They change from month to month as SKU sales shift and SKUs enter and exit (CGJ, pp. 10 and 19). The published article defines them the same way (Chaudhuri et al., 2006, eq. 1, p. 1487). Group prices therefore vary for two reasons, through SKU prices and through the weights (CGJ, p. 19). Aggregating firms into groups ignores competition among firms with the same molecule and status, which would normally overstate market power. CGJ argue that the aggregation fits the question. Patent enforcement removes all domestic versions of a molecule at once and leaves the foreign patent holder as a monopolist, so the competition that aggregation suppresses would vanish anyway.

Lower level. Let $i = 1, \ldots, J$ index the quinolone groups, with $J = 7$. The revenue share of group i in quinolone spending is

$$w_i = \alpha_i + \sum_{j=1}^{J} \gamma_{ij} \ln p_j + \beta_i \ln \frac{X_Q}{P_Q}, \qquad w_i = \frac{p_i q_i}{\sum_j p_j q_j} = \frac{p_i q_i}{X_Q}, \tag{5.136}$$

with the translog quinolone price index

$$\ln P_Q = \alpha_0 + \sum_i \alpha_i \ln p_i + \frac{1}{2} \sum_i \sum_j \gamma_{ij} \ln p_i \ln p_j. \tag{5.137}$$

This is the AIDS of (5.27) with quinolone spending in place of income (CGJ, eqs. 3.2–3.4). CGJ impose adding up ($\sum_i \alpha_i = 1$, $\sum_i \beta_i = 0$, $\sum_i \gamma_{ij} = 0$), homogeneity ($\sum_j \gamma_{ij} = 0$) and symmetry ($\gamma_{ij} = \gamma_{ji}$), as in Proposition 5.19. Symmetry alone leaves $\frac{J(J+1)}{2} = 28$ distinct price coefficients. Homogeneity removes seven more, leaving $\frac{J(J-1)}{2} = 21$.

Pair-type restrictions. CGJ judge that their limited number of observations cannot support the general form (p. 13). They therefore add restrictions based on what is observable about each pair of groups. For groups i and j define the pair type

$$d(i,j) = \begin{cases} (1,0) & \text{if } M_i = M_j \text{ and } DF_i \neq DF_j \quad \text{(same molecule, different status)}, \\ (0,1) & \text{if } M_i \neq M_j \text{ and } DF_i = DF_j \quad \text{(different molecule, same status)}, \\ (0,0) & \text{if } M_i \neq M_j \text{ and } DF_i \neq DF_j \quad \text{(different molecule and status)}, \end{cases} \tag{5.138}$$

and let $D_i^{ab} = \{j : d(i,j) = (a,b)\}$ be the set of groups of type (a,b) relative to i (CGJ, eqs. 3.5–3.6). The type $(1,1)$ is the group itself. Each equation gets one coefficient per pair type:

$$w_i = \alpha_i + \gamma_{ii} \ln p_i + \gamma_{i,10} \sum_{j \in D_i^{10}} \ln p_j + \gamma_{i,01} \sum_{j \in D_i^{01}} \ln p_j + \gamma_{i,00} \sum_{j \in D_i^{00}} \ln p_j + \beta_i \ln \frac{X_Q}{P_Q}. \tag{5.139}$$

Here $\gamma_{i,10}$ measures substitution with the other-status version of the same molecule (CGJ, eq. 3.7). The coefficient $\gamma_{i,01}$ measures substitution with other molecules of the same status, and $\gamma_{i,00}$ substitution with other molecules of the other status. Before the theory restrictions each equation has four price coefficients, except domestic sparfloxacin, which has three because it has no same-molecule partner. That makes 27 in total.

The estimating equation. CGJ make two changes before estimation. They let the intercepts vary by region, writing $\alpha_i + \alpha_{ir}$, and they add an error term. The equation estimated for group i in region r and month t is

$$\begin{aligned} w_{irt} = \alpha_i + \alpha_{ir} + \gamma_{ii} \ln p_{irt} + \gamma_{i,10} \sum_{j \in D_i^{10}} \ln p_{jrt} + \gamma_{i,01} \sum_{j \in D_i^{01}} \ln p_{jrt} \\ + \gamma_{i,00} \sum_{j \in D_i^{00}} \ln p_{jrt} + \beta_i \ln \frac{X_{Qrt}}{P_{Qrt}} + \xi_{irt} \end{aligned} \tag{5.140}$$

(CGJ, eq. 3.8, where the error is written ε_{irt}). The group-region effects α_{ir} have two interpretations. They control for the perceived quality of each drug, which may differ by region. They also absorb regional demographics and other demand shifters, which barely change over a two-year sample. The error ξ_{irt} contains demand shocks (an advertising campaign, a regional epidemic) and measurement error in the group prices, as Section 5.9.5 explains. An earlier version of the paper without regional effects gave similar results.

Upper level. Index sub-segments by G and H. The upper-level share equation is

$$w_{Grt} = \alpha_G + \alpha_{Gr} + \sum_H \gamma_{GH} \ln P_{Hrt} + \beta_G \ln \frac{X_{rt}}{P_{rt}} + \xi_{Grt}, \qquad \ln P_{rt} = \sum_H w_{Hrt} \ln P_{Hrt}. \tag{5.141}$$

Here w_{Grt} is the share of sub-segment G in total antibacterial spending X_{rt}, and P_{Hrt} is the price index of sub-segment H. The index P_{rt} is a Stone index (CGJ, eqs. 3.9 and 3.11). The upper level imposes adding up, homogeneity and symmetry and nothing else. Cross-segment substitution is left unconstrained.

Unconditional elasticities. The counterfactuals need elasticities that let quinolone spending respond. The general two-level formula is (5.79). In CGJ's notation (eq. 3.10) it reads

$$\varepsilon_{ij} = \varepsilon_{ij}\big|_{X_Q} + \frac{\partial \ln q_i}{\partial \ln X_Q} \frac{\partial \ln X_Q}{\partial \ln P_Q} \frac{\partial \ln P_Q}{\partial \ln p_j}. \tag{5.142}$$

Each factor has a closed form. The conditional elasticity is the AIDS elasticity of (5.38),

$$\varepsilon_{ij}\big|_{X_Q} = -\mathbf{1}(i=j) + \frac{\gamma_{ij} - \beta_i \left(w_j - \beta_j \ln \frac{X_Q}{P_Q} \right)}{w_i}. \tag{5.143}$$

CGJ's printed formula omits the term $-\mathbf{1}(i = j)$, but their own-price elasticities include it.[6] The other three factors are those derived in Section 5.5.4. The second factor is the expenditure elasticity within quinolones, $\eta_i^Q = 1 + \frac{\beta_i}{w_i}$. The last factor is $\frac{\partial \ln P_Q}{\partial \ln p_j} = w_j - \beta_j \ln \frac{X_Q}{P_Q}$, by Shephard's lemma applied to (5.137). The middle factor is (5.80). With total antibacterial spending X held fixed, $\frac{\partial \ln X_Q}{\partial \ln P_Q} = 1 + \varepsilon_Q$, where ε_Q is the price elasticity of the quinolone segment from the upper level. With a Stone index at the top, and treating its weights as fixed, $1 + \varepsilon_Q = \frac{\gamma_{QQ}}{w_Q} - \beta_Q$. Collecting terms gives (5.81) in CGJ's notation,

$$\varepsilon_{ij} = -\mathbf{1}(i = j) + \frac{\gamma_{ij} - \beta_i \left(w_j - \beta_j \ln \frac{X_Q}{P_Q} \right)}{w_i} + \left(1 + \frac{\beta_i}{w_i} \right) (1 + \varepsilon_Q) \left(w_j - \beta_j \ln \frac{X_Q}{P_Q} \right). \tag{5.144}$$

CGJ estimate $\varepsilon_Q = -1.11$ (standard error 0.24). A 1 percent rise in the quinolone price index therefore lowers quinolone spending by only 0.11 percent, and the unconditional correction in (5.144) is small. We return to this when we decompose the welfare loss.

What the restrictions leave. Symmetry interacts with the pair-type restrictions in a way that is easy to miss. Number the groups $1, \dots, 7$ in the order foreign ciprofloxacin, norfloxacin and ofloxacin, then domestic ciprofloxacin, norfloxacin, ofloxacin and sparfloxacin.

Proposition 5.58 (Pair types under symmetry)**.** *Suppose the lower-level coefficients satisfy* (5.139)*, symmetry and homogeneity. Then the price coefficients take only six free values. There is a same-molecule coefficient for each of ciprofloxacin, norfloxacin and ofloxacin, written γ_{10}^C, γ_{10}^N and γ_{10}^O. There is one coefficient γ_{01}^F for pairs of foreign groups and one coefficient γ_{01}^D for pairs of domestic groups. Finally, γ_{00} applies to all pairs that differ in both molecule and status. The matrix of price coefficients is*

$$\Gamma = \begin{array}{c|ccc|cccc} & \text{FC} & \text{FN} & \text{FO} & \text{DC} & \text{DN} & \text{DO} & \text{DS} \\ \hline \text{FC} & \gamma_{11} & \gamma_{01}^F & \gamma_{01}^F & \gamma_{10}^C & \gamma_{00} & \gamma_{00} & \gamma_{00} \\ \text{FN} & \gamma_{01}^F & \gamma_{22} & \gamma_{01}^F & \gamma_{00} & \gamma_{10}^N & \gamma_{00} & \gamma_{00} \\ \text{FO} & \gamma_{01}^F & \gamma_{01}^F & \gamma_{33} & \gamma_{00} & \gamma_{00} & \gamma_{10}^O & \gamma_{00} \\ \hline \text{DC} & \gamma_{10}^C & \gamma_{00} & \gamma_{00} & \gamma_{44} & \gamma_{01}^D & \gamma_{01}^D & \gamma_{01}^D \\ \text{DN} & \gamma_{00} & \gamma_{10}^N & \gamma_{00} & \gamma_{01}^D & \gamma_{55} & \gamma_{01}^D & \gamma_{01}^D \\ \text{DO} & \gamma_{00} & \gamma_{00} & \gamma_{10}^O & \gamma_{01}^D & \gamma_{01}^D & \gamma_{66} & \gamma_{01}^D \\ \text{DS} & \gamma_{00} & \gamma_{00} & \gamma_{00} & \gamma_{01}^D & \gamma_{01}^D & \gamma_{01}^D & \gamma_{77} \end{array} \tag{5.145}$$

where F and D denote foreign and domestic and C, N, O, S the molecules. Each own coefficient equals minus the sum of the other entries in its row.

Proof. Take a foreign group i and a domestic group j with different molecules. Then $\gamma_{ij} = \gamma_{i,00}$ and $\gamma_{ji} = \gamma_{j,00}$, so symmetry gives $\gamma_{i,00} = \gamma_{j,00}$. Every foreign group has a domestic partner with a different molecule, and every domestic group has a foreign one. Foreign ciprofloxacin pairs with domestic norfloxacin, ofloxacin and sparfloxacin. Domestic ciprofloxacin pairs with foreign norfloxacin and ofloxacin, and foreign norfloxacin pairs with domestic ofloxacin. These

[6] Without the term, domestic sparfloxacin would have a conditional own elasticity near -1.8 instead of the -2.9 reported in Table 6A. See Example 5.60.

links connect all seven groups, so all the $\gamma_{i,00}$ are equal to a common γ_{00}. The same argument within the three foreign groups gives a common γ_{01}^{F}, and within the four domestic groups a common γ_{01}^{D}. For same-molecule pairs, symmetry equates the coefficients of the two versions of each molecule, which gives γ_{10}^{C}, γ_{10}^{N} and γ_{10}^{O}. Domestic sparfloxacin has no same-molecule partner. This leaves thirteen distinct values: seven own coefficients and six cross coefficients. Homogeneity requires each row to sum to zero, which determines each own coefficient from the cross coefficients. For example, $\gamma_{77} = -3\gamma_{00} - 3\gamma_{01}^{D}$. Adding up across columns then holds automatically, because Γ is symmetric with zero row sums. □

The proposition has a substantive consequence. In this specification the own-price coefficients are not free parameters. A domestic group responds strongly to its own price exactly when it substitutes strongly with the other groups, through γ_{01}^{D} and γ_{00}. The pair-type structure also forces every pair of domestic molecules to share one coefficient, so domestic ciprofloxacin and sparfloxacin substitute with the same γ as domestic norfloxacin and ofloxacin. The elasticities still differ across pairs, because they divide by different shares. With six price parameters, six free expenditure coefficients and the group-region effects, the lower level is estimable from 24 months of data in four regions.

5.9.5 Identification and estimation

The usual worry in demand estimation is that firms set prices with knowledge of demand shocks, as in Section 5.6.8. CGJ argue that price regulation makes this channel less important here, since SKU prices are set by a regulator and change rarely. Their main concern is how group prices are built.

The group price as a proxy. The lower-level share equation holds for an exact price index p_j^T of each group, with demand shock ς_i (CGJ, p. 18). Even with fixed SKU prices, p_j^T changes over time because the set of SKUs changes. The exact index would require a model of choice among SKUs within a group, that is, a third budgeting stage. CGJ reject a third stage for three reasons. Some groups contain over a hundred SKUs, SKU prices barely move, and the SKU choice set changes over time. A discrete-choice model, which handles changing choice sets well, would require converting revenue shares into physical shares at the upper levels. Combining multi-stage budgeting at the top with discrete choice at the bottom would be feasible, but inconsistent with a single utility-maximization problem (CGJ, pp. 18–19).

CGJ therefore use the revenue-weighted average $p_j^A = \sum_{k \in j} \omega_k p_k$ of (5.135) as an approximation, with log approximation error $m_j = \ln p_j^A - \ln p_j^T$ (CGJ write $\ln \mu_j$). This is the measurement problem of Section 5.6.8. The equation taken to the data is (5.97), whose composite error $\xi_i = \varsigma_i - \sum_j \gamma_{ij} m_j$ is correlated with the observed prices for two reasons. The first is measurement error. The proxy contains m_j by construction, and m_j also appears in ξ_i. The second is the weights. The revenue weights ω_k depend on group spending, so a demand shock ς_i that shifts spending across SKUs also moves p_j^A. By (5.98), both channels push least squares toward less elastic demand, and least squares is inconsistent even if SKU prices are exogenous. The group average is therefore a good price measure only when its movements come from the supply side, such as regulatory price revisions or SKU launches unrelated to demand. The instruments below are meant to isolate such movements.

Instruments. CGJ instrument the group prices with the number of SKUs in each group, the prices of the five largest SKUs in each group, and all exogenous variables of the system. The

exogenous variables are the group-region dummies and total antibiotic spending at the upper level.

Assumption 5.59 (Instrument validity in CGJ)**.** Let z_{rt} collect the number of SKUs and the prices of the five largest SKUs of every group in region r and month t. It also contains the exogenous variables. Then (i) $\mathbb{E}[z_{rt}\,\varsigma_{irt}] = 0$ for every group i, (ii) $\mathbb{E}[z_{rt}\sum_j \gamma_{ij} m_{jrt}] = 0$, and (iii) z_{rt} is correlated with the group prices $\ln p^A_{jrt}$.

The case for relevance is direct. Group prices move mostly because the SKU mix changes, and the count of SKUs tracks that mix. CGJ report first-stage R^2 values between 0.57 and 0.95, except 0.17 for domestic ciprofloxacin (fn. 23). The low value fits Table 5.20, since domestic ciprofloxacin's price barely moves over time. Regulated SKU prices are valid instruments if one accepts that SKU prices are exogenous, which is the premise of the regulation argument.

Exclusion is harder to defend, and CGJ say so. Three threats stand out. First, firms may add or drop SKUs in response to demand, for example during a regional outbreak, which would correlate the SKU count with ς_{irt}. Second, a new SKU may raise demand directly. A new dosage or formulation can serve patients better, and launches often come with promotion. Third, one demand shock may move many SKU prices at once. CGJ raise the second threat themselves and write: "Our hope is that this is not too often the case." Part (ii) of the assumption fails if the measurement error grows with the number of SKUs, which CGJ cannot check (fn. 22). The product effects absorb persistent quality differences, so only time-varying quality shocks threaten exclusion.

Estimator and inference. Estimation has two steps. First, regress each group price on all instruments. Second, replace prices with their fitted values in (5.140) and estimate all equations jointly by least squares subject to the cross-equation restrictions:

$$\hat{\theta} = \arg\min_{\theta} \sum_t \sum_r \sum_i \left[w_{irt} - \hat{w}_{irt}(\theta)\right]^2 \quad \text{subject to} \quad R\theta = 0. \tag{5.146}$$

Here $\hat{w}_{irt}(\theta)$ is the right side of (5.140) with fitted prices. The constraint $R\theta = 0$ stacks adding up, homogeneity, symmetry and the pair-type restrictions. When the first step is a linear projection of the log prices, this is restricted two-stage least squares on an equation that is linear in log prices, given the quinolone index. The second-step standard errors are invalid, because the residuals that enter them are computed with fitted prices. Analytical standard errors with many cross-equation restrictions are cumbersome, so CGJ use the bootstrap. They draw months with replacement and keep all products and regions of a drawn month together. This preserves the correlation of errors across groups and regions within a month, which a national advertising campaign would create. They use 300 bootstrap samples (p. 21). The same procedure gives standard errors for the upper level. Resampling months treats months as independent, so serial correlation in the demand shocks is not accounted for.

The counterfactual standard errors come from the same bootstrap. For each of the 300 samples CGJ re-estimate both levels, recompute costs, re-solve every counterfactual and recompute every welfare number. Draws in which the counterfactual solver did not converge are dropped (fn. 29). This propagates estimation error through the nonlinear counterfactual, which would be tedious with the delta method (Appendix A).

5.9.6 Demand estimates

Table 5.21 reproduces the lower-level coefficients. The pattern of Proposition 5.58 is visible. The coefficient on foreign groups with a different molecule is −0.003 in all three foreign rows.

The coefficient on domestic groups with a different molecule is 0.058 in all four domestic rows. The coefficient for pairs that differ in both molecule and status is 0.004 in every row. The same-molecule coefficients are 0.115 for ciprofloxacin, −0.005 for norfloxacin and 0.008 for ofloxacin, identical in the foreign and domestic rows.

Table 5.21: Lower-level AIDS coefficients

			Cross-price coefficients			
Product group	Constant	Own price	Same molecule, different status	Different molecule, foreign group	Different molecule, domestic group	Quinolone expenditure
Foreign cipro	0.013	−0.120*	0.115*	−0.003†	0.004*	0.010
	(0.02)	(0.05)	(0.05)	(0.00)	(0.00)	(0.01)
Foreign norflo	−0.006	0.000	−0.005	−0.003†	0.004*	0.001
	(0.01)	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)
Foreign oflo	0.047*	−0.013	0.008	−0.003†	0.004*	0.005
	(0.02)	(0.01)	(0.01)	(0.00)	(0.00)	(0.01)
Domestic cipro	0.603*	−0.298*	0.115*	0.004*	0.058*	0.102*
	(0.04)	(0.05)	(0.05)	(0.00)	(0.00)	(0.02)
Domestic norflo	−0.206*	−0.177*	−0.005	0.004*	0.058*	−0.038*
	(0.03)	(0.02)	(0.00)	(0.00)	(0.00)	(0.01)
Domestic oflo	0.339*	−0.191*	0.008	0.004*	0.058*	−0.008
	(0.04)	(0.01)	(0.01)	(0.00)	(0.00)	(0.02)
Domestic sparflo	0.209*	−0.186*		0.004*	0.058*	−0.072*
	(0.03)	(0.02)		(0.00)	(0.00)	(0.01)

Notes: Reproduced from CGJ, Table A2. Bootstrap standard errors in parentheses. * significant at 5 percent, † at 10 percent. The columns "foreign group" and "domestic group" refer to the status of the other group j. In a foreign row they are $\gamma_{i,01}$ and $\gamma_{i,00}$, and in a domestic row $\gamma_{i,00}$ and $\gamma_{i,01}$. The table also reports East, West and South intercept shifts, omitted here. Each equation uses 96 month-region observations (24 months, 4 regions).

The restrictions can be verified directly from the table. Homogeneity for domestic ciprofloxacin requires the own coefficient, the same-molecule coefficient, two foreign-group coefficients and three domestic-group coefficients to sum to zero:

$$-0.298 + 0.115 + 2(0.004) + 3(0.058) = -0.001.$$

For domestic sparfloxacin, $-0.186 + 3(0.004) + 3(0.058) = 0.000$. Adding up holds for the intercepts, $\sum_i \alpha_i = 0.999$, and for the expenditure coefficients,

$$0.010 + 0.001 + 0.005 + 0.102 - 0.038 - 0.008 - 0.072 = 0.000.$$

The other rows and the column sums all lie within 0.001 of zero, the rounding error of three-decimal entries.

The pattern in Table 5.21 carries most of the economics. The domestic-domestic coefficient (0.058) is about fifteen times the coefficient linking domestic and foreign groups with different molecules (0.004). The expenditure coefficients show that domestic ciprofloxacin gains share as quinolone spending grows ($\beta = 0.102$), while domestic sparfloxacin and norfloxacin lose share.

Elasticities. CGJ discuss the implied unconditional elasticities rather than the coefficients. Table 5.22 reproduces the Northern table. The elasticities are evaluated at average revenue shares, and the other regions give very similar numbers (Table 6B). For example, the own

Table 5.22: Unconditional price and expenditure elasticities, Northern region

Notes: Reproduced from CGJ, Table 6A (working paper Table 6(a), identical to the published Table 6A). Rows give the group whose quantity responds, columns the price that changes. The last column is the elasticity with respect to quinolone expenditure. Standard errors in parentheses. Elasticities evaluated at average revenue shares. * significant at 5 percent, † at 10 percent.

elasticity of foreign ciprofloxacin is −5.57 in the North, −5.94 in the East, −4.27 in the West and −5.60 in the South.

Five findings stand out (CGJ, pp. 26–28).

1. Own-price elasticities are negative and significant for six of the seven groups. Four of the six are below −2. The exception is foreign norfloxacin, with 0.07 percent of quinolone sales, whose own elasticity of −0.45 is insignificant. Demand of this size would be unusual in rich countries, where elasticities like these appear mainly for generic drugs or uninsured consumers (fn. 32). The elasticities are for whole product groups, which makes them more striking.

2. Domestic ciprofloxacin, with the largest share and a relatively high price, is among the least elastic groups (−1.68). Foreign ciprofloxacin is very elastic (−5.57), which is plausible since it competes with about 75 domestic sellers of the same molecule.

3. All expenditure elasticities are positive, so every group is a normal good within quinolones.

4. Domestic groups are close substitutes for one another. In the rows of domestic norfloxacin, ofloxacin and sparfloxacin, the elasticities with respect to the other domestic prices lie between 0.40 and 1.15. Domestic quantities respond weakly to foreign prices, with elasticities of at most 0.18, even for the same molecule. For norfloxacin and ofloxacin, domestic groups with different molecules are closer substitutes than the foreign version of the same molecule. Ciprofloxacin is the exception in one direction: foreign ciprofloxacin's quantity rises strongly with the domestic ciprofloxacin price (4.01).

5. Six of the 49 price elasticities have unexpected signs. They are the cross elasticities among different foreign groups, which are negative and significant. CGJ attribute them to the tiny foreign shares, since few consumers switch between two very small foreign groups (fn. 33). These elasticities hardly matter for the counterfactuals, which move the prices of

domestic groups (fn. 34).

Figure 5.7 displays the cross elasticities as a heat map. The domestic-domestic block in the lower right is uniformly blue. The block of domestic responses to foreign prices, in the lower left, is pale.

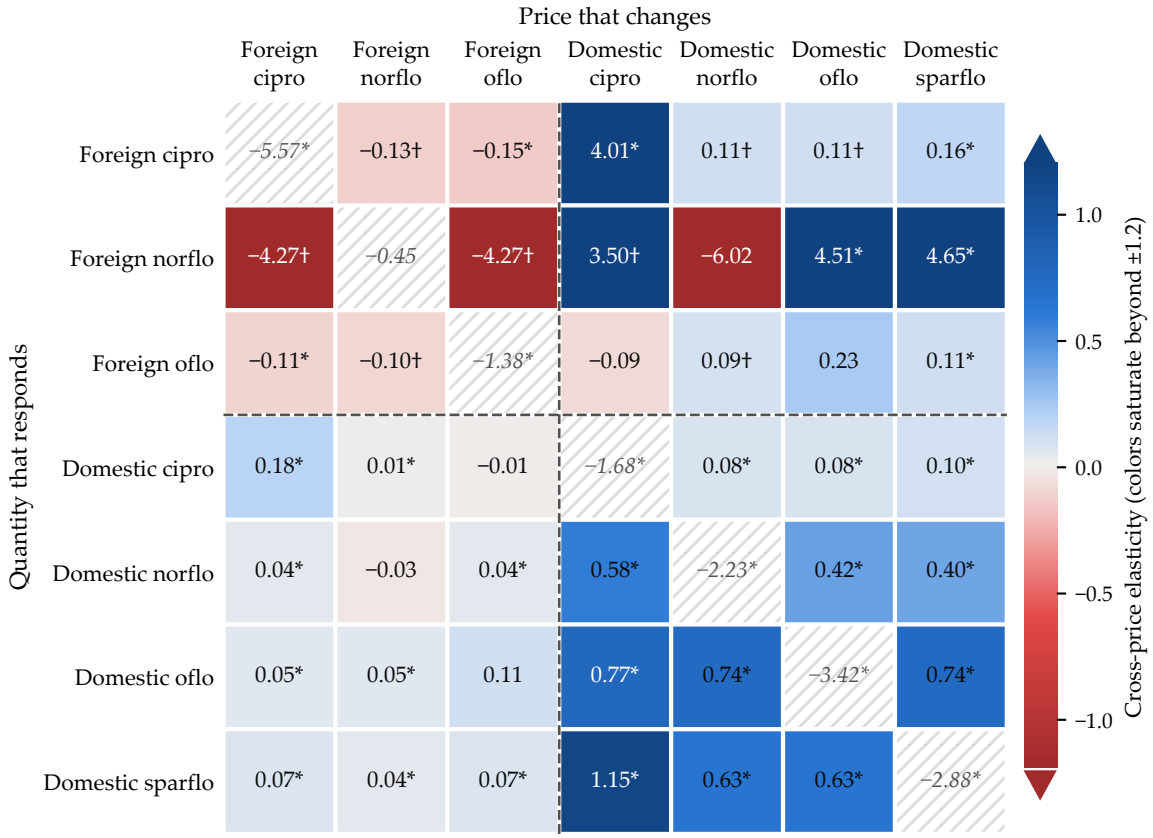

Figure 5.7: Unconditional price elasticities among the seven quinolone groups in the Northern region. Rows respond to the price in the column. Colors encode cross elasticities (blue positive, red negative) and saturate beyond ±1.2. The hatched diagonal shows own-price elasticities, which are excluded from the color scale. Marks: * significant at 5 percent, † at 10 percent. Source: constructed from Chaudhuri, Goldberg and Jia (2006), Table 6A.

Ease of access. Why would a patient who loses domestic norfloxacin switch to domestic ofloxacin rather than to foreign norfloxacin? The pattern is not built in by the specification, since the pair-type coefficients are free in sign and size. CGJ propose an explanation based on distribution, which they call *ease of access* (pp. 27–28). Domestic firms as a group reach far more retail pharmacists than multinational subsidiaries. Large Indian firms spread the fixed cost of medical representatives over larger portfolios, and there are simply many more domestic firms and products. A local pharmacist is therefore more likely to stock two domestic molecules than the domestic and foreign versions of one molecule. Patients or doctors who would rather switch molecules than search another pharmacy then produce, in aggregate data, the substitution pattern of Table 5.22. Together with the domestic price premium of Table 5.18, the evidence shows no premium for multinational brands.

The segment elasticity. The upper level (CGJ, Table A3) gives a price elasticity of the quinolone

segment of −1.11, with standard error 0.24. Demand for the segment is elastic, but less so than demand for any single group within it, except the tiny foreign norfloxacin group, whose insignificant own elasticity is −0.45. The number can be checked from the quinolone row of Table A3, where $\gamma_{QQ} = -0.02$ and $\beta_Q = 0.04$. With the Northern quinolone share of antibiotic spending, $w_Q = \frac{31.25}{119.88} = 0.26$ (Table 5.19), the Stone-index formula gives

$$\varepsilon_Q = -1 + \frac{\gamma_{QQ}}{w_Q} - \beta_Q = -1 - \frac{0.02}{0.26} - 0.04 = -1.12.$$

This matches the reported value up to the rounding of γ_{QQ} to two decimals.

Robustness. CGJ report two alternative specifications (pp. 28–29). Adding group-specific seasonal effects for summer, monsoon and winter leaves the elasticities nearly unchanged (Table A4). Estimating the system by least squares (Table A5) gives smaller own elasticities in absolute value, as (5.98) predicts. Table 5.23 compares the own elasticities. The least-squares own elasticity of foreign ciprofloxacin is −2.76, half the instrumented −5.57. Smaller elasticities would imply larger markups and larger welfare losses, so instrumenting makes the welfare estimates more conservative. The least-squares cross elasticities among domestic groups remain positive and significant. In the rows of domestic norfloxacin, ofloxacin and sparfloxacin they are large (between 0.39 and 1.25), and they mostly exceed the same-molecule cross elasticities. CGJ call the close substitutability of domestic products "one of the most robust findings of the paper."

Table 5.23: Own-price elasticities under alternative specifications, Northern region

	Preferred (IV)	Least squares	IV with seasonal effects		
Product group	Table 6A	Table A5	Summer	Monsoon	Winter
Foreign cipro	−5.57*	−2.76*	−6.06*	−5.80*	−5.66*
Foreign norflo	−0.45	1.24	0.12	−0.35	−0.20
Foreign oflo	−1.38*	−0.99*	−1.58*	−1.51*	−1.55*
Domestic cipro	−1.68*	−1.56*	−1.72*	−1.72*	−1.73*
Domestic norflo	−2.23*	−2.18*	−2.04*	−2.10*	−2.22*
Domestic oflo	−3.42*	−3.16*	−3.67*	−3.20*	−3.08*
Domestic sparflo	−2.88*	−2.76*	−2.81*	−2.82*	−2.56*

Notes: Compiled from CGJ, Tables 6A, A4(a) to A4(c), and A5. Standard errors omitted. * significant at 5 percent.

Example 5.60 (Reproducing Tables 6A and 7 from Tables A2 and 3)**.** The published coefficients, the published shares and the formulas of Section 5.9.4 nearly reproduce the published elasticities. We compute Northern revenue shares from the Northern sales in Table 5.19. Total Northern quinolone sales of the seven groups are Rs. 1,563.56 million, so for example $w_7 = \frac{156.17}{1563.56} = 0.0999$ for domestic sparfloxacin.

Expenditure elasticities. The elasticity with respect to quinolone spending is $\eta_i^Q = 1 + \frac{\beta_i}{w_i}$. For domestic sparfloxacin,

$$\eta_7^Q = 1 + \frac{-0.072}{0.0999} = 0.28,$$

exactly the value in Table 6A. Table 5.24 shows that the formula reproduces all seven entries of the last column within 0.02.

Own-price elasticities. The term $\beta_j \ln \frac{X_Q}{P_Q}$ in (5.144) depends on α_0 and on the units of prices, and CGJ do not report it. Setting it to zero gives our approximation. For domestic sparfloxacin the conditional part is

$$\varepsilon_{77}\big|_{X_Q} \approx -1 + \frac{\gamma_{77} - \beta_7 w_7}{w_7} = -1 + \frac{-0.186 + 0.072 \times 0.0999}{0.0999} = -2.79.$$

The unconditional term adds $\eta_7^Q(1+\varepsilon_Q)w_7 = 0.28 \times (-0.11) \times 0.0999 = -0.003$. The approximation, -2.79, is close to the published -2.88. Across the 42 entries of Table 6A outside the foreign norfloxacin row, the approximation has a root mean squared error of 0.036 and a largest error of about 0.15. Choosing the omitted term to fit the table best lowers the root mean squared error only to 0.024. Most of the remaining gap probably reflects the rounding of the published coefficients to three decimals.

Foreign norfloxacin. Here the approximation fails. With $\gamma_{22} = 0.000$ and $w_2 = 0.0008$, it gives an own elasticity of -1.00 against the published -0.45. Every coefficient in this row is divided by a share of 0.08 percent, which magnifies rounding and sampling error about 1,250 times. This is why the foreign norfloxacin row is so imprecise in Table 5.22.

Markups. Section 5.9.7 shows that CGJ's upper bound on the Lerner index is $-\frac{1}{\varepsilon_{ii}}$. The simple average of this ratio across the four regional own elasticities of Tables 6A and 6B reproduces every markup in Table 7 to two decimals. For domestic oflo, for instance, the regional own elasticities -3.42, -2.95, -2.57 and -2.96 give an average Lerner index of 0.34, the value in Table 7. The Northern ratio alone, 0.29, would miss it.

Table 5.24: Consistency checks: elasticities and markups recomputed from the published coefficients

		Expenditure elasticity		Own-price elasticity		Lerner index bound	
Product group	w_i (North)	$1 + \frac{\beta_i}{w_i}$	Table 6A	Approx.	Table 6A	Mean of $-\frac{1}{\varepsilon_{ii}}$	Table 7
Foreign cipro	0.0267	1.37	1.37	−5.50	−5.57	0.19	0.19
Foreign norflo	0.0008	2.22	2.20	−1.00	−0.45	n.a.	n.a.
Foreign oflo	0.0348	1.14	1.16	−1.38	−1.38	0.70	0.70
Domestic cipro	0.6154	1.17	1.17	−1.67	−1.68	0.59	0.59
Domestic norflo	0.1423	0.73	0.73	−2.22	−2.23	0.43	0.43
Domestic oflo	0.0800	0.90	0.89	−3.39	−3.42	0.34	0.34
Domestic sparflo	0.0999	0.28	0.28	−2.79	−2.88	0.37	0.37

Notes: Our computations from CGJ's Tables 3, A2, 6A, 6B and 7. Shares are Northern sales shares among the seven groups. "Approx." is (5.144) with $\ln \frac{X_Q}{P_Q}$ set to zero and $\varepsilon_Q = -1.11$. The Lerner bound is the simple average across the four regions of minus the inverse own elasticity. For foreign norfloxacin the own elasticity is below one in absolute value in every region, so no bound exists.

5.9.7 Supply: bounds on costs and markups

The counterfactual needs marginal costs, which are not observed. The standard approach of Chapter 4 infers them from the first-order conditions of an assumed pricing game (Section 5.7.5). CGJ argue that price regulation makes unconstrained period-by-period profit maximization untenable here, and the regulation is too complex to model. They bound costs instead, using the argument of Proposition 5.52.

The bounds are those of (5.119) (CGJ, eqs. 3.12 and 3.13). Perfect competition within a group gives the upper bound $c_i^U = p_i$ and a zero markup. Perfect collusion among the firms of group i, with price controls ignored, gives the monopoly condition for the group as a whole. It yields the lower bound $c_i^L = p_i\left(1 + \frac{1}{\varepsilon_{ii}}\right)$ and the upper bound $-\frac{1}{\varepsilon_{ii}}$ on the Lerner index, where ε_{ii} is the unconditional own-price elasticity. Collusion within the group overstates market power, because it assumes away competition among the dozens of firms that sell each molecule (fn. 19). Regulation pushes prices further below the monopoly level. Both forces keep the price at or below the group monopoly price, as Assumption 5.51 requires, so c_i^L is a lower bound. The bound requires $\varepsilon_{ii} < -1$. CGJ compute c_i^L region by region and report national averages.

Table 5.25 reproduces the bounds. The upper bound on profit is the upper-bound markup times revenue, since $(p_i - c_i^L)q_i = \frac{p_i - c_i^L}{p_i}\, p_i q_i$. Annual sales of domestic ciprofloxacin, summed over the regions of Table 5.19, are Rs. 2,931 million. Multiplying by a Lerner index of 0.586 gives about Rs. 1,717 million, against Rs. 1,701.9 million in the table. The small gap reflects CGJ's population weights.

Table 5.25: Bounds on marginal cost, markup and annual profit by product group

	Collusive bound			Competitive bound
	Lower bound for marginal cost (Rs.)	Upper bound for markup (%)	Upper bound for profit (Rs. million)	Upper bound for marginal cost (Rs.)
Foreign cipro	8.3*	19	26.9	10.3
	(1.23)	(0.12)	(16.55)	
Foreign norflo	n.a.	n.a.	n.a.	5.3
Foreign oflo	32.3	70*	106.1*	108.5
	(23.16)	(0.21)	(31.85)	
Domestic cipro	4.7*	59*	1,701.9*	11.2
	(1.14)	(0.10)	(298.58)	
Domestic norflo	5.2*	43*	280.7*	9.0
	(0.20)	(0.02)	(15.32)	
Domestic oflo	58.7*	34*	161.2*	90.1
	(2.18)	(0.02)	(12.80)	
Domestic sparflo	49.5*	37*	198.5*	78.8
	(1.57)	(0.02)	(11.00)	

Notes: Reproduced from CGJ, Table 7. National averages of regional estimates. Standard errors in parentheses, with markup standard errors expressed as fractions. * significant at 5 percent. The competitive bound sets marginal cost equal to price, so the markup and profit are zero. CGJ's column heading labels the markup column "(Rs.)", although its entries are percentages. No collusive bound exists for foreign norfloxacin, whose estimated own elasticity is below one in absolute value.

The markup bounds are plausible (CGJ, p. 29). Domestic ciprofloxacin combines a high price, a large share and relatively inelastic demand. It has one of the highest markup bounds (59 percent) and earns nearly 70 percent of the sub-segment's profits. Indeed $\frac{1701.9}{2475.3} = 0.69$, where Rs. 2,475.3 million is the sum of the profit column. Foreign ciprofloxacin faces the stiffest domestic competition and has the lowest bound (19 percent). The four domestic profit bounds sum to Rs. 2,342 million. This number reappears below as the domestic profit loss when all four domestic groups are withdrawn.

CGJ stress that these numbers are bounds. They do not measure actual costs. Regulation means the unconstrained first-order condition need not hold, and aggregation across firms makes the collusive benchmark extreme. Most of their counterfactuals use c^L, because it

gives the largest possible profits. That is the worst case for Indian firms and the best case for multinationals under patents.

5.9.8 Counterfactual design

Scenarios. The benchmark is the most extreme policy. Foreign firms face no price controls, and *compulsory licensing* is unavailable. Under compulsory licensing a government authorizes other firms to produce a patented drug in exchange for a royalty to the patent holder. CGJ consider five withdrawal scenarios, each removing one or more domestic groups (p. 22).

