Compare the IPV benchmark with the same triangular marginal. On $[0,\frac{1}{2}]$, $F(v)=2v^2$, and the bid of (14.29) is

$$\beta^{IPV}(v) = v - \frac{\int_0^v (2x^2)^{n-1}dx}{(2v^2)^{n-1}} = v - \frac{v}{2n-1} = \frac{2n-2}{2n-1}\,v.$$

For $n=2$ this equals the APV bid $\frac{2}{3}v$. For $n=3$ it is $\frac{4}{5}v$, above the APV bid $\frac{3}{4}v$ (Li et al., 2002, footnote 17). Figure 15.11 shows both strategies on the whole support. Affiliation makes low types bid less aggressively and high types more aggressively. A bidder with a low value expects rivals with low values, so she faces weak competition. A bidder with a high value expects strong competition and shades less.

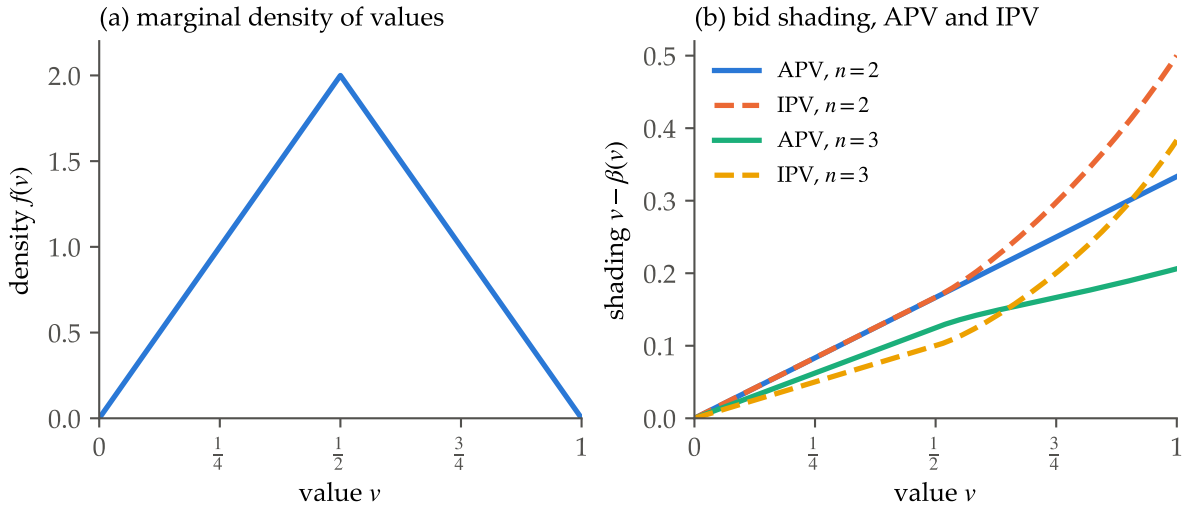

Figure 15.11: The Monte Carlo design of Li et al. (2002). Panel (a): the triangular marginal density of values when $V_i = Q + E_i$ with $Q \sim U[\frac{1}{4},\frac{3}{4}]$ and $E_i \sim U[-\frac{1}{4},\frac{1}{4}]$. Panel (b): bid shading $v-\beta(v)$ in the APV equilibrium (solid) and in the IPV equilibrium with the same marginal density (dashed), for $n=2$ and $n=3$. The APV bids use equations (10)–(12) of Li et al. (2002), which we checked against a numerical solution of (15.30). Our computation, with no random numbers (script `lpv_design.py`).

Each replication draws 100 auctions with two bidders and 100 auctions with three bidders, which gives 500 bids. The experiment is replicated 1,000 times (Li et al., 2002, p. 179).

Each replication takes less than three seconds (Li et al., 2002, p. 182). The average first-step bandwidths (h_G, h_g) are $(0.148, 0.177)$ for $n = 2$ and $(0.076, 0.122)$ for $n = 3$.

Results. The median estimate of the inverse bid function tracks the truth closely and lies slightly above it. The pointwise 90 percent band contains the true function except near the boundaries (their Figures 1–2). The estimated marginal density follows the triangle except near the kink, where kernel smoothing rounds the peak (their Figures 3–5). The winner's *informational rent* in auction t is

$$\mathrm{IR}_t = \frac{v_{wt} - b_{wt}}{v_{wt}}, \tag{15.38}$$

with v_{wt} and b_{wt} the winner's value and bid (Li et al., 2002, eq. (16)). For $n = 2$ the APV bid is $\frac{2}{3}v$ on the whole support, so the true rent is exactly one third. Table 15.7 reports the true mean rent and the distribution across replications of the estimated average rent. The APV estimator slightly overstates the rent, consistent with the slight upward bias in $\hat{\xi}$. Rents fall from $n = 2$ to $n = 3$, a competition effect.