1. Only domestic ciprofloxacin, a large group.
2. Only domestic ofloxacin, a small group.
3. Domestic ciprofloxacin, ofloxacin and norfloxacin.
4. Domestic ciprofloxacin, ofloxacin and sparfloxacin.
5. All four domestic groups.

The remaining firms keep their product sets. The scenarios are illustrative. Most of the quinolone patents had expired by the time of writing (norfloxacin's U.S. patent already in 1998), so none of the scenarios would materialize (fn. 26). They show how the presence and extent of domestic competition affect the welfare calculation, which may matter for therapeutic classes whose patents have not expired.

The equilibrium system. Let $\mathcal{W}$ be the set of withdrawn groups. For each withdrawn group $i \in \mathcal{W}$, the virtual price p_{ir}^{V} sets its share to zero (CGJ, eq. 3.14):

$$\begin{aligned} 0 = \alpha_{ir} + \gamma_{ii} \ln p_{ir}^{V} + \gamma_{i,10} \sum_{j \in D_i^{10}} \ln p'_{jr} + \gamma_{i,01} \sum_{j \in D_i^{01}} \ln p'_{jr} \\ + \gamma_{i,00} \sum_{j \in D_i^{00}} \ln p'_{jr} + \beta_i \ln \frac{X'_{Qr}}{P'_{Qr}}. \end{aligned} \tag{5.147}$$

Here α_{ir} now includes the common intercept, and p'_{jr} is the new price of group j. A withdrawn group j enters the sums at its own virtual price. For each remaining group $k \notin \mathcal{W}$, the price solves the group's monopoly first-order condition (CGJ, eq. 3.15):

$$p'_{kr} = c_{kr} \left(1 + \frac{1}{\varepsilon_{kk}(p'_r, p_r^{V})} \right)^{-1}. \tag{5.148}$$

The marginal cost c_{kr} is set to c_{kr}^{L} or c_{kr}^{U}, and the unconditional elasticity of (5.144) is evaluated at the new prices. Quinolone spending X'_{Qr} and the index P'_{Qr} come from the upper level. The index P'_{Qr} is the translog of (5.137) at the new prices, and X'_{Qr} follows from the upper-level share at the new index, with the other sub-segments' price indices held fixed. The system is solved region by region. National figures are population-weighted averages of the regional ones.

Equation (5.147) is the Marshallian zero-share condition at counterfactual spending, discussed in Section 5.7.2. Each withdrawn group's equation is quadratic in its log virtual price, because the index P'_{Qr} contains $\frac{1}{2}\gamma_{ii}(\ln p_{ir}^{V})^2$ ((5.112)). With several groups withdrawn

the conditions must hold jointly. CGJ do not describe their solver. The block iteration of Section 5.7.7, which alternates between the virtual prices, the two budgeting levels and the pricing conditions (5.148), is one natural scheme. Foreign norfloxacin has no cost bound, so CGJ fix its counterfactual price at chosen values and report that the results are robust to them (notes to Table 9).

Welfare. Let p^0 be the observed price vector, p' the counterfactual vector (virtual prices for the withdrawn groups, new prices for the others), and u^0 the representative consumer's initial utility. Let $e(p, u)$ be the expenditure function of the upper-level AIDS, in which the lower level enters through the quinolone index P_Q. The compensating variation is

$$CV = e(p', u^0) - e(p^0, u^0) \tag{5.149}$$

(CGJ, eq. 3.16). It is positive for a loss. CGJ split it into three parts with two intermediate price vectors. The vector p^1 sets virtual prices for the withdrawn groups while holding X_Q and all other prices fixed. The vector p^2 recomputes the virtual prices letting X_Q respond to the new quinolone index, again with all other prices fixed. Then

$$CV = \underbrace{e(p^1, u^0) - e(p^0, u^0)}_{\text{pure loss of variety}} + \underbrace{e(p^2, u^0) - e(p^1, u^0)}_{\text{expenditure switching}} + \underbrace{e(p', u^0) - e(p^2, u^0)}_{\text{reduced competition}}. \tag{5.150}$$

This is the general decomposition of Section 5.7.7 applied to CGJ's two levels. The first term is the loss from the disappearance of products with everything else held fixed. It would be zero if consumers treated the domestic and foreign versions of a molecule as identical, as earlier simulation studies assumed. The second term is what CGJ call expenditure switching. It records how the Marshallian virtual prices shift when quinolone spending responds to the higher index. The vector p^2 is the closest match to patents combined with strict price regulation that holds the remaining prices at their pre-patent levels. The third term adds the price increases of the remaining groups.

Profits and national welfare. Profits are $\pi_k = (p'_k - c_k)q'_k$ at the counterfactual prices and quantities. CGJ define Indian welfare as consumer welfare plus the profits of domestic firms. Foreign profits are excluded, but CGJ compute them separately as a gauge of the incentive that Indian patents would give multinationals. Losses are reported as positive numbers, so a negative domestic profit loss is a gain (fn. 38). With c^L, pre-patent profits are at their largest, so the computed domestic profit loss is an upper bound.

Remark 5.61 (The competitive cost bound in the simulation). The two cost bounds play different roles in (5.148). With $c^L_k = p^0_k(1 + \frac{1}{\varepsilon_{kk}})$, the observed prices satisfy (5.148) before any withdrawal, so simulated price changes are caused by the withdrawal alone. With $c^U_k = p^0_k$ they do not. Before any withdrawal, (5.148) would already set $p'_k = p^0_k \frac{\varepsilon_{kk}}{1+\varepsilon_{kk}} > p^0_k$ whenever $\varepsilon_{kk} < -1$. The c^U simulations therefore combine zero markups before the policy with group monopoly pricing after it. This reading may explain why CGJ's Table A6, which uses c^U, gives a much larger loss than Table 8 when only domestic ofloxacin is withdrawn (Rs. 4.08 billion against 0.23). CGJ describe the c^U losses as "slightly higher" and of the same order of magnitude for the larger scenarios.

5.9.9 Counterfactual results

Consumer welfare. Table 5.26 reproduces CGJ's Table 8. All numbers in this subsection use the cost lower bound c^L. The columns are cumulative. The first column holds X_Q and the

remaining prices fixed, the second adds expenditure switching, and the third adds the price response of the remaining groups.

Table 5.26: Consumer welfare losses from product withdrawal (Rs. billion per year)

		Loss of variety and	
Domestic groups withdrawn	Pure loss of variety	expenditure switching	price adjustment and expenditure switching
Only cipro	4.98*	4.92*	7.32*
	(0.87)	(0.89)	(1.46)
Only oflo	0.08	0.08	0.23*
	(0.08)	(0.08)	(0.10)
Cipro, oflo, norflo	7.52*	7.40*	12.53*
	(1.77)	(1.80)	(4.15)
Cipro, oflo, sparflo	6.14*	6.03*	10.58*
	(1.42)	(1.45)	(3.31)
All four	11.76†	11.35†	17.81
	(6.43)	(6.34)	(12.70)

Notes: Reproduced from CGJ, Table 8 (identical to the published table). Compensating variation computed with the cost lower bound. Standard errors in parentheses. * significant at 5 percent, † at 10 percent. The published table adds that the exchange rate is 45 rupees per U.S. dollar and that total sales of systemic antibacterials in 2000 were Rs. 27 billion.

Figure 5.8 splits each total into its three parts. In the all-four scenario the total loss is Rs. 17.81 billion (CGJ, p. 31). The variety loss contributes Rs. 11.76 billion, or 66 percent of the total. Expenditure switching reduces the loss by Rs. 0.41 billion (−2 percent). Price increases add a further Rs. 6.46 billion (36 percent). The shares are similar across scenarios. The variety loss accounts for 58 to 68 percent in every scenario except the removal of ofloxacin alone, where the total is small.

Three results matter for policy. First, expenditure switching is small in every scenario, although the segment elasticity is −1.11. The reason is the factor $1 + \varepsilon_Q = -0.11$ derived above: a higher quinolone index moves little spending out of the segment. Switching lowers the loss in four scenarios and leaves it unchanged when only ofloxacin is withdrawn. CGJ read the term as consumers escaping to other sub-segments. Formally, the upper-level expenditure function already lets consumers reallocate spending across sub-segments. The term arises because the Marshallian zero-share condition (5.147) moves the virtual prices when X_Q falls (Section 5.7.7). The higher quinolone index lowers X_Q slightly. That lowers the virtual price of a withdrawn group with $\beta_i > 0$, such as domestic ciprofloxacin, and raises it for groups with $\beta_i < 0$. The sign of the term is therefore not fixed by theory. For the claim of TRIPS proponents to hold, CGJ conclude, unpatented substitutes must exist within narrowly defined therapeutic categories. Substitution across broad segments does little.

Second, the loss of variety is large. It arises only because consumers distinguish domestic from foreign versions of the same molecule. CGJ interpret it as the ease-of-access effect. Price regulation cannot remove it, since regulation acts on the third term. This suggests an independent role for compulsory licensing, which keeps domestic versions on the market, either alongside price regulation or in its place.

Third, the losses are superadditive. Withdrawing all four domestic groups costs Rs. 17.81 billion. Withdrawing one group at a time costs 7.32 (ciprofloxacin), 0.23 (ofloxacin), about 0.1 (norfloxacin) and close to zero (sparfloxacin), for a sum of about Rs. 7.6 billion (fn. 37).

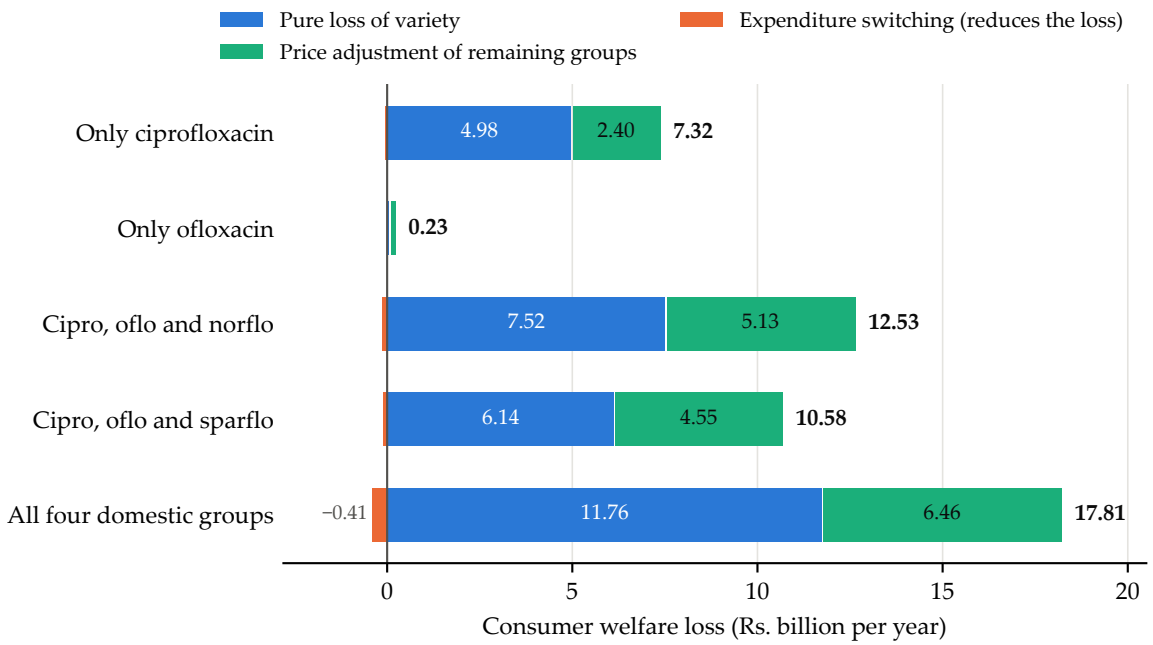

Figure 5.8: Decomposition of the consumer welfare loss in each withdrawal scenario. Blue: pure loss of variety (Table 8, first column). Orange, left of zero: expenditure switching (second column minus first). Green: price adjustment of the remaining groups (third column minus second). The bold number is the total loss, equal to the blue and green segments minus the orange one. Standard errors are in Table 5.26. Source: constructed from Chaudhuri, Goldberg and Jia (2006), Table 8.

The joint loss is more than twice the sum of the separate losses. The three-group rows show the mechanism in our arithmetic. Adding sparfloxacin to the ciprofloxacin, ofloxacin and norfloxacin withdrawal raises the loss from 12.53 to 17.81, by Rs. 5.28 billion. Adding norfloxacin to the other triple raises it from 10.58 to 17.81, by Rs. 7.23 billion. Yet each costs at most Rs. 0.1 billion alone. When one domestic group exits, consumers move to the other domestic groups, so the loss is small. When the last domestic group exits, no close substitute remains. Studies that add up losses estimated market by market can therefore understate the cost of patents substantially.

Prices. Table 5.27 reports the counterfactual prices of the groups that remain. Shaded cells in CGJ's table, dots here, mark withdrawn groups. Foreign norfloxacin's price is fixed by assumption.

Table 5.27: Counterfactual prices of the remaining groups (% of original prices)

	Foreign groups			Domestic groups			
Domestic groups withdrawn	Cipro	Norflo	Oflo	Cipro	Norflo	Oflo	Sparflo
Only cipro	189.4*	314.7	98.2*	.	148.6*	141.4*	164.1*
	(0.18)		(0.21)		(0.09)	(0.08)	(0.08)
Only oflo	100.4*	150.0	102.9*	102.4*	108.3*	.	110.7*
	(0.01)		(0.08)	(0.01)	(0.01)		(0.01)
Cipro, oflo, norflo	247.6*	627.8	154.4*	.	.	.	296.3*
	(0.42)		(0.39)				(0.70)
Cipro, oflo, sparflo	255.2*	627.8	158.3*	.	250.1*	.	.
	(0.40)		(0.37)		(0.64)		
All four	396.4	627.8	318.4†	.	.	.	.
	(3.34)		(1.73)				

Notes: Reproduced from CGJ, Table 9. Prices with expenditure switching and within-segment price adjustment, cost lower bound. Dots mark withdrawn groups. Standard errors in parentheses. * significant at 5 percent, † at 10 percent. Foreign norfloxacin's price is fixed at the values shown, because its cost bound is not available.

Remark 5.62 (Reading Table 9). The heading of CGJ's Table 9 says the entries are percentages of original prices. Under that reading, foreign ciprofloxacin's price would rise to 3.96 times its original level when all domestic groups exit, an increase of about 296 percent. Two features of the table support the heading. The entries in the ofloxacin-only row are close to 100, which is what a small withdrawal should produce. The standard errors are of the order of 0.01 to 3.34, which makes sense for ratios of new to old prices. CGJ's text reads the entries differently. It says that foreign prices would rise "between 100% and 400%", the range of the foreign entries. It also says that the price of foreign ciprofloxacin would be "approximately 5 times higher than it is now" in the all-four scenario. We report the entries as printed and leave the ambiguity open. Under either reading, removing all domestic competition multiplies the foreign prices several times.

CGJ check plausibility against Pakistan, a country with similar demographics but a market structure close to what patents would create in India, with multinational subsidiaries dominant. CGJ (p. 33), citing Lanjouw (1998, p. 39, Table 2), report that ciprofloxacin cost about seven times as much in Pakistan as in India. CGJ's all-four prediction for foreign ciprofloxacin is of the same order of magnitude, though lower (p. 33).

The domestic groups that remain also raise their prices, by 41 to 64 percent when only ciprofloxacin is withdrawn (reading the entries as percentages of original prices). These

increases follow from the collusive conduct assumed in (5.148). A remaining domestic group is priced as if its 17 to 40 firms maximized joint profit, and its demand becomes less elastic once a close domestic substitute disappears. The Le Chatelier principle of Section 5.7.2 makes the second step precise. Let i be the withdrawn group, whose virtual price adjusts. The compensated own-price elasticity of a remaining group j is then $\varepsilon^h_{jj} - \varepsilon^h_{ji}\frac{p_j S_{ij}}{p_i S_{ii}}$ by (5.111), with all terms evaluated at the virtual price. It is smaller in absolute value than the unrestricted compensated elasticity at that price. The correction is largest for the closest substitutes, the other domestic quinolones. This channel is a property of demand and holds under any conduct. Collusive conduct converts it into a large price increase. With competitive pricing inside the group, the domestic price increases, and the third column of Table 8, would be smaller.

Profits and total welfare. Table 5.28 combines CGJ's Tables 10, 11 and 12.

Table 5.28: Domestic profit losses, total Indian welfare losses and foreign profit gains (Rs. billion per year)

Domestic groups withdrawn	Pure loss of variety	Loss of variety and expenditure switching	Loss of variety and price adjustment and expenditure switching
Panel A. Foregone profits of domestic producers (Table 10)			
Only cipro	0.95* (0.16)	1.09* (0.08)	0.40 (0.31)
Only oflo	−0.04* (0.01)	−0.03† (0.02)	−0.14* (0.04)
Cipro, oflo, norflo	1.24* (0.17)	1.40* (0.11)	0.42 (0.60)
Cipro, oflo, sparflo	1.11* (0.17)	1.26* (0.11)	0.48 (0.50)
All four	2.34* (0.19)	2.34* (0.19)	2.34* (0.19)
Panel B. Total welfare losses to India (Table 11)			
Only cipro	5.94* (0.94)	6.01* (0.87)	7.72* (1.20)
Only oflo	0.04 (0.08)	0.05 (0.09)	0.09 (0.10)
Cipro, oflo, norflo	8.76* (1.84)	8.80* (1.77)	12.95* (3.61)
Cipro, oflo, sparflo	7.25* (1.46)	7.28* (1.42)	11.07* (2.88)
All four	14.10* (6.57)	13.70* (6.48)	20.16 (12.85)
Panel C. Profit gains of foreign producers (Table 12)			
Only cipro	0.17* (0.03)	0.14* (0.06)	0.35* (0.17)
Only oflo	0.02 (0.01)	0.02 (0.01)	0.01 (0.02)
Cipro, oflo, norflo	0.36* (0.05)	0.28* (0.11)	0.71† (0.40)
Cipro, oflo, sparflo	0.37* (0.05)	0.30* (0.10)	0.79* (0.38)
All four	1.17* (0.31)	0.88* (0.41)	2.43† (1.44)

Notes: Reproduced from CGJ, Tables 10, 11 and 12. Cost lower bound. Standard errors in parentheses. * significant at 5 percent, † at 10 percent. Losses are positive numbers, so a negative entry in Panel A is a gain for domestic firms as a group. Panel B equals Table 8 plus Panel A, up to rounding.

Domestic profits fall by Rs. 2.34 billion when all four groups exit, in every column. This is the whole pre-patent profit of the domestic groups, the sum of the domestic profit bounds in Table 5.25. In the partial scenarios, the remaining domestic firms gain from reduced competition, and these gains offset part of the losses. When only ofloxacin is withdrawn, the domestic sector as a whole gains, because consumers switch to other domestic molecules. This may explain why the Indian industry was divided over TRIPS. The association of leading Indian firms and multinational subsidiaries supported stronger patents, while associations of smaller firms were more skeptical (fn. 39). In every scenario, consumer losses dwarf domestic profit losses.

Panel B is consumer loss plus domestic profit loss. The identity can be checked row by row. For the all-four scenario,

$$13.70 \approx 11.35 + 2.34 \qquad \text{and} \qquad 20.16 \approx 17.81 + 2.34,$$

with the differences due to rounding. The columns of Panel A also show how expenditure switching and price responses redistribute profits. When only ciprofloxacin is withdrawn, switching raises the domestic loss from 0.95 to 1.09, because the remaining domestic groups sell less as quinolone spending falls. Price adjustment then cuts the loss to 0.40, because the remaining domestic groups raise their prices.

The headline numbers. With the exchange rate of 45 rupees per dollar, CGJ's summary numbers follow from Tables 8 to 12 (pp. 34–35).

- Without price regulation or compulsory licensing, the total welfare loss to India from withdrawing all four domestic groups is Rs. 20.16 billion per year, about US$450 million.
- With regulation holding prices at pre-patent levels, the loss is Rs. 13.7 billion, about US$305 million. This is about 50 percent of the 2000 sales of all systemic antibacterials ($\frac{13.7}{27} = 0.51$). Foregone domestic profits are about Rs. 2.3 billion (US$50 million), roughly one-sixth of the total.
- If the variety loss is transitional, or licensing could neutralize it, subtracting it leaves a lower bound of Rs. 6.5 billion (20.16−13.7), about US$144 million per year. The subtraction removes the variety loss (11.76), the switching term (−0.41) and the domestic profit loss (2.34). The remainder equals the price-adjustment term of Table 5.26, $17.81 - 11.35 = 6.46$. This is about 30 percent of the upper bound and about 24 percent of antibiotic sales in 2000.
- Foreign profit gains are only Rs. 2.4 billion (US$53 million) without regulation and Rs. 0.88 billion (US$19.6 million) with it.

CGJ put the foreign gains in perspective with the sales of Bayer's Cipro, about US$1.6 billion in 2000. At a markup of 40 percent, often quoted for the industry, that is about US$640 million of annual profit from one product. The gain from Indian patents on the whole quinolone segment would be a small fraction of this. Indian patents on these drugs would hardly change multinationals' incentives to do research on the diseases of poor countries.

The welfare numbers are large relative to the market. Total quinolone sales in 2000 were near Rs. 5.7 billion, by our computation from Table 5.17. The all-four consumer loss is about three times this amount ($\frac{17.81}{5.7} \approx 3.1$), and the variety loss alone about twice ($\frac{11.76}{5.7} \approx 2.1$). Such numbers are possible because the compensating variation is an area under the Hicksian demand curve up to the virtual price, far above observed prices. That area depends on the curvature of AIDS demand outside the range of the data (Section 5.7.2). The standard error of the all-four total loss, Rs. 12.70 billion, reflects this uncertainty.

The upper cost bound. Table A6 repeats the consumer welfare calculation with c^U. The first two columns are unchanged in point estimate, because they do not involve costs. The full loss in the all-four scenario is Rs. 19.46 billion, against 17.81 with c^L. CGJ explain that higher costs produce larger price increases. As Remark 5.61 notes, the c^U simulation also builds in price increases that would occur without any withdrawal, which shows up clearly in the small scenarios.

5.9.10 Interpretation, limitations and contribution

CGJ draw three policy lessons. Product availability matters as much as affordability for consumer welfare, so patent policy should be judged by both. Compulsory licensing has a role distinct from price regulation, because only the former addresses the loss of variety. And the two policies are in tension. Patents without price controls strengthen multinationals' incentives to build distribution networks or to license domestic firms, which would shrink the variety loss over time. Price controls limit price increases but weaken these incentives, which could make the variety loss permanent. No combination of policies is likely to neutralize all the welfare costs.

The study has several limitations, most of which CGJ acknowledge.

- *Representative consumer.* The framework cannot say which households lose most. That would require micro data on purchases, which do not exist for Indian pharmaceuticals (fn. 30). The aggregate compensating variation is also a statement about a representative household, as discussed in Section 5.4.
- *Uniform pricing.* The model rules out price discrimination, which could change both welfare losses and profit gains (fn. 31).
- *Static analysis.* The model has no research response, no new launches and no investment in distribution. The product sets of the remaining firms are held fixed. If foreign firms expand distribution, alone or through joint ventures with Indian firms, the ease-of-access loss would be transitional. CGJ report media accounts of such initiatives.
- *Aggregation and conduct.* Groups aggregate dozens of firms, and the cost bound c^L treats each group as a cartel. This inflates pre-patent markups and the price responses of the remaining domestic groups.
- *Functional form and extrapolation.* Virtual prices lie far outside the observed price range. The welfare loss, several times the segment's sales, depends on AIDS curvature where no data exist. Logit or CES demand would give different answers, as Proposition 5.48 shows.
- *Identification.* The SKU-count instruments fail if SKU entry responds to demand shocks or raises demand directly. Domestic ciprofloxacin, the most important group, has the weakest first stage and little price variation over time.
- *Restrictions.* The pair-type restriction forces one coefficient on all domestic pairs, and homogeneity then ties the own-price coefficients to the cross coefficients (Proposition 5.58). The ease-of-access pattern is estimated, but its uniformity across domestic pairs is imposed.
- *Small foreign groups.* Foreign norfloxacin's estimates are unreliable, and the negative cross elasticities among foreign groups are unexplained.
- *Revealed preference.* Doctors choose most prescriptions, and they or their patients may err or follow promotion. If choices do not reflect informed preferences, welfare computed from them may mislead. Antibiotic use also has external effects, such as bacterial resistance, that private demand ignores.

Several open questions follow. Did TRIPS spur research, including by Indian firms? Is Pakistan a credible benchmark for post-patent prices in India? Which consumers rely most on domestic firms? Would ease of access persist once multinationals expand distribution or license their molecules?

The paper made three contributions. It gave the first estimates of the welfare effects of TRIPS that rest on estimated demand and cost parameters, where earlier studies had assumed them. It allowed consumers to distinguish domestic from foreign versions of the same molecule, which revealed a variety channel that price-based analyses miss. And it estimated cross-price effects flexibly, which showed that losses compound when several domestic groups disappear. Methodologically, it shows how a multi-level AIDS, simple instruments, cost bounds and virtual prices combine into a transparent counterfactual.

5.10 Retrospective evidence: what happened after patents arrived

CGJ's analysis is prospective in the sense of Section 5.1.1. It predicts the effects of a policy before the policy exists. India introduced product patents for pharmaceuticals in 2005, and a retrospective analysis then became possible. Such an analysis measures what happened after the policy, using variation in its timing or reach. Duggan et al. (2016) (DGG henceforth) provide it. This section reports their setting, design and main results and asks why the two answers differ.[7]

5.10.1 Setting and data

TRIPS required product patents in all fields of technology, with a minimum term of 20 years. India had no product patents when TRIPS came into force in 1995, so it received a transition period of ten years (DGG, p. 105). From 1995 a "mailbox" collected patent applications, and the government published neither their number nor their content. The 2005 reform kept several flexibilities. A grandfather clause lets a generic firm that invested in a molecule before 2005 continue to produce it after paying a "reasonable royalty" to the patent holder. DGG call this a de facto compulsory license for existing generic producers (p. 106). Section 3(d) of the amended Act limits patents on chemical entities known before 1995 to inventions with significantly greater therapeutic efficacy (p. 107).

Compulsory licensing and price controls also remained available, but India used them sparingly. Its first compulsory license came in March 2012. Natco was allowed to sell a generic version of Bayer's cancer drug Nexavar for a royalty of 6 percent, at about $176 a month against Bayer's $5,600 (p. 106). Price controls covered only 74 drugs until 2013, when they were extended to nearly 350 (p. 106). DGG add that the mere threat of these tools may have restrained prices (p. 101).

The timing of grants was hard to predict. The first pharmaceutical product patent, for Roche's hepatitis C drug Pegasys, came only in 2006 (pp. 107 and 110). That was more than a year after the mailbox applications were opened for review on 1 January 2005 (p. 107). Section 3(d) also left the patent office wide discretion (p. 107). In April 2013 the Supreme Court upheld the denial of a patent for Novartis's cancer drug Glivec, which the office had judged an incremental change to an older compound (fn. 5). DGG argue that this uncertainty makes the date of a grant a plausibly exogenous shock to each molecule's market (pp. 107–108).

The sales data are quarterly retail sales from the MIDAS database of IMS Health. They come from an audit of about 5,100 stockists that covers 80 to 85 percent of the Indian market (p. 108). DGG use all single-molecule products, which account for over half of sales (p. 109). The estimation sample runs from the second quarter of 2004 to the end of 2011. It keeps

[7] We cite the published article in the *American Economic Review* 106(1), 2016. Page, table, equation and footnote numbers refer to it.

molecules with positive sales in the first quarter of 2005 (p. 108 and fn. 8). It contains more than 6,000 products and about 1,000 molecules (p. 101). A patent search firm matched granted Indian patents to molecules by keyword searches. About one-third of the molecules are covered by at least one product patent by the end of 2011. The outcomes are aggregated to the molecule-quarter level. They are the log of the average price per standard unit, the log of quantity, the number of selling firms and the Herfindahl index of sales.

5.10.2 Design

The identifying variation is the timing of patent grants. Different molecules received Indian patents in different quarters after the 2005 amendment. If the timing of a grant is unrelated to other changes in a molecule's market, molecules that have not yet received a patent serve as controls for those that have. Let m index molecules and t quarters. The baseline regression is DGG's eq. (1),

$$Y_{mt} = \mu_m + \tau_t + \vartheta\, t \cdot \mathbf{1}\{\text{ever patented}\}_m + \phi\, \mathbf{1}\{\text{has patent}\}_{mt} + u_{mt}. \tag{5.151}$$

Here μ_m are molecule fixed effects and τ_t year-by-quarter fixed effects. The third term gives molecules that receive a single-molecule patent during the sample their own linear trend. The indicator $\mathbf{1}\{\text{has patent}\}_{mt}$ equals one in the quarters in which molecule m is covered by at least one single-molecule patent. DGG write α_m, δ_t, λ and β for the coefficients, which we rename to avoid clashes with the AIDS parameters. The coefficient ϕ is a difference in differences. It compares the change in a molecule's outcome when its patent arrives with the change over the same quarters for molecules without a patent. Standard errors are clustered by molecule.

The event-study version is DGG's eq. (2). Let g_m be the quarter in which molecule m receives its first patent and $\bar{p}_{mt}$ the average price of its products. Then

$$\ln \bar{p}_{mt} = \mu_m + \tau_t + \sum_{k \neq 0} \phi_k\, \mathbf{1}\{t - g_m = k\} + u_{mt}. \tag{5.152}$$

The event-time indicators run from $k = -8$ to $k = 8$. DGG write the limits of the sum as $-8+$ and $8+$, so the end points bin all earlier and all later quarters. The grant quarter $k = 0$ is the omitted category, and the molecule-specific trend is dropped. Each ϕ_k measures the average log price k quarters from the grant, relative to the grant quarter and net of molecule and quarter effects.

Identification rests on two assumptions. Absent patents, log prices of molecules with early and late grants would have moved in parallel. And prices do not respond before the grant. The leads ϕ_k for $k < 0$ test both, since they should be near zero. DGG also probe anticipation directly. For molecules whose first application sat in the mailbox, firms knew least about the timing of the decision. The estimate of ϕ for this sample is 0.025 (0.012), against 0.027 (0.013) for the full sample (fn. 22). With staggered timing and effects that vary across molecules or over event time, two-way fixed-effects regressions like (5.151) can weight effects in unintended ways. Estimators robust to this problem are discussed in Appendix A.

5.10.3 Results

Figure 5.9 reproduces DGG's Figure 1. Before the grant, the point estimates lie close to zero, and the confidence bands include zero in every quarter. Prices begin to rise in the first quarters after the grant. From the third quarter on, the estimates are about 0.036 to 0.041, and the lower

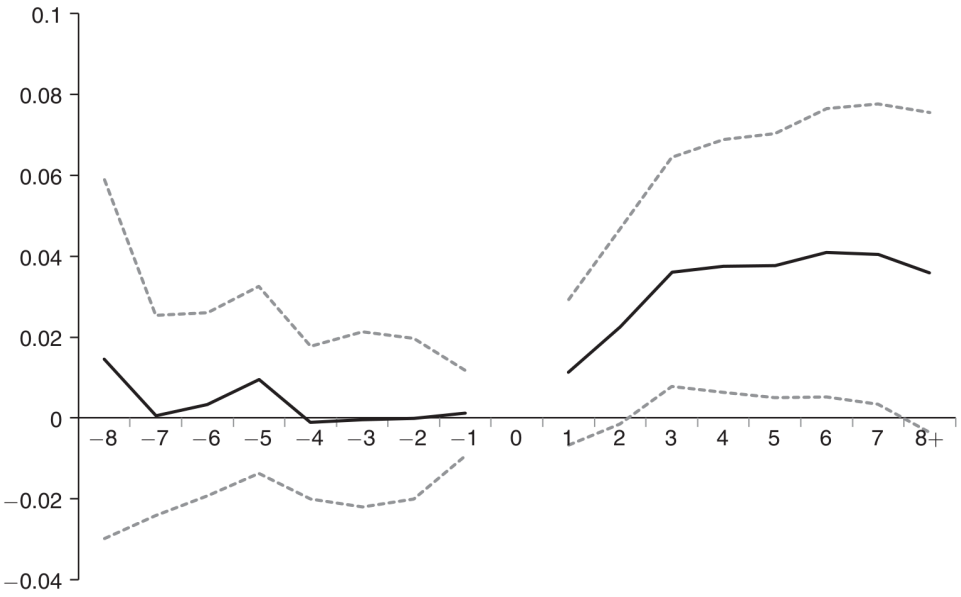

Figure 5.9: Event-study estimates for the log of the average price before and after a patent is granted, from (5.152). The horizontal axis shows quarters relative to the grant, from −8 to 8+, and the end points bin all earlier and all later quarters. The solid line shows point estimates and the dashed lines show 95 percent confidence intervals, with standard errors clustered by molecule. The grant quarter is the omitted category. Source: Duggan, Garthwaite and Goyal (2016), Figure 1.

confidence bound lies just above zero in quarters 3 to 7. The bound for the binned quarter 8+ includes zero.

Table 5.29 collects the difference-in-differences estimates. In the full sample a patent raises the average price of a molecule by 2.7 percent, and the 95 percent confidence interval rules out increases above 5.3 percent (p. 117). Among molecules that are eventually patented, where only the timing of grants varies, the estimate falls to 0.016 and is insignificant. Patents matter more for newer molecules. Among patented molecules, those first sold in India after 1995 see prices rise 4.9 percent more than older ones. The estimate for older molecules is −0.014 (0.012). In the sample of molecules approved in the United States between 1996 and 2004, patented molecules see their prices rise by about 6 percent relative to molecules with pending applications (Table 5).

The mechanism points to the grandfather clause. Among molecules first sold after 1995, a patent raises the price of a molecule that had only one producer in 2005 by about 0.17 log points, nearly 20 percent (Table 6). For molecules with several producers the estimate is 0.026 (0.022), small and insignificant. Where generic producers already existed, the royalty rule let them keep selling, and the patent holder's pricing power stayed limited (p. 122). The number of firms barely changes, and the Herfindahl index of the molecule's sales rises by 0.014 (Table 7). Sales shift toward the patent holder without exit by the incumbents. The price effects are also concentrated in molecules with small sales. Molecules with one producer sold about $0.10 million a quarter, against $1.28 million for the others (p. 125). Weighting the post-1995 regression by sales turns an estimate of 0.054 (0.019) into −0.003 (0.016) (fn. 28). DGG summarize the price effect of a patent as an average increase of 3 to 6 percent, with little effect on quantities or on the number of firms (p. 99). They add that the single-producer molecules resemble future innovations, which will face no generic rival when their patents are granted

Table 5.29: Effects of a patent grant on molecule outcomes in India

Outcome	Sample and coefficient	Estimate	Molecules	Obs.
Log price	All molecules, has patent	0.027	1,012	29,845
		(0.013)		
Log price	Patented molecules, has patent	0.016	335	10,264
		(0.013)		
Log price	Patented molecules, has patent × post-1995	0.049	335	10,264
		(0.022)		
Log price	U.S.-approved 1996–2004, has patent	0.061	46	1,236
		(0.029)		
Log price	Post-1995 molecules, has patent × only firm in 2005	0.169	651	18,908
		(0.099)

		(0.007)		

Notes: OLS estimates of (5.151) with molecule and year-by-quarter fixed effects. Standard errors clustered by molecule in parentheses. Rows 1, 2 and 6: DGG Table 4, columns 1, 2 and 5. Rows 7 and 8: Table 7, columns 1 and 5. Row 3: Table 4, column 4, the triple difference of DGG's eq. (3). Row 4: Table 5, column 1, molecules granted a patent or with a pending application. Row 5: Table 6, column 1. The Herfindahl index is measured on a scale from 0 to 1.

(pp. 124–125).

5.10.4 Why the forecast and the evidence differ

CGJ's text describes foreign price increases of between 100 and 400 percent (see Remark 5.62 for the reading of their Table 9). DGG measured 3 to 6 percent. Is the model wrong, or did the policy differ from the scenario that CGJ simulated? DGG themselves doubt that demand is the explanation. CGJ's estimates imply that an unregulated monopolist would set a price at least twice the pre-patent price (DGG, p. 122). Most of the gap comes from the scenario.

- *Which molecules.* Under the transition rules, product patents could be granted only for inventions whose applications were filed from 1995 onward. Older molecules, including all four quinolones, stayed open to generic competition. CGJ themselves note that most quinolone patents had expired and that none of their scenarios would materialize (fn. 26).
- *Grandfathering.* Indian firms already producing drugs whose patent applications were filed between 1995 and 2005 may continue to produce them on payment of a royalty (CGJ, fn. 6, and DGG, p. 106). A patent grant therefore need not remove domestic versions from the market, which is exactly the event CGJ simulate. DGG's estimates for molecules with one producer in 2005 show what happens when no domestic version remains.
- *Scope of patents.* Section 3(d) limits patents on new forms of known substances. It restricts the practice of extending protection through minor changes to a molecule, as the Glivec decision showed.
- *Remaining policy tools.* Compulsory licensing and price controls stayed available, even if they were rarely used. In CGJ's framework, compulsory licensing targets the first term of (5.150) and price controls target the third.
- *Timing.* The reform was announced a decade in advance, and grants arrived one molecule at a time. CGJ's scenario is a sudden withdrawal of all domestic versions of a molecule, with no regulation, which they present as the most extreme case.

The two studies also measure different objects. CGJ's percentages are the price changes of a remaining foreign group after every domestic competitor of the molecule disappears. DGG's estimate averages over all products in molecules that received patents under the rules India adopted, including molecules where domestic versions remained. The mechanisms CGJ identify, the loss of variety through ease of access and the compounding of losses across close domestic substitutes, are not refuted by DGG. They were not tested, because the simulated event did not occur.

The episode teaches a general lesson. A counterfactual is only as relevant as the policy scenario it simulates. Prospective and retrospective analyses complement each other. The prospective model gives welfare numbers and mechanisms for policies not yet tried, while the retrospective study measures the effects of the policy that was chosen. A credible prospective study should therefore simulate the policy most likely to be adopted, alongside the extreme case.

5.11 Assessment: what product-space demand can and cannot do

The AIDS is a flexible demand system in product space with an explicit link to preferences. It is a first-order approximation to any demand system (Proposition 5.23), and the restrictions of utility

maximization are linear in its parameters (Proposition 5.19). It aggregates across households of different incomes through a representative budget level (Section 5.4). Its expenditure function gives the compensating variation in closed form, and its finite virtual prices let it value the withdrawal of a product (Section 5.7). Combined with first-order conditions or cost bounds, it supports counterfactual equilibria, as CGJ show. At the point of approximation, only theory restricts its substitution patterns. This flexibility is its main advantage over logit and CES demand.

The costs are equally clear. The number of price parameters grows with the square of the number of products, about $\frac{J^2}{2}$, so applications need a few product groups and a multi-stage budgeting tree. Two-stage budgeting requires separability assumptions that restrict substitution across groups (Section 5.5), and the grouping must be chosen before estimation. Each price needs an instrument, and product-space parameters are product specific, so the characteristics-based instruments of discrete-choice models are unavailable. CGJ go further and impose pair-type restrictions, which tie own-price effects to cross effects. Welfare numbers for disappearing products rest on the curvature of demand far outside the data. Merger simulations show that this curvature matters: AIDS tends to predict larger price effects than logit or linear demand (Crooke et al., 1999).

Counterfactual results from such a model are informative, but they depend on three choices. The functional form fixes the shape of demand beyond the data. The instruments determine whether the elasticities are credible. And the simulated scenario must match the policy that will be adopted. The CGJ and DGG comparison shows how the third choice can dominate the other two.

The alternative is to model demand in the space of characteristics. Products become bundles of a few attributes, so the number of parameters no longer grows with the square of the number of products. New and withdrawn products are handled naturally, and characteristics of rival products supply instruments. The price is a different set of assumptions: an idiosyncratic taste shock for every product and functional forms for the distribution of tastes. Chapter 6 develops the discrete-choice foundations, Chapter 7 the logit and nested logit models with the inversion of Berry (1994), and Chapter 8 random-coefficient models such as Nevo (2001). The valuation of new goods, the mirror image of CGJ's withdrawals, returns in Chapter 10 with the multi-level demand system of Hausman (1997). Merger simulation with estimated demand systems is the subject of Chapter 11.

5.12 Bibliographic notes

The AIDS belongs to a line of work on demand systems that are consistent with utility maximization and flexible enough to test it. The linear expenditure system of Stone (1954) was the first such system estimated from an explicit utility function. The Rotterdam model of Theil (1965) and Barten (1969) and the translog model of Christensen et al. (1975) added flexibility, a property that Diewert (1974) defined formally. Deaton and Muellbauer (1980a) combined the virtues of these models. Their book (Deaton and Muellbauer, 1980b) remains the standard reference. Its §3.4 (pp. 75–78) derives the AIDS from Working-Leser Engel curves and tests homogeneity on the British data. Chapter 5 (pp. 119–147) treats separability and two-stage budgeting, and chapter 6 (pp. 148–166) treats market demand and aggregation. Its §4.3 (pp. 109–114) covers rationing and shadow prices, and §7.1 (pp. 170–179) cost-of-living indices. Deaton (1978) discusses specification and testing in applied demand analysis.

The theory of aggregation starts with the exact aggregation results of Gorman (1953, 1961).

Muellbauer (1975, 1976) introduced the PIGL and PIGLOG classes and the representative budget level that underlie the almost exact aggregation of the AIDS. The Engel curves of Working (1943) and Leser (1963) motivated the logarithmic form. Gorman (1981) bounded the rank of exactly aggregable demand systems, Lewbel (1991) defined the rank and showed how to estimate it, and Banks et al. (1997) proposed the quadratic AIDS. Hurwicz and Uzawa (1971) give conditions under which a demand system is generated by preferences. Gorman (1959) characterized two-stage budgeting, and Goldman and Uzawa (1964) and Gorman (1971) derived its implications for substitution. Barten and Turnovsky (1966) showed that weak separability alone supports a first stage with two price indices per group, and Gorman (1970) introduced implicit separability. Blackorby et al. (1978) give a comprehensive treatment of separability. On index numbers, Diewert (1976) established when the Tornqvist index is exact.

Several papers address the econometrics of the AIDS. Barten (1969) showed that maximum likelihood estimates do not depend on which share equation is dropped. Moschini (1995) analyzed the units problem of the Stone index, and Green and Alston (1990) the computation of elasticities in the linear approximate model. Lau (1978) and Moschini (1999) show how to impose curvature through a Cholesky factorization. On the welfare side, the virtual prices of Hicks (1940) and Rothbarth (1941) value products that are absent from the market. Willig (1976) bounds the gap between Marshallian surplus and the exact measures, and Hausman and Newey (1995) estimate exact consumer surplus nonparametrically.

Industrial organization adopted the multi-level AIDS for antitrust and policy analysis. Hausman et al. (1994) estimated it for beer, identified it with prices in other cities, and used it to simulate mergers. Hausman (1997) applied the same framework to value a new cereal brand, and the comment of Bresnahan (1997) questioned both the instruments and the competitive assumptions. Ellison et al. (1997) estimated a multi-stage AIDS for cephalosporin antibiotics, and Hausman and Leonard (2002) studied the competitive effects of a new product introduction. The instruments draw on the panel-data logic of Hausman and Taylor (1981), and their validity can be probed with the specification test of Hausman (1978). Nevo (2001) carried them into characteristic space. Crooke et al. (1999) show that the functional form of demand shapes simulated merger effects. Chaudhuri et al. (2006) brought these tools to patent policy, and Lanjouw (1998) supplies the Pakistani price comparison that they use as a check. Duggan et al. (2016) provide the retrospective evaluation of patents in India.

The inversion of Berry (1994) opened a different route. It made characteristic-space demand models estimable with market data and instruments for prices, and it is the starting point of Chapters 7 and 8.

5.13 Exercises

1. Start from the AIDS cost function (5.20) with unrestricted coefficients γ^*_{kj}.

   (a) Derive the Hicksian and the Marshallian budget shares. Show that demand identifies only the symmetric part $\gamma_{ij} = \frac{1}{2}(\gamma^*_{ij} + \gamma^*_{ji})$.

   (b) Show that the cost function is homogeneous of degree one in p if and only if (5.21) holds.

   (c) Count the free parameters of a J-good AIDS with adding up and homogeneity imposed, with and without symmetry. Evaluate both counts for $J = 8$ and $J = 50$, and compare them with the number of observations in the British application of Section 5.6.7.

(d) Derive the compensated and uncompensated price elasticities of the AIDS. Show that the derivative of the Hicksian share $\frac{\partial w_i(p,u)}{\partial \ln p_j}$ equals $\gamma_{ij} + \beta_i\beta_j \ln \frac{I}{\mathbf{P}}$, so that it is close to γ_{ij} when $\beta_i\beta_j$ is small (Deaton and Muellbauer, 1980b, Exercise 3.13).

(e) Suppose the AIDS holds only in the long run, and the true model is

$$w_{it} - \delta_i w_{i,t-1} = \alpha_i + \sum_{L=0}^{M} \sum_j \gamma_{ij}^L \ln p_{j,t-L} + \sum_{L=0}^{N} \beta_i^L \ln \frac{I_{t-L}}{\mathbf{P}_{t-L}} + u_{it},$$

with serially uncorrelated u_{it}. Which parameter values justify estimating the static model in levels, and which justify first differences? With $M = N = 0$ and $\delta_i > 0$, would you expect static levels estimates to reject homogeneity? How would you test the static models against this one (Deaton and Muellbauer, 1980b, Exercise 3.14)?

2. Use the running example of Example 5.21 at unit prices, and write $r = \ln I$.

(a) Verify Cournot aggregation for the second and third columns of the Marshallian matrix in Table 5.2. Verify the symmetry of $w_i \varepsilon_{ij}^h$ for the pairs $(1,3)$ and $(2,3)$.

(b) Write the matrix K of (5.32) as a function of r. Compute its nonzero eigenvalues at $r = 0$ and at $r = 4$.

(c) Show that all budget shares lie in $[0,1]$ exactly when $-\frac{10}{3} \le r \le 5$. Determine whether K stays negative semidefinite on this interval. Explain why the check must be repeated at other price vectors.

3. Three households have budgets $I_1 = 1$, $I_2 = 2$ and $I_3 = 5$ and the preferences of the running example, with $\kappa_h = 1$. All prices equal one.

(a) Compute $\bar{I}$, the representative budget I_0, the Theil index $\mathcal{T}$ and the entropy measure Z of Section 5.4.4.

(b) Compute the aggregate budget shares and compare them with the shares of a consumer whose budget is $\bar{I}$.

(c) Show that a transfer from a poorer to a richer household, holding $\bar{I}$ fixed, raises I_0. What happens to the aggregate share of a luxury, and why?

(d) A researcher fits the AIDS to a time series in which inequality rises with mean expenditure. Use the omitted-variable formula of Section 5.4.4 to predict the sign of the bias in the estimated β_i of a luxury.

(e) Give the three households PIGL preferences with $\psi = -1$ instead. Compute I_0 from (5.54), verify that it equals $\bar{I}(1 + \frac{\sigma^2}{\bar{I}^2})$, and compare it with the PIGLOG value of part (a). Prove that $I_0 = \bar{I}$ for every distribution when $\psi = 1$ (Deaton and Muellbauer, 1980b, Exercise 6.10).

4. Consider a two-level system with an AIDS at each level and a Stone index at the top.

(a) Derive the unconditional elasticity (5.79) and its closed form (5.81), stating where the Stone weights are held fixed.

(b) Show that the unconditional elasticity of q_i with respect to the category budget is the product of the expenditure elasticities at the two levels.

(c) For domestic sparfloxacin, use the segment elasticity $\varepsilon_Q = -1.11$ of Chaudhuri et al. (2006) and the share and expenditure elasticity in Table 5.24. Compute the unconditional correction to the own-price elasticity, and explain why it is small.

(d) For which values of the group's own elasticity is the unconditional own elasticity of a good smaller in magnitude than its conditional elasticity? Give the economic intuition.

5. Let good i have share $s_i = 0.10$ and signed own-price elasticity $\varepsilon_{ii} = -3$ at observed prices, with all other prices held fixed.

(a) For an AIDS good with $\beta_i = 0$, derive the virtual price and the compensating variation of removing the good, as in Proposition 5.48(c). Compute $\frac{p_i^V}{p_i^0}$ and $\frac{CV}{I}$.

(b) Compute the loss under a CES system calibrated to the same share and elasticity, and under a logit with $p_i = 1$. Compare the three numbers.

(c) Explain why the CES and logit losses are fixed by the share and one elasticity. Why does this matter for the analysis of product withdrawals such as those in Section 5.9?

6. Consider the one-product model of Section 5.8.5, with prices in city n' used as instruments for prices in city n.

(a) Suppose there are no national demand shocks, but the local demand shocks of cities n' and n have covariance $\sigma_{e,n'n} > 0$, for example because the two cities are served by one regional chain. Derive the probability limit of the IV estimator of the slope a.

(b) Propose a test of the identifying assumption that uses the residuals of the same brand in different cities in the same week. State the null hypothesis and the alternative.

(c) Explain why adding a measure of national advertising to the demand equation does not settle the issue.

7. Use the estimates of Chaudhuri et al. (2006) in Tables 5.21, 5.22 and 5.25.

(a) Write the seven price coefficients of the foreign ciprofloxacin equation and verify homogeneity. Use Proposition 5.58 to explain why the coefficient on other foreign groups is the same in all three foreign rows.

(b) Compute the conditional own-price elasticity of domestic norfloxacin at its Northern share in Table 5.24, ignoring the term $\beta_j \ln \frac{X_Q}{P_Q}$. Compare it with Table 5.22.

(c) Compute $-\frac{1}{\varepsilon_{ii}}$ from the Northern own elasticities and compare the results with the markup bounds in Table 5.25. Why does averaging over regions matter?

(d) Explain why no cost bound exists for foreign norfloxacin, and what this implies for the counterfactual.

8. Chaudhuri et al. (2006) predict that the prices of foreign quinolones would rise several-fold if all domestic versions were withdrawn. Duggan et al. (2016) estimate average price increases of 3 to 6 percent after patents were granted.

(a) List three reasons for the difference. For each, say whether it concerns the model, the simulated scenario or the object being measured.

(b) Design a retrospective study that would test the ease-of-access mechanism. State the data you would need, the source of variation and the estimating equation.

(c) Suppose prescriptions respond to promotion more than to patients' preferences. Discuss how this would change the interpretation of the welfare losses in Table 5.26.

Chapter 6

Discrete Choice Foundations and the Vertical Model

A car buyer compares the size, power and fuel economy of a few dozen models, looks at their prices, and buys one of them or keeps her old car. A demand model for such a market must say how her choice responds to the price and the attributes of every model. It must aggregate many such choices into market shares. It must also have few enough parameters that market data can pin them down, and it must predict demand at prices and for sets of products that the data have never shown.

This chapter builds the discrete choice framework that empirical industrial organization uses for this purpose. Products are bundles of characteristics, and each consumer buys the product that gives her the highest utility. Market demand for a product is the mass of consumers for whom it is the best option, so it depends on the whole distribution of tastes. The number of parameters grows with the number of characteristics and with the dimension of consumer heterogeneity. In the product-space systems of Chapter 5 it grows with the square of the number of products. The framework is the foundation of the logit, nested logit and random coefficients models of Chapters 7 and 8.

The chapter has three parts. The first develops the theory. Section 6.1 explains what the characteristics approach buys and what it costs, including the difficulty of finding instruments when firms choose their characteristics. Section 6.2 sets out random utility models and aggregates choices into market shares. It also discusses the outside good, the normalizations of utility, and the inversion from shares to mean utilities. Section 6.3 derives the closed forms of the type-I extreme value model: the logit, the log-sum formula and the generalized extreme value family. Section 6.4 then places the classical models of product differentiation in this framework and compares them.

The second part studies the *vertical model*, in which consumers agree on a ranking of products by quality and differ only in their price sensitivity. Section 6.5 derives every step of the model in closed form: the frontier of products that sell, the cutoffs, the shares, their inversion, the substitution patterns and the markups. Section 6.6 studies its leading application. Bresnahan (1987) uses the model to ask whether the American automobile boom of 1955 was a price war. His paper is the first structural test of conduct in a market with differentiated products.

The third part asks what the idiosyncratic shock of logit-type models assumes about the world. Section 6.7 shows that with the shock the product space is never exhausted. Markups stay bounded away from zero however crowded the market becomes, and every new product

adds surplus, even an exact copy of an existing one. Pure characteristics models, which drop the shock, behave differently. Section 6.8 studies how Berry and Pakes (2007) estimate them from market data. Section 6.9 studies the hedonic approach of Rosen (1974) and its adaptation to oligopolistic markets by Bajari and Benkard (2005).

The chapter draws on earlier material. The multi-product pricing condition, the existence results for price equilibria and the representative-consumer foundations of the logit come from Chapter 4. The identification of conduct in homogeneous-goods markets, which Bresnahan's test extends, is the subject of Chapter 3. Maximum likelihood, the generalized method of moments and model selection tests are covered in Appendix A, and extreme value distributions and contraction mappings in Appendix B. Looking ahead, the ownership matrix of Section 6.5.6 is the object that merger simulation changes (Chapter 11). The welfare formulas of Sections 6.3.3 and 6.7 are the starting point for valuing new goods in Chapter 10. Appendix C fits the vertical model to data simulated from a random coefficients logit and compares it with the models of Chapters 7 and 8.

6.1 Demand in characteristic space

6.1.1 Products as bundles of characteristics

The demand systems of Chapter 5 are written in product space. Each good carries its own parameters, and the model states directly how the demand for one good responds to the price of another. This chapter develops the alternative. In the *characteristics approach*, a product is a bundle of characteristics, and consumers have preferences over the characteristics rather than over the products themselves (Lancaster, 1966; Gorman, 1980). A car is a combination of size, engine power, fuel economy and brand. A breakfast cereal is a combination of sugar, fiber, texture and taste. Two products are close substitutes when they offer similar characteristics at similar prices.

The empirical form of the approach is a *discrete choice* model (McFadden, 1974). Each consumer buys at most one unit of one product, or buys nothing. Consumers differ in their tastes, so they choose different products, and in the aggregate every product is chosen by someone. The market demand for a product is the mass of consumers for whom that product is the best option. Aggregate demand therefore depends on the entire distribution of consumer tastes. A single representative taste cannot summarize it, because the products that compete for the marginal consumers determine the substitution patterns.

6.1.2 Product space and characteristic space

The first advantage of the characteristics approach is dimensionality. Consider a linear demand system $q = a + Ap$ for J products, where q and p are J-vectors. The $J \times J$ matrix A contains J^2 price coefficients. With $J = 50$ brands the system has 2,500 price coefficients, and a log-linear system has the same count (Berry and Pakes, 2007, footnote 1).[1] The restrictions of consumer theory and the separability assumptions of Chapter 5 reduce this number, but the count still grows with J. In a characteristics model the number of parameters grows with the number K of characteristics and with the dimension of consumer heterogeneity. A model in which each

[1]Throughout the chapter, page, footnote, equation and table numbers of Berry and Pakes (2007) refer to the author manuscript dated July 2, 2007 (41 pages). They do not refer to the pagination of the article in the *International Economic Review* 48(4), 1193–1225.

of K characteristics has a mean taste and a standard deviation of tastes has $2K$ taste parameters, whatever the number of products.

The second advantage concerns new products. A product that is a new combination of existing characteristics can be placed in the estimated demand system before it is launched. A new car whose size and engine power lie inside the range of existing models is an example. Products with new characteristics are a different matter. The first electric cars offered a driving range, a charging time and an absence of fuel costs that no existing car had. The data on existing cars contain no information on how consumers value those characteristics, so the model cannot predict their demand.

The characteristics approach has several drawbacks.

1. It needs more data. The researcher must observe the relevant characteristics of every product, and the richer models also use information on consumers.
2. Estimation is harder. Market shares are integrals over the distribution of tastes, so estimation involves nonlinear optimization and often simulation.
3. The functional forms can have restrictive or odd implications. The leading example is the "too many characteristics" problem of logit-type models, studied in Section 6.7.
4. Single-choice models cannot generate complementarity. Corollary 6.8 shows that any two goods in a single-choice additive random utility model are substitutes.
5. Some attributes cannot be measured. The relevant attributes of books, films or recipes are hard to code as a short vector of characteristics.

The last point underlies the objection of Hausman (1997, sec. 5.5). He describes each brand of cereal by its own indicator variable, because "no reasonable metric exists to describe 'how close' attributes are" for products such as Apple-Cinnamon Cheerios. Chapter 10 returns to this debate.

6.1.3 Two branches of theory

The theory of competition in characteristic space has two branches. The first takes the set of products as given and studies price competition. Its central question is the existence of a price equilibrium. The general answer is due to Caplin and Nalebuff (1991).[2] They obtain a pure-strategy Bertrand-Nash price equilibrium for any number of single-product firms and any configuration of products (their Theorem 2, p. 14). Two assumptions deliver it. Their assumption A1 requires each consumer's utility to be linear in an n-dimensional vector a of consumer characteristics (p. 4). It is enough that A1 and the next assumption hold for some parameterization of preferences (p. 6).

Their assumption A2 requires the density f of consumer types a to be *ρ-concave* with $\rho = -\frac{1}{n+1}$ (p. 5). A density f is ρ-concave if f^ρ is concave when $\rho > 0$, $\ln f$ is concave when $\rho = 0$, and f^ρ is convex when $\rho < 0$. A ρ-concave function is also ρ'-concave for every $\rho' < \rho$. Log-concavity is the case $\rho = 0$, so every log-concave density satisfies A2, and A2 is the weaker condition. It also covers the multivariate t distribution with at least one degree of freedom, which includes the multivariate Cauchy. Caplin and Nalebuff list the lognormal as

[2]The copy we use is Cowles Foundation Discussion Paper 937 of February 1990, the working-paper version of the article. Page numbers refer to that version.

a distribution that A2 excludes (p. 6). The exclusion applies to dispersed lognormals.[3] The proof aggregates individual demands with theorems of Prékopa and Borell. Under A1 and A2 the reciprocal $\frac{1}{D(p)}$ of each firm's demand is convex in its own price, so profit is quasi-concave in own price (their Proposition 4, p. 14). Kakutani's fixed point theorem then delivers the equilibrium. They also give conditions for uniqueness. The framework covers location models, characteristics models and probabilistic choice models such as the logit. Chapter 4 states and uses these results.

The second branch lets firms choose their positions in characteristic space, with or without a later stage of price competition. Hotelling (1929) placed firms on a line and Salop (1979) on a circle. d'Aspremont et al. (1979) showed that firms in Hotelling's model differentiate as much as they can when they anticipate price competition. Shaked and Sutton (1982) found the same force in quality choice. Sections 6.4.2 and 6.4.5 state these results. The empirical literature is almost entirely about the first branch. Empirical models of product choice are rarer, and that gap matters for identification, as the next subsection explains.

6.1.4 Endogenous characteristics and instruments

Empirical demand models in characteristic space lead to an estimating equation of the form

$$\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}. \tag{6.1}$$

Here δ_{jt} is the mean utility of product j in market t. The row vector x_{jt} collects its K observed characteristics. The price is p_{jt}, and ξ_{jt} is product quality that consumers and firms observe but the econometrician does not. Section 6.2.7 explains how δ_{jt} is recovered from market shares. Firms set prices knowing ξ_{jt}, so price is correlated with the error, and Equation (6.1) must be estimated with instruments (Chapter 7).

Two families of instruments dominate. The first consists of cost shifters, variables that move marginal cost but not utility. The second consists of functions of the characteristics of other products, such as the sums $\sum_{k \in \mathcal{J}_f, k \neq j} x_{kt}$ and $\sum_{k \notin \mathcal{J}_f} x_{kt}$ over the firm's other products and over rivals' products (Berry et al., 1995). These functions shift the markup of product j, because they measure how crowded its neighborhood is. When firms set prices by the multi-product first-order condition, the effect of other products' characteristics on the price of j also depends on who owns those products. Ackerberg et al. (2007, p. 29) trace this reasoning back at least to Bresnahan (1987). He stressed that markups are lower in "crowded" parts of the product space, and higher when "nearby" products have the same owner.[4] Section 6.6 shows both effects at work in his model. The validity of these instruments rests on the mean independence condition

$$\mathbb{E}\left[\xi_{jt} \,\middle|\, x_{1t}, \ldots, x_{J_t t}\right] = 0. \tag{6.2}$$

Characteristics-based instruments are inefficient, and they are probably inconsistent. Most researchers know this and use them for lack of better alternatives. The two problems are distinct.

[3] With one taste dimension, $n = 1$ and A2 requires $f^{-\frac{1}{2}}$ to be convex. Let $\ln a \sim N(0, \sigma^2)$ and $y = \ln a$. Then $f(a)^\rho = C \exp(\phi(y))$ with $\phi(y) = -\rho y - \frac{\rho y^2}{2\sigma^2}$ and a constant $C > 0$. Two applications of the chain rule give $\frac{d^2}{da^2} f^\rho = \frac{f^\rho}{a^2}\left[\phi'(y)^2 - \phi'(y) + \phi''(y)\right]$. The term $\phi'^2 - \phi'$ reaches its minimum $-\frac{1}{4}$ at $\phi' = \frac{1}{2}$, and ϕ' takes every real value. With $\phi'' = -\frac{\rho}{\sigma^2}$ and $\rho = -\frac{1}{2}$, the density meets A2 if and only if $\frac{1}{2\sigma^2} \geq \frac{1}{4}$, that is, $\sigma^2 \leq 2$.

[4] Page numbers of Ackerberg et al. (2007) refer to the author manuscript of June 14, 2006, prepared for the *Handbook of Econometrics*.

The first problem is consistency. Condition (6.2) treats characteristics as exogenous. Firms choose characteristics, however, and they know ξ_{jt} when they design products. The design team even has some control over ξ_{jt} itself (Ackerberg et al., 2007, p. 30). A carmaker that knows its new model has an attractive design may also give it a larger engine. Rivals may position their products close to a successful product. In both cases x_{jt} is correlated with ξ_{jt}, the moment condition fails, and the instrumental variables estimator is inconsistent. Predetermination does not repair the problem. A characteristic chosen before prices does not respond to shocks realized at the pricing stage. It still responds to any component of ξ_{jt} that the firm could foresee at the design stage. Condition (6.2) needs a timing and information assumption: the firm fixes x_{jt} before it learns ξ_{jt}, and ξ_{jt} is unpredictable at that time. This is where the second branch of theory meets identification. If product positioning is endogenous, characteristics cannot serve as instruments without a model of how they were chosen.

The second problem is efficiency. Suppose (6.2) holds. Then every function of the characteristics is a valid instrument, and sums of rival characteristics are an arbitrary choice. Chamberlain (1987) derives the efficient instrument for a conditional moment restriction $\mathbb{E}[\xi_{jt}(\theta_0) \mid z_t] = 0$, where z_t collects the exogenous variables of market t. Under conditional homoskedasticity it is proportional to

$$D(z_t) = \mathbb{E}\left[\frac{\partial \xi_{jt}(\theta_0)}{\partial \theta} \,\middle|\, z_t\right]. \tag{6.3}$$

Ad hoc sums of characteristics do not reproduce this function. In addition, characteristics vary little across markets and over time, so instruments built from them are often weak. Chapter 8 discusses approximations to (6.3).

We now make the characteristics approach precise. Section 6.2 writes it as a random utility model and aggregates individual choices into market shares. Section 6.3 derives the closed forms that one distribution of the idiosyncratic shock delivers. These two sections supply the language in which every demand model of this chapter and of Chapters 7 and 8 is written.

6.2 Random utility and aggregation to market shares

6.2.1 The random utility model

We consider a market with consumers $i = 1, \ldots, I$ and products $j = 0, 1, \ldots, J$. Product 0 is the *outside good*, the option of buying none of the inside products $\mathcal{J} = \{1, \ldots, J\}$. We suppress the market index t when no confusion arises. Consumer i obtains utility

$$u_{ij} = U(x_j, p_j, \xi_j, \nu_i; \theta), \qquad j = 0, 1, \ldots, J, \tag{6.4}$$

from product j. Here ν_i is a vector of consumer tastes drawn from a distribution F, and θ is a vector of demand parameters. The conduct parameter of Chapter 3 does not appear in this chapter. Firm conduct enters through the ownership or cooperation matrix Ω instead (Section 6.6). The consumer buys product j if and only if $u_{ij} \geq u_{ik}$ for every k.

Definition 6.1 (Random utility model and market shares)**.** A *random utility model* specifies the utility function (6.4) and the taste distribution F. The *acceptance set* of product j is the set of tastes for which j is optimal,

$$A_j(\theta) = \left\{\nu : U(x_j, p_j, \xi_j, \nu; \theta) \geq U(x_k, p_k, \xi_k, \nu; \theta) \text{ for all } k = 0, 1, \ldots, J\right\}. \tag{6.5}$$

The *market share* of product j is the probability mass of its acceptance set,

$$s_j(\theta) = \int \mathbf{1}\{v \in A_j(\theta)\}\, \mathrm{d}F(v) = \mathbb{P}\big(v_i \in A_j(\theta)\big). \tag{6.6}$$

With M potential buyers in the market, the demand for product j is $q_j = M s_j(\theta)$.

The acceptance sets of two products can overlap only at tastes where the consumer is indifferent between them. We rule out such ties with positive probability.

Assumption 6.2 (No ties)**.** For every pair $j \neq k$, $\mathbb{P}\big(U(x_j, p_j, \xi_j, v_i; \theta) = U(x_k, p_k, \xi_k, v_i; \theta)\big) = 0$.

The assumption holds in the models of this book. In an additive model $u_{ij} = V_{ij} + \epsilon_{ij}$ with a continuously distributed vector ϵ_i, a tie requires $\epsilon_{ij} - \epsilon_{ik} = V_{ik} - V_{ij}$, an event of probability zero. In the vertical model of Section 6.5, two products tie for a single value of the scalar taste, which has probability zero when F is continuous. Under Assumption 6.2 the acceptance sets partition the taste space up to a null set, and

$$\sum_{j=0}^{J} s_j(\theta) = 1.$$

The market size M counts the potential buyers, including those who choose the outside good. It is never observed directly. The researcher must assume it, for example as the number of households in a market, and the choice affects the estimates through the outside share $s_0 = 1 - \sum_{j \geq 1} \frac{q_j}{M}$.

The latent variable formulation. McFadden (1984, sec. 3.1) places the random utility model inside a broader class of qualitative response models. Let m responses be indexed by $j = 1, \ldots, m$. A vector of latent variables $y^* = x\beta - \epsilon$ takes values in $\mathbb{R}^h$, and ϵ has distribution $F(\epsilon \mid x)$. A partition $A_1, \ldots, A_m$ of $\mathbb{R}^h$ defines a generalized indicator: response j is observed if and only if $y^* \in A_j$. The response probability is

$$P_j = \mathbb{P}(x\beta - \epsilon \in A_j \mid x) = F\big(\{x\beta\} - A_j \mid x\big), \qquad \{x\beta\} - A_j = \{\epsilon : x\beta - \epsilon \in A_j\} \tag{6.7}$$

(McFadden, 1984, eq. 3.2, p. 1403). Utility maximization is the case $h = m$ in which y_j^* is the utility of alternative j and A_j is the set of latent vectors whose j-th component is largest. The same apparatus covers ordered responses, where a scalar latent variable falls between thresholds, and vectors of binary responses, where the sets A_j are products of half-lines (McFadden, 1984, pp. 1403–1404).

Two observations of McFadden (1984) frame the rest of this chapter. The first concerns the meaning of the disturbance. It may represent factors known to the decision maker but not to the econometrician. It may also represent randomness in the decision protocol itself, so that the same person facing the same options could choose differently. McFadden (1984, p. 1412) notes that the two readings cannot ordinarily be distinguished, unless the decision protocol is observable or individuals face many decisions in experiments. The second concerns the direction of modeling. One could write down a convenient probability model and then ask whether a population of utility maximizers could have generated it. For consumers, the known sufficient conditions for this are quite restrictive (McFadden, 1984, p. 1406). The additive random utility models of Section 6.2.4 avoid the question by construction: they start from utilities and derive the probabilities.

What the shock represents. In applications the idiosyncratic term has several readings. It may capture consumer characteristics that the econometrician does not observe, such as the distance from a consumer's home to a dealer. It may capture product characteristics that consumers value differently. It may absorb measurement error in prices or characteristics, or the approximation error of a parametric utility function. Finally, it may reflect psychological biases or optimization errors. The last reading matters for welfare. The welfare formulas of Section 6.3.3 count the realized shock as utility. If the shock is a mistake, those formulas overstate the benefit of choice, a point taken up in Section 6.7 and Chapter 10.

Why a structural error is needed. The product-level term ξ_j plays the role of the error in a classical demand and supply model. Without it, a model with a few parameters cannot fit J observed shares, because products with identical observed characteristics would have identical predicted shares. With it, the model fits the data, and the source of price endogeneity becomes explicit: firms see ξ_j when they set prices. Chapter 7 treats the resulting instrumental variables problem in full.

Single-unit purchases. The model assumes that each consumer buys one unit of one product. This is a good approximation for durable goods bought one at a time, such as cars, airline tickets and houses. It is a poor approximation for groceries. A household buys several units and several varieties of cereal or yogurt on a single trip, so a single-choice model misses both the quantity decision and any complementarity between varieties. Extensions handle multiple discrete choices (Hendel, 1999), treated in Chapter 7, and bundles of complementary goods (Gentzkow, 2007), treated in Chapter 10.

6.2.2 The outside good

Most demand models in characteristic space include an outside good. Three reasons favor it, and one cost comes with it.

1. It allows the demand for the whole category to respond to prices. Without it, a common price increase leaves total category demand unchanged (Proposition 6.3).
2. It provides the location normalization of utility. Inside utilities are measured relative to the utility of not buying (Proposition 6.4).
3. It is needed for welfare analysis. A new product can draw consumers who previously bought nothing, and its value depends on how many do.
4. It has a cost. Shares of the outside good require a definition of market size, which is an assumption.

Proposition 6.3 (Demand without an outside good)**.** *Suppose consumers choose only among the inside products $j = 1, \dots, J$, with*

$$u_{ij} = x_j\beta + \xi_j - \alpha_i p_j + \mu_{ij} + \epsilon_{ij},$$

where $\alpha_i > 0$, and μ_{ij} and ϵ_{ij} do not depend on prices. For every scalar c and every product j, $s_j(p + c\mathbf{1}) = s_j(p)$, where $\mathbf{1}$ is the J-vector of ones. Hence total category demand equals M at all prices. Moreover, consider a firm that owns all J products and has constant marginal costs mc_j. Its profit satisfies $\Pi(p + c\mathbf{1}) = \Pi(p) + cM$, which is unbounded in c, so the firm has no finite profit-maximizing price vector.

Proof. Raising every price by c changes each utility of consumer i by the same amount:

$$u_{ij}(p + c\mathbf{1}) = u_{ij}(p) - \alpha_i c \qquad \text{for all } j.$$

The utility differences $u_{ij} - u_{ik}$ are unchanged, so every consumer makes the same choice and every share is unchanged. Total demand is $M \sum_{j=1}^{J} s_j = M$. For the profit of the multi-product firm,

$$\begin{aligned}\Pi(p + c\mathbf{1}) &= \sum_{j=1}^{J} (p_j + c - mc_j)\, M s_j(p + c\mathbf{1}) \\ &= \sum_{j=1}^{J} (p_j - mc_j)\, M s_j(p) + cM \sum_{j=1}^{J} s_j(p) \\ &= \Pi(p) + cM.\end{aligned}$$

The last expression grows without bound as $c \to \infty$. □

The result depends on two features: the absence of an outside option and utility that is linear in price. With an outside good $u_{i0} = \epsilon_{i0}$ whose price is normalized to zero, a common price increase lowers every inside utility relative to the outside option, and the inside shares fall. With income effects, a common price increase changes utility differences, because the marginal utility of money changes with the money left over. The outside good is the natural fix, and every discrete choice model in the rest of the book includes one.

6.2.3 Normalizations and what is identified

Utility is ordinal. Only the ranking of alternatives matters for choice, so many utility functions generate the same choices. The next proposition states the invariance that drives the normalizations used in practice.

Proposition 6.4 (Invariance of choices)**.** *Let $\tilde{u}_{ij} = a_i + b_i u_{ij}$ for $j = 0, 1, \ldots, J$, where a_i and $b_i > 0$ may depend on the consumer, on her tastes and on anything common to all alternatives, but not on j. Then consumer i makes the same choice under $\tilde{u}$ as under u, and every acceptance set and every market share is unchanged.*

Proof. For any pair j, k,

$$\tilde{u}_{ij} \geq \tilde{u}_{ik} \iff a_i + b_i u_{ij} \geq a_i + b_i u_{ik} \iff u_{ij} \geq u_{ik},$$

where the last step divides by $b_i > 0$. The optimal choice is therefore the same for every taste vector. The acceptance sets (6.5) and the shares (6.6) are unchanged. □

The same argument applies to any strictly increasing transformation that is common to the alternatives. Two normalizations follow.

1. *Location.* Setting $a_i = -u_{i0}$ and $b_i = 1$ gives $\tilde{u}_{i0} = 0$. Inside utilities are then measured relative to the outside good. When the outside utility contains a random term, $u_{i0} = V_{i0} + \epsilon_{i0}$, the usual normalization sets only its deterministic part to zero, $V_{i0} = 0$.

2. *Scale.* Setting $b_i = \frac{1}{\sigma_\epsilon}$ in a model $u_{ij} = V_{ij} + \sigma_\epsilon \epsilon_{ij}$ removes the scale of the shock. The parameter vectors $(\beta, \alpha, \sigma_\epsilon)$ and $(c\beta, c\alpha, c\sigma_\epsilon)$ with $c > 0$ are observationally equivalent. We must fix one of them, either the variance of the shock or one coefficient. In the vertical model of Section 6.5 the analogous step fixes the mean of the price sensitivity ν_i.

A consumer-specific scale b_i is also not identified separately from tastes. A model in which the scale of utility varies across consumers is observationally equivalent to a random coefficients model in which all of a consumer's coefficients move in proportion.

Remark 6.5 (Variables that do not vary across alternatives). A consumer attribute that enters all utilities in the same way cancels from every comparison. In $u_{ij} = x_j\beta + z_i\gamma + \epsilon_{ij}$, the term $z_i\gamma$ drops out, and γ is not identified from choices (McFadden, 1984, p. 1412). Consumer attributes matter only through interactions with alternative-specific terms. Examples are an income-price interaction, or the specification $z_i\gamma_j$ with alternative-specific coefficients. The latter needs a normalization such as $\gamma_0 = 0$ (McFadden, 1984, eq. 3.16, p. 1413). The same logic restricts the multinomial probit of Section 6.3.5. Only the covariance matrix of utility differences matters, and it is identified only up to scale. With $J + 1$ alternatives the differences relative to one alternative have a $J \times J$ covariance matrix with $\frac{J(J+1)}{2}$ distinct elements, and one of them is fixed by the scale normalization.

Income. Income enters utility through a function $f(y_i, p_j)$ of income y_i and price,

$$u_{ij} = f(y_i, p_j) + \delta_j + \mu_{ij} + \epsilon_{ij}. \tag{6.8}$$

In this subsection δ_j collects only the non-price part of mean utility, because price enters through f. Economic sense suggests $f_y > 0$, $f_p < 0$ and $f_{py} \geq 0$. The first says that money left over raises utility. The second says that price lowers it. The third says that the marginal disutility of price falls with income, so richer consumers are less price sensitive. Berry et al. (1995) use $f(y_i, p_j) = \alpha \ln(y_i - p_j)$, for which

$$\begin{aligned} f_y &= \frac{\alpha}{y_i - p_j} > 0, \\ f_p &= -\frac{\alpha}{y_i - p_j} < 0, \\ f_{py} &= \frac{\partial}{\partial y_i}\left(-\frac{\alpha}{y_i - p_j}\right) = \frac{\alpha}{(y_i - p_j)^2} > 0. \end{aligned}$$

The price sensitivity $-f_p$ falls as income rises. The quasi-linear form $f(y_i, p_j) = \alpha(y_i - p_j)$ has $f_{py} = 0$. The term αy_i is then common to all alternatives, including the outside good with $u_{i0} = \alpha y_i + \epsilon_{i0}$, and it cancels by Proposition 6.4. Income matters for choices only when $f_{py} \neq 0$ or when income interacts with other terms.

6.2.4 Additive random utility and the social surplus function

Most empirical models separate utility into a part that depends on observables and parameters and an additive random part.