Table 15.7: Winners' informational rents in the Monte Carlo of Li et al. (2002)

	APV estimator (Table 1)		IPV estimator (Table 2)	
	$n = 2$	$n = 3$	$n = 2$	$n = 3$
True mean IR	33.33	23.47	33.33	23.47
Estimated average IR	36.76	26.96	38.65	29.11
Empirical 5th percentile	32.44	19.32	31.53	19.05
Empirical 95th percentile	41.18	34.69	49.33	44.97

Notes. Percent. The informational rent is (15.38). Each column summarizes 1,000 replications, each with 100 two-bidder and 100 three-bidder auctions. The APV columns use the estimator (15.34)–(15.36). The IPV columns apply the estimator of Guerre et al. (2000) to the same affiliated bids. Source: Li et al. (2002, Tables 1 and 2).

Imposing independence on affiliated data. The authors then apply the IPV estimator of Guerre et al. (2000) to the same simulated bids. The estimated inverse bid function matches the truth for low bids but lies well above it for high bids (their Figures 6–7). The implied value density is too dispersed (their Figures 8–9), and rents are overstated (Table 15.7). The authors report overstatements of 17 and 24 percent for $n = 2$ and $n = 3$ (Li et al., 2002, p. 186). Relative to the true means in the table, the overstatements are 16 and 24 percent (our calculation).

A short calculation shows why. With $n = 2$ the bid is $\frac{2}{3}v$, so the marginal bid distribution is $G(b) = F(\frac{3}{2}b)$ with density $g(b) = \frac{3}{2}f(\frac{3}{2}b)$. The IPV inversion returns

$$\xi^{IPV}(b) = b + \frac{G(b)}{g(b)} = \frac{2}{3}v + \frac{2}{3}\frac{F(v)}{f(v)}, \qquad v = \tfrac{3}{2}b.$$

For $v \le \frac{1}{2}$, $\frac{F(v)}{f(v)} = \frac{2v^2}{4v} = \frac{v}{2}$, so $\xi^{IPV} = v$ and low values are recovered exactly. For $v > \frac{1}{2}$, $\frac{F(v)}{f(v)} = \frac{1-2(1-v)^2}{4(1-v)}$. At $v = \frac{3}{4}$ this is $\frac{7}{8}$, so $\xi^{IPV} = \frac{1}{2} + \frac{7}{12} = \frac{13}{12}$ against a true value of $\frac{3}{4}$. The inversion explodes near the top because the marginal density vanishes there. The IPV model reads the aggressive bidding of high types under affiliation as evidence of high values.

Assessment. The paper extends the indirect approach to dependent values and supplies a usable guide. Its limits are statistical and economic. The density of values is n-variate, so data

demands grow quickly with n, and estimation proceeds separately for each n. The estimator conditions on the number of bidders, so it cannot by itself say how affiliation interacts with entry. Under APV, bids can fall as n rises (Pinkse and Tan, 2005). Regressions of bids on n therefore cannot separate private from common values (Section 15.6.2). Finally, correlation in values may come from auction features that bidders observe and the econometrician does not. That alternative is observationally equivalent to affiliation with a fixed n, and Section 15.7 treats it.

15.5.2 What the two highest bids reveal

Many first-price data sets record only the winning bid, or the two highest bids. Procurement agencies keep the second-lowest bid in case the winner defaults. Participants also track the gap between the top two bids, which they call "money left on the table" (Athey and Haile, 2002, p. 2123). Two bids suffice for part of the identification problem. Equation (15.32) involves only the distribution of the highest rival bid given one's own bid. In equilibrium the top two bids come from the bidders with the top two values. Let $I^{(n:n)}$ denote the identity of the winner.

Proposition 15.33 (Athey and Haile, 2002, Lemma 1, Theorem 7 and Corollary 1)**.** *Consider the APV model of the first-price auction, and suppose the two highest bids are observed. If bidders are asymmetric, suppose the identity of the winner is also observed.*

(i) The equilibrium bid functions β_i, $i = 1, \dots, n$, are identified.

(ii) With symmetric bidders, the joint distribution of $(V^{(n:n)}, V^{(n-1:n)})$ is identified.

(iii) With symmetric bidders, the joint distribution F of values is not identified if any lower bid is unobserved.