Definition 6.6 (Additive random utility model)**.** An *additive random utility model* (ARUM) has

$$u_{ij} = V_{ij} + \epsilon_{ij}, \qquad j = 0, 1, \ldots, J, \tag{6.9}$$

where V_{ij} is a deterministic function of product attributes, consumer attributes and parameters. The vector $\epsilon_i = (\epsilon_{i0}, \ldots, \epsilon_{iJ})$ has a joint density, finite means, and is independent of $V_i = (V_{i0}, \ldots, V_{iJ})$. The choice probabilities are

$$P_j(V_i) = \mathbb{P}\big(V_{ij} + \epsilon_{ij} > V_{ik} + \epsilon_{ik} \text{ for all } k \neq j\big).$$

The *social surplus function* is the expected maximum utility,

$$G(V) = \mathbb{E}\Big[\max_{j=0,\ldots,J} (V_j + \epsilon_j)\Big]. \tag{6.10}$$

Random coefficients fit this definition conditional on the taste draw. With $u_{ij} = \delta_j + \mu_{ij} + \epsilon_{ij}$, we set $V_{ij} = \delta_j + \mu_{ij}$ for a given draw ν_i, and the market share averages $P_j(V_i)$ over the distribution of ν_i. The next theorem is the foundation of welfare analysis with discrete choice models.

Theorem 6.7 (Williams, Daly and Zachary)**.** *Under Definition 6.6, the social surplus function has the following properties.*

(i) G is finite and convex, and $G(V + c\mathbf{1}) = G(V) + c$ for every scalar c.

(ii) G is differentiable, and $\frac{\partial G(V)}{\partial V_j} = P_j(V)$ for every j.

Proof. Write $m(V, \epsilon) = \max_j (V_j + \epsilon_j)$, so that $G(V) = \mathbb{E}[m(V, \epsilon)]$.

Finiteness. Since $|m(V, \epsilon)| \leq \sum_j |V_j| + \sum_j |\epsilon_j|$ and each ϵ_j has a finite mean, $G(V)$ is finite.

Translation. Adding c to every V_j adds c to every term inside the maximum:

$$m(V + c\mathbf{1}, \epsilon) = \max_j (V_j + c + \epsilon_j) = c + m(V, \epsilon).$$

Taking expectations gives $G(V + c\mathbf{1}) = G(V) + c$.

Convexity. For fixed ϵ, $V \mapsto m(V, \epsilon)$ is the maximum of the affine functions $V \mapsto V_j + \epsilon_j$, so it is convex. For $\lambda \in [0, 1]$,

$$m(\lambda V + (1 - \lambda)V', \epsilon) \leq \lambda m(V, \epsilon) + (1 - \lambda) m(V', \epsilon).$$

Taking expectations preserves the inequality, so G is convex.

Derivative. Fix j and let e_j be the j-th unit vector. Because ϵ has a density, the event that two alternatives tie has probability zero. Fix a realization ϵ without ties. If j is the unique maximizer, then for h small enough j remains the maximizer, and $m(V + he_j, \epsilon) - m(V, \epsilon) = h$. If j is not the maximizer, then for h small enough the maximum does not change. Hence

$$\lim_{h \to 0} \frac{m(V + he_j, \epsilon) - m(V, \epsilon)}{h} = \mathbf{1}\{j \text{ maximizes } V_k + \epsilon_k\}$$

for almost every ϵ. The maximum changes by at most $|h|$ when one argument changes by h, so the difference quotient is bounded by one in absolute value. By dominated convergence,

$$\frac{\partial G(V)}{\partial V_j} = \mathbb{E}\left[\lim_{h \to 0} \frac{m(V + he_j, \epsilon) - m(V, \epsilon)}{h}\right] = \mathbb{P}\big(j \text{ maximizes } V_k + \epsilon_k\big) = P_j(V).$$

A convex function whose partial derivatives exist at a point is differentiable at that point, which completes the proof. □

The result is due to Williams (1977) and Daly and Zachary (1978), and McFadden (1981) developed it. Its corollaries are the discrete choice counterparts of the integrability conditions of consumer theory.

Corollary 6.8 (Properties of choice probabilities)**.** *Under Definition 6.6, the following hold.*

(a) $\sum_{j=0}^{J} P_j(V) = 1$.

(b) $P_j(V + c\mathbf{1}) = P_j(V)$, *so* $\sum_{k=0}^{J} \frac{\partial P_j}{\partial V_k} = 0$ *wherever* P_j *is differentiable.*

(c) $\frac{\partial P_j}{\partial V_k} \le 0$ *for* $k \neq j$, *and* $\frac{\partial P_j}{\partial V_j} \ge 0$.

(d) If G *is twice continuously differentiable,* $\frac{\partial P_j}{\partial V_k} = \frac{\partial P_k}{\partial V_j}$ *for all* j, k.

Proof. For (a), differentiate the translation property of Theorem 6.7 with respect to c: $\sum_j \frac{\partial G}{\partial V_j} = 1$. For (b), the event that j is chosen does not change when all V_k rise by c. Differentiating $P_j(V + c\mathbf{1}) = P_j(V)$ with respect to c gives the sum. For (c), raising V_k with $k \neq j$ shrinks the event $\{V_j + \epsilon_j > V_l + \epsilon_l \text{ for all } l \neq j\}$, so P_j weakly falls. The own derivative then satisfies $\frac{\partial P_j}{\partial V_j} = -\sum_{k \neq j} \frac{\partial P_j}{\partial V_k} \ge 0$ by (b). For (d), $\frac{\partial P_j}{\partial V_k} = \frac{\partial^2 G}{\partial V_k \partial V_j} = \frac{\partial^2 G}{\partial V_j \partial V_k} = \frac{\partial P_k}{\partial V_j}$ by Young's theorem. □

Theorem 6.7 plays the role of Roy's identity: choice probabilities are the gradient of a surplus function. Part (d) of the corollary is the counterpart of Slutsky symmetry. Part (c) shows that all alternatives are substitutes in a single-choice model: an increase in the attractiveness of k can only lower the probability of choosing j. Since price lowers V_k, this means $\frac{\partial s_j}{\partial p_k} \ge 0$ for all $k \neq j$, which is the absence of complementarity noted in Section 6.1.2. McFadden (1981) also proves a converse. Under sign conditions on its higher mixed partial derivatives, a function with the properties of Theorem 6.7 is the social surplus function of some ARUM. For the hierarchical models of Section 6.3.4, McFadden (1984, p. 1425) introduces a generating function H whose logarithmic derivatives are the response probabilities. He notes that it "can be interpreted as a measure of social utility".

Welfare. The social surplus function measures welfare in money when utility is quasi-linear. Let

$$V_{ij} = \alpha(y_i - p_j) + w_j, \qquad p_0 = 0, \quad w_0 = 0, \tag{6.11}$$

where w_j collects the non-price terms. Consider a change in the environment from (p^0, w^0) to (p^1, w^1), with deterministic utilities V^0 and V^1. The change may also add or remove products. The *compensating variation* $CV(\epsilon)$ of a consumer with shock vector ϵ is the income that can be taken from her after the change while leaving her original maximum utility intact. A negative value is a payment to her. It solves

$$\max_j \left[\alpha(y_i - CV - p_j^1) + w_j^1 + \epsilon_j\right] = \max_j \left[V_j^0 + \epsilon_j\right].$$

The left side equals $\max_j(V_j^1 + \epsilon_j) - \alpha\, CV$. Solving,

$$CV(\epsilon) = \frac{1}{\alpha}\Big[\max_j(V_j^1 + \epsilon_j) - \max_j(V_j^0 + \epsilon_j)\Big].$$

Taking expectations over ϵ gives the expected compensating variation of Small and Rosen (1981),

$$\mathbb{E}[CV] = \frac{1}{\alpha}\big[G(V^1) - G(V^0)\big]. \tag{6.12}$$

Expected consumer surplus is therefore $\frac{G(V)}{\alpha}$ up to an additive constant. By Theorem 6.7 its derivative with respect to a price is $\frac{1}{\alpha}\frac{\partial G}{\partial V_k}\frac{\partial V_k}{\partial p_k} = -P_k$, the expected demand for k. A price change thus has the familiar welfare cost of the area to the left of the demand curve. Without quasi-linearity the marginal utility of money varies with income, and the welfare change has no closed form. Section 6.3.3 evaluates (6.12) in closed form for the logit.

6.2.5 A first example: two goods with additive shocks

The geometry of acceptance sets is easiest to see with two inside goods. Let

$$u_{i0} = 0, \qquad u_{ij} = \delta_j + \epsilon_{ij}, \quad j = 1, 2,$$

where $(\epsilon_{i1}, \epsilon_{i2})$ has a joint density g. The consumer compares three utilities, and the (ϵ_1, ϵ_2) plane splits into three regions.

- She buys nothing if $\delta_1 + \epsilon_1 < 0$ and $\delta_2 + \epsilon_2 < 0$, that is, if $\epsilon_1 < -\delta_1$ and $\epsilon_2 < -\delta_2$.
- She buys good 1 if $\delta_1 + \epsilon_1 > 0$ and $\delta_1 + \epsilon_1 > \delta_2 + \epsilon_2$, that is, if $\epsilon_1 > -\delta_1$ and $\epsilon_2 < \epsilon_1 + \delta_1 - \delta_2$.
- She buys good 2 if $\epsilon_2 > -\delta_2$ and $\epsilon_2 > \epsilon_1 + \delta_1 - \delta_2$.

The three boundaries meet at the corner point $(-\delta_1, -\delta_2)$. One ray runs down from the corner along $\epsilon_1 = -\delta_1$ and separates goods 0 and 1. One ray runs left along $\epsilon_2 = -\delta_2$ and separates goods 0 and 2. The third ray runs up and to the right along the 45-degree line $\epsilon_2 = \epsilon_1 + \delta_1 - \delta_2$ and separates goods 1 and 2. Figure 6.1 draws the partition. The shares are the probability masses of the regions:

$$\begin{aligned} s_0 &= \int_{-\infty}^{-\delta_1} \int_{-\infty}^{-\delta_2} g(\epsilon_1, \epsilon_2)\, \mathrm{d}\epsilon_2\, \mathrm{d}\epsilon_1, \\ s_1 &= \int_{-\delta_1}^{\infty} \int_{-\infty}^{\epsilon_1 + \delta_1 - \delta_2} g(\epsilon_1, \epsilon_2)\, \mathrm{d}\epsilon_2\, \mathrm{d}\epsilon_1, \\ s_2 &= 1 - s_0 - s_1. \end{aligned}$$

With independent shocks and marginal *cumulative distribution functions* (CDFs) F_1 and F_2 with densities f_1 and f_2, these reduce to $s_0 = F_1(-\delta_1)F_2(-\delta_2)$ and $s_1 = \int_{-\delta_1}^{\infty} f_1(\epsilon)F_2(\epsilon + \delta_1 - \delta_2)\, \mathrm{d}\epsilon$.

Raising δ_1 moves the corner point to the left and shifts the 45-degree boundary up. Region 1 grows at the expense of both other regions. How much it takes from each depends on the density g near the moving boundaries. With independent standard Gumbel shocks, the shares take the logit form of Proposition 6.11. For $\delta_1 = 0.5$ and $\delta_2 = 1$ the shares of goods 0, 1 and 2 are 0.186, 0.307 and 0.507. After δ_1 rises to 1.3 they are 0.135, 0.497 and 0.368. Goods 0 and 2 each keep the same fraction, 0.727, of their original share. This proportional loss is the independence of irrelevant alternatives property of Section 6.3.4. A density with more mass near the 45-degree ray would make good 2 the closer substitute and change the split.

6.2.6 From individual choices to data

Micro data. Suppose we observe the choices of n consumers. Let $y_{ij} = 1$ if consumer i chooses j and $y_{ij} = 0$ otherwise, and let x_i collect the attributes of the consumer and of the alternatives

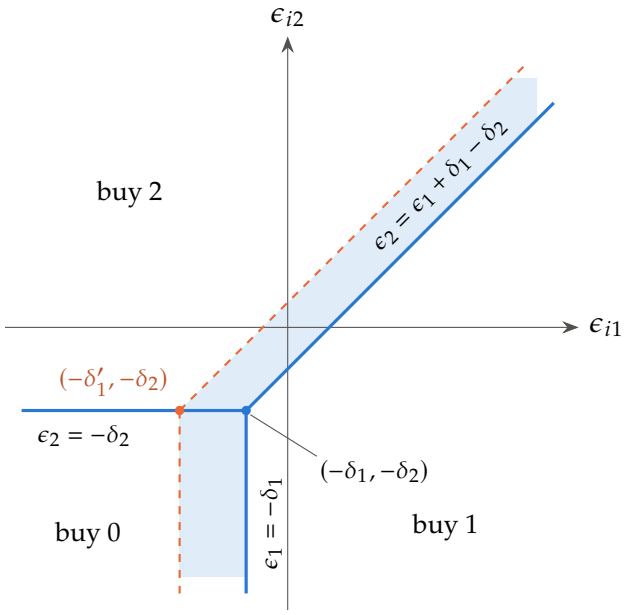

Figure 6.1: Acceptance sets in the two-goods model $u_{ij} = \delta_j + \epsilon_{ij}$, $u_{i0} = 0$. Solid lines are the boundaries for $\delta_1 = 0.5$ and $\delta_2 = 1$. Dashed lines are the boundaries after δ_1 rises to $\delta_1' = 1.3$. The boundary $\epsilon_2 = -\delta_2$ does not move. The shaded areas are the tastes that switch to good 1, from good 0 (lower strip) and from good 2 (upper band).

she faces. Let $P_j(x_i, \theta)$ be the model's choice probability. With independent observations the normalized log-likelihood is

$$L_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \sum_{j=0}^{J} y_{ij} \ln P_j(x_i, \theta) \tag{6.13}$$

(McFadden, 1984, eqs. 3.5–3.6, p. 1407). McFadden (1984, sec. 3.2) gives regularity conditions under which the maximum likelihood estimator is consistent and asymptotically normal. Informally they are the following. The response probabilities are measurable in x and continuous in θ, and the true value θ_0 is interior. A global identification condition holds: for every $r > 0$ there is a $\kappa > 0$ such that $|\theta - \theta_0| \geq r$ implies

$$\int \sum_j P_j(x, \theta_0) \ln \frac{P_j(x, \theta_0)}{P_j(x, \theta)} \, \mathrm{d}p(x) \geq \kappa, \tag{6.14}$$

where $p(x)$ is the distribution of the explanatory variables. The left side is the expected Kullback-Leibler divergence between the true and the candidate response probabilities. The condition says that no other parameter value fits the population as well as θ_0. Further conditions bound the probabilities and their first derivatives near θ_0, and require a nonsingular information matrix

$$\mathcal{I}(\theta_0) = \int \sum_j P_j(x, \theta_0) \frac{\partial \ln P_j(x, \theta_0)}{\partial \theta} \frac{\partial \ln P_j(x, \theta_0)}{\partial \theta^\top} \, \mathrm{d}p(x).$$

Under these conditions McFadden's Theorems 1 to 3 establish three results (McFadden, 1984, p. 1408). Any sequence of approximate maximizers of L_n converges almost surely to θ_0. A

unique root of the likelihood equations eventually exists and is consistent. Finally, $\sqrt{n}(\hat{\theta} - \theta_0)$ converges to a normal distribution with covariance matrix $\mathcal{I}(\theta_0)^{-1}$. The theorems require no second or third derivatives. They also do not imply that every root of the first-order conditions is consistent (McFadden, 1984, p. 1409).

The *multinomial logit*, derived in Section 6.3.2, illustrates the conditions. Let $P_j(x_i, \theta) = \frac{e^{x_{ij}\theta}}{\sum_k e^{x_{ik}\theta}}$, where x_{ij} is a $1 \times K$ row of attributes of alternative j for consumer i. The contribution of consumer i to the log-likelihood is

$$\ell_i(\theta) = \sum_j y_{ij} x_{ij} \theta - \ln \sum_k e^{x_{ik}\theta},$$

where we used $\sum_j y_{ij} = 1$. Differentiating,

$$\frac{\partial \ell_i(\theta)}{\partial \theta} = \sum_j y_{ij} x_{ij}^\top - \sum_k P_k(x_i, \theta) x_{ik}^\top = \sum_j y_{ij} \big(x_{ij} - \bar{x}_i(\theta)\big)^\top, \tag{6.15}$$

with $\bar{x}_i(\theta) = \sum_k P_k(x_i, \theta) x_{ik}$ (McFadden, 1984, eq. 3.11, p. 1409). The derivative of $\bar{x}_i(\theta)^\top$ is $\sum_k P_k x_{ik}^\top (x_{ik} - \bar{x}_i) = \sum_k P_k (x_{ik} - \bar{x}_i)^\top (x_{ik} - \bar{x}_i)$, so the Hessian is

$$\frac{\partial^2 \ell_i(\theta)}{\partial \theta \, \partial \theta^\top} = -\sum_k P_k(x_i, \theta) \big(x_{ik} - \bar{x}_i(\theta)\big)^\top \big(x_{ik} - \bar{x}_i(\theta)\big). \tag{6.16}$$

It is negative semidefinite for every θ, because for every $v \in \mathbb{R}^K$

$$v^\top \frac{\partial^2 \ell_i(\theta)}{\partial \theta \, \partial \theta^\top} v = -\sum_k P_k(x_i, \theta) \big((x_{ik} - \bar{x}_i(\theta))v\big)^2 \le 0.$$

The deviations always satisfy $\sum_k P_k (x_{ik} - \bar{x}_i) = 0$, so they are linearly dependent. One consumer's Hessian is therefore singular whenever K is at least the number of alternatives. Summed over consumers, the Hessian is negative definite unless some $v \neq 0$ satisfies $(x_{ik} - \bar{x}_i)v = 0$ for every i and k. That happens exactly when $x_{ik} v$ is the same for all alternatives of every consumer, a condition that does not depend on θ. The logit log-likelihood is therefore globally concave, and any stationary point is the global maximum (McFadden, 1984, pp. 1409 and 1413). The first-order condition $\sum_i \sum_j y_{ij} (x_{ij} - \bar{x}_i(\hat{\theta})) = 0$ is a moment-matching condition. The average attributes of the chosen alternatives equal the averages predicted by the model. When x_{ij} contains a dummy for each alternative, the corresponding equations read $\sum_i y_{ij} = \sum_i P_j(x_i, \hat{\theta})$. The alternative constants then fit the observed shares exactly, an idea that returns in Section 6.2.7.

Market data. Industrial organization usually works with market data: prices, characteristics and quantities q_{jt} in many markets t. The observed shares are $s_{jt} = \frac{q_{jt}}{M_t}$. If M_t consumers choose independently with probabilities σ_{jt}, the observed share is an average of M_t Bernoulli draws, and its standard deviation is

$$\operatorname{sd}(s_{jt}) = \sqrt{\frac{\sigma_{jt}(1 - \sigma_{jt})}{M_t}}. \tag{6.17}$$

The relative error $\frac{\operatorname{sd}(s_{jt})}{\sigma_{jt}}$ is about $\frac{1}{\sqrt{M_t \sigma_{jt}}}$, so it depends on the number of buyers $M_t \sigma_{jt}$. With a million potential buyers and a true share of 0.0001, a product has about 100 buyers, and its

observed share has a relative standard deviation of about 10 percent. With a share of 0.01 the relative error falls to about 1 percent. Small shares are therefore measured with noticeable error even in large markets, which matters when the model is inverted to recover ξ_{jt} (Section 6.8 and Berry et al., 2004b).

A likelihood for market data is harder to write than (6.13). The model share $\sigma_j(x_t, p_t, \xi_t; \theta)$ depends on the unobserved ξ_t, and equilibrium prices depend on ξ_t as well. A likelihood would need the joint distribution of prices and ξ_t, which requires a full model of pricing. The inversion strategy avoids this step.

6.2.7 The inversion strategy

The inversion strategy turns a nonlinear demand model into a linear instrumental variables problem. Write the model shares in market t as functions of the vector of mean utilities $\delta_t = (\delta_{1t}, \ldots, \delta_{J_t t})$ and of the parameters θ_2 that govern the consumer-specific terms μ_{ijt},

$$s_t = \sigma(\delta_t; \theta_2). \tag{6.18}$$

The strategy has three steps.

1. For a given θ_2, solve the system $s_t = \sigma(\delta_t; \theta_2)$ for the mean utilities that match the observed shares exactly: $\delta_t(\theta_2) = \sigma^{-1}(s_t; \theta_2)$.
2. Write the recovered mean utilities as the linear model (6.1), $\delta_{jt}(\theta_2) = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$. The structural error ξ_{jt} enters linearly, like the error of a regression.
3. Estimate (β, α), and θ_2 if present, from moment conditions $\mathbb{E}[z_{jt}\xi_{jt}(\theta)] = 0$ with instruments z_{jt} for price.

In the plain logit, $\sigma_j(\delta_t) = \frac{e^{\delta_{jt}}}{1+\sum_k e^{\delta_{kt}}}$. Dividing by the outside share $\sigma_0 = \frac{1}{1+\sum_k e^{\delta_{kt}}}$ gives $\frac{s_{jt}}{s_{0t}} = e^{\delta_{jt}}$, so

$$\delta_{jt} = \ln s_{jt} - \ln s_{0t}.$$

This is the inversion of Berry (1994), studied in Chapter 7.

The first step requires that $\sigma(\cdot\,; \theta_2)$ be invertible. Existence and uniqueness of the inverse are properties of the demand model. Berry (1994) proved invertibility for a broad class of models with an additive shock. Berry et al. (2013) gave general conditions they call *connected substitutes*. Raising the mean utility of one good weakly lowers the demand for every other good. In addition, every subset of inside goods substitutes strictly toward some good outside the subset, possibly the outside good. The chapter meets four instances of the strategy. The vertical model has a closed-form inverse (Section 6.5.4). The logit inverts in one line (Chapter 7). Random coefficients models invert by a contraction mapping (Chapter 8). The pure characteristics model needs a more delicate argument (Section 6.8.4).

6.3 Type-I extreme value algebra and the logit model

The logit model owes its popularity to one distribution. Suppose the shocks ϵ_{ij} are independent draws from the type-I extreme value distribution. Then the integral over the maximum that defines a market share has a closed form, and so does the expected maximum utility. This section derives these closed forms and their generalizations. The logit's elasticities, its substitution patterns and the Berry inversion are in Chapter 7.

6.3.1 The Gumbel distribution

The *type-I extreme value* or *Gumbel* distribution with location η and scale $\sigma_\epsilon > 0$ has CDF and density

$$F(x) = \exp\left(-e^{-\frac{x-\eta}{\sigma_\epsilon}}\right), \qquad f(x) = \frac{1}{\sigma_\epsilon}\, e^{-\frac{x-\eta}{\sigma_\epsilon}} \exp\left(-e^{-\frac{x-\eta}{\sigma_\epsilon}}\right). \tag{6.19}$$

The *standard* Gumbel has $\eta = 0$ and $\sigma_\epsilon = 1$, so $F(x) = \exp(-e^{-x})$ and $f(x) = e^{-x}\exp(-e^{-x})$. If ϵ is standard Gumbel, then $\eta + \sigma_\epsilon \epsilon$ has CDF (6.19).

Moments. We derive the moments of the standard Gumbel from its moment generating function. For $t < 1$,

$$\mathbb{E}\left[e^{t\epsilon}\right] = \int_{-\infty}^{\infty} e^{tx}\, e^{-x} \exp\left(-e^{-x}\right) \mathrm{d}x.$$

Substitute $w = e^{-x}$. Then $x = -\ln w$, $e^{tx} = w^{-t}$, $e^{-x} = w$ and $\mathrm{d}x = -\frac{\mathrm{d}w}{w}$. As x runs from $-\infty$ to ∞, w runs from ∞ to 0. Hence

$$\begin{aligned}
\mathbb{E}\left[e^{t\epsilon}\right] &= \int_{\infty}^{0} w^{-t}\, w\, e^{-w} \left(-\frac{\mathrm{d}w}{w}\right) \\
&= \int_{0}^{\infty} w^{-t} e^{-w}\, \mathrm{d}w \\
&= \Gamma(1-t),
\end{aligned}$$

where Γ is the gamma function. Let $\gamma_E \approx 0.5772$ denote Euler's constant. The digamma function $\psi = \frac{\Gamma'}{\Gamma}$ satisfies $\psi(1) = -\gamma_E$ and $\psi'(1) = \frac{\pi^2}{6}$, and $\Gamma'' = \Gamma(\psi^2 + \psi')$ (Appendix B). With $\Gamma(1) = 1$ these give $\Gamma'(1) = -\gamma_E$ and $\Gamma''(1) = \gamma_E^2 + \frac{\pi^2}{6}$. Differentiating the moment generating function at $t = 0$,

$$\begin{aligned}
\mathbb{E}[\epsilon] &= \frac{\mathrm{d}}{\mathrm{d}t}\Gamma(1-t)\Big|_{t=0} = -\Gamma'(1) = \gamma_E, \\
\mathbb{E}[\epsilon^2] &= \frac{\mathrm{d}^2}{\mathrm{d}t^2}\Gamma(1-t)\Big|_{t=0} = \Gamma''(1) = \gamma_E^2 + \frac{\pi^2}{6}, \\
\mathrm{Var}(\epsilon) &= \mathbb{E}[\epsilon^2] - \big(\mathbb{E}[\epsilon]\big)^2 = \frac{\pi^2}{6} \approx 1.645.
\end{aligned}$$

For general location and scale, the mean is $\eta + \sigma_\epsilon \gamma_E$ and the variance is $\frac{\sigma_\epsilon^2 \pi^2}{6}$. The distribution is skewed to the right. The log density $-x - e^{-x}$ has derivative $-1 + e^{-x}$, which vanishes at $x = 0$, so the mode is 0. The median solves $\exp(-e^{-x}) = \frac{1}{2}$, which gives $x = -\ln\ln 2 \approx 0.367$. Mode, median and mean are ordered $0 < 0.367 < 0.577$, and the coefficient of skewness is about 1.14. Panel (a) of Figure 6.2 compares the standard Gumbel with a normal density with the same mean and variance.

The algebra of the logit rests on two lemmas. The first says that the Gumbel family is closed under maximization.

Lemma 6.9 (Max-stability)**.** *Let $\epsilon_0, \ldots, \epsilon_J$ be independent standard Gumbel variables and $V_0, \ldots, V_J$ constants. Then $\max_j(V_j + \epsilon_j)$ is Gumbel with location $\ln \sum_{j=0}^{J} e^{V_j}$ and scale one. Equivalently, $\max_j(V_j + \epsilon_j) = \ln \sum_j e^{V_j} + \epsilon^*$, where ϵ^* is standard Gumbel.*

Proof. The maximum is at most x if and only if every term is at most x. By independence,

$$\begin{aligned}\mathbb{P}\Big(\max_j (V_j+\epsilon_j)\le x\Big) &= \prod_{j=0}^{J}\mathbb{P}(\epsilon_j\le x-V_j)\\ &= \prod_{j=0}^{J}\exp\big(-e^{-(x-V_j)}\big)\\ &= \exp\Big(-e^{-x}\sum_{j=0}^{J}e^{V_j}\Big)\\ &= \exp\Big(-e^{-\left(x-\ln\sum_j e^{V_j}\right)}\Big).\end{aligned}$$

The last expression is the Gumbel CDF (6.19) with $\eta=\ln\sum_j e^{V_j}$ and $\sigma_\epsilon=1$. □

With scale σ_ϵ, the same steps show that $\max_j(V_j+\sigma_\epsilon\epsilon_j)$ is Gumbel with location $\sigma_\epsilon\ln\sum_j e^{\frac{V_j}{\sigma_\epsilon}}$ and scale σ_ϵ. The second lemma concerns differences.

Lemma 6.10 (Differences of Gumbels are logistic)**.** *Let ϵ_1 and ϵ_2 be independent standard Gumbel variables. Then*

$$\mathbb{P}(\epsilon_1-\epsilon_2\le z)=\frac{1}{1+e^{-z}}\equiv\Lambda(z),$$

the standard logistic CDF. Its density is $\Lambda(z)\big(1-\Lambda(z)\big)$, which is symmetric about zero, and its variance is $\frac{\pi^2}{3}$.

Proof. Condition on $\epsilon_2=e$ and integrate:

$$\begin{aligned}\mathbb{P}(\epsilon_1-\epsilon_2\le z) &= \int_{-\infty}^{\infty}F(z+e)\,f(e)\,\mathrm{d}e\\ &= \int_{-\infty}^{\infty}\exp\big(-e^{-z}e^{-e}\big)\,e^{-e}\exp\big(-e^{-e}\big)\,\mathrm{d}e\\ &= \int_{-\infty}^{\infty}e^{-e}\exp\big(-e^{-e}(1+e^{-z})\big)\,\mathrm{d}e.\end{aligned}$$

Substitute $t=e^{-e}$, so that $\mathrm{d}t=-e^{-e}\,\mathrm{d}e$ and t runs from ∞ to 0:

$$\mathbb{P}(\epsilon_1-\epsilon_2\le z)=\int_0^{\infty}\exp\big(-t(1+e^{-z})\big)\,\mathrm{d}t=\frac{1}{1+e^{-z}}.$$

Differentiating gives the density $\frac{e^{-z}}{(1+e^{-z})^2}=\Lambda(z)(1-\Lambda(z))$, which is unchanged when z is replaced by $-z$. By independence the variance is $\mathrm{Var}(\epsilon_1)+\mathrm{Var}(\epsilon_2)=\frac{\pi^2}{3}$. □

The logistic distribution looks like a normal distribution with fatter tails. Its excess kurtosis is 1.2, against zero for the normal. Panel (b) of Figure 6.2 compares the two at equal variance. The densities are close near the center, while the log-scale inset shows the much thicker logistic tails. For example, the logistic gives $\mathbb{P}(Z>6)\approx 0.0025$, about five times the value 0.00047 for a normal variable with the same variance. The binary logit and probit of McFadden (1984, eqs. 2.5–2.6, p. 1397) use the two CDFs Λ and the standard normal Φ. The probit normalizes the error variance to one and the logit to $\frac{\pi^2}{3}$, so matched on variance the logit coefficients are about $\frac{\pi}{\sqrt{3}}\approx 1.81$ times the probit coefficients. McFadden notes that the two models are rarely distinguishable empirically (McFadden, 1984, p. 1398, footnote 1).

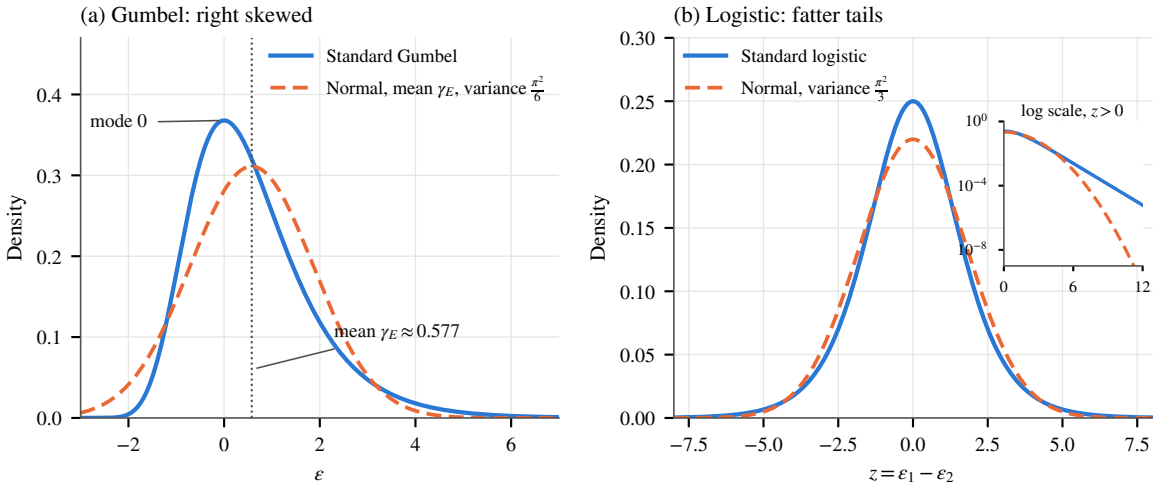

Figure 6.2: Extreme value algebra. (a) The standard Gumbel density (mode 0, mean γ_E) against a normal density with the same mean and variance $\frac{\pi^2}{6}$. (b) The standard logistic density, the distribution of the difference of two independent standard Gumbels, against a normal density with the same variance $\frac{\pi^2}{3}$. The inset plots both densities on a log scale for $z > 0$.

6.3.2 Logit choice probabilities

Proposition 6.11 (Logit choice probabilities). *Let $u_{ij} = V_{ij} + \sigma_\epsilon \epsilon_{ij}$ for $j = 0, 1, \ldots, J$, with ϵ_{ij} independent and identically distributed standard Gumbel and $\sigma_\epsilon > 0$. Then*

$$P_{ij} = \frac{\exp\left(\frac{V_{ij}}{\sigma_\epsilon}\right)}{\sum_{k=0}^{J} \exp\left(\frac{V_{ik}}{\sigma_\epsilon}\right)}. \tag{6.20}$$

With $V_{i0} = 0$, $V_{ij} = \delta_j$ for $j \geq 1$ and $\sigma_\epsilon = 1$, the market share is

$$s_j = \frac{e^{\delta_j}}{1 + \sum_{k=1}^{J} e^{\delta_k}}.$$

First proof (direct integration). Drop the index i and fix j. Product j is chosen when $V_j + \sigma_\epsilon \epsilon_j \geq V_k + \sigma_\epsilon \epsilon_k$ for every k, that is, when $\epsilon_k \leq \epsilon_j + a_k$ with $a_k = \frac{V_j - V_k}{\sigma_\epsilon}$. Note that $a_j = 0$. Condition on $\epsilon_j = e$. By independence,

$$\begin{aligned} P_j &= \int_{-\infty}^{\infty} f(e) \prod_{k \neq j} F(e + a_k)\, \mathrm{d}e \\ &= \int_{-\infty}^{\infty} e^{-e} \exp\left(-e^{-e}\right) \prod_{k \neq j} \exp\left(-e^{-e} e^{-a_k}\right) \mathrm{d}e \\ &= \int_{-\infty}^{\infty} e^{-e} \exp\left(-e^{-e} \sum_{k=0}^{J} e^{-a_k}\right) \mathrm{d}e, \end{aligned}$$

where the factor $\exp(-e^{-e})$ from the density supplies the term $k = j$, since $e^{-a_j} = 1$. Let $A = \sum_{k=0}^{J} e^{-a_k} = \sum_{k=0}^{J} \exp\left(\frac{V_k - V_j}{\sigma_\epsilon}\right)$. Substitute $t = e^{-e}$, with $\mathrm{d}t = -e^{-e}\,\mathrm{d}e$:

$$P_j = \int_0^\infty e^{-At}\,\mathrm{d}t = \frac{1}{A} = \frac{\exp\left(\frac{V_j}{\sigma_\epsilon}\right)}{\sum_{k=0}^{J} \exp\left(\frac{V_k}{\sigma_\epsilon}\right)}. \qquad \square$$

Second proof (max-stability). Divide utilities by σ_ϵ, which does not change choices (Proposition 6.4). Let $W_k = \frac{V_k}{\sigma_\epsilon}$. By Lemma 6.9 applied to the alternatives other than j,

$$\max_{k \neq j}(W_k + \epsilon_k) = L_{-j} + \epsilon^*, \qquad L_{-j} = \ln \sum_{k \neq j} e^{W_k},$$

where ϵ^* is standard Gumbel and independent of ϵ_j. Product j is chosen when $W_j + \epsilon_j \geq L_{-j} + \epsilon^*$, that is, when $\epsilon^* - \epsilon_j \leq W_j - L_{-j}$. By Lemma 6.10,

$$P_j = \Lambda(W_j - L_{-j}) = \frac{1}{1 + e^{L_{-j} - W_j}} = \frac{e^{W_j}}{e^{W_j} + \sum_{k \neq j} e^{W_k}},$$

which is (6.20). $\square$

Income, constants and the normalization. Terms common to all alternatives cancel from (6.20). Consider

$$u_{ij} = \bar{u} + \alpha(y_i - p_j) + x_j\beta + \xi_j + \sigma_\epsilon \epsilon_{ij}, \qquad u_{i0} = \bar{u} + \alpha y_i + \sigma_\epsilon \epsilon_{i0},$$

with a common constant $\bar{u}$. The factor $\exp\left(\frac{\bar{u} + \alpha y_i}{\sigma_\epsilon}\right)$ appears in the numerator and in every term of the denominator, so it cancels:

$$P_{ij} = \frac{\exp\left(\frac{x_j\beta + \xi_j - \alpha p_j}{\sigma_\epsilon}\right)}{1 + \sum_{k=1}^{J} \exp\left(\frac{x_k\beta + \xi_k - \alpha p_k}{\sigma_\epsilon}\right)}.$$

The probabilities depend on the parameters only through $\frac{\beta}{\sigma_\epsilon}$, $\frac{\alpha}{\sigma_\epsilon}$ and $\frac{\xi_j}{\sigma_\epsilon}$. Only one of the price coefficient and the scale of the shock can be normalized. The usual choice sets $\sigma_\epsilon = 1$ and estimates α, so that $\delta_j = x_j\beta - \alpha p_j + \xi_j$ is measured in units of the shock. The alternative sets $\alpha = 1$ and estimates σ_ϵ, so that utility is measured in dollars and σ_ϵ is the dollar scale of the taste shocks. Writing $u_{ij} = (y_i - p_j) + \delta_j + \epsilon_{ij}$ with a standard Gumbel shock imposes both normalizations at once. That specification assumes the standard deviation of the taste shock equals $\frac{\pi}{\sqrt{6}} \approx 1.28$ dollars, a restriction that the data cannot test once the price coefficient is fixed.

The two limits of the scale. Write (6.20) as $P_j = \left[\sum_k \exp\left(\frac{V_k - V_j}{\sigma_\epsilon}\right)\right]^{-1}$. As $\sigma_\epsilon \to 0$, every term with $V_k < V_j$ vanishes and every term with $V_k > V_j$ explodes. If V_j is the unique maximum, then $P_j \to 1$. If some V_k exceeds V_j, then $P_j \to 0$. Choice becomes deterministic, and the consumer picks $\arg\max_k V_k$. As $\sigma_\epsilon \to \infty$, every term tends to one, and $P_j \to \frac{1}{J+1}$. Choice becomes uniform and ignores the attributes. The scale σ_ϵ, or its inverse $\mu_\epsilon = \frac{1}{\sigma_\epsilon}$, is the bridge to the "modified BLP" model of Berry and Pakes (2007). BLP abbreviates the random coefficients logit of Berry, Levinsohn and Pakes (Berry et al., 1995), the subject of Chapter 8. The modified BLP model adds $\sigma_\epsilon \epsilon_{ij}$ to a pure characteristics model, and it approaches the pure characteristics model as $\sigma_\epsilon \to 0$ (Section 6.7).

Remark 6.12 (The logit as a model of tastes for products). McFadden (1984, p. 1412) observes that the multinomial logit is a special case of a random coefficients model in which only the coefficients of alternative-specific dummy variables are random. Write

$$u_{ij} = V_{ij} + \sum_{k=0}^{J} \epsilon_{ik}\, d_{jk}, \qquad d_{jk} = \mathbf{1}\{j = k\}.$$

The dummy d_{jk} is a "characteristic" that only product k possesses, and ϵ_{ik} is consumer i's random taste for it. Berry and Pakes (2007) attribute this reading to Caplin and Nalebuff (1991) and call such models models with "tastes for products". Under this reading the dimension of the characteristic space grows with the number of products. Section 6.7 shows that this growth drives the logit's implications for markups and welfare as products are added.

6.3.3 Expected maximum utility and the log-sum formula

Proposition 6.13 (Log-sum formula)**.** *Under the assumptions of Proposition 6.11,*

$$\mathbb{E}\Big[\max_{k} u_{ik}\Big] = \sigma_\epsilon \ln \sum_{k=0}^{J} \exp\left(\frac{V_{ik}}{\sigma_\epsilon}\right) + \sigma_\epsilon \gamma_E. \tag{6.21}$$

Its gradient with respect to $(V_{i0}, \dots, V_{iJ})$ is the vector of logit probabilities (6.20). In addition, the distribution of the maximum utility does not depend on which alternative attains it: for every j and x,

$$\mathbb{P}\Big(j \text{ chosen and } \max_{k} u_{ik} \le x\Big) = P_{ij}\, \mathbb{P}\Big(\max_{k} u_{ik} \le x\Big). \tag{6.22}$$

Proof. Write $\max_k (V_k + \sigma_\epsilon \epsilon_k) = \sigma_\epsilon \max_k \left(\frac{V_k}{\sigma_\epsilon} + \epsilon_k\right)$. By Lemma 6.9, $\max_k \left(\frac{V_k}{\sigma_\epsilon} + \epsilon_k\right)$ is Gumbel with location $\ln \sum_k e^{\frac{V_k}{\sigma_\epsilon}}$ and scale one, so its mean is that location plus γ_E. Multiplying by σ_ϵ gives (6.21). Differentiating,

$$\frac{\partial}{\partial V_j}\left[\sigma_\epsilon \ln \sum_k e^{\frac{V_k}{\sigma_\epsilon}}\right] = \sigma_\epsilon \cdot \frac{1}{\sigma_\epsilon} \frac{e^{\frac{V_j}{\sigma_\epsilon}}}{\sum_k e^{\frac{V_k}{\sigma_\epsilon}}} = P_j,$$

as Theorem 6.7 requires.

For (6.22), set $\sigma_\epsilon = 1$ without loss of generality. When j is chosen, the maximum equals $V_j + \epsilon_j$. Repeating the first proof of Proposition 6.11 with the extra restriction $V_j + e \le x$,

$$\begin{aligned}
\mathbb{P}\Big(j \text{ chosen and } \max_k u_k \le x\Big) &= \int_{-\infty}^{x - V_j} e^{-e} \exp\left(-Ae^{-e}\right) \mathrm{d}e \\
&= \int_{e^{-(x-V_j)}}^{\infty} e^{-At}\, \mathrm{d}t \\
&= \frac{1}{A} \exp\left(-Ae^{-(x-V_j)}\right),
\end{aligned}$$

with $A = \sum_k e^{V_k - V_j}$. Since $\frac{1}{A} = P_j$ and $Ae^{V_j} = \sum_k e^{V_k}$, the last expression equals $P_j \exp\left(-e^{-x} \sum_k e^{V_k}\right)$. By the proof of Lemma 6.9 the second factor is $\mathbb{P}(\max_k u_k \le x)$. □

Equation (6.22) says that the identity of the chosen alternative and the level of the maximum utility are independent. Consumers who choose a product with low V_j have, on average, a large ϵ_j that exactly compensates. All buyers therefore enjoy the same expected utility, whatever they bought. In the two-goods example of Section 6.2.5, the expected maximum utility is $\ln(1 + e^{0.5} + e) + \gamma_E \approx 2.26$. A simulation with two million draws gives conditional means of 2.26 for each of the three choices.

Logit consumer surplus. Combine (6.21) with the welfare formula (6.12). Let $u_{ij} = \alpha(y_i - p_j) + x_j\beta + \xi_j + \epsilon_{ij}$ for $j \geq 1$ and $u_{i0} = \alpha y_i + \epsilon_{i0}$, with $\sigma_\epsilon = 1$ and $\delta_j = x_j\beta - \alpha p_j + \xi_j$. Then $\mathbb{E}[\max_k u_{ik}] = \alpha y_i + \ln\left(1 + \sum_k e^{\delta_k}\right) + \gamma_E$, and dividing by the marginal utility of income gives the expected consumer surplus

$$CS_i = \frac{1}{\alpha} \ln\left(1 + \sum_{k=1}^{J} e^{\delta_k}\right) + C, \tag{6.23}$$

where $C = y_i + \frac{\gamma_E}{\alpha}$ is a constant that drops out of every comparison. For a change from a choice set $\mathcal{J}^0$ with mean utilities δ^0 to a choice set $\mathcal{J}^1$ with mean utilities δ^1,

$$\Delta CS_i = \frac{1}{\alpha}\left[\ln\left(1 + \sum_{k \in \mathcal{J}^1} e^{\delta^1_k}\right) - \ln\left(1 + \sum_{k \in \mathcal{J}^0} e^{\delta^0_k}\right)\right]. \tag{6.24}$$

Because $1 + \sum_k e^{\delta_k} = \frac{1}{s_0}$ in the logit, (6.23) can be written $CS_i = -\frac{1}{\alpha}\ln s_0 + C$, and (6.24) becomes $\Delta CS_i = \frac{1}{\alpha}\ln\frac{s_0^0}{s_0^1}$. In the logit, the outside share and the price coefficient alone determine the welfare change. In the two-goods example the rise in δ_1 from 0.5 to 1.3 lowers s_0 from 0.186 to 0.135, a gain of $\ln\frac{0.186}{0.135} \approx 0.32$ utils, or $\frac{0.32}{\alpha}$ dollars. Differentiating (6.23) with respect to p_j gives $-\frac{1}{\alpha} \cdot \frac{\alpha e^{\delta_j}}{1+\sum_k e^{\delta_k}} = -s_j$, the logit version of the Roy identity noted after Corollary 6.8. The logit elasticities and the Berry inversion are in Chapter 7, and the welfare value of new goods is in Chapter 10. Section 6.7 shows that (6.24) assigns positive value to every added product, including an exact copy of an existing one.

6.3.4 Luce's axiom, IIA and the generalized extreme value family

The choice axiom and IIA. Luce (1959) proposed an axiom for probabilistic choice. Let $P(j \mid C)$ be the probability of choosing j from a set C. The *choice axiom* requires $P(j \mid C) = P(j \mid A)\,P(A \mid C)$ for every subset $A \subseteq C$ that contains j, where $P(A \mid C) = \sum_{k \in A} P(k \mid C)$. When all probabilities are positive, the axiom implies that there are scale values $w_k > 0$ with $P(j \mid C) = \frac{w_j}{\sum_{k \in C} w_k}$. The logit is the case $w_k = e^{V_k}$. The axiom is equivalent to the *independence of irrelevant alternatives* (IIA): the odds of choosing j over k do not depend on the other alternatives. In the logit,

$$\frac{P_j}{P_k} = \exp\left(\frac{V_j - V_k}{\sigma_\epsilon}\right), \tag{6.25}$$

which depends only on j and k. McFadden (1984, eq. 3.17, p. 1413) states the property for a model in which $V_j = x_j\theta$ depends only on the attributes of j: $\ln\frac{P_j}{P_k} = (x_j - x_k)\theta$, independent of the attributes of every other alternative.

IIA has three consequences. First, the probabilities for a smaller or larger choice set follow from (6.20) by deleting or adding terms in the denominator. A model estimated on existing alternatives can then forecast the demand for a new one, provided the new alternative brings no new parameters (McFadden, 1984, p. 1414). Second, the cross-elasticity of the probability of j with respect to an attribute of k is the same for every $j \neq k$ (p. 1414). A rise in the price of k sends its customers to the other alternatives in proportion to their shares, as the two-goods example showed. Third, ranked data can be used. The probability of a complete ranking is the product of logit probabilities of choosing the best alternative from successively smaller sets (Marschak, 1960). McFadden (1984, p. 1414) calls IIA "theoretically implausible in many applications", while noting that the logit often fits and predicts well in practice.

Remark 6.14 (Why Gumbel). Is the Gumbel distribution the only way to obtain Luce's axiom from random utility? Yellott (1977) studies random utility models with independent and identically distributed errors from a location family. He shows that in this class the choice axiom holds for all choice sets of at least three alternatives only if the errors are Gumbel. We state the result without proof. It explains why the logit and the independent Gumbel model are the same object.

Remark 6.15 (Universal logit). IIA comes from restricting V_j to depend on the attributes of j alone. The logistic functional form does not imply it by itself. Suppose instead that $V_j = z_j(x)\theta$ may depend on the attributes x of all alternatives. Then the logit form

$$P_j = \frac{e^{z_j(x)\theta}}{\sum_k e^{z_k(x)\theta}}$$

can approximate any continuous positive response probability model on a compact set, to any desired accuracy (McFadden, 1984, eq. 3.18, pp. 1414–1415). This *universal logit* can describe any pattern of cross-elasticities. The approximation may be computationally impractical, and it makes consistency with utility maximization hard to impose or verify. Its main use is to suggest specification tests (p. 1415).

The most common test of IIA uses the property that the logit parameters are the same on any subset of the choice set. Let $\hat{\beta}_C$ and $\hat{V}_C$ be the estimates and their estimated covariance matrix from the full choice set C, and $\hat{\beta}_D$ and $\hat{V}_D$ those from a subset D. Under IIA both estimators are consistent and the full-set estimator is efficient, so

$$S = (\hat{\beta}_D - \hat{\beta}_C)^\top (\hat{V}_D - \hat{V}_C)^{-1} (\hat{\beta}_D - \hat{\beta}_C) \tag{6.26}$$

is asymptotically chi-squared with degrees of freedom equal to the rank of $\hat{V}_D - \hat{V}_C$ (McFadden, 1984, eq. 3.23, pp. 1417–1418). Hausman and McFadden (1984) analyze the test. McFadden warns that it is an omnibus test and that it has little power unless the departures from the logit are substantial. Chapter 7 applies it.

Remark 6.16 (Aggregating alternatives). The logit form survives aggregation of alternatives into types (McFadden, 1984, eqs. 3.19–3.20, p. 1415). Suppose type g contains M_g elemental alternatives with attributes x_{gj} and mean attributes $\bar{x}_g$. The probability of choosing some alternative of type g is

$$\sum_{j \in g} P_{gj} = \frac{\sum_{j \in g} e^{x_{gj}\theta}}{\sum_h \sum_{l \in h} e^{x_{hl}\theta}}, \qquad \sum_{j \in g} e^{x_{gj}\theta} = \exp\left(\bar{x}_g \theta + \ln M_g + \omega_g\right),$$

where $\omega_g = \ln\left[\frac{1}{M_g}\sum_{j\in g} e^{(x_{gj}-\bar{x}_g)\theta}\right]$ corrects for heterogeneity within the type and is zero when the alternatives in g are identical. Choice among types is therefore a logit with utility $\bar{x}_g\theta + \ln M_g + \omega_g$. The term $\ln M_g$ shows how the logit counts products. Doubling the number of alternatives of a type, with the new ones identical to the old, adds $\ln 2$ to the utility of the type. This is the tastes-for-products reading of Remark 6.12 at work.

Remark 6.17 (Sampling alternatives). IIA has a practical use when the choice set is large, as when households choose among thousands of houses. The denominator of each logit probability then sums over every alternative. McFadden (1984, sec. 3.6, pp. 1416–1417) shows that the logit can be estimated from a sampled subset of alternatives for each consumer. Let C be the full choice set, and let consumer i choose $j_i \in C$. The researcher draws a subset $\mathcal{D}_i \subseteq C$ that contains j_i, under a known protocol that selects $\mathcal{D}$ with probability $r(\mathcal{D} \mid j_i, x_i)$. We write r for McFadden's π, which this book reserves for profit. The protocol must have the *positive conditioning property*: $r(\mathcal{D}_i \mid k, x_i) > 0$ for every $k \in \mathcal{D}_i$. Had any member of $\mathcal{D}_i$ been chosen, the protocol could have produced the same subset.

The probability that consumer i chose k, given the sampled subset, follows from Bayes' rule:

$$\mathbb{P}(j_i = k \mid \mathcal{D}_i, x_i) = \frac{P_k(x_i,\theta)\, r(\mathcal{D}_i \mid k, x_i)}{\sum_{l\in\mathcal{D}_i} P_l(x_i,\theta)\, r(\mathcal{D}_i \mid l, x_i)}.$$

The sum runs over $\mathcal{D}_i$ only, because the protocol never produces a subset that excludes the chosen alternative. We substitute the logit $P_k(x_i,\theta) = \frac{e^{x_{ik}\theta}}{\sum_{m\in C} e^{x_{im}\theta}}$. The full-set denominator appears in every term and cancels, which leaves

$$\mathbb{P}(j_i = k \mid \mathcal{D}_i, x_i) = \frac{\exp\left(x_{ik}\theta + \ln r(\mathcal{D}_i \mid k, x_i)\right)}{\sum_{l\in\mathcal{D}_i} \exp\left(x_{il}\theta + \ln r(\mathcal{D}_i \mid l, x_i)\right)}. \tag{6.27}$$

This is a logit on $\mathcal{D}_i$ with $\ln r(\mathcal{D}_i \mid k, x_i)$ added to each utility. Positive conditioning keeps every logarithm finite. The average of $\ln \mathbb{P}(j_i \mid \mathcal{D}_i, x_i)$ over consumers is McFadden's modified log-likelihood (his eq. 3.22). Under positive conditioning and a standard identification condition, its maximizer is consistent for θ. It is a conditional likelihood, so the inverse of its information matrix estimates the covariance matrix as usual (p. 1417).

The correction cancels when $r(\mathcal{D}_i \mid k, x_i)$ is the same for every $k \in \mathcal{D}_i$, the *uniform conditioning property*. McFadden's example draws the chosen alternative and one other alternative at random (his eq. 3.21):

$$r(\mathcal{D} \mid j_i, x_i) = \begin{cases} \frac{1}{|C|-1} & \text{if } \mathcal{D} = \{j_i, k\} \text{ with } k \neq j_i, \\ 0 & \text{otherwise,} \end{cases}$$

where $|C|$ is the number of alternatives. Either member of $\mathcal{D}_i$, had it been chosen, would have produced $\mathcal{D}_i$ with the same probability. The logit can then be estimated from binary choices between the chosen alternative and one random rival. The argument needs IIA. The full-set denominator cancels only because the ratio $\frac{P_k}{P_l}$ does not depend on the alternatives outside $\mathcal{D}_i$.

Generalized extreme value models. McFadden (1978) found a class of joint distributions for the shocks that keeps closed forms while relaxing IIA. Models in this class are called *generalized extreme value* (GEV) models.

Theorem 6.18 (Generalized extreme value models). *Let $H : \mathbb{R}_+^{J+1} \to \mathbb{R}_+$ satisfy three conditions.*
(G1) H is homogeneous of degree one: $H(\lambda y) = \lambda H(y)$ for $\lambda > 0$.

(G2) $H(y) \to \infty$ *as* $y_j \to \infty$*, for any* j*.*

(G3) For any r *distinct indices* $j_1, \dots, j_r$*, the mixed partial derivative* $\frac{\partial^r H}{\partial y_{j_1} \cdots \partial y_{j_r}}$ *is nonnegative if* r *is odd and nonpositive if* r *is even.*

Then the following hold.

(a) $F(\epsilon_0, \dots, \epsilon_J) = \exp\left(-H(e^{-\epsilon_0}, \dots, e^{-\epsilon_J})\right)$ *is the CDF of a multivariate extreme value distribution whose marginals are Gumbel.*

(b) In the ARUM $u_j = V_j + \epsilon_j$ *with* ϵ *distributed as in (a), the choice probabilities are*

$$P_j = \frac{y_j H_j(y)}{H(y)} = \frac{\partial \ln H(e^{V_0}, \dots, e^{V_J})}{\partial V_j}, \qquad y = (e^{V_0}, \dots, e^{V_J}), \tag{6.28}$$

where H_j *is the partial derivative of* H *with respect to its* j*-th argument.*

(c) The social surplus function is $G(V) = \ln H(e^{V_0}, \dots, e^{V_J}) + \gamma_E$*.*

Proof. Part (a) is the theorem of McFadden (1978), restated by McFadden (1984, eqs. 3.29–3.31, p. 1421). We take it as given. Its marginals follow by sending the other arguments to infinity: $F_j(\epsilon_j) = \exp\left(-e^{-\epsilon_j} H(e_j)\right)$, a Gumbel CDF with location $\ln H(e_j)$, where e_j is the j-th unit vector.

For (c), the maximum is at most x if and only if $\epsilon_k \le x - V_k$ for every k. Using (a) and then homogeneity with $\lambda = e^{-x}$,

$$\mathbb{P}\Big(\max_k (V_k + \epsilon_k) \le x\Big) = \exp\Big(-H\big(e^{V_0 - x}, \dots, e^{V_J - x}\big)\Big) = \exp\Big(-e^{-\left(x - \ln H(y)\right)}\Big).$$

The maximum is Gumbel with location $\ln H(y)$, so its mean is $\ln H(y) + \gamma_E$.

For (b), the density of the event that j is chosen with $\epsilon_j = e$ is $\frac{\partial F}{\partial \epsilon_j}$ evaluated at $\epsilon_k = e + V_j - V_k$ for all k. Differentiating F,

$$\frac{\partial F}{\partial \epsilon_j}(\epsilon) = F(\epsilon)\, H_j(e^{-\epsilon_0}, \dots, e^{-\epsilon_J})\, e^{-\epsilon_j}.$$

At the evaluation point, $e^{-\epsilon_k} = \lambda y_k$ with $\lambda = e^{-e - V_j} = \frac{e^{-e}}{y_j}$. Homogeneity of degree one implies $H(\lambda y) = \lambda H(y)$, and its derivative H_j is homogeneous of degree zero, so $H_j(\lambda y) = H_j(y)$. Hence

$$\begin{aligned} P_j &= \int_{-\infty}^{\infty} \exp\Big(-\frac{e^{-e}}{y_j} H(y)\Big) H_j(y)\, e^{-e}\, \mathrm{d}e \\ &= H_j(y) \int_0^{\infty} \exp\Big(-t\, \frac{H(y)}{y_j}\Big)\, \mathrm{d}t = \frac{y_j H_j(y)}{H(y)}, \end{aligned}$$

where the second line substitutes $t = e^{-e}$. Finally, $\frac{\partial \ln H(e^V)}{\partial V_j} = \frac{H_j(y)\, e^{V_j}}{H(y)}$, which is the same expression. It equals the derivative of G in (c), as Theorem 6.7 requires. □

The logit is the generating function $H(y) = \sum_j y_j$. It satisfies (G1) and (G2), its first derivatives equal one, and its higher mixed derivatives vanish. Then $F(\epsilon) = \prod_j \exp(-e^{-\epsilon_j})$, the shocks are independent, and (6.28) gives $P_j = \frac{y_j}{\sum_k y_k}$. McFadden's version, $H(y) = \left(\sum_j y_j^{\frac{1}{\lambda}}\right)^{\lambda}$ with $0 < \lambda \le 1$, gives the logit with scale λ (McFadden, 1984, eq. 3.32, p. 1421).

The nested logit is the leading member of the family that relaxes IIA. Partition the inside products into nests $g = 1, \ldots, G$, and place the outside good in its own nest. With nesting parameter $\sigma \in [0, 1)$, let

$$H(y) = y_0 + \sum_{g=1}^{G} \Big(\sum_{j \in g} y_j^{\frac{1}{1-\sigma}} \Big)^{1-\sigma}. \tag{6.29}$$

Write $D_g = \sum_{k \in g} y_k^{\frac{1}{1-\sigma}}$. For j in nest g, the derivative is $H_j = D_g^{-\sigma} y_j^{\frac{\sigma}{1-\sigma}}$, so $y_j H_j = D_g^{-\sigma} y_j^{\frac{1}{1-\sigma}}$ and

$$P_j = \frac{y_j^{\frac{1}{1-\sigma}}}{D_g} \cdot \frac{D_g^{1-\sigma}}{y_0 + \sum_{h=1}^{G} D_h^{1-\sigma}}.$$

The first factor is the probability of choosing j within its nest, and the second is the probability of choosing nest g. With $\sigma = 0$ the model is the logit. As σ approaches one, the products within a nest become close substitutes. McFadden (1984, sec. 3.10, pp. 1422–1425) develops the general hierarchical version, the nested multinomial logit, with an "independence" parameter at each node, here $1 - \sigma$. He notes that estimates of these parameters outside the unit interval indicate a misspecified tree (pp. 1425–1426), and that the likelihood is not concave in all parameters (p. 1426). Chapter 7 develops the nested logit, its elasticities and its estimation.

6.3.5 The multinomial probit

The *multinomial probit* assumes jointly normal shocks, $\epsilon_i \sim N(0, \Sigma_\epsilon)$, with a $(J+1) \times (J+1)$ covariance matrix Σ_ϵ. Product j is chosen when $\epsilon_{ik} - \epsilon_{ij} \leq V_{ij} - V_{ik}$ for every $k \neq j$. The vector of these J differences is normal with covariance matrix $B_j \Sigma_\epsilon B_j^\top$, where B_j is the $J \times (J+1)$ matrix that subtracts ϵ_{ij} from the other shocks. The choice probability is a J-dimensional normal orthant probability, which has no closed form (McFadden, 1984, sec. 3.8). A version with an economic interpretation sets $u_{ij} = x_{ij} a_i$ with normally distributed taste weights $a_i \sim N(\beta, \Omega_a)$, so that utilities have covariance $x_i \Omega_a x_i^\top$ across alternatives (p. 1418).

The probit has the flexibility that the logit lacks. With correlated shocks it does not have IIA, and it permits very general patterns of cross-elasticities (p. 1418). The cost is computation. McFadden reports that probabilities with up to three alternatives cost about as much to compute as logit probabilities (p. 1418). With five or more alternatives and an unrestricted covariance matrix, they were usually too costly for iterative estimation at the time. The probit log-likelihood is also not known to be concave (p. 1419). One remedy restricts the covariance with a factor structure,

$$\epsilon_{ij} = \zeta_{ij} + \sum_{l=1}^{L} \gamma_{jl} v_{il},$$

with independent normal ζ_{ij} and v_{il} (McFadden, 1984, eq. 3.25, p. 1419). The loading γ_{jl} can be read as the level in alternative j of an unobserved characteristic l, and v_{il} as the consumer's random taste for it. This is a random coefficients model on unobserved characteristics. Simulation methods developed since then make probit models with many alternatives feasible (Train, 2009).

The independent probit, with Σ_ϵ the identity matrix, has essentially the same restrictions on substitution as the logit, and McFadden (1984, p. 1420) sees little reason to prefer one over the other. The lesson matters for the rest of the book. The logit's substitution problems come from shocks that are independent across products, which leave products with no notion of

similarity. The shape of the Gumbel distribution plays little role. Fixing the problems requires correlation in tastes across similar products. Nesting supplies it within groups (Chapter 7), and random coefficients on characteristics supply it along each characteristic (Chapter 8).

6.3.6 Choosing a functional form

McFadden (1984, sec. 3.3) judges functional forms by computational practicality and by flexibility in representing similarity across alternatives. He groups the concrete forms into three families. Logit models descend from Luce (1959). Probit models descend from Thurstone (1927). Elimination models, in which alternatives are screened out until one remains, descend from Tversky (1972). His verdict (p. 1410) is that the multinomial logit scores well on simplicity and computation but poorly on flexibility. The multinomial probit is simple and flexible but scores poorly on computation. The nested logit and the factor-structure probit try to achieve both. He adds that functional forms allowing similar substitution patterns tend to fit existing data comparably. This observation anticipates the strategy of modern empirical work. The choice of a model is mainly a choice of substitution patterns, and the distribution of the idiosyncratic shock matters mostly through its implications for computation and welfare.

Remark 6.19 (A representative-consumer foundation). Logit demand also arises from a single representative consumer (Anderson et al., 1988a, 1992). Suppose the consumer allocates one unit of consumption across the alternatives $j = 0, 1, \ldots, J$ to maximize

$$\sum_{j=0}^{J} \delta_j q_j - \sum_{j=0}^{J} q_j \ln q_j \qquad \text{subject to} \qquad \sum_{j=0}^{J} q_j = 1,$$

with $\delta_0 = 0$. The entropy term rewards spreading consumption across products. The first-order conditions $\delta_j - \ln q_j - 1 - \lambda = 0$, with multiplier λ, give $q_j \propto e^{\delta_j}$, and the constraint yields $q_j = \frac{e^{\delta_j}}{1+\sum_{k\geq 1} e^{\delta_k}}$, the logit shares. A weight σ_ϵ on the entropy term produces the logit with scale σ_ϵ. The two foundations, a population of consumers with Gumbel shocks and a representative consumer with a taste for variety, give the same aggregate demand. Chapter 4 gives the full derivation and shows that the constant elasticity of substitution (CES) demand system is a logit in log prices.

6.4 Models of product differentiation as random utility models

The random utility model of Section 6.2 is a general language for demand. A model of product differentiation fills in two objects of that language. The first is the utility function $U(x_j, p_j, \xi_j, \nu_i; \theta)$. The second is the distribution F of the consumer tastes ν_i. The classical models of the theory literature (address models, ideal-point models, vertical models) and the logit-type models of empirical work differ only in these two choices. This section places them in one framework. The comparison matters because each specification fixes, before any data are used, which products compete with which. Those restrictions drive every counterfactual the model produces. Table 6.1 at the end of the section collects the comparison.

6.4.1 Horizontal and vertical differentiation

Products are *differentiated* when consumers do not regard them as perfect substitutes. Two polar forms of differentiation organize the theory. They differ in whether consumers agree on

how to rank the products when prices are equal.

Definition 6.20 (Vertical and horizontal differentiation)**.** Let a consumer of type v obtain utility $U(x_j, p, v)$ from product j sold at price p. The products are *vertically differentiated* if at any common price every consumer ranks them in the same order. Formally, for all products j and k, all prices p, and all types v and v',

$$U(x_j, p, v) > U(x_k, p, v) \iff U(x_j, p, v') > U(x_k, p, v').$$

The products are *horizontally differentiated* if at some common price two types rank some pair of products differently.

Under vertical differentiation a scalar index summarizes the common ranking. We call it *quality* and write it δ_j. Consumers agree that higher quality is better. They disagree only about how much extra money the extra quality is worth. Under horizontal differentiation no such index exists. At the same price some consumers prefer a sweetened breakfast cereal and others a plain one, and neither group is mistaken. Most markets mix the two forms. Every buyer prefers a luxury sedan to an economy sedan at the same price, while buyers disagree about a sedan and a pickup truck.

The models below share a property that makes their demand systems tractable when tastes are one-dimensional.

Definition 6.21 (Single crossing)**.** Let the type v be a scalar. Utility has the *single-crossing property* if, for every pair of products $j \neq k$ and all prices, the difference $U(x_j, p_j, v) - U(x_k, p_k, v)$ changes sign at most once as v increases. A sufficient condition is that the difference be strictly monotone in v.

Under single crossing the utilities of two products, viewed as functions of the type, cross at most once. The types that prefer j to k then form a half-line. The types that choose j from the whole menu form an interval, the intersection of such half-lines. Market shares become differences of the CDF F evaluated at interval end points. Both the Hotelling model with quadratic transport costs and the vertical model have this property. It is the reason their demand systems have closed forms, and the reason each product competes only with its immediate neighbors.

6.4.2 Address models: Hotelling and Salop

In an *address model* each product has a location x_j in a space of characteristics, and each consumer has an ideal location in the same space. A consumer who buys a product away from her ideal suffers a disutility that rises with the distance. Hotelling (1929) introduced the idea with consumers spread along a line. In random utility form, with quadratic distance costs,

$$u_{ij} = \bar{u} + (y_i - p_j) - \tau\, d(x_j, v_i)^2, \tag{6.30}$$

where $\bar{u}$ is a utility constant common to all consumers, y_i is income, v_i is the consumer's ideal location, and d is distance. The coefficient $\tau > 0$ is the *transport cost*. We reserve θ for the generic parameter vector of Section 6.2, so the transport cost is always τ. The taste v_i is now a location, and its distribution F plays the role that the error distribution plays in an additive random utility model. Products are horizontally differentiated. At equal prices each consumer ranks products by distance, and consumers at different locations disagree.

Example 6.22 (Hotelling duopoly with quadratic transport costs)**.** Two firms sit at the ends of the unit interval, $x_1 = 0$ and $x_2 = 1$, and produce at common marginal cost c. A mass M of consumers is uniform on $[0, 1]$, so $F(v) = v$. A consumer who buys nothing obtains y_i. We assume $\bar{u}$ is large enough that every consumer buys one unit (full coverage). Income and $\bar{u}$ then enter both inside utilities and cancel from the comparison.

The first step finds the indifferent consumer. A consumer at v prefers firm 1 if $-p_1 - \tau v^2 > -p_2 - \tau(1 - v)^2$. The indifferent type v^* solves

$$\begin{aligned} p_1 + \tau(v^*)^2 &= p_2 + \tau(1 - v^*)^2, \\ \tau\left[(v^*)^2 - (1 - v^*)^2\right] &= p_2 - p_1, \\ \tau(2v^* - 1) &= p_2 - p_1, \end{aligned}$$

so that

$$v^* = \frac{1}{2} + \frac{p_2 - p_1}{2\tau}. \tag{6.31}$$

The utility difference $u_{i1} - u_{i2} = p_2 - p_1 + \tau(1 - 2v_i)$ falls in v_i (single crossing), so every consumer to the left of v^* buys from firm 1.

The second step writes demand. Firm 1 sells $q_1 = MF(v^*) = Mv^*$ and firm 2 sells $q_2 = M(1 - v^*)$. These formulas hold when $0 < v^* < 1$, that is, when $|p_2 - p_1| < \tau$. Demand is linear in prices, with $\frac{\partial q_1}{\partial p_1} = -\frac{M}{2\tau}$.

The third step finds best responses. Firm 1 maximizes $\pi_1 = (p_1 - c)Mv^*(p_1, p_2)$, a concave quadratic in p_1. Its first-order condition is

$$M\left[v^* - \frac{p_1 - c}{2\tau}\right] = 0.$$

Substituting (6.31) gives $\frac{1}{2} + \frac{p_2 - p_1}{2\tau} = \frac{p_1 - c}{2\tau}$. Multiplying by 2τ and collecting terms gives the best response

$$p_1 = \frac{p_2 + c + \tau}{2}.$$

The fourth step imposes symmetry. With $p_1 = p_2 = p$, the best response becomes $p = \frac{p + c + \tau}{2}$, so

$$p_1 = p_2 = c + \tau, \qquad v^* = \frac{1}{2}, \qquad \pi_1 = \pi_2 = \frac{M\tau}{2}. \tag{6.32}$$

The markup equals the transport cost. As $\tau \to 0$ the two products become perfect substitutes and the price falls to marginal cost, the Bertrand outcome of Chapter 2. Full coverage holds in this equilibrium when the consumer at $v = \frac{1}{2}$ prefers buying, $\bar{u} - c - \tau - \frac{\tau}{4} \geq 0$, that is, $\bar{u} \geq c + \frac{5\tau}{4}$. The equilibrium is the case $x_1 = 0$, $x_2 = 1$ of Proposition 4.53. Linear transport costs with the firms at the end points give the same indifferent consumer and the same prices (Section 4.8.1).

The quadratic form of the transport cost keeps demand continuous. With linear costs $\tau\, d(x_j, v_i)$, demand jumps when one firm cuts its price far enough below its rival's to capture the consumers at the rival's own location. d'Aspremont et al. (1979) show that no pure-strategy price equilibrium then exists when the two firms are located near the center of the line at distinct points (Proposition 4.52). With quadratic costs a price equilibrium exists for every pair of locations. In the two-stage game in which firms first choose locations and then prices, the firms move to the two ends of the line, because distance softens price competition. Proposition 4.53 derives this maximal differentiation in the location stage, and Section 4.8.2 shows that it exceeds the efficient differentiation.

Salop (1979) removed the end points of the line by placing consumers on a circle. Consider N firms spaced evenly on a circle of circumference one, each with marginal cost c. Transport cost is linear with coefficient τ. A mass M of consumers is uniform on the circle, and every consumer buys. Take a firm that charges p while its two neighbors, each at distance $\frac{1}{N}$, charge $\bar{p}$. A consumer at distance z from the firm, on the arc toward a neighbor, is indifferent when

$$p + \tau z = \bar{p} + \tau\Big(\frac{1}{N} - z\Big), \qquad \text{so} \qquad z = \frac{1}{2N} + \frac{\bar{p} - p}{2\tau}.$$

The firm serves consumers on both arcs, so its demand is

$$q = 2Mz = M\Big[\frac{1}{N} + \frac{\bar{p} - p}{\tau}\Big] \qquad \text{for } |\bar{p} - p| \le \frac{\tau}{N}.$$

Demand depends on the prices of the two neighbors and on no other price. By Proposition 4.55, the symmetric equilibrium price is $p = c + \frac{\tau}{N}$, so the markup falls as products crowd the circle. With a fixed cost of entry, free entry yields twice the efficient number of firms. Every consumer buys, so the markup is a transfer, and the only distortion is in the number of firms. An entrant takes business from its neighbors, while society gains only the saving in transport costs (Tirole, 1988, sec. 7.1.2). Entry remains excessive with quadratic transport costs (Section 4.8.3). Each firm in the Salop model competes only with its two neighbors, a feature it shares with the vertical model below.

6.4.3 The ideal-point model

The address model extends to K characteristics. In the *ideal-point model* (Anderson et al., 1992) consumer i has an ideal level v_{ik} of each characteristic k, and utility is

$$u_{ij} = f(y_i, p_j) + \delta_j - \sum_{k=1}^{K} \alpha_k (x_{jk} - v_{ik})^2, \qquad \alpha_k > 0. \tag{6.33}$$

Here $f(y_i, p_j)$ is the utility of the income left after the purchase, with $f_y > 0$, $f_p < 0$ and $f_{py} \ge 0$ as in Section 6.2.3. The term δ_j is a product effect common to all consumers, and α_k is the weight of distance along dimension k. We write the distance term with a minus sign and positive weights, so that utility falls with distance.[5] The next result shows that the ideal-point model is a special case of the pure characteristics model introduced below.

Proposition 6.23 (Ideal points are random coefficients)**.** *Under* (6.33)*,*

$$u_{ij} = f(y_i, p_j) + \Big[\delta_j - \sum_{k=1}^{K} \alpha_k x_{jk}^2\Big] + \sum_{k=1}^{K} 2\alpha_k v_{ik}\, x_{jk} - \sum_{k=1}^{K} \alpha_k v_{ik}^2. \tag{6.34}$$

Consequently, the following hold.

(i) Comparisons among inside products depend on the tastes only through the interactions $v_{ik}x_{jk}$. The model is a random coefficients model without an idiosyncratic shock. Its mean utility is $\delta_j - \sum_k \alpha_k x_{jk}^2$, and characteristic x_{jk} carries the random coefficient $2\alpha_k v_{ik}$.

[5] Some presentations write the distance term with a plus sign. The weights must then be negative for distance to be costly. We use the minus sign with positive weights.

(ii) The term $-\sum_k \alpha_k \nu_{ik}^2$ is the same for every inside product, so it cancels from every comparison among them. Relative to an outside good with utility $f(y_i, 0)$, it acts as a random coefficient on a characteristic that equals one for every inside product.

Proof. Expand each square:

$$(x_{jk} - \nu_{ik})^2 = x_{jk}^2 - 2x_{jk}\nu_{ik} + \nu_{ik}^2.$$

Multiply by $-\alpha_k$ and sum over k:

$$-\sum_k \alpha_k (x_{jk} - \nu_{ik})^2 = -\sum_k \alpha_k x_{jk}^2 + \sum_k 2\alpha_k \nu_{ik} x_{jk} - \sum_k \alpha_k \nu_{ik}^2.$$

Substituting into (6.33) gives (6.34). For two inside products j and l,

$$u_{ij} - u_{il} = f(y_i, p_j) - f(y_i, p_l) + \left[\delta_j - \sum_k \alpha_k x_{jk}^2\right] - \left[\delta_l - \sum_k \alpha_k x_{lk}^2\right] + \sum_k 2\alpha_k \nu_{ik}(x_{jk} - x_{lk}),$$

in which ν_{ik}^2 no longer appears. This proves (i) and the first part of (ii). The difference $u_{ij} - u_{i0}$ keeps the term $-\sum_k \alpha_k \nu_{ik}^2$, which is the product of a consumer-specific coefficient and the constant one. This proves the rest of (ii). □

Berry and Pakes (2007, eq. 6) make the same point. They write the ideal-point model with a distance between the consumer's location and the product's location. With Euclidean distance, they note, expanding the squares leaves a mean utility that depends on characteristics. The individual term is then built from interactions of consumer and product characteristics. The quadratic term $-\alpha_k x_{jk}^2$ in mean utility is what distinguishes ideal points from linear random coefficients. It makes the value of a characteristic peak at the consumer's ideal and decline beyond it. With linear random coefficients and tastes ν_{ik} of both signs, consumers also disagree about the direction in which a characteristic is good, which is another form of horizontal differentiation.

6.4.4 Two families of empirical models

The empirical models of this book fall into two families. The first is the *pure characteristics model* (Berry and Pakes, 2007), in which consumers have tastes for characteristics and for nothing else:

$$u_{ij} = f(y_i, p_j) + \delta_j + \sum_{k=1}^{K} \sigma_k \nu_{ik} x_{jk}. \tag{6.35}$$

Here ν_{ik} is a standardized taste for characteristic k and $\sigma_k \geq 0$ its dispersion, the k-th diagonal element of the matrix Σ in the random coefficients notation of Chapter 8. The model is also called the *pure hedonic* model. By Proposition 6.23, the ideal-point model belongs to this family once its quadratic terms are counted among the characteristics and a constant inside-good characteristic is added. The second family adds an idiosyncratic shock ϵ_{ij}:

$$u_{ij} = f(y_i, p_j) + \delta_j + \sum_{k=1}^{K} \sigma_k \nu_{ik} x_{jk} + \epsilon_{ij}, \tag{6.36}$$

with ϵ_{ij} i.i.d. across products and consumers. With type-I extreme value shocks this is the random coefficients logit model of Berry et al. (1995), the subject of Chapter 8. With $\sigma_k = 0$ for all k it is the logit model of Section 6.3.

The function f carries income effects. In the quasi-linear case $f(y_i, p_j) = \alpha(y_i - p_j)$ income enters every alternative equally and cancels, and the price coefficient α is common to all consumers. Berry et al. (1995) use $f(y_i, p_j) = \alpha \ln(y_i - p_j)$, which makes richer consumers less price sensitive ($f_{py} > 0$). The properties of f are derived in Section 6.2.3.

The key difference between (6.35) and (6.36) is the shock ϵ_{ij}. With ϵ_{ij} in the model, the product space can never be exhausted. Each new product arrives with a fresh draw of ϵ_{ij} for every consumer, which guarantees it a positive share and some market power wherever it is placed. In the pure characteristics model a new product placed next to an existing one is a near-perfect substitute for it. Section 6.7 develops the consequences for markups and for the welfare value of new products. The vertical model, to which we now turn, is the pure characteristics model with a single characteristic, quality, and a single random coefficient, on price.

6.4.5 The vertical model as a random utility model

The *vertical model* specifies

$$u_{ij} = \delta_j - \nu_i p_j, \qquad \nu_i > 0, \tag{6.37}$$

with outside good $u_{i0} = 0$. The products are vertically differentiated in the sense of Definition 6.20. At any common price p, $u_{ij} - u_{ik} = \delta_j - \delta_k$ for every consumer, so all consumers rank products by δ_j. Consumers differ only in their *price sensitivity* ν_i, the utility cost of a dollar. A consumer with high ν_i dislikes paying and buys cheap, low-quality products. A consumer with low ν_i pays a lot for quality. The cabins of an airline (first, business, economy) fit this description. Every traveler prefers the front cabin at equal prices, and travelers sort across cabins by willingness to pay. Storage or memory tiers of an otherwise identical device are a second example.

Dividing (6.37) by $\nu_i > 0$ gives an equivalent form. With $v_i = \frac{1}{\nu_i}$,

$$\frac{u_{ij}}{\nu_i} = v_i \delta_j - p_j. \tag{6.38}$$

Here v_i is the consumer's willingness to pay for a unit of quality. A consumer-specific positive rescaling of utility leaves choices unchanged (Section 6.2.3), so the two forms imply the same demand. The form (6.38) is the one used by Mussa and Rosen (1978) and by Bresnahan (1987), who attributes the demand system to Prescott and Visscher (1977). In this form the consumer buys the product with the lowest "total price" $p_j - v_i \delta_j$.

The vertical model has the single-crossing property. For two products with $p_k > p_j$,

$$u_{ij} - u_{ik} = (\delta_j - \delta_k) + \nu_i (p_k - p_j) \tag{6.39}$$

is strictly increasing in ν_i. The preference for the cheaper product rises with price sensitivity. More generally, consider any model with a scalar type in which all consumers agree on the quality ranking. It is vertical and single crossing whenever the marginal rate of substitution between quality and money is monotone in the type. Gabszewicz and Thisse (1979) obtain such a model from income differences. In their specification $u_{ij} = \delta_j(y_i - p_j)$, and a consumer with income y prefers j to k (with $\delta_j > \delta_k$ and $p_j > p_k$) if and only if

$$\delta_j(y - p_j) > \delta_k(y - p_k) \iff y(\delta_j - \delta_k) > \delta_j p_j - \delta_k p_k \iff y > \frac{\delta_j p_j - \delta_k p_k}{\delta_j - \delta_k}.$$

Richer consumers buy higher quality, and the cutoffs now live in income space. Shaked and Sutton (1982) embed this demand system in a two-stage game. Firms first choose qualities and then compete in prices, and in equilibrium they choose distinct qualities to relax price competition. Mussa and Rosen (1978) study a monopolist that offers a menu of qualities to consumers with utility $v_i\delta - p$. The monopolist screens consumers by quality and supplies every type except the highest a quality below the efficient level. These theory results take the vertical structure as given. Section 6.5 develops its demand side for estimation.

6.4.6 The logit as a model of differentiation

The logit model $u_{ij} = \delta_j - \alpha p_j + \epsilon_{ij}$, with ϵ_{ij} i.i.d. type-I extreme value (Proposition 6.11), is also a model of differentiation. Each product carries its own taste dimension. Remark 6.12 reads the shock ϵ_{ij} as consumer i's random taste for a characteristic that only product j possesses, the product's own dummy variable. Under this reading, which Berry and Pakes (2007) attribute to Caplin and Nalebuff (1991), the characteristic space of the logit has one dimension per product. Adding a product adds a dimension, so every product owns a neighborhood of taste space that no rival can enter. This is the formal content of the statement that the product space is never exhausted.

The logit treats every pair of products as equally distant. Consumers who leave a product spread over the others in proportion to their shares, the independence of irrelevant alternatives property examined in Section 6.3.4 and Chapter 7. Anderson et al. (1989) give the logit a deterministic address representation, with no random utility shock. Their consumers have ideal points as in (6.33), with utility linear in price and a common weight on every characteristic. With J products and no outside good, each demand rises strictly with every rival price, at every price vector, only if the products span at least $J-1$ dimensions (Anderson et al., 1989, Proposition 1). We follow Anderson et al. (1989) and place product J at the origin and each product $j < J$ at the same distance along the axis of characteristic j. These locations span exactly $J-1$ dimensions. We also give the products equal quality. Logit demand then arises from a unique density of ideal points, which has a single peak at the point equidistant from all products (Anderson et al., 1989, Propositions 2 and 4). Other locations that span $J-1$ dimensions also give a unique density, though a different one (Anderson et al., 1989, p. 26). The nested logit adds a taste common to the products of a group, and the random coefficients logit adds tastes for characteristics. Both keep the product-specific shock. Table 6.1 summarizes how the models differ.

6.5 The vertical model

The vertical model is the simplest model in characteristic space that delivers closed-form demand, an exact inversion from market shares to qualities, and a transparent supply side. It is the demand system of the first structural test of conduct in a differentiated-products industry (Bresnahan, 1987), the case study of Section 6.6. It is also the building block from which Berry and Pakes (2007) compute shares in the pure characteristics model (Section 6.8). This section develops the model for a general taste distribution F, then specializes to exponential and uniform tastes. Every derivation is carried out in the notation of (6.37).

6.5.1 Setup and the ordering of products

Assumption 6.24 (Vertical model)**.**

Table 6.1: Discrete choice models of product differentiation compared

Model and utility	Dimension of heterogeneity	Who substitutes with whom	Closed-form shares	Markups as products crowd the space	Surplus from an added clone
Hotelling, Salop $-p_j - \tau\, d(x_j, \nu_i)^2$	1 (location)	Neighbors on the line or circle	Yes	Fall to zero ($\frac{\tau}{N}$ in Salop)	Zero
Ideal point $\delta_j - p_j - \sum_k \alpha_k (x_{jk} - \nu_{ik})^2$	K (ideal points)	Products close in characteristic space	No	Fall to zero	Zero
Pure characteristics $\delta_j - \alpha p_j + \sum_k \sigma_k \nu_{ik} x_{jk}$	K (tastes for characteristics)	Products close in characteristics and price	No	Fall to zero	Zero
Vertical $\delta_j - \nu_i p_j$	1 (price sensitivity)	Price neighbors only	Yes	Fall to zero for neighbors owned by rivals	Zero
Logit $\delta_j - \alpha p_j + \epsilon_{ij}$	J (one taste per product)	All products, in proportion to shares	Yes	Bounded below by $\frac{1}{\alpha}$	Positive
Nested logit $\delta_j - \alpha p_j + \zeta_{ig} + (1-\sigma)\epsilon_{ij}$	J plus one per nest	Mostly within the nest, in proportion to shares	Yes	Bounded below by $\frac{1-\sigma}{\alpha}$	Positive
Random coefficients logit $\delta_j - \alpha p_j + \sum_k \sigma_k \nu_{ik} x_{jk} + \epsilon_{ij}$	K plus J	Mostly toward products with similar characteristics	No	Bounded away from zero	Positive

Notes: Utilities omit income, which cancels under quasi-linearity. τ is the transport cost, d a distance, ν_i the consumer's type, and σ_k the dispersion of the taste for characteristic k. In the nested logit, $\sigma \in [0, 1)$ is the nesting parameter and ζ_{ig} is a taste for nest g whose distribution makes $\zeta_{ig} + (1-\sigma)\epsilon_{ij}$ type-I extreme value. Markup bounds are for single-product firms facing an outside good. "Surplus from an added clone" is the gain in expected consumer surplus, at fixed prices, from adding an exact copy of an existing product. Section 6.7 derives the logit entries, and Chapters 7 and 8 treat the nested and random coefficients logit.

(i) A market has M consumers and J inside products. Consumer i obtains $u_{ij} = \delta_j - v_i p_j$ from product j, where δ_j is the product's quality and $p_j > 0$ its price.

(ii) The outside good $j = 0$ has $\delta_0 = p_0 = 0$, so $u_{i0} = 0$.

(iii) The price sensitivities v_i are i.i.d. draws from a distribution with continuous and strictly increasing CDF F on $(0, \infty)$ and density $f = F' > 0$. We set $F(x) = 0$ for $x \le 0$.

(iv) Each consumer buys one unit of the product with the highest utility.

(v) Inside prices are distinct.

Part (iii) makes ties a probability-zero event, so choices are well defined for almost every consumer. The quality δ_j summarizes everything consumers value about product j, observed and unobserved. In estimation we write $\delta_j = x_j\beta + \xi_j$. Part (v) is generic. If two products had the same price, every consumer would buy the higher-quality one, and the other would sell nothing. The price sensitivity is the only dimension of consumer heterogeneity. Consumers agree on how characteristics combine into quality and disagree only on the marginal utility of money.

Lemma 6.25 (Ordering)**.** *Under Assumption 6.24, if $p_j > p_k$ and product j sells a positive quantity, then $\delta_j > \delta_k$. Hence the products with positive sales, together with the outside good, can be indexed so that*

$$0 = p_0 < p_1 < \cdots < p_J \qquad \text{and} \qquad 0 = \delta_0 < \delta_1 < \cdots < \delta_J. \tag{6.40}$$

Proof. Suppose $p_j > p_k$ and $\delta_j \le \delta_k$. For every $v > 0$,

$$u_j(v) - u_k(v) = (\delta_j - \delta_k) - v(p_j - p_k) \le -v(p_j - p_k) < 0.$$

Every consumer strictly prefers k to j, so j sells nothing. The contrapositive is the first claim. Applying it with $k = 0$ shows that every product with positive sales has $\delta_j > 0$. Applying it to every pair of products with positive sales orders their qualities as their prices. □

Among products that sell, price and quality rise together. A product that charges more than a rival and offers less quality loses every consumer to that rival. We say it is *dominated outright*. A subtler form of domination is possible. A product can offer more quality than every cheaper product and still sell nothing, because a combination of two rivals beats it for every consumer. The geometry of the (p, δ) plane makes this precise.

Proposition 6.26 (The quality-price frontier)**.** *Let $\mathcal{P} = \{(p_0, \delta_0), (p_1, \delta_1), \ldots, (p_J, \delta_J)\}$ be the points of the (p, δ) plane occupied by the outside good and the J products, with prices distinct but qualities arbitrary. Under Assumption 6.24 the following hold.*

(i) A consumer of type v chooses product j if and only if every other point of $\mathcal{P}$ lies strictly below the line through (p_j, δ_j) with slope v.

(ii) Product $j \ge 1$ sells a positive quantity if and only if (p_j, δ_j) is a vertex of the quality-price frontier*. The frontier is the rising part of the upper boundary of the convex hull of $\mathcal{P}$.*

(iii) Equivalently, delete the products that sell nothing and index the rest by price. Then the slopes $\bar{v}_j = \frac{\delta_j - \delta_{j-1}}{p_j - p_{j-1}}$, $j = 1, \ldots, J$, satisfy $\bar{v}_1 > \bar{v}_2 > \cdots > \bar{v}_J > 0$.

Proof. For (i), type v chooses j if and only if $\delta_j - vp_j > \delta_k - vp_k$ for all $k \neq j$. Rearranging, this holds if and only if

$$\delta_k < \delta_j + v(p_k - p_j) \qquad \text{for all } k \neq j.$$

The right side is the height at p_k of the line through (p_j, δ_j) with slope v.

For (ii), consider lines through (p_j, δ_j) that lie strictly above every other point of $\mathcal{P}$. Such a line exists if and only if (p_j, δ_j) is a vertex of the upper boundary of the convex hull of $\mathcal{P}$. Let a_j be the slope of the hull edge to the left of that vertex. Let b_j be the slope of the edge to its right, with $b_j = -\infty$ at the right end of the hull. Concavity of the upper boundary gives $a_j > b_j$. A line through the vertex lies strictly above all other points if and only if its slope lies in the open interval (b_j, a_j). By (i), the types that choose j form the set $(b_j, a_j) \cap (0, \infty)$. Because F has a positive density on $(0, \infty)$, this set has positive probability if and only if $a_j > 0$. In words, the vertex must lie on the rising part of the hull. The share is then $F(a_j) - F(\max\{b_j, 0\})$. A point that lies on a hull edge without being a vertex is chosen at most by the single type whose slope equals that edge's slope, a probability-zero event.

For (iii), the products that sell are the vertices of the rising part of the hull. Indexed by price, the edges between consecutive vertices have strictly decreasing slopes, because the upper boundary is strictly concave at each vertex. The last slope is positive because the hull rises up to the highest-quality product. Conversely, suppose the slopes of the chain through the remaining points are positive and strictly decreasing. Then the chain is strictly concave and rising, so every point on it is a vertex of the frontier. □

Figure 6.3 draws the frontier. The slopes of its edges are the *cutoffs* studied in Section 6.5.2. A product strictly below the frontier sells nothing. We say it is *dominated out of the market*. Two cases arise in the figure. Product a is dominated outright by product 1, which is cheaper and better. Product b has more quality than every cheaper product, yet it lies below the chord between products 2 and 3. Any consumer who would consider b prefers either 2 or 3. The frontier is computed by a scan over products sorted by price, the monotone-chain construction of the convex hull.

Step 1. Sort the products by price and place the outside good $(0, 0)$ first.

Step 2. Delete every product whose quality does not exceed the quality of every cheaper product, including the outside good. These products are dominated outright (Lemma 6.25).

Step 3. Scan the remaining products in increasing order of price, keeping a list of frontier candidates that starts with the outside good. Before adding a new product, compare two slopes: the slope from the second-to-last candidate to the last, and the slope from the last candidate to the new product. If the first is less than or equal to the second, the last candidate lies on or below the chord, so delete it. Repeat the check until it fails, then add the new product.

Step 4. The final list is the frontier. Its products sell positive quantities, and the slopes between consecutive products are the cutoffs $\bar{v}_1 > \cdots > \bar{v}_J$.

6.5.2 Cutoffs and single crossing

From now on we index only the products on the frontier, in increasing order of price, as in (6.40). A consumer compares each product first with its two price neighbors. She prefers j to

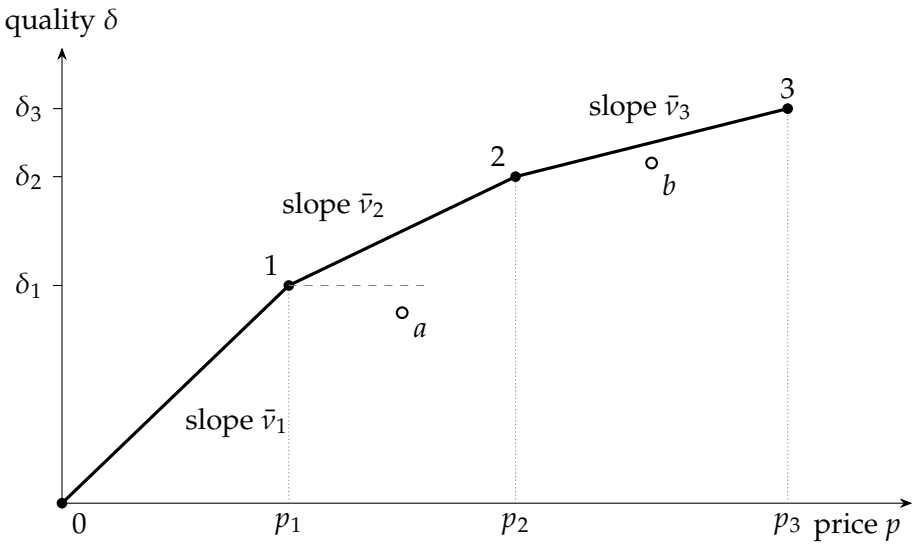

Figure 6.3: The quality-price frontier. Points are products in the (p, δ) plane, with the outside good at the origin. The bold line is the rising part of the upper boundary of the convex hull, and its vertices 1, 2 and 3 are the products that sell. The slope of the edge ending at product j is the cutoff $\bar{v}_j = \frac{\delta_j - \delta_{j-1}}{p_j - p_{j-1}}$. Product a is dominated outright by product 1 (higher price, lower quality). Product b offers more quality than every cheaper product but lies below the chord between products 2 and 3, so it sells nothing. The products are $(p_j, \delta_j) = (1, 1.6), (2, 2.4), (3.2, 2.9)$, with $a = (1.5, 1.4)$ and $b = (2.6, 2.5)$.

the next more expensive product $j+1$ if and only if

$$\begin{aligned} & \delta_j - \nu p_j > \delta_{j+1} - \nu p_{j+1} \\ \iff & \nu(p_{j+1} - p_j) > \delta_{j+1} - \delta_j \\ \iff & \nu > \frac{\delta_{j+1} - \delta_j}{p_{j+1} - p_j}. \end{aligned}$$

She prefers j to the next cheaper product $j-1$ if and only if

$$\begin{aligned} & \delta_j - \nu p_j > \delta_{j-1} - \nu p_{j-1} \\ \iff & \delta_j - \delta_{j-1} > \nu(p_j - p_{j-1}) \\ \iff & \nu < \frac{\delta_j - \delta_{j-1}}{p_j - p_{j-1}}. \end{aligned}$$

Both thresholds are slopes of frontier edges. We define the *cutoffs*

$$\bar{v}_j = \frac{\delta_j - \delta_{j-1}}{p_j - p_{j-1}}, \qquad j = 1, \dots, J, \qquad \text{with} \qquad \bar{v}_0 = \infty, \quad \bar{v}_{J+1} = 0. \tag{6.41}$$

The cutoff $\bar{v}_j$ is the type indifferent between $j-1$ and j. It measures the extra quality per extra dollar gained by moving up from $j-1$ to j. In particular $\bar{v}_1 = \frac{\delta_1}{p_1}$ is the type indifferent between buying product 1 and buying nothing. On the frontier the cutoffs are strictly decreasing (Proposition 6.26).

Proposition 6.27 (Choice intervals)**.** *Under Assumption 6.24, let all J products lie on the frontier, so that $\bar{v}_1 > \bar{v}_2 > \cdots > \bar{v}_J > 0$. Then consumer i chooses product $j \in \{0, 1, \ldots, J\}$ if and only if*

$$\bar{v}_{j+1} < v_i < \bar{v}_j. \tag{6.42}$$

In particular, the two comparisons with the price neighbors are sufficient for the choice of j.

Proof. By (6.39), for $k > j$ the difference $u_j(v) - u_k(v)$ is strictly increasing in v (single crossing). The two equivalences above state that $j \succ j+1$ if and only if $v > \bar{v}_{j+1}$, and $j \succ j-1$ if and only if $v < \bar{v}_j$.

Necessity. If i chooses j, then j beats both neighbors, so $\bar{v}_{j+1} < v_i < \bar{v}_j$. For $j = 0$ only the comparison with product 1 applies, and it gives $v_i > \bar{v}_1$. For $j = J$ only the comparison with $J-1$ applies, and $v_i > 0 = \bar{v}_{J+1}$ holds by assumption.

Sufficiency. Suppose $\bar{v}_{j+1} < v_i < \bar{v}_j$. Consider first the more expensive products. For every $m \geq j+1$ the cutoffs decrease, so $\bar{v}_m \leq \bar{v}_{j+1} < v_i$. Hence $m - 1 \succ m$ for every such m, and the chain

$$u_j(v_i) > u_{j+1}(v_i) > \cdots > u_J(v_i)$$

shows that j beats every more expensive product. Consider next the cheaper products. For every $m \leq j$, $\bar{v}_m \geq \bar{v}_j > v_i$. Hence $m \succ m-1$, and the chain

$$u_j(v_i) > u_{j-1}(v_i) > \cdots > u_0(v_i)$$

shows that j beats every cheaper product. Types exactly at a cutoff have probability zero. □

The proof uses the decreasing cutoffs at every step. If instead $\bar{v}_j \leq \bar{v}_{j+1}$ for some j, the interval in (6.42) is empty and product j sells nothing. In the (p, δ) plane such a product lies on or below the chord between $j-1$ and $j+1$, as Proposition 6.26 says. Consumers sort by price sensitivity. The least price-sensitive consumers buy the top product, and the most price-sensitive buy nothing. Figure 6.4 shows the construction with utility lines.

Without the frontier assumption, the same logic gives a single formula that holds for any qualities (Berry and Pakes, 2007, eqs. 14–17). Keep all products ordered by price, but let qualities be arbitrary. Product j beats product k if and only if $v(p_j - p_k) < \delta_j - \delta_k$. For a cheaper product $k < j$, dividing by $p_j - p_k > 0$ gives $v < \frac{\delta_j - \delta_k}{p_j - p_k}$. For a more expensive product $k > j$, dividing by $p_j - p_k < 0$ reverses the inequality and gives $v > \frac{\delta_k - \delta_j}{p_k - p_j}$. Product j is chosen if and only if $\underline{v}_j(\delta, p) < v < \bar{v}_j(\delta, p)$, where

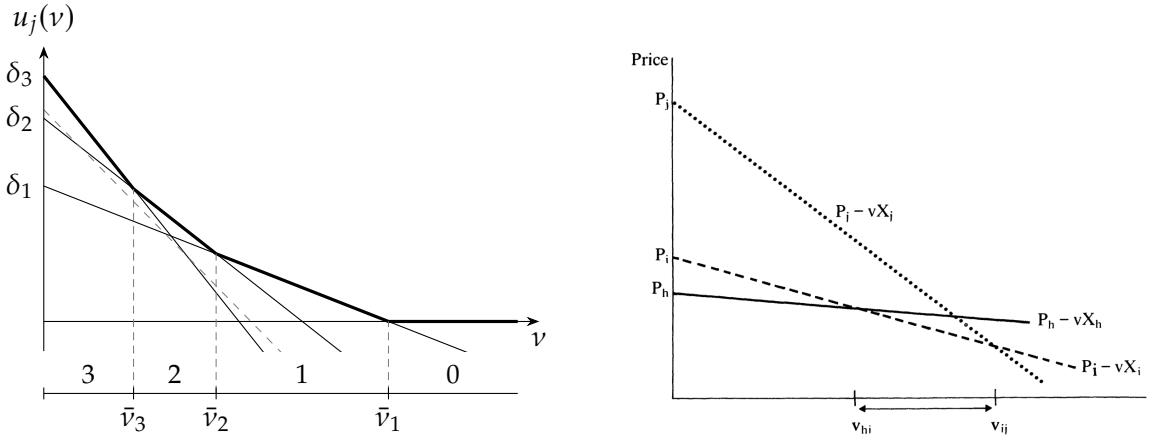
$$\bar{v}_j(\delta, p) = \min_{k<j} \frac{\delta_j - \delta_k}{p_j - p_k}, \qquad \underline{v}_j(\delta, p) = \max_{k>j} \frac{\delta_k - \delta_j}{p_k - p_j}, \tag{6.43}$$

with the conventions $\bar{v}_0(\delta, p) = \infty$ and $\underline{v}_J(\delta, p) = 0$. The share of product j is

$$s_j = \left[F(\bar{v}_j(\delta, p)) - F(\underline{v}_j(\delta, p))\right] \mathbf{1}\left\{\bar{v}_j(\delta, p) > \underline{v}_j(\delta, p)\right\}. \tag{6.44}$$

Berry and Pakes (2007) write these cutoffs as $\overline{\Delta}_j$ and $\underline{\Delta}_j$ and the price sensitivity as α_i.

Remark 6.28 (General and adjacent cutoffs). Formula (6.44) has three useful properties. First, for a product on the frontier, $\bar{v}_j(\delta, p) = \bar{v}_j$ and $\underline{v}_j(\delta, p) = \bar{v}_{j+1}$, the adjacent cutoffs of (6.41). The slope of the chord from j back to a cheaper frontier product k is an average of the edge slopes $\bar{v}_{k+1}, \ldots, \bar{v}_j$. Each of these is at least $\bar{v}_j$, so the minimum is attained at $k = j-1$. Points



(a) Utility lines and the upper envelope

(b) Total price lines in Bresnahan's form

Figure 6.4: Utility lines and cutoffs in the vertical model. (a) The utility $u_j(v) = \delta_j - vp_j$ of each product is a line with intercept δ_j and slope $-p_j$, and the outside good is the horizontal axis. The products are those of Figure 6.3. The bold upper envelope gives the chosen product, and adjacent lines cross at the cutoffs $\bar{v}_3 < \bar{v}_2 < \bar{v}_1$, here 0.42, 0.8 and 1.6. The strip below the axis shows the product chosen on each interval of v. The dashed gray line is product b, which never reaches the envelope. (b) The same construction in the form $\frac{u_{ij}}{v_i} = v_i\delta_j - p_j$ used by Bresnahan (1987). A consumer with taste for quality $v = \frac{1}{v}$ buys the product with the lowest total price $P - vX$, where Bresnahan writes P for price and X for quality. Product i is bought on the marked interval $[v_{hi}, v_{ij}]$. Because v is the reciprocal of v, the order of products along the horizontal axis is reversed. Source: Bresnahan (1987), Figure 1.

below the frontier give chords at least as steep, so they do not change the minimum. The same argument applies to the maximum. Second, the formula assigns a zero share to every product off the frontier, so one expression serves for every parameter value. This matters in estimation, where a trial parameter value can reorder qualities. Third, the vertical model predicts exact zero shares for some parameter values, which models with an idiosyncratic shock never do. Since observed shares are positive, the true parameters must place every product with positive sales on the frontier. Deleting the products dominated outright is not enough to impose this. Product b in Figure 6.3 beats every cheaper product in quality and still sells nothing.

6.5.3 Market shares

Integrating the choice intervals over the taste distribution gives the demand system.

Proposition 6.29 (Vertical market shares)**.** *Under Assumption 6.24, with all J products on the frontier, the market shares are*

$$s_j = F(\bar{v}_j) - F(\bar{v}_{j+1}), \quad j = 1, \dots, J, \qquad s_0 = 1 - F(\bar{v}_1) = 1 - F\Big(\frac{\delta_1}{p_1}\Big), \tag{6.45}$$

with $F(\bar{v}_{J+1}) = F(0) = 0$. Quantities are $q_j = Ms_j$.

Proof. By Proposition 6.27, $s_j = \mathbb{P}(\bar{v}_{j+1} < v_i < \bar{v}_j)$. Since F is continuous, the end points carry no mass, and $s_j = F(\bar{v}_j) - F(\bar{v}_{j+1})$. For the outside good, $s_0 = \mathbb{P}(v_i > \bar{v}_1) = 1 - F(\bar{v}_1)$. For the top product, $s_J = F(\bar{v}_J) - F(0) = F(\bar{v}_J)$. Summing over $j = 0, \dots, J$ telescopes to one. □

Four features of (6.45) recur below. Shares depend on qualities and prices only through the J cutoffs. The share of product j depends only on its own price and the prices of its two neighbors. The outside share depends only on the price and quality of the cheapest product. Zero shares are possible, for any product off the frontier. Figure 6.5 draws the shares as areas under the density.

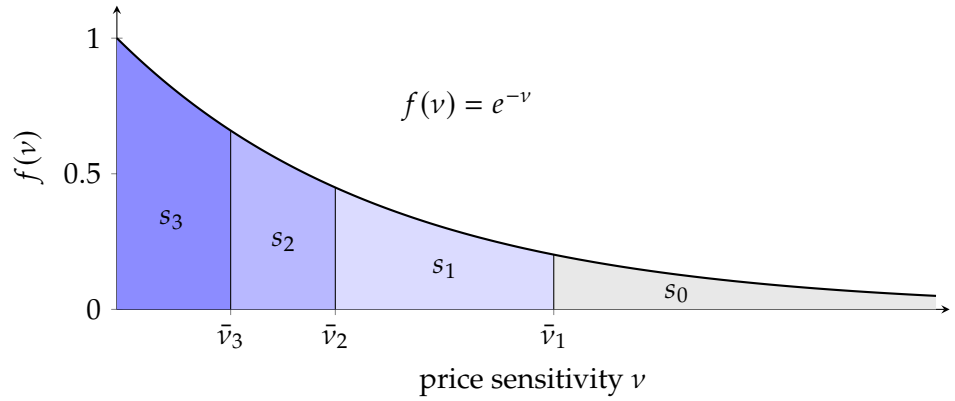


Figure 6.5: Market shares as areas under the taste density. The density is exponential with mean one, and the cutoffs are those of Figure 6.4, $\bar{v}_3 = 0.42$, $\bar{v}_2 = 0.8$ and $\bar{v}_1 = 1.6$. The least price-sensitive consumers buy the top product. The shares are $s_3 = 0.341$, $s_2 = 0.210$, $s_1 = 0.247$ and $s_0 = 0.202$.

Example 6.30 (Uniform tastes for quality)**.** Bresnahan (1987) works with the form (6.38) and assumes that the taste for quality $v_i = \frac{1}{\nu_i}$ is uniform on $[0, \bar{v}]$ with density κ, so the market has $M = \kappa\bar{v}$ consumers.[6] In v-space the cutoff between $j-1$ and j is the reciprocal of (6.41),

$$v_{j-1,j} = \frac{1}{\bar{\nu}_j} = \frac{p_j - p_{j-1}}{\delta_j - \delta_{j-1}},$$

and consumers with $v > v_{j-1,j}$ prefer j (Bresnahan, 1987, eq. 4). The implied CDF of $\nu = \frac{1}{v}$ is

$$F(\nu) = \mathbb{P}\Big(v \geq \frac{1}{\nu}\Big) = 1 - \frac{1}{\bar{v}\,\nu}, \qquad \nu \geq \frac{1}{\bar{v}},$$

and zero below $\frac{1}{\bar{v}}$. Substituting into (6.45),

$$s_j = \Big[1 - \frac{1}{\bar{v}\,\bar{\nu}_j}\Big] - \Big[1 - \frac{1}{\bar{v}\,\bar{\nu}_{j+1}}\Big] = \frac{1}{\bar{v}}\big(v_{j,j+1} - v_{j-1,j}\big),$$

so that $q_j = Ms_j = \kappa\,(v_{j,j+1} - v_{j-1,j})$, or

$$q_j = \kappa\Big[\frac{p_{j+1} - p_j}{\delta_{j+1} - \delta_j} - \frac{p_j - p_{j-1}}{\delta_j - \delta_{j-1}}\Big], \qquad q_J = \kappa\Big[\bar{v} - \frac{p_J - p_{J-1}}{\delta_J - \delta_{J-1}}\Big]. \tag{6.46}$$

These are equations (10) and (11) of Bresnahan (1987). Demand is linear in prices because the cutoffs in v-space are linear in prices. The support of ν starts at $\frac{1}{\bar{v}}$ instead of zero, so the top product sells only if $v_{J-1,J} < \bar{v}$. Bresnahan assumes that the consumer with the highest taste, $\bar{v}$, always buys a car. In his application the alternative to a new car is a used car of quality δ_{u} and price p_{u}, which replaces the origin as the point (p_0, δ_0) (Section 6.5.7).

[6] Bresnahan writes quality as x, the taste density as δ, and the upper bound as $V_{\max}$. We write δ_j, κ and $\bar{v}$ to keep the notation of this chapter.

6.5.4 Inverting market shares

Estimation requires the reverse map, from observed shares to qualities (Section 6.2.7). In the vertical model the inverse exists, is unique, and has a closed form. Let

$$S_j = \sum_{k \geq j} s_k, \qquad j = 1, \dots, J, \tag{6.47}$$

be the *cumulative share from the top*, the share of consumers who buy product j or a more expensive product.

Proposition 6.31 (Inversion)**.** *Under Assumption 6.24, let the prices satisfy $0 < p_1 < \cdots < p_J$ and let the observed shares $s_j = \frac{q_j}{M}$ be positive for $j = 1, \dots, J$, with $s_0 = 1 - \sum_j s_j > 0$. There is exactly one quality vector δ under which all J products lie on the frontier and the predicted shares (6.45) equal the observed shares. It is given by*

$$\bar{v}_j = F^{-1}(S_j), \tag{6.48}$$

$$\delta_j = \delta_{j-1} + (p_j - p_{j-1})\, F^{-1}(S_j), \qquad \delta_0 = 0, \tag{6.49}$$

$$\delta_j = \sum_{m=1}^{j} (p_m - p_{m-1})\, F^{-1}\Big(\sum_{k \geq m} s_k \Big). \tag{6.50}$$

Proof. The first step sums shares from the top. Under (6.45),

$$S_j = \sum_{k=j}^{J} \big[F(\bar{v}_k) - F(\bar{v}_{k+1}) \big] = F(\bar{v}_j) - F(\bar{v}_{J+1}) = F(\bar{v}_j).$$

The second step proves uniqueness. Because F is continuous and strictly increasing on $(0, \infty)$, its inverse F^{-1} is well defined on $(0, 1)$. Each S_j lies in $(0, 1)$, since $s_J > 0$ and $1 - S_1 = s_0 > 0$. Hence $\bar{v}_j = F^{-1}(S_j)$ is the only cutoff consistent with the data. The definition (6.41) gives $\delta_j - \delta_{j-1} = (p_j - p_{j-1})\bar{v}_j$, which is (6.49). Starting from $\delta_0 = 0$ and iterating gives (6.50), so every quality is pinned down.

The third step proves existence. Define δ by (6.50). All shares are positive, so $S_1 > S_2 > \cdots > S_J > 0$. Because F^{-1} is strictly increasing, $\bar{v}_1 > \bar{v}_2 > \cdots > \bar{v}_J > 0$. Qualities then increase with price and the cutoffs decrease, so by Proposition 6.26 every product lies on the frontier. Proposition 6.29 gives predicted shares $F(\bar{v}_j) - F(\bar{v}_{j+1}) = S_j - S_{j+1} = s_j$. □

Several consequences follow. The price ordering determines the quality ordering, so the data reveal the ranking of products without any parameter. Every vector of positive shares is rationalized by some quality vector, whatever the increasing distribution F. A single market's prices and shares therefore never reject the vertical model. Its testable content comes from restrictions across products and markets, such as $\delta_{jt} = x_{jt}\beta + \xi_{jt}$, and from the supply side.

The result is an instance of the general invertibility theory of Berry et al. (2013). On the set of qualities at which every product sells, raising δ_j raises $\bar{v}_j$ and lowers $\bar{v}_{j+1}$. It therefore raises s_j, lowers s_{j-1} and s_{j+1} (or s_0 when $j = 1$), and leaves every other share unchanged. Inside goods are weak substitutes in this sense. The chain $0, 1, \dots, J$ of strict substitution between neighbors connects every inside good to the outside good. These are the "connected substitutes" conditions under which Berry et al. (2013) prove that demand is invertible. The proof above exploits the special structure and also delivers the inverse in closed form.

Market size enters through every share. Holding unit sales fixed, a larger M lowers every cumulative share S_j, which lowers every cutoff and every quality. A market with more nonbuyers is rationalized by products that are worse relative to the outside good. The choice of M is an assumption, and it matters for the level of the recovered qualities.

Example 6.32 (Exponential tastes)**.** Let $F(v) = 1 - e^{-\lambda v}$ with $\lambda > 0$, so that $\mathbb{E}[v_i] = \frac{1}{\lambda}$. Solving $u = 1 - e^{-\lambda v}$ for v gives

$$F^{-1}(u) = -\frac{1}{\lambda}\ln(1-u).$$

Substituting into (6.50),

$$\delta_j = -\frac{1}{\lambda}\sum_{m=1}^{j}(p_m - p_{m-1})\ln(1-S_m), \qquad 1 - S_m = s_0 + \sum_{l<m} s_l, \tag{6.51}$$

where $1 - S_m$ is the share of consumers who buy the outside good or a product cheaper than m. Now let there be markets $t = 1, \dots, T$, and let (m) denote the m-th cheapest product of market t. For the product j that occupies position k in market t, define the observable

$$y_{jt} \equiv -\sum_{m=1}^{k}\left(p_{(m)t} - p_{(m-1)t}\right)\ln(1-S_{mt}), \tag{6.52}$$

which uses prices and shares only. By (6.51), $y_{jt} = \lambda\delta_{jt}$. Substituting $\delta_{jt} = x_{jt}\beta + \xi_{jt}$ gives the estimable equation

$$y_{jt} = x_{jt}(\lambda\beta) + \lambda\xi_{jt}. \tag{6.53}$$

Proposition 6.33 (Scale of tastes)**.** *In Example 6.32, λ is not identified. For every $c > 0$ the parameters (λ, β, ξ) and $(\frac{\lambda}{c}, c\beta, c\xi)$ imply the same choice for every consumer and hence the same shares. More generally, for any F, the pairs $(F(\cdot), \delta)$ and $(F(\frac{\cdot}{c}), c\delta)$ are observationally equivalent.*

Proof. Let v have CDF F and define $v' = cv$. Then $\mathbb{P}(v' \le x) = \mathbb{P}(v \le \frac{x}{c}) = F(\frac{x}{c})$. A consumer of type v facing qualities δ compares $\delta_j - vp_j$ across products. Multiplying by $c > 0$ gives

$$c\delta_j - (cv)p_j = c\delta_j - v'p_j,$$

which ranks products in the same order. So a consumer of type v' facing qualities $c\delta$ makes the same choice as a consumer of type v facing δ. Integrating over types, the shares under $(F(\frac{\cdot}{c}), c\delta)$ equal those under (F, δ). For the exponential distribution, $F(\frac{x}{c}) = 1 - e^{-\frac{\lambda}{c}x}$ is exponential with parameter $\frac{\lambda}{c}$, and $c\delta_j = x_j(c\beta) + c\xi_j$. □

The economic content is that choices reveal quality only in units of willingness to pay. Doubling every quality and doubling every consumer's price sensitivity describes the same consumers making the same choices. This is the scale normalization of Section 6.2.3 in the vertical model. We set $\lambda = 1$, so that $\mathbb{E}[v_i] = 1$. A consumer with the mean price sensitivity then values one unit of quality at one dollar, and (6.53) becomes $y_{jt} = x_{jt}\beta + \xi_{jt}$.

With $\lambda = 1$ the demand parameters are identified under two conditions. The first is the moment condition $\mathbb{E}[x_{jt}^\top \xi_{jt}] = 0$, and the second is full rank of $\mathbb{E}[x_{jt}^\top x_{jt}]$. Then $\beta = \mathbb{E}[x_{jt}^\top x_{jt}]^{-1}\mathbb{E}[x_{jt}^\top y_{jt}]$, and the OLS regression of y_{jt} on x_{jt} is consistent. Price is not a regressor. It enters only the construction of y_{jt}, an exact function of observed prices and shares. Firms that observe ξ_{jt} set higher prices for better products, so p_{jt} and ξ_{jt} are correlated. This correlation

does not bias the regression, because the vertical model has no price coefficient left to estimate. The normalized distribution F plays the role of the price coefficient. It states how many consumers have each price sensitivity, and nothing about it remains unknown. Standard errors should be clustered by market. The values y_{jt} of products in the same market are built from the same cumulative shares. Any sampling error in observed shares, or any misspecification of F, therefore enters the errors of all products in a market and accumulates along the price ladder.

The same feature is the model's main weakness. With F fully specified, every substitution pattern is determined by functional form and by the observed prices and shares (Proposition 6.37 below). Exogenous variation in prices is never used to learn how demand responds to prices. Two further cautions apply. The moment condition fails if firms choose characteristics with knowledge of ξ_{jt} (Section 6.1). If F is misspecified, y_{jt} differs from δ_{jt} by a function of prices and shares, and the regression error inherits that function.

Remark 6.34 (Shape parameters and instruments). Suppose that after the scale normalization F still has an unknown shape parameter. An example is $\ln \nu_i \sim N(0, \sigma^2)$, whose median is fixed at one. With Φ the standard normal CDF, $F_\sigma^{-1}(u) = \exp(\sigma \Phi^{-1}(u))$, and the inversion gives

$$\delta_{jt}(\sigma) = \sum_{m=1}^{k} \left(p_{(m)t} - p_{(m-1)t}\right) \exp\left(\sigma\, \Phi^{-1}(S_{mt})\right).$$

For any trial value of σ, OLS of $\delta_{jt}(\sigma)$ on x_{jt} produces residuals orthogonal to x_{jt}. The K moments $\mathbb{E}[x_{jt}^\top \xi_{jt}] = 0$ therefore cannot determine the $K+1$ parameters (β, σ). Identification of σ requires at least one excluded instrument z_{jt}. This is a variable uncorrelated with ξ_{jt} that moves prices or shares, such as a cost shifter or a characteristic of rival products. Stack the instruments in $Z_{jt} = (x_{jt}, z_{jt})$ and define $\xi_{jt}(\sigma, \beta) = \delta_{jt}(\sigma) - x_{jt}\beta$. The GMM estimator uses $\mathbb{E}[Z_{jt}^\top \xi_{jt}(\sigma, \beta)] = 0$. For fixed σ the estimate of β is the linear IV estimator

$$\hat{\beta}(\sigma) = (X^\top Z W Z^\top X)^{-1} X^\top Z W Z^\top \delta(\sigma),$$

where X, Z and $\delta(\sigma)$ stack the observations and W is a weighting matrix. Concentrating out β leaves a search over σ alone,

$$\hat{\sigma} = \arg\min_{\sigma}\; g_N(\sigma)^\top W g_N(\sigma), \qquad g_N(\sigma) = \frac{1}{N} \sum_{j,t} Z_{jt}^\top \big(\delta_{jt}(\sigma) - x_{jt}\hat{\beta}(\sigma)\big).$$

This is the structure of the estimator for the nonlinear parameters θ_2 in Chapter 8. Price endogeneity now matters. Prices enter $\delta_{jt}(\sigma)$ in a way that depends on σ, so the instruments must move prices independently of ξ_{jt}. Standard errors are again clustered by market.

The uniform model of Example 6.30 inverts in the same way. Summing (6.46) from the top gives $\sum_{k \geq j} q_k = \kappa(\bar{v} - v_{j-1,j})$. Dividing by $M = \kappa \bar{v}$ gives $v_{j-1,j} = \bar{v}(1 - S_j)$, so

$$\delta_j - \delta_{j-1} = \frac{p_j - p_{j-1}}{\bar{v}(1 - S_j)}.$$

Given the market size, $\bar{v}$ only sets the units of quality, in line with Proposition 6.33.

6.5.5 Substitution patterns

We now hold qualities fixed and differentiate shares with respect to prices. Each price enters only the two cutoffs that involve its product. Differentiating (6.41),

$$\frac{\partial \bar{v}_j}{\partial p_j} = -\frac{\delta_j - \delta_{j-1}}{(p_j - p_{j-1})^2} = -\frac{\bar{v}_j}{p_j - p_{j-1}}, \qquad \frac{\partial \bar{v}_j}{\partial p_{j-1}} = \frac{\delta_j - \delta_{j-1}}{(p_j - p_{j-1})^2} = \frac{\bar{v}_j}{p_j - p_{j-1}},$$

and, shifting the index,

$$\frac{\partial \bar{v}_{j+1}}{\partial p_j} = \frac{\bar{v}_{j+1}}{p_{j+1} - p_j}, \qquad \frac{\partial \bar{v}_{j+1}}{\partial p_{j+1}} = -\frac{\bar{v}_{j+1}}{p_{j+1} - p_j}.$$

A higher own price lowers the upper cutoff of j and raises its lower cutoff, so the interval of buyers shrinks from both ends. It is convenient to define

$$g_j = f(\bar{v}_j)\,\frac{\bar{v}_j}{p_j - p_{j-1}} > 0, \quad j = 1, \dots, J, \qquad g_{J+1} = 0. \tag{6.54}$$

The number g_j is the density of consumers at the boundary between $j-1$ and j, times the speed at which that boundary moves when either price changes.

Proposition 6.35 (Price derivatives)**.** *Under Assumption 6.24, with all products on the frontier and qualities held fixed,*

$$\frac{\partial s_j}{\partial p_j} = -g_j - g_{j+1} = -\frac{f(\bar{v}_j)\bar{v}_j}{p_j - p_{j-1}} - \frac{f(\bar{v}_{j+1})\bar{v}_{j+1}}{p_{j+1} - p_j}, \tag{6.55}$$

$$\frac{\partial s_j}{\partial p_{j-1}} = g_j, \qquad \frac{\partial s_j}{\partial p_{j+1}} = g_{j+1}, \qquad \frac{\partial s_j}{\partial p_k} = 0 \ \text{for } |k - j| \geq 2, \tag{6.56}$$

$$\frac{\partial s_0}{\partial p_1} = g_1, \qquad \frac{\partial s_0}{\partial p_k} = 0 \ \text{for } k \geq 2. \tag{6.57}$$

The second term of (6.55) is absent for the top product. The $J \times J$ Jacobian Δ^s with $\Delta^s_{jk} = \frac{\partial s_j}{\partial p_k}$ is tridiagonal and symmetric, with $\Delta^s_{j,j+1} = \Delta^s_{j+1,j} = g_{j+1}$. Each column of the $(J+1) \times J$ matrix that adds the outside-good row sums to zero.

Proof. Write $s_j = F(\bar{v}_j) - F(\bar{v}_{j+1})$. The price p_j enters $\bar{v}_j$ and $\bar{v}_{j+1}$ only, so by the chain rule

$$\frac{\partial s_j}{\partial p_j} = f(\bar{v}_j)\frac{\partial \bar{v}_j}{\partial p_j} - f(\bar{v}_{j+1})\frac{\partial \bar{v}_{j+1}}{\partial p_j} = -f(\bar{v}_j)\frac{\bar{v}_j}{p_j - p_{j-1}} - f(\bar{v}_{j+1})\frac{\bar{v}_{j+1}}{p_{j+1} - p_j}.$$

The price p_{j-1} enters s_j only through $\bar{v}_j$, so $\frac{\partial s_j}{\partial p_{j-1}} = f(\bar{v}_j)\frac{\bar{v}_j}{p_j - p_{j-1}} = g_j$. The price p_{j+1} enters s_j only through $\bar{v}_{j+1}$, so

$$\frac{\partial s_j}{\partial p_{j+1}} = -f(\bar{v}_{j+1})\frac{\partial \bar{v}_{j+1}}{\partial p_{j+1}} = f(\bar{v}_{j+1})\frac{\bar{v}_{j+1}}{p_{j+1} - p_j} = g_{j+1}.$$

No other price enters s_j. For the outside good, $s_0 = 1 - F(\bar{v}_1)$ with $\bar{v}_1 = \frac{\delta_1}{p_1}$, so $\frac{\partial s_0}{\partial p_1} = f(\bar{v}_1)\frac{\bar{v}_1}{p_1} = g_1$. Symmetry follows by comparing $\Delta^s_{j,j+1} = g_{j+1}$ with $\Delta^s_{j+1,j} = \frac{\partial s_{j+1}}{\partial p_j} = g_{j+1}$, the second identity in (6.56) applied to product $j+1$. Column k has the entries g_k in row $k-1$ (the outside row when $k = 1$), $-g_k - g_{k+1}$ in row k, and g_{k+1} in row $k+1$. They sum to zero. □

Symmetry has a simple reading. The number g_{j+1} measures the consumers at the boundary between j and $j+1$. A small rise in p_j moves these marginal consumers from j to $j+1$, and an equal rise in p_{j+1} moves the same consumers back. The flow across a shared boundary is the same in both directions. Symmetry also follows from the envelope argument behind Theorem 6.7. Dividing utility by v_i gives $\frac{u_{ij}}{v_i} = \frac{\delta_j}{v_i} - p_j$, which is quasi-linear in money for each consumer. The level $M\,\mathbb{E}\big[\max_j(\frac{\delta_j}{v_i} - p_j)\big]$ is infinite when $\mathbb{E}\big[\frac{1}{v_i}\big] = \infty$, as with exponential tastes. We therefore measure aggregate consumer surplus relative to a fixed price vector p^0:

$$CS(p) = M\,\mathbb{E}\Big[\max_j\Big(\frac{\delta_j}{v_i} - p_j\Big) - \max_j\Big(\frac{\delta_j}{v_i} - p_j^0\Big)\Big].$$

The two maxima differ by at most $\max_j |p_j - p_j^0|$, so $CS(p)$ is finite. By the envelope theorem it satisfies $\frac{\partial CS}{\partial p_j} = -q_j$, and the symmetry of its second derivatives gives $\frac{\partial q_j}{\partial p_k} = \frac{\partial q_k}{\partial p_j}$. The zero column sums say that a price change only reallocates the M consumers among the alternatives.

The structure of Δ^s has further consequences used in Section 6.5.6. In row j with $2 \le j \le J$, the off-diagonal entries g_j and g_{j+1} sum to $|\Delta^s_{jj}|$. In the first row, $|\Delta^s_{11}| = g_1 + g_2$ exceeds the single off-diagonal entry g_2, because product 1 also loses consumers to the outside good. So Δ^s is weakly diagonally dominant, strictly so in the first row. Because Δ^s is tridiagonal with nonzero off-diagonal entries, it is also irreducible. An irreducible matrix that is weakly diagonally dominant with at least one strictly dominant row is nonsingular (Berman and Plemmons, 1994, ch. 6). Lemma 6.46 in Section 6.6.4 states and proves this fact in the form we need.

The *diversion ratio* from j to k is the fraction of the consumers lost by j after a price increase who switch to k (Chapter 4). We write it $D_{jk} = -\frac{\Delta^s_{kj}}{\Delta^s_{jj}}$. Here

$$D_{j,j-1} = \frac{g_j}{g_j + g_{j+1}}, \qquad D_{j,j+1} = \frac{g_{j+1}}{g_j + g_{j+1}},$$

and all other diversion ratios are zero. Every consumer who leaves j goes to a price neighbor, with the outside good counting as the lower neighbor of product 1.

We write the elasticity of the share of j with respect to the price of k as $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$. The diagonal entries are negative, and the own-price elasticity in the positive convention of the book is $\varepsilon_j = -\varepsilon_{jj} = \frac{(g_j+g_{j+1})p_j}{s_j}$. The outside good has the single nonzero elasticity $\varepsilon_{01} = \frac{g_1 p_1}{s_0}$.

Closeness in price means closeness in substitution. Holding a cutoff fixed, the cross derivative $g_{j+1} = f(\bar v_{j+1})\frac{\bar v_{j+1}}{p_{j+1}-p_j}$ grows without bound as $p_{j+1} - p_j \to 0$, and the own derivatives of both products grow with it. In the data the cutoff is pinned down by shares through $\bar v_{j+1} = F^{-1}(S_{j+1})$. Two products that sell at nearly the same price are therefore read as near-perfect substitutes, whatever the products are. With uniform tastes the derivatives are constant. Using $f(v) = \frac{1}{\bar v v^2}$ from Example 6.30,

$$M g_j = \kappa\bar v \cdot \frac{1}{\bar v\,\bar v_j^2} \cdot \frac{\bar v_j}{p_j - p_{j-1}} = \frac{\kappa}{\bar v_j(p_j - p_{j-1})} = \frac{\kappa}{\delta_j - \delta_{j-1}}.$$

Hence $\frac{\partial q_j}{\partial p_j} = -\kappa\big(\frac{1}{\delta_j - \delta_{j-1}} + \frac{1}{\delta_{j+1} - \delta_j}\big)$ and $\frac{\partial q_{j\pm1}}{\partial p_j} = \frac{\kappa}{|\delta_{j\pm1} - \delta_j|}$. Demand is linear, and the quality gap measures how close two products are. In Bresnahan's words, the products are perfect

substitutes "in the limit as x_i goes to x_h," where x is his notation for quality (Bresnahan, 1987, p. 462).

Is this a reasonable model of substitution? The restriction that only price neighbors substitute is strong. A price cut on a mid-size sedan has no effect on a model two steps away on the price ladder, however similar the two cars are physically. Conversely, a minivan and a sports car at the same price are treated as close substitutes because they are neighbors on the ladder. The restriction is natural where quality is essentially one-dimensional, as with airline cabins or storage tiers. It is also the source of the power of the conduct test in Section 6.6. Where products differ along several dimensions, it can mislead badly.

A simulated illustration shows how badly (Appendix C). Market data are generated by a random coefficients logit model in 100 markets, each offering between four and nine of ten products. The vertical model with exponential tastes and $\lambda = 1$ is then fitted to these data. In one market the fitted own-price elasticities ε_{jj} range from -358.4 to -16.8, while the true ε_{jj} range from -3.85 to -2.57. The largest elasticities belong to products whose price neighbor sells at almost the same price. The two products with the largest elasticities in that market are price neighbors whose prices differ by only 0.019. Across all markets, the median gap between adjacent prices is 0.057, and 58 of the 554 gaps are below 0.01. The vertical model can explain why consumers split across products with similar prices only by placing those products almost on top of each other in quality. Under multi-product Nash pricing it then implies a mean markup of 0.048, against a true mean markup of 0.386.

6.5.6 Pricing and recovering marginal costs

Firms indexed by f own disjoint sets of products $\mathcal{J}_f$ and produce at constant marginal costs mc_j. Firm f chooses the prices of its products to maximize $M \sum_{k \in \mathcal{J}_f} (p_k - mc_k) s_k(p)$. The first-order condition for p_j, $j \in \mathcal{J}_f$, is

$$s_j + \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j} = 0.$$

With the ownership matrix Ω ($\Omega_{jk} = 1$ if j and k have the same owner) and $\odot$ the element-wise product, the conditions stack into

$$s + (\Omega \odot \Delta^{s\top})(p - mc) = 0 \qquad \Longrightarrow \qquad mc = p + (\Omega \odot \Delta^{s\top})^{-1} s, \tag{6.58}$$

the multi-product markup formula of Chapter 4. By Proposition 6.35, the condition for product j involves only its neighbors. Writing $m_j = p_j - mc_j$ for the markup,

$$s_j - (g_j + g_{j+1})\, m_j + \Omega_{j,j+1}\, g_{j+1}\, m_{j+1} + \Omega_{j,j-1}\, g_j\, m_{j-1} = 0, \tag{6.59}$$

with $\Omega_{1,0} = 0$ because the outside good earns no markup. A single-product firm sets $m_j = \frac{s_j}{g_j + g_{j+1}}$, which is the inverse elasticity rule $\frac{m_j}{p_j} = \frac{1}{\varepsilon_j}$. Equation (6.59) is the general-F version of the conduct equation that Bresnahan (1987) estimates (Section 6.6).

Corollary 6.36 (Only neighbors' ownership matters)**.** *Under the conditions of Proposition 6.35, the matrix $\Omega \odot \Delta^{s\top}$ is block diagonal. Each block corresponds to a maximal run of consecutive products with the same owner. Two ownership structures that agree on which adjacent pairs share an owner imply the same first-order conditions, and hence the same markups and implied marginal costs. Moreover, $\Omega \odot \Delta^{s\top}$ is nonsingular, and the markups $m = -(\Omega \odot \Delta^{s\top})^{-1} s$ are positive.*

Proof. Because $\Delta^{s\top}$ is tridiagonal, $(\Omega \odot \Delta^{s\top})_{jk} = \Omega_{jk}\Delta^s_{kj}$ vanishes unless $|j-k| \le 1$. For $|j-k| = 1$ it equals $g_{\max\{j,k\}}$ if the two products share an owner and zero otherwise. So the matrix depends on Ω only through the entries $\Omega_{j,j+1}$, and it breaks into blocks at every adjacent pair with different owners. Within a block that starts at product a, the first row has diagonal entry $-(g_a + g_{a+1})$ and off-diagonal entry g_{a+1}, so it is strictly diagonally dominant by $g_a > 0$. The other rows are weakly dominant, as in the discussion after Proposition 6.35. Each block is tridiagonal with nonzero off-diagonal entries, hence irreducible. The negative of each block therefore has a positive diagonal, nonpositive off-diagonal entries, nonnegative row sums and a strictly positive first row sum. By Lemma 6.46(a) it is a nonsingular M-matrix whose inverse has positive entries. Since $s > 0$, the markups $m = \left(-(\Omega \odot \Delta^{s\top})\right)^{-1} s$ are positive. □

The corollary is a sharp prediction. A firm that owns products 1 and 3 but not product 2 prices exactly as two independent firms would. Joint ownership raises markups only when it links products that compete for the same marginal consumers.

The vertical model has a second, more surprising property. When F is known up to scale, the markups require no demand estimate at all.

Proposition 6.37 (Markups from prices and shares)**.** *Under Assumption 6.24, suppose $F(v) = F_1(\lambda v)$ for a known CDF F_1 with density f_1 and an unknown scale $\lambda > 0$. Then the Jacobian Δ^s, the markups $-(\Omega \odot \Delta^{s\top})^{-1}s$ and the implied marginal costs depend only on observed prices and shares. They depend on no demand parameter, including λ and β. With exponential tastes,*

$$\bar{v}_j = -\frac{1}{\lambda}\ln(1-S_j), \qquad f(\bar{v}_j) = \lambda(1-S_j), \qquad g_j = \frac{-(1-S_j)\ln(1-S_j)}{p_j - p_{j-1}}. \tag{6.60}$$

Proof. By Proposition 6.31, $\bar{v}_j = F^{-1}(S_j) = \frac{1}{\lambda}F_1^{-1}(S_j)$. The density is $f(v) = \lambda f_1(\lambda v)$. Hence

$$f(\bar{v}_j)\,\bar{v}_j = \lambda f_1\big(F_1^{-1}(S_j)\big) \cdot \frac{1}{\lambda}F_1^{-1}(S_j) = f_1\big(F_1^{-1}(S_j)\big)\,F_1^{-1}(S_j),$$

and $g_j = \frac{f_1(F_1^{-1}(S_j))F_1^{-1}(S_j)}{p_j - p_{j-1}}$ depends on prices and shares only. Proposition 6.35 builds Δ^s from the g_j, and (6.58) builds the markups and marginal costs from Δ^s, s and p. For the exponential case, $F_1(x) = 1 - e^{-x}$, so $F_1^{-1}(u) = -\ln(1-u)$ and $f_1(F_1^{-1}(u)) = e^{\ln(1-u)} = 1-u$. □

The scale drops out for a reason. Markups are measured in dollars, while the scale normalization concerns the units of utility, so no choice of units can change them. The proposition has two practical consequences. First, the supply side can be estimated without any demand estimate. The implied marginal cost of each product is a known function of the data. Second, demand and supply share no parameter. When the demand error ξ_{jt} and the cost error ω_{jt} are independent, estimating the two equations separately loses no efficiency. The flip side is the caution raised in Section 6.5.4. The model reads market power off the spacing of prices and the cumulative shares, never off exogenous price variation.

The supply equations take two forms, one per conduct assumption. Under marginal-cost pricing,

$$p_{jt} = x_{jt}\gamma_1 + \gamma_2 z_{jt} + \omega_{jt}. \tag{6.61}$$

Under multi-product Nash pricing,

$$p_{jt} + \left[(\Omega_t \odot \Delta_t^{s\top})^{-1}s_t\right]_j = x_{jt}\gamma_1 + \gamma_2 z_{jt} + \omega_{jt}. \tag{6.62}$$

Here z_{jt} is a cost shifter excluded from demand, and γ_1 and γ_2 are cost coefficients, unrelated to Euler's constant γ_E. Under either assumption the left side is data, so OLS under $\mathbb{E}[\omega_{jt} \mid x_{jt}, z_{jt}] = 0$ estimates the cost parameters. The conduct assumption determines how large the markup is, and so how much of the price variation across products is attributed to cost. Comparing the two specifications is the logic of the conduct test in Section 6.6.

Remark 6.38 (Existence of a price equilibrium). Bresnahan (1987, footnote 6) observes that a price equilibrium always exists in quality models of this kind, while it can fail in location models. With uniform tastes, consider product j as its own price falls. Its interval of buyers widens, and at some price the next product $j+1$ is dominated out of the market. Demand for j stays continuous at that price, because the interval of $j+1$ shrinks continuously to zero. The slope of demand changes from $-\kappa\big(\frac{1}{\delta_{j+1}-\delta_j} + \frac{1}{\delta_j-\delta_{j-1}}\big)$ to $-\kappa\big(\frac{1}{\delta_{j+2}-\delta_j} + \frac{1}{\delta_j-\delta_{j-1}}\big)$. The second is smaller in absolute value, because $\delta_{j+2} - \delta_j > \delta_{j+1} - \delta_j$. So demand is flatter below the kink than above it, and the derivative $\frac{\partial q_j}{\partial p_j}$ falls as p_j rises. Demand is concave in own price across the kink, and the same holds where the lower neighbor drops out. Profit $(p_j - mc_j)q_j$ is then concave in p_j on the range of prices at which j sells with a positive markup, and it is zero beyond that range. Profit is therefore quasi-concave, and standard fixed-point arguments give an equilibrium. In the Hotelling model with linear costs, demand jumps when a firm captures the rival's location, and existence can fail (Section 6.4.2). Caplin and Nalebuff (1991, Theorem 2) cover general taste densities with single-product firms. Utility must be linear in the taste parameter, as in (6.38) with type v_i. The density of v_i must be ρ-concave with $\rho = -\frac{1}{2}$, the case $n = 1$ of their assumption A2. This means that $\frac{1}{\sqrt{f}}$ is convex, a condition that every log-concave density meets (Section 6.1.3 and Chapter 4).

Example 6.39 (A worked example)**.** Three products and an outside good face exponential tastes with $\lambda = 1$. Observed prices are $p = (1.0, 1.5, 2.5)$ and observed shares are $s = (0.20, 0.15, 0.10)$, so $s_0 = 0.55$. Table 6.2 reports every step, computed to more digits than shown.

The first step inverts the shares. Cumulative shares are $S = (0.45, 0.25, 0.10)$. By (6.60), the cutoffs are $\bar{v}_1 = -\ln 0.55 = 0.598$, $\bar{v}_2 = -\ln 0.75 = 0.288$ and $\bar{v}_3 = -\ln 0.90 = 0.105$. They decrease, as Proposition 6.31 guarantees, so all three products are on the frontier. The recursion (6.49) gives

$$\begin{aligned} \delta_1 &= 1.0 \times 0.598 = 0.598, \\ \delta_2 &= 0.598 + 0.5 \times 0.288 = 0.742, \\ \delta_3 &= 0.742 + 1.0 \times 0.105 = 0.847. \end{aligned}$$

Recomputing the shares at these qualities with (6.44) returns the observed shares exactly. Simulating two million consumers returns them up to simulation error.

The second step computes substitution. The densities at the cutoffs are $f(\bar{v}_j) = 1 - S_j = (0.55, 0.75, 0.90)$. Formula (6.54) gives $g_1 = \frac{0.55 \times 0.598}{1.0} = 0.329$, $g_2 = \frac{0.75 \times 0.288}{0.5} = 0.432$ and $g_3 = \frac{0.90 \times 0.105}{1.0} = 0.095$. These fill the Jacobian through Proposition 6.35. Product 2 has the most elastic demand, $\varepsilon_2 = 5.26$. It sits between two neighbors, and its lower neighbor is only 0.5 away in price. Product 3, at the top, has a single neighbor and the least elastic demand, $\varepsilon_3 = 2.37$. The outside good responds only to p_1.

The third step backs out markups and marginal costs under three ownership structures, holding the observed prices and shares fixed. Under (a) single-product firms, $m_j = \frac{s_j}{g_j + g_{j+1}}$, which gives markups of 0.263, 0.285 and 1.055. Under (b) joint ownership of products 1 and 2,

the boundary between them, where $g_2 = 0.432$ is large, is internalized. The implied markups of 1 and 2 roughly triple to 0.794 and 0.936. The markup of product 3 is unchanged at 1.055, since its own first-order condition does not change. Under (c) a single owner of all three products, the implied markups are 1.369, 1.948 and 3.002. They exceed the prices, so the implied marginal costs are negative. The observed prices are too low to be monopoly prices under this demand system, and conduct (c) is rejected by the requirement that costs be nonnegative. Finally, joint ownership of products 1 and 3 alone reproduces the numbers of case (a) to every digit, as Corollary 6.36 predicts.

Table 6.2: Worked example of the vertical model with exponential tastes

Panel A. Inversion

Product j	p_j	s_j	S_j	$\bar{v}_j$	$f(\bar{v}_j)$	δ_j	g_j
1	1.0	0.20	0.45	0.598	0.55	0.598	0.329
2	1.5	0.15	0.25	0.288	0.75	0.742	0.432
3	2.5	0.10	0.10	0.105	0.90	0.847	0.095

Panel B. Share derivatives $\frac{\partial s_j}{\partial p_k}$ and elasticities ε_{jk}

	Derivative with respect to			Elasticity with respect to		
	p_1	p_2	p_3	p_1	p_2	p_3
Product 1	−0.760	0.432	0	−3.802	3.236	0
Product 2	0.432	−0.526	0.095	2.877	−5.263	1.580
Product 3	0	0.095	−0.095	0	1.422	−2.371
Outside good	0.329	0	0	0.598	0	0

Panel C. Implied markups m_j and marginal costs mc_j at the observed prices

	Markup m_j			Marginal cost mc_j		
Ownership	1	2	3	1	2	3
(a) Single-product firms	0.263	0.285	1.055	0.737	1.215	1.445
(b) Products 1 and 2 joint	0.794	0.936	1.055	0.206	0.564	1.445
(c) One firm owns all	1.369	1.948	3.002	−0.369	−0.448	−0.502

Notes: Tastes are exponential with $\lambda = 1$ and the outside share is $s_0 = 0.55$. In Panel A, $S_j = \sum_{k \geq j} s_k$, $\bar{v}_j = -\ln(1 - S_j)$, $f(\bar{v}_j) = 1 - S_j$, δ_j follows (6.49), and g_j follows (6.54). In Panel B, rows are shares and columns are prices, and $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$. In Panel C, $m = -(\Omega \odot \Delta^{s\top})^{-1}s$ and $mc = p - m$. Joint ownership of products 1 and 3 gives the numbers of row (a).

6.5.7 Extensions

The basic model extends in several directions that the rest of the chapter uses.

Remark 6.40 (An outside alternative with quality). The outside good need not sit at the origin. In the market for new cars, a consumer who buys no new car keeps or buys a used car. Bresnahan (1987, eq. 2) gives this alternative a quality δ_u and a price p_u, so the outside option is the point (p_u, δ_u) of the (p, δ) plane. Every result of this section goes through with $(p_0, \delta_0) = (p_u, \delta_u)$. The lowest cutoff becomes $\bar{v}_1 = \frac{\delta_1 - \delta_u}{p_1 - p_u}$, and in Bresnahan's form the demand for the lowest-quality new car is

$$q_1 = \kappa\left[\frac{p_2 - p_1}{\delta_2 - \delta_1} - \frac{p_1 - p_u}{\delta_1 - \delta_u}\right]$$

(Bresnahan, 1987, eq. 9). In Bresnahan's words, "it is exactly as if there were some other 'product' below the lowest-quality product" (Bresnahan, 1987, p. 463).

Remark 6.41 (Quality measured with error). Suppose consumers know each product's quality but the econometrician observes only a noisy proxy, $\delta_j = \delta(x_j) + \eta_j$ with η_j unobserved. Each consumer still substitutes only between price neighbors. The demand predicted by the econometrician, averaged over η, depends on several neighbors, because the frontier itself is uncertain. Measurement error in quality thus spreads substitution across more products, a step toward random coefficients models. Section 6.6 uses this device as a robustness check.

Remark 6.42 (Income heterogeneity). In the specification $u_{ij} = \delta_j(y_i - p_j)$ of Gabszewicz and Thisse (1979), the type is income. Section 6.4.5 shows that the cutoff between $j-1$ and j is the income $\frac{\delta_j p_j - \delta_{j-1} p_{j-1}}{\delta_j - \delta_{j-1}}$. With an income distribution in place of F, shares, the inversion and the derivatives follow the same steps, with higher incomes buying higher qualities.

Remark 6.43 (A building block for the pure characteristics model). Let $u_{ij} = x_j\beta_i - \alpha_i p_j + \xi_j$ with random coefficients β_i on the characteristics and α_i on price. Conditional on β_i, this is a vertical model in the price sensitivity α_i, with qualities $x_j\beta_i + \xi_j$. Shares are therefore a mixture of vertical shares (6.44) over the distribution of β_i (Berry and Pakes, 2007, eq. 18). The general cutoffs (6.43) are essential here, because the frontier changes with β_i. Section 6.8.3 develops the computation.

Remark 6.44 (Natural oligopolies). When firms choose qualities before prices, vertical differentiation limits the number of firms that can survive. A duopoly example of Tirole (1988, sec. 7.5.1), which follows Gabszewicz and Thisse (1979) and Shaked and Sutton (1982), shows the mechanism. Utility is $v\delta_j - p_j$, with v uniform on $[\underline{v}, \bar{v}]$ and $\bar{v} = \underline{v} + 1$. Both firms have unit cost c, qualities satisfy $\delta_1 < \delta_2$, and $h = \delta_2 - \delta_1$. Suppose qualities are high enough that every consumer buys. The type indifferent between the two products is $v^* = \frac{p_2 - p_1}{h}$, so $q_1 = v^* - \underline{v}$ and $q_2 = \bar{v} - v^*$. The first-order conditions for maximizing $(p_1 - c)q_1$ and $(p_2 - c)q_2$ are

$$p_1 = \frac{p_2 + c - \underline{v}h}{2}, \qquad p_2 = \frac{p_1 + c + \bar{v}h}{2}.$$

Substituting the second condition into the first and solving gives

$$p_1 - c = \frac{(\bar{v} - 2\underline{v})h}{3}, \qquad p_2 - c = \frac{(2\bar{v} - \underline{v})h}{3},$$

with quantities $q_1 = \frac{\bar{v} - 2\underline{v}}{3}$ and $q_2 = \frac{2\bar{v} - \underline{v}}{3}$. Profits are

$$\pi_1 = \frac{(\bar{v} - 2\underline{v})^2 h}{9}, \qquad \pi_2 = \frac{(2\bar{v} - \underline{v})^2 h}{9}.$$

Both profits rise with the quality gap h. If qualities are chosen at no cost from a fixed interval before prices are set, the two firms therefore locate at its two ends. The low-quality firm sells a positive quantity only if $\bar{v} > 2\underline{v}$. When $\bar{v} \le 2\underline{v}$, consumers are too similar, and price competition drives the low-quality firm from the market even though entry is free. Shaked and Sutton (1983) generalize this force into a *finiteness result*. Suppose that every consumer would buy the highest quality if all qualities sold at unit cost. Then only a bounded number of firms can have positive market shares, however large the market becomes. The condition requires that unit costs not rise too quickly with quality. It is more likely to hold when the cost of quality falls mainly on research and development or other fixed costs. Tirole contrasts the result with the Salop model, in which the number of firms grows without bound as fixed costs fall.

6.6 Case study: the 1955 automobile price war

The vertical model entered empirical industrial organization through a study of conduct. Bresnahan (1987) asks whether the American automobile boom of 1955 was a price war. The paper embeds the vertical model of Section 6.5 in an oligopoly model with multi-product firms. It solves the model under two conduct hypotheses, collusion and Bertrand-Nash competition, and estimates each version by maximum likelihood for the model years 1954, 1955 and 1956. Non-nested tests then ask which hypothesis the data favor in each year. No cost data enter. Conduct is identified from the fine structure of the cross-section of products. What matters is which products are close neighbors in quality, and whether a close neighbor belongs to the same firm or to a rival.

The section follows the order of a full case study. We state the question and the facts (Sections 6.6.1 and 6.6.2), describe the data (Section 6.6.3), and set out the model (Section 6.6.4). We then prove the equilibrium properties on which the test rests. Markups rise whenever a pair of neighbors starts to cooperate, collusive markups have a closed form, and Bertrand markups of close rivals vanish. Estimation, the non-nested test, the estimates, the counterfactual and the robustness checks follow (Sections 6.6.5 to 6.6.9). The section closes with identification, critiques and the contribution of the paper (Sections 6.6.10 to 6.6.12).

6.6.1 The question and why it matters

In the 1955 model year, American passenger car production was about 45 percent higher than in the two surrounding years, while quality-adjusted prices were lower (Bresnahan, 1987, p. 457). Aggregate demand models fit that year poorly. Chow (1960a, pp. 168–169), a leading study of automobile demand, reports that "the year 1955 is an exception" to the rule of small residuals. Its 1955 residual is "twice as large as the standard error" (quoted in Bresnahan, 1987, footnote 1). Paul Samuelson stated the puzzle more sharply. He "would flunk any econometrics paper that claimed to provide an explanation of 1955 auto sales."[7]

Higher output at a lower price is the signature of a supply shift. A pure demand shock moves the market along an upward-sloping supply relation and raises price, so it cannot produce a price trough in a boom on its own. Bresnahan therefore looks for a supply shock, and he proposes one of a specific form. His hypothesis is a one-year breakdown of tacit collusion among the automakers. Under this hypothesis firms priced to maximize joint profits in the 1954 and 1956 model years and competed in prices in the 1955 model year. The 1955 boom was then, in part, a price war.

The paper matters for three reasons. First, it is the first structural test of conduct in a differentiated-products industry, and it works without any data on costs. Berry et al. (1995, p. 844) call it "perhaps the first attempt at simultaneously modeling and estimating the demand and oligopoly pricing sides of the market." Conduct is encoded in a cooperation matrix Ω, the same object that merger simulation changes when two firms combine (Chapter 11). Second, it shows that conduct can change over time within one industry. This links it to the empirical study of collusion (Chapter 13), where Porter (1983a) documents switches between collusive and non-collusive periods in a railroad cartel from time-series data. Bresnahan instead uses the cross-section of products within each year.

Third, a price war in a boom year speaks to theories of collusion over the business cycle (Chapter 12). In Rotemberg and Saloner (1986), collusion is hardest to sustain when current

[7] Bresnahan reports the classroom remark and attributes the anecdote to Robert E. Hall (Bresnahan, 1987, footnote 2).

demand is high relative to future demand, so collusive prices fall in booms. They read Bresnahan's results as support for their theory, because 1955 was a boom year.[8] In Green and Porter (1984), by contrast, price wars follow unexpectedly low demand. The 1955 episode fits the first theory better. Bresnahan does not test either theory. His contribution is to show that the conduct of 1955 differed from that of the neighboring years. He later judged that such evidence had not separated the theories, and he doubted that further studies of the same kind would. Rotemberg and Saloner combine the regime switches that Porter (1983a) reports with the pattern of conduct that Bresnahan (1987) finds. Bresnahan (1989, p. 1025) sees "little in these investigations that differentiates among the various theories." The timing of changes in conduct is harder to estimate than its average level. A study of what starts and ends price wars has as many observations as there are price wars, far fewer than the number of periods.

6.6.2 Setting and aggregate facts

The American industry of the mid-1950s consisted of three large firms, General Motors (GM), Ford and Chrysler, and a fringe of smaller producers that included American Motors (AMC). Firms sell several models each. The time unit is the *model year*: the row labelled 1955 in the tables covers the fourth quarter of 1954 through the third quarter of 1955. Bresnahan treats the model year as a short run in a precise sense. Within it, firms set prices and quantities, but their product lines are predetermined. With fixed costs of product development, products are imperfect substitutes in equilibrium. Even the "competitive" model therefore has market power. The label refers to noncooperative conduct. Even competing firms are not price takers (Bresnahan, 1987, p. 458).

Table 6.3: Aggregate indicators of the automobile market, model years 1953–1957

	1953	1954	1955	1956	1957
Automobile market (Bresnahan's Table I)					
(1) Production, millions of units	6.13	5.51	7.94	5.80	6.12
(2) Real price: CPI for new cars relative to the CPI	1.01	0.99	0.95	0.97	0.98
(3) Quality-adjusted price (Cagan), percent change	NA	NA	−2.5	6.3	6.1
(4) Real sales, billions of 1957 dollars	14.5	13.9	18.4	15.7	16.2
(5) Quantity index, (4) divided by (2), 1957 = 100	86.8	84.9	117.2	97.9	100.0
Outside the automobile market (Bresnahan's Table II)					
(6) Per capita disposable personal income	1623	1609	1659	1717	1732
(7) Three-month Treasury bill rate, percent	1.9	0.9	1.7	2.6	3.2
(8) Non-auto durables spending, billions of 1957 dollars	14.5	14.5	16.1	17.1	17.0
(9) Accounting profits of the automakers	2.58	2.25	3.91	2.21	2.38

Notes: Reproduced from Bresnahan (1987, Tables I and II, p. 459). Rows are model years. Nominal values are deflated with the GNP deflator. Row (3) is the percentage change in Cagan's (1971) quality-adjusted price index, which uses only physically unchanged models. Row (4) is auto output in constant dollars from the National Income and Product Accounts. The source's note for row (6) reads "billions of 1957 dollars", which cannot apply to a per capita figure. The values are 1957 dollars per person. Row (9) is the profit of the five largest automobile companies. The note that should give its units is not printed in the source.

Table 6.3 shows why 1955 is anomalous. Production jumped to 7.94 million cars. This is 44 percent above 1954, 37 percent above 1956, and 40.4 percent above the average of the two years.

[8] The 1984 NBER working-paper version of Rotemberg and Saloner (1986) discusses Bresnahan's study in its section on evidence.

Bresnahan's round figure of 45 percent is close to the comparison with 1954. At the same time the real price of new cars hit its trough of 0.95. Quality adjustment does not change the picture. The quality-adjusted index of Cagan (1971) fell by 2.5 percent in 1955 and rose by 6.3 percent in 1956. Bresnahan notes that the hedonic index of Griliches (1964) behaves similarly.

Row (4) adds a second fact. Real sales in value terms rose by 32 percent between 1954 and 1955, much less than the 44 percent rise in units. The implicit quantity index of row (5) rose by more than real sales. Bresnahan reads this as a one-year shift of buyers toward smaller, lower-value cars, and he points to production by price group in *Ward's Automotive Yearbook* (his footnote 3). The shift matters later, because the price war hypothesis predicts that competition intensifies most in the small-car segment.

Rows (6) to (8) show that demand factors explain part of the boom. Per capita income rose by 3.1 percent in 1955. The Treasury bill rate of 1.7 percent was below its 1956 and 1957 levels. Spending on other durables rose by 11 percent in 1955, but it did not fall in 1956, while automobile output collapsed. Bresnahan concludes that some of the 1955 increase was due to demand, but that a full demand-side explanation would "need to be fairly fancy" (Bresnahan, 1987, p. 460).

Row (9) invites a wrong inference. Accounting profits jumped from 2.25 to 3.91 in 1955, which seems to suggest less competition. Automobile production, however, has large fixed costs for plant and product development. These are joint costs of production over many years, and accounting practice spreads them smoothly over time. High-volume years therefore look profitable in the accounting sense whatever happens to economic margins. There is no stable time-series relation between accounting profits and price-cost margins. This is why Bresnahan estimates margins from a structural model. His conclusion makes the general point that accounting-based measures of market power are unsuitable for studies of single industries (Bresnahan, 1987, p. 479).

The window of 1954 to 1956 is not arbitrary.[9] It starts after the end of wartime controls, ends before foreign entry, and contains no long strike. Each of the three years is estimated separately, and no restriction links the parameters across years.

6.6.3 Data and the quantity aggregation problem

The unit of observation is a physically distinct car model in a model year. Since demand elasticities in the model are driven by quality differences between products, the definition of a product is central. Model names are not useful for this purpose, because naming conventions vary across firms and over time.[10] Bresnahan treats two models as distinct in three cases. They are of different makes, they have different engines, frames or body types, or they differ in weight or length by more than one percent. Pontiac and Chevrolet are different makes in this sense, although GM produces both. Only hardtop and four-door sedan bodies enter, with two-door sedans standing in for models without a four-door version. The result is about 80 to 85 models per year, against 140 to 150 at the finest possible disaggregation (pp. 468 and 480).

Prices are list prices in mid-April of the model year, the "PA" prices of Ohta and Griliches (1976). Options are excluded, except heaters where the information is available, and power

[9] Korean War price and quantity controls were lifted in February and March 1953. Foreign competition of any consequence begins with the entry of Volkswagen in 1957. No labor-based work stoppage lasted more than ten days within the period (Bresnahan, 1987, footnote 13).

[10] Independent manufacturers sometimes doubled the number of model names offered for sale with only trivial changes in the set of physical products. Bresnahan notes that this was usually a warning sign of impending exit (Bresnahan, 1987, footnote 8).

steering and brakes are included only when standard. No correction for dealer discounts is made, because the discount was constant across models before 1959. List prices appear in tables in the three trade journals *Ward's*, *Automotive News* and *Automotive Industries*, and in the Company Pages of *Ward's*. The *Ward's* and *Automotive News* tables failed to match on about two percent of all prices. In every such case the other two sources gave a three-way match (Bresnahan, 1987, p. 480).

The physical characteristics are those of the hedonic study of Ohta and Griliches (1976). They are length (bumper to bumper, in thousands of inches), curb weight (in thousands of pounds), advertised maximum brake horsepower (in hundreds), the number of cylinders, and a hardtop dummy. We collect them in the row vector x_j of Section 6.1. Quantities are model-year production. They come from *Automotive News*, *Ward's* and Heasley (1977), with gaps filled from monthly production and the dates of model changeover. Production ties each number to a physical product, but it does not correspond exactly to a market. Fleet sales and end-of-year bargains, in particular, cannot be treated adequately.

Production is often reported more coarsely than the product definition. In the 1954 data, for example, Chrysler reports production for the V-8 DeSoto, but both the Firedome and the Fireflite were sold with the V-8 engine. The solution is to aggregate predicted quantities to the level of the data. Let observed quantities be indexed by $m = 1, \dots, N_q$ and let $\mathcal{I}_m$ be the set of models whose production is reported jointly as q_m, with $k_m = |\mathcal{I}_m|$ models in it. The residual for observation m is

$$q_m - \sum_{j \in \mathcal{I}_m} q_j^*, \tag{6.63}$$

where q_j^* is the model's prediction for model j. If each model's quantity error has variance σ_q^2 and errors are independent across models, the aggregated error has variance $k_m \sigma_q^2$. Coarser aggregation thus produces heteroskedasticity of a known form, which the likelihood of Section 6.6.5 handles by weighting.

6.6.4 The model

We write Bresnahan's model in the notation of this chapter. His quality x is our δ, and his physical characteristics z are our x. His taste density δ is our κ, and his upper endpoint $V_{\max}$ is our $\bar{v}$. His used-car quality and price (γ, E) are our $(\delta_{\mathrm{u}}, p_{\mathrm{u}})$. His marginal-cost scale μ is our ψ, and his cooperation matrix H is our Ω. His number of models n is our J.

Assumption 6.45 (Bresnahan's environment)**.**

(i) *Unit demand.* Each consumer buys one new car or none. A consumer who buys no new car obtains a used car, the outside option.

(ii) *Utility.* A consumer with taste for quality v and income y obtains

$$\begin{aligned} u(\delta_j, y, v) &= v\,\delta_j + y - p_j \quad \text{from new car } j, \\ u(\delta_{\mathrm{u}}, y, v) &= v\,\delta_{\mathrm{u}} + y - p_{\mathrm{u}} \quad \text{from the used car.} \end{aligned} \tag{6.64}$$

(iii) *Tastes.* The taste v is uniformly distributed on $[0, \bar{v}]$ with density κ. The number of potential buyers is $M = \kappa \bar{v}$.

(iv) *Costs.* Model j costs $C(\delta_j, q_j) = FC(\delta_j) + mc(\delta_j)\, q_j$ with $mc(\delta) = \psi e^{\delta}$ and $\psi > 0$. The fixed cost $FC(\delta_j)$ is sunk at the pricing stage.

(v) *Used-car price.* $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$.

(vi) *Product set.* Qualities are fixed and ordered, $\delta_{\mathrm{u}} < \delta_1 < \cdots < \delta_J$, and the last quality step costs less than the highest taste for quality, $\frac{mc(\delta_J) - mc(\delta_{J-1})}{\delta_J - \delta_{J-1}} < \bar{v}$.

Parts (i) to (iii) are the vertical model of Assumption 6.24, except that the price sensitivity has support $[\frac{1}{\bar{v}}, \infty)$ and the outside option is a used car, as we show below. Part (v) is a restriction that Bresnahan imposes in estimation, because the used-car price and quality were hard to tell apart in the data (p. 468). Part (vi) says that the consumer with the highest valuation of quality values the last quality step at more than its cost. By convexity of mc, $\bar{v} > mc'(\delta_J)$ is a sufficient condition. Part (vi) guarantees that every product sells when prices equal marginal costs.

Demand

A consumer of type v buys the product with the lowest "total price" $p_j - v\delta_j$, since income enters utility additively. Consider two products h and i with $\delta_i > \delta_h$. The consumer is indifferent when

$$p_i - v\,\delta_i = p_h - v\,\delta_h.$$

Solving for v gives the cutoff type

$$v_{hi} = \frac{p_i - p_h}{\delta_i - \delta_h}, \tag{6.65}$$

and every type above v_{hi} strictly prefers the higher-quality product i. With products ordered by quality and all of them on the frontier, product j is bought by the types in $[v_{j-1,j}, v_{j,j+1}]$. The used car enters as a product 0 with quality δ_{u} and price p_{u}. Comparing the two utilities in (6.64) gives the cutoff $v_{01} = \frac{p_1 - p_{\mathrm{u}}}{\delta_1 - \delta_{\mathrm{u}}}$, which has exactly the form of (6.65). At the top, the type $\bar{v}$ buys the best car. Multiplying the length of each interval by the density κ gives Bresnahan's demand system (his eqs. 9–11):

$$\begin{aligned} q_1 &= \kappa\left[\frac{p_2 - p_1}{\delta_2 - \delta_1} - \frac{p_1 - p_{\mathrm{u}}}{\delta_1 - \delta_{\mathrm{u}}}\right], \\ q_j &= \kappa\left[\frac{p_{j+1} - p_j}{\delta_{j+1} - \delta_j} - \frac{p_j - p_{j-1}}{\delta_j - \delta_{j-1}}\right], \qquad 1 < j < J, \\ q_J &= \kappa\left[\bar{v} - \frac{p_J - p_{J-1}}{\delta_J - \delta_{J-1}}\right]. \end{aligned} \tag{6.66}$$

Demand is linear in prices. Bresnahan chose the uniform distribution for exactly this reason (Bresnahan, 1987, p. 460), and he credits the demand system to Prescott and Visscher (1977).

Equation (6.66) is the vertical model of Section 6.5 in another parametrization. Dividing utility (6.64) by $v > 0$ gives $\delta_j - \frac{p_j}{v} + \frac{y}{v}$. The last term is common to all options and drops out, so the consumer has price sensitivity $\nu = \frac{1}{v}$. The cutoff (6.65) is then the reciprocal $v_{j-1,j} = \frac{1}{\nu_j}$ of the cutoff of Section 6.5.2. Example 6.30 derives the implied distribution $F(\nu) = 1 - \frac{1}{\bar{v}\nu}$ of the price sensitivity and shows that Proposition 6.29 then reproduces the interior and top equations of (6.66). The first equation is the used-car extension of Remark 6.40. Besides the support of the price sensitivity, two differences from Section 6.5 remain. The outside option has a quality δ_{u} and a price p_{u} instead of the normalization $\delta_0 = p_0 = 0$. The scale of quality is not a free normalization here, because quality also enters marginal cost, as Section 6.6.10 explains.

Let $h_j = \delta_j - \delta_{j-1}$ be the quality gap below product j, with $h_1 = \delta_1 - \delta_u$. Differentiating (6.66) gives constant derivatives:

$$\frac{\partial q_j}{\partial p_j} = -\kappa\Big(\frac{1}{h_j} + \frac{1}{h_{j+1}}\Big)\ (j < J), \qquad \frac{\partial q_J}{\partial p_J} = -\frac{\kappa}{h_J}, \qquad \frac{\partial q_{j+1}}{\partial p_j} = \frac{\partial q_j}{\partial p_{j+1}} = \frac{\kappa}{h_{j+1}}, \tag{6.67}$$

and all other cross derivatives are zero. These are the derivatives of Proposition 6.35 multiplied by the market size. In the notation of (6.54), uniform tastes give $Mg_j = \frac{\kappa}{h_j}$, as computed at the end of Section 6.5.5. The number g_j of the general model is thus inversely proportional to the quality gap h_j. As in Chapter 4, we write Δ for the $J \times J$ matrix of quantity derivatives, $\Delta_{jk} = \frac{\partial q_j}{\partial p_k}$. It is symmetric and tridiagonal, and it equals M times the share Jacobian Δ^s of Section 6.5.5.

The quality gap measures closeness. The diversion ratio from product j to its upper neighbor is

$$D_{j,j+1} = \frac{\frac{\partial q_{j+1}}{\partial p_j}}{-\frac{\partial q_j}{\partial p_j}} = \frac{\frac{1}{h_{j+1}}}{\frac{1}{h_j} + \frac{1}{h_{j+1}}} = \frac{h_j}{h_j + h_{j+1}}.$$

Diversion goes mostly to the closer neighbor. As $h_{j+1} \to 0$, the own and cross derivatives both diverge and their ratio tends to one in absolute value, so the two products become perfect substitutes (Bresnahan, 1987, p. 462). Demand is continuous in prices even where a product's interval shrinks to zero, and a price equilibrium exists (Remark 6.38).

Costs and conduct

The cost function $C(\delta, q) = FC(\delta) + mc(\delta)q$ has a fixed cost and a constant marginal cost at each quality. Marginal cost must increase with quality. Otherwise the best product is also the cheapest to make, and only it would be produced. Bresnahan also wants mc convex. Consumers trade money for quality at a constant marginal rate, so convex costs mean decreasing returns to spending on quality, which rules out degenerate equilibria (his footnote 7). Convexity has a sharp implication in this model. Define the chord slopes

$$\chi_j = \frac{mc(\delta_j) - mc(\delta_{j-1})}{\delta_j - \delta_{j-1}}, \quad j = 1, \dots, J, \qquad mc(\delta_0) \equiv mc(\delta_u) = p_u, \qquad \chi_{J+1} \equiv \bar{v}. \tag{6.68}$$

At marginal-cost prices, the cutoff between $j-1$ and j equals χ_j. Strict convexity makes the chord slopes increase, $\chi_1 < \chi_2 < \cdots < \chi_J$, and Assumption 6.45(vi) gives $\chi_J < \bar{v}$. Every product therefore sells at marginal-cost prices, with quantity

$$q_j(mc) = \kappa\,(\chi_{j+1} - \chi_j) > 0, \qquad j = 1, \dots, J. \tag{6.69}$$

The exponential $mc(\delta) = \psi e^{\delta}$ is the simplest increasing and convex form with one parameter. It follows the log-linear hedonic price equations of Ohta and Griliches (1976).

Each model earns $\pi_j = (p_j - mc_j)q_j - FC(\delta_j)$, where $mc_j = mc(\delta_j)$. Bresnahan considers two conduct hypotheses. Under *collusion* (C), all firms set prices to maximize the sum of all profits, as a single monopolist would. Under *Bertrand-Nash competition* (B), each firm sets the prices of its own models to maximize its own profit, taking rivals' prices as given. Bresnahan's tables call the second hypothesis "Nash-Competition" or "Bertrand". Because demand links only neighbors, conduct enters through the relation between each model and its two neighbors.

Consider first a model whose neighbors do not cooperate with it. Its owner sets the derivative of π_j with respect to p_j to zero (his eq. 15):

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} = 0 \quad \Longleftrightarrow \quad p_j - mc_j = \frac{q_j}{-\frac{\partial q_j}{\partial p_j}}. \tag{6.70}$$

The markup equals quantity divided by the absolute slope of the model's own demand curve. If instead j and $j+1$ cooperate, because one firm makes both or because firms collude, the price of j also accounts for the profit of $j+1$ (his eq. 16):

$$q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + (p_{j+1} - mc_{j+1})\frac{\partial q_{j+1}}{\partial p_j} = 0. \tag{6.71}$$

The extra term is the effect of j's price on its neighbor's profit. It is large when the two products are close, since $\frac{\partial q_{j+1}}{\partial p_j} = \frac{\kappa}{h_{j+1}}$. This is why changing the conduct hypothesis has large effects where products are closely spaced.

The *cooperation matrix* Ω records which products cooperate (his eq. 17):

$$\Omega_{jk} = \begin{cases} 1 & \text{if products } j \text{ and } k \text{ cooperate,} \\ 0 & \text{otherwise.} \end{cases} \tag{6.72}$$

It is symmetric with ones on the diagonal. Under Bertrand it is the ownership matrix of Section 6.5.6. Under collusion every entry is one. In Bresnahan's three-product example, GM makes products 1 and 2 and Chrysler makes product 3 (his eqs. 18–19):

$$\Omega^{\mathrm{B}} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \Omega^{\mathrm{C}} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}. \tag{6.73}$$

With this notation the first-order condition for every model takes one form (his eq. 20):

$$0 = q_j + (p_j - mc_j)\frac{\partial q_j}{\partial p_j} + \Omega_{j,j+1}(p_{j+1} - mc_{j+1})\frac{\partial q_{j+1}}{\partial p_j} + \Omega_{j,j-1}(p_{j-1} - mc_{j-1})\frac{\partial q_{j-1}}{\partial p_j}, \tag{6.74}$$

where terms that refer to products outside $1, \dots, J$ are absent. The used car has an exogenous price and no first-order condition. Solving the demand system (6.66) together with the J conditions (6.74) gives the equilibrium (his eq. 21)

$$p^* = p^*(\delta, \Omega, \delta_{\mathrm{u}}, \bar{v}, \kappa, \psi), \qquad q^* = q^*(\delta, \Omega, \delta_{\mathrm{u}}, \bar{v}, \kappa, \psi). \tag{6.75}$$

Because demand is linear, profits are quadratic in prices and the first-order conditions are linear.

The equilibrium as a linear system

The linear structure lets us prove the properties on which Bresnahan's test rests. Write $m_j = p_j - mc_j$ for the markup of model j and $m = (m_1, \dots, m_J)^\top$. We substitute $p_j = mc_j + m_j$ into (6.66). Each quantity splits into its value at marginal-cost prices and a term in markups,

$$q_j = \kappa\left[\frac{(mc_{j+1} - mc_j) + (m_{j+1} - m_j)}{h_{j+1}} - \frac{(mc_j - mc_{j-1}) + (m_j - m_{j-1})}{h_j}\right],$$

where $m_0 = 0$ because $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$. For $j = J$ the first term is replaced by $\kappa\bar{v}$. Using (6.68) and (6.67), this is

$$q = q(mc) + \Delta\, m.$$

The first-order conditions (6.74) read $q_j + \sum_k \Omega_{jk}\Delta_{kj} m_k = 0$, or $q + (\Omega \odot \Delta^{\top})m = 0$ in the notation of Section 6.5.6. Since Δ is symmetric, substituting $q = q(mc) + \Delta m$ gives

$$A(\Omega)\, m = q(mc), \qquad A(\Omega) = -\big(\Delta + \Omega \odot \Delta\big). \tag{6.76}$$

The entries of $A(\Omega)$ are

$$A_{jj} = 2\kappa\Big(\frac{1}{h_j} + \frac{1}{h_{j+1}}\Big)\ (j < J), \qquad A_{JJ} = \frac{2\kappa}{h_J}, \qquad A_{j,j+1} = A_{j+1,j} = -\big(1 + \Omega_{j,j+1}\big)\frac{\kappa}{h_{j+1}}, \tag{6.77}$$

and all other entries are zero. The diagonal does not depend on Ω because $\Omega_{jj} = 1$. Only the neighbor entries $\Omega_{j,j+1}$ matter. The row sums are

$$\begin{aligned} \textstyle\sum_k A_{1k} &= \frac{2\kappa}{h_1} + \big(1 - \Omega_{12}\big)\frac{\kappa}{h_2} > 0, \\ \textstyle\sum_k A_{jk} &= \big(1 - \Omega_{j-1,j}\big)\frac{\kappa}{h_j} + \big(1 - \Omega_{j,j+1}\big)\frac{\kappa}{h_{j+1}} \geq 0, \qquad 1 < j < J, \\ \textstyle\sum_k A_{Jk} &= \big(1 - \Omega_{J-1,J}\big)\frac{\kappa}{h_J} \geq 0. \end{aligned} \tag{6.78}$$

The first row is strictly positive because the lowest new car competes with the used car, whose price nobody in the industry controls. These properties make $A(\Omega)$ a nonsingular M-matrix. We state the facts we need and prove them for completeness, since Appendix B does not cover M-matrices.

Lemma 6.46 (M-matrices)**.** *Let A be an $n \times n$ matrix with the following three properties.*

(i) $A_{jj} > 0$ *for all j, and* $A_{jk} \leq 0$ *for $j \neq k$.*

(ii) A is irreducible. For all $j \neq k$ there is a chain $j = j_0, j_1, \ldots, j_r = k$ with $A_{j_{s-1}j_s} \neq 0$ for $s = 1, \ldots, r$.

(iii) Every row sum is nonnegative, and at least one row sum is strictly positive.

Then the following hold.

(a) A is nonsingular, and every entry of A^{-1} is strictly positive.

(b) If A' also has properties (i) to (iii), $A' \leq A$ entrywise and $A' \neq A$, then every entry of $A'^{-1} - A^{-1}$ is strictly positive.

Matrices with these properties are nonsingular M-matrices (Berman and Plemmons, 1994, ch. 6).

Proof. (a) Let $\Lambda = \mathrm{diag}(A_{11}, \ldots, A_{nn})$ and $T = \Lambda^{-1}(\Lambda - A)$. Then $T \geq 0$, T has a zero diagonal, and $A = \Lambda(I - T)$. The row sums of T are

$$\sum_k T_{jk} = 1 - \frac{\sum_k A_{jk}}{A_{jj}} \leq 1,$$

with strict inequality in the rows with a positive row sum of A. Let $\mathbf{1}$ be the vector of ones and $r^{(t)} = T^t\mathbf{1}$. Then $r^{(1)} \leq \mathbf{1}$. Since $T \geq 0$,

$$r^{(t+1)} = T^t r^{(1)} \leq T^t\mathbf{1} = r^{(t)},$$

so each entry of $r^{(t)}$ is nonincreasing in t and at most one. Suppose $r_k^{(t)} < 1$ and $T_{jk} > 0$. Then

$$r_j^{(t+1)} = \sum_l T_{jl} r_l^{(t)} \le \sum_l T_{jl} - T_{jk}\left(1 - r_k^{(t)}\right) < \sum_l T_{jl} \le 1.$$

The set of rows with $r_j^{(t)} < 1$ is therefore nonempty at $t = 1$, never shrinks, and grows to include every row that points to one of its members. By irreducibility every row reaches a strict row through a chain of length at most $n-1$, so $r_j^{(n)} < 1$ for all j. For a nonnegative matrix the largest row sum is the matrix norm $\|T^n\|_\infty$, hence $\|T^n\|_\infty < 1$. The Neumann series then converges, $(I-T)^{-1} = \sum_{t\ge 0} T^t$, and $A^{-1} = \left(\sum_{t\ge 0} T^t\right)\Lambda^{-1}$. The diagonal entries of A^{-1} are at least $\frac{1}{A_{jj}} > 0$. For $j \neq k$, a chain of length r from j to k gives $(T^r)_{jk} > 0$, so $(A^{-1})_{jk} > 0$.

(b) Direct multiplication verifies the identity

$$A'^{-1} - A^{-1} = A'^{-1}\left(A - A'\right)A^{-1}.$$

By part (a) both inverses have strictly positive entries, and $A - A' \ge 0$ has at least one positive entry. Each entry of the product is a sum of nonnegative terms, at least one of which is positive. □

Proposition 6.47 (Cooperation raises every markup)**.** *Let Assumption 6.45 hold and let Ω be any symmetric matrix with entries in $\{0,1\}$ with unit diagonal. Then (6.76) has a unique solution $m(\Omega)$, and every markup is strictly positive. If Ω' is obtained from Ω by switching some $\Omega_{i,i+1} = \Omega_{i+1,i}$ from 0 to 1, then $m_k(\Omega') > m_k(\Omega)$ for every $k = 1, \dots, J$. In particular $0 < m(\Omega) \le m(\Omega^{\mathrm{C}})$ for every Ω, where Ω^{C} is the matrix of ones.*

Proof. By (6.77) and (6.78), $A(\Omega)$ has a positive diagonal and nonpositive off-diagonal entries, nonnegative row sums, and a strictly positive first row sum. It is irreducible because every super- and sub-diagonal entry is nonzero, so any two indices are linked by a chain of neighbors. By Lemma 6.46(a), $A(\Omega)^{-1}$ exists and has strictly positive entries. Since $q(mc) > 0$ by (6.69), the solution $m(\Omega) = A(\Omega)^{-1} q(mc)$ is unique and strictly positive. Switching $\Omega_{i,i+1}$ from 0 to 1 lowers $A_{i,i+1}$ and $A_{i+1,i}$ by $\frac{\kappa}{h_{i+1}}$ and leaves the other entries unchanged. Hence $A(\Omega') \le A(\Omega)$ with $A(\Omega') \neq A(\Omega)$, and $A(\Omega')$ also satisfies the conditions of the lemma. By Lemma 6.46(b),

$$m(\Omega') - m(\Omega) = \left[A(\Omega')^{-1} - A(\Omega)^{-1}\right] q(mc)$$

is a matrix with strictly positive entries times a strictly positive vector, so every entry is positive. The last claim follows by switching the zero neighbor entries of Ω to one, one pair at a time. □

Proposition 6.47 proves the claim that Bresnahan states as "easy to show": changing any $\Omega_{i,i+1}$ from zero to one raises $p_k - mc_k$ for all k (Bresnahan, 1987, p. 465). Cooperation between one pair raises the markups of that pair directly. Prices are *strategic complements* here: each model's best-response price rises with its neighbors' prices. The neighbors of the pair therefore raise their prices in response, and the effect travels along the whole quality ladder. One caveat applies. The proposition concerns the solution of the linear system. That solution is an equilibrium of the pricing game when every model sells a positive quantity, which we assume from now on, as Bresnahan does.

The collusive solution has a closed form that clarifies what collusion does in this model.

Proposition 6.48 (Collusive prices)**.** *Let Assumption 6.45 hold. The solution of (6.76) with $\Omega = \Omega^{\mathrm{C}}$ is*

$$m_j^{\mathrm{C}} = \frac{1}{2}\Big[\bar{v}\,(\delta_j - \delta_{\mathrm{u}}) - \big(mc_j - mc(\delta_{\mathrm{u}})\big)\Big], \qquad j = 1, \dots, J. \tag{6.79}$$

The collusive cutoffs are $v^{\mathrm{C}}_{j-1,j} = \frac{1}{2}(\bar{v} + \chi_j)$, every model sells, and $q_j^{\mathrm{C}} = \frac{1}{2} q_j(mc)$ for every j.

Proof. Joint profit, net of fixed costs, is $\Pi = \sum_j m_j q_j = \kappa \sum_{j=1}^{J} m_j\,(v_{j,j+1} - v_{j-1,j})$ with $v_{J,J+1} \equiv \bar{v}$. We rewrite it by summation by parts. With $m_0 \equiv 0$,

$$\begin{aligned}
\sum_{j=1}^{J} m_j\,(v_{j,j+1} - v_{j-1,j}) &= m_J \bar{v} + \sum_{j=1}^{J-1} m_j v_{j,j+1} - \sum_{j=1}^{J} m_j v_{j-1,j} \\
&= m_J \bar{v} + \sum_{j=2}^{J} m_{j-1} v_{j-1,j} - \sum_{j=1}^{J} m_j v_{j-1,j} \\
&= \sum_{j=1}^{J} (m_j - m_{j-1})\,(\bar{v} - v_{j-1,j}),
\end{aligned}$$

where the last step uses $m_J = \sum_{j=1}^{J}(m_j - m_{j-1})$. Let $d_j = m_j - m_{j-1}$ denote the markup increment. Because $p_{\mathrm{u}} = mc(\delta_{\mathrm{u}})$, each cutoff depends only on its own increment, $v_{j-1,j} = \chi_j + \frac{d_j}{h_j}$. Therefore

$$\Pi = \kappa \sum_{j=1}^{J} d_j \Big(\bar{v} - \chi_j - \frac{d_j}{h_j}\Big).$$

The map from m to $(d_1, \dots, d_J)$ is linear and invertible, and Π is a sum of strictly concave quadratics, one for each increment. The first-order condition for d_j is $\bar{v} - \chi_j - \frac{2d_j}{h_j} = 0$, so

$$d_j = \frac{1}{2}\big(\bar{v}\, h_j - (mc_j - mc_{j-1})\big).$$

Summing over j gives (6.79), because the gaps sum to $\delta_j - \delta_{\mathrm{u}}$ and the cost differences telescope. These first-order conditions are equivalent to (6.74) with Ω^{C}, since both are the stationarity conditions of Π. Substituting d_j into the cutoff gives $v^{\mathrm{C}}_{j-1,j} = \frac{1}{2}(\bar{v} + \chi_j)$. These cutoffs increase in j and lie below $\bar{v}$ because $\chi_1 < \cdots < \chi_J < \bar{v}$, so every model sells. Finally, $q_j^{\mathrm{C}} = \kappa(v^{\mathrm{C}}_{j,j+1} - v^{\mathrm{C}}_{j-1,j}) = \frac{\kappa}{2}(\chi_{j+1} - \chi_j) = \frac{1}{2} q_j(mc)$, with $v^{\mathrm{C}}_{J,J+1} = \bar{v} = \chi_{J+1}$. □

Equation (6.79) formalizes half of Bresnahan's intuition. Under collusion, the markup of model j depends on its own quality and on the used car, but not on where the other models sit or who owns them. A model with a close neighbor keeps a large markup. The cartel acts like a monopolist facing linear demand, and it sells half the marginal-cost quantity of every model. The next remark shows that a region of the quality ladder owned by one firm behaves the same way even under Bertrand competition.

Remark 6.49 (A region owned by one firm). Suppose one firm owns the consecutive top models $k, k+1, \dots, J$, and let the conduct be Bertrand. Then the equilibrium price increments $p_j - p_{j-1}$ for $j = k+1, \dots, J$ equal their collusive values. Hence $q_j^{\mathrm{B}} = q_j^{\mathrm{C}}$ for $j = k+1, \dots, J$, and the

markup gap $m_j^{\mathrm{C}} - m_j^{\mathrm{B}}$ is the same for all $j \geq k$. To see this, apply the summation by parts of the proof above to the firm's own profit:

$$\sum_{j=k}^{J} m_j \left(v_{j,j+1} - v_{j-1,j}\right) = m_k \left(\bar{v} - v_{k-1,k}\right) + \sum_{j=k+1}^{J} d_j \left(\bar{v} - v_{j-1,j}\right).$$

The firm chooses $(m_k, d_{k+1}, \ldots, d_J)$, a relabelling of its own prices. For $j > k$ the cutoff $v_{j-1,j}$ depends only on d_j, so the first-order condition for d_j is the collusive one. Only the level m_k responds to competition from model $k-1$, which another firm owns.

The last result concerns close neighbors, the configuration that gives the test its power.

Proposition 6.50 (Close neighbors)**.** *Let Assumption 6.45 hold. Fix all qualities except δ_{i+1} for some $1 \leq i < J$, and let $h = h_{i+1} = \delta_{i+1} - \delta_i \downarrow 0$. Suppose the solution of (6.76) is an interior equilibrium along the sequence. There is a constant C, independent of h, such that:*

(a) If models i and $i+1$ do not cooperate ($\Omega_{i,i+1} = 0$), then $0 < m_i \leq Ch$ and $0 < m_{i+1} \leq Ch$.

(b) If they cooperate ($\Omega_{i,i+1} = 1$), then $|m_i - m_{i+1}| \leq Ch$, and both markups are bounded below by a positive constant independent of h.

Proof. We first bound markups and quantities. By Propositions 6.47 and 6.48,

$$0 < m_k \leq m_k^{\mathrm{C}} \leq \frac{1}{2}\bar{v}\left(\delta_J - \delta_{\mathrm{u}}\right) \equiv B$$

for every k, where the second inequality uses $mc_k > mc(\delta_{\mathrm{u}})$, and δ_J is the largest quality along the sequence. Equilibrium quantities satisfy $0 < q_k \leq \kappa\bar{v}$. For small h we also have $h_{i+2} = \delta_{i+2} - \delta_i - h \geq \frac{1}{2}(\delta_{i+2} - \delta_i)$ when $i + 2 \leq J$.

(a) With $\Omega_{i,i+1} = 0$, condition (6.74) for model i reads

$$\kappa\Big(\frac{1}{h_i} + \frac{1}{h}\Big)m_i = q_i + \Omega_{i-1,i}\frac{\kappa}{h_i}m_{i-1} \leq \kappa\bar{v} + \frac{\kappa B}{h_i},$$

where the cooperation term is absent if $i = 1$. The left side is at least $\frac{\kappa}{h}m_i$, so $m_i \leq h\left(\bar{v} + \frac{B}{h_i}\right)$. If $i + 1 < J$, the condition for model $i+1$ gives in the same way

$$\kappa\Big(\frac{1}{h} + \frac{1}{h_{i+2}}\Big)m_{i+1} = q_{i+1} + \Omega_{i+1,i+2}\frac{\kappa}{h_{i+2}}m_{i+2} \leq \kappa\bar{v} + \frac{\kappa B}{h_{i+2}},$$

so $m_{i+1} \leq h\left(\bar{v} + \frac{B}{h_{i+2}}\right)$. If $i + 1 = J$, the condition is $\frac{\kappa}{h}m_J = q_J \leq \kappa\bar{v}$, so $m_J \leq h\bar{v}$.

(b) With $\Omega_{i,i+1} = 1$, condition (6.74) for model i can be written as

$$\frac{\kappa}{h}\left(m_{i+1} - m_i\right) = -q_i + \frac{\kappa}{h_i}m_i - \Omega_{i-1,i}\frac{\kappa}{h_i}m_{i-1}.$$

The right side is bounded by $\kappa\bar{v} + \frac{2\kappa B}{h_i}$ in absolute value, so $|m_{i+1} - m_i| \leq h\left(\bar{v} + \frac{2B}{h_i}\right)$. For the lower bound, let $\Omega^{(i)}$ be the identity matrix with $\Omega^{(i)}_{i,i+1} = \Omega^{(i)}_{i+1,i} = 1$. By Proposition 6.47, $m(\Omega) \geq m(\Omega^{(i)})$, so it suffices to bound $m(\Omega^{(i)})$. Under $\Omega^{(i)}$, add the conditions for models i and $i+1$. The terms in $\frac{1}{h}$ cancel, and

$$q_i + q_{i+1} = \frac{\kappa}{h_i}m_i + \frac{\kappa}{h_{i+2}}m_{i+1},$$

where the last term is absent if $i+1 = J$. The left side is the demand for the pair, $\kappa(v_{i+1,i+2} - v_{i-1,i})$. Because all markups are positive,

$$v_{i-1,i} = \chi_i + \frac{m_i - m_{i-1}}{h_i} \le \chi_i + \frac{m_i}{h_i}, \qquad v_{i+1,i+2} = \chi_{i+2} + \frac{m_{i+2} - m_{i+1}}{h_{i+2}} \ge \chi_{i+2} - \frac{m_{i+1}}{h_{i+2}},$$

with $v_{J,J+1} = \bar{v} = \chi_{J+1}$ in the top case. Combining the last three displays gives

$$2\left(\frac{m_i}{h_i} + \frac{m_{i+1}}{h_{i+2}}\right) \ge \chi_{i+2} - \chi_i,$$

where again the term in h_{i+2} is absent in the top case. As $h \to 0$, χ_{i+2} tends to the chord slope of mc between δ_i and δ_{i+2} (or to $\bar{v}$ in the top case). By strict convexity this limit exceeds χ_i, the chord slope between δ_{i-1} and δ_i. The weighted sum of m_i and m_{i+1} is therefore bounded below by a positive constant. Since the two markups differ by at most Ch, each of them is bounded below by a positive constant for small h. □

Proposition 6.50 is the formal core of the test. Two nearly identical cars sold by rival firms are priced almost at marginal cost under Bertrand competition, whatever the rest of the market looks like. If the same two cars cooperate, they behave like a single product whose demand is the pair's combined interval and whose demand slope is set by the outer gaps h_i and h_{i+2}. Their markups stay positive and converge to each other. The proof also shows that part (b) holds under the weakest form of cooperation, a single cooperating pair. Full collusion only raises the markups further. Figure 6.6 traces the three cases in a numerical example.

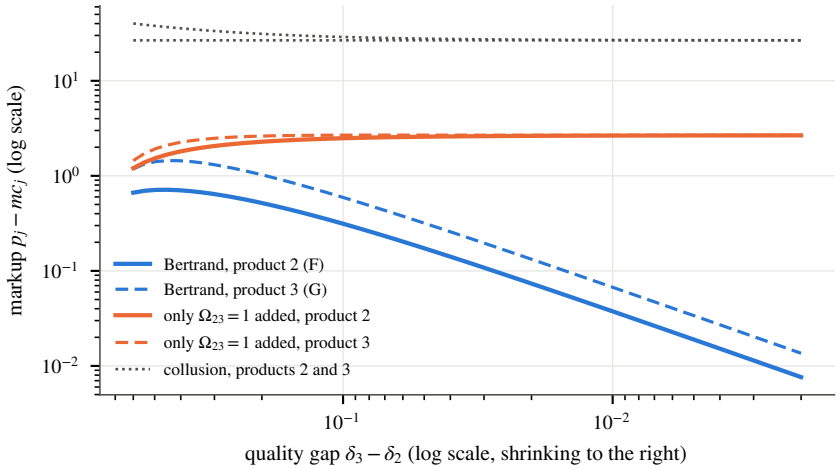

Figure 6.6: Markups of products 2 and 3 as their quality gap shrinks, in the seven-product design of Figure 6.7. Under Bertrand competition between their owners (blue) both markups fall in proportion to the gap, as in Proposition 6.50(a). If the Bertrand ownership matrix is changed only by letting products 2 and 3 cooperate, $\Omega_{23} = 1$ (orange), the markups converge to a common positive value near 2.67, as in part (b). Under full collusion (gray) they converge to about 26.7, the value given by Equation (6.79). Both axes are logarithmic. Computed with `bresnahan_fig2_sim.py`.

The intuition and Bresnahan's Figure 2

Bresnahan states the intuition in two sentences (Bresnahan, 1987, p. 458). If firms compete in prices, price is near marginal cost for the products that have a close substitute sold by a

competitor. If firms collude, the markup on one firm's product hardly depends on whether its close substitutes are sold by competitors or by the firm itself. Propositions 6.48 and 6.50 make both sentences precise. Bresnahan adds a general point. Conduct hypotheses differ in the comparative statics of price and quantity with respect to demand elasticities. So conduct can be discerned even when marginal costs are unobserved, the same logic as the rotation argument of Chapter 3.

His Figure 2 illustrates the point with seven products in quality space and two firms, labelled G and F. We recreate its design by solving the model. Products 2 and 3 are almost identical and belong to different firms. Products 5, 6 and 7, at the top, all belong to G. Figure 6.7 plots marginal cost and equilibrium prices against quality under both conduct hypotheses, and Figure 6.8 shows the original.[11]