Proof. (i) Take bidder 1 and a bid b in the support of B_1. Multiply the numerator and denominator of the markdown by the density of B_1 at b. Then translate each event into events about the top two bids:

$$\frac{G_{M_1|B_1}(b \mid b)}{g_{M_1|B_1}(b \mid b)} = \frac{\frac{\partial}{\partial y}\mathbb{P}\left(M_1 \le b,\ B_1 \le y\right)\big|_{y=b}}{\frac{\partial^2}{\partial x\,\partial y}\mathbb{P}\left(M_1 \le x,\ B_1 \le y\right)\big|_{x=y=b}} = \frac{\frac{\partial}{\partial x}\mathbb{P}\left(B^{(n:n)} \le x,\ I^{(n:n)} = 1\right)\big|_{x=b}}{\frac{\partial^2}{\partial x\,\partial y}\mathbb{P}\left(B^{(n-1:n)} \le x,\ B^{(n:n)} \le y,\ I^{(n:n)} = 1\right)\big|_{x=y=b}}.$$

For the numerator, $\mathbb{P}(B^{(n:n)} \le x,\ I^{(n:n)} = 1) = \mathbb{P}(B_1 \le x,\ M_1 < B_1)$, whose derivative at $x = b$ is $\mathbb{P}(M_1 < b \mid B_1 = b)\, g_{B_1}(b)$. For the denominator, take $x < y$. The event $\{B^{(n-1:n)} \le x,\ B^{(n:n)} \le y,\ I^{(n:n)} = 1\}$ equals $\{M_1 \le x,\ B_1 \le y\}$ minus $\{M_1 \le x,\ B_1 \le M_1\}$. The probability of the second set does not depend on y. So the cross partial equals the joint density of (M_1, B_1) at (x, y), and we let $x \uparrow y = b$. Both final expressions involve only the top two bids and the winner's identity. The markdown is therefore identified, and with it $\beta_1^{-1}(b) = b + \frac{G_{M_1|B_1}(b|b)}{g_{M_1|B_1}(b|b)}$ for almost every b.

(ii) With symmetric bidders the top two bids are $\beta(V^{(n:n)})$ and $\beta(V^{(n-1:n)})$. Apply the identified β^{-1} to both.

(iii) The construction of Theorem 15.9 applies. Shift probability mass between small neighborhoods of two value vectors that differ only in the j-th order statistic, for some $j < n-1$, and symmetrize over permutations. The new distribution is exchangeable. The distribution

of the highest rival value, and hence every bidder's best response, is unchanged. Only the unobserved order statistic $V^{(j:n)}$ changes its distribution, so observables are unchanged (Athey and Haile, 2007, proof of Theorem 3.4). □

Part (ii) is more useful than it looks. The joint law of the top two values determines the revenue from a second-price or ascending auction and the effect of a reserve price. It also determines the outcome under many other selling mechanisms (Athey and Haile, 2002, p. 2124). Part (i) delivers the bid functions, which measure the wedge between bids and values. Part (iii) is a limit. Bid functions depend only on the distribution of the highest rival bid, so they carry no information about the distribution of lower bids. The design of an optimal auction needs the full F and therefore all bids. The two highest bids also suffice for a test of private against common values, which Theorem 15.43 develops. Athey and Haile (2007, Section 3.3.2) note that estimators built on part (i) had not yet been explored.

15.5.3 Asymmetric affiliated private values: Campo, Perrigne and Vuong (2003)

Question. Federal auctions of offshore oil leases allowed firms to bid jointly as consortia. Joint bidding may pool capital and information, and it may create ex ante asymmetry among bidders. Campo et al. (2003) ask whether an asymmetric APV model can be identified and estimated without solving its equilibrium. They then use joint and solo bids to measure asymmetry, affiliation, unobserved tract heterogeneity and informational rents. They also confront the pure common value model that dominated earlier work on these auctions.

Model. There are two types. Type 1 (strong, here joint bidders) has n_1 bidders and type 0 (weak, here solo bidders) has n_0 bidders, with $n_1 + n_0 = n \geq 2$. Values $(v_{11}, \ldots, v_{1n_1}, v_{01}, \ldots, v_{0n_0})$ are drawn from an absolutely continuous distribution F on $[\underline{v}, \bar{v}]^n$. The distribution is affiliated and exchangeable within each type (Campo et al., 2003, Section 2.1). Let $\mathcal{P}$ denote this set of distributions. Within a type, bidders use the same strictly increasing strategy, s_1 or s_0. Let y_1^* be the highest value among the other type-1 bidders and y_0 the highest type-0 value. A type-1 bidder with value v_1 solves

$$\max_b \, (v_1 - b)\, \mathbb{P}\big(y_1^* \leq s_1^{-1}(b),\ y_0 \leq s_0^{-1}(b) \mid v_1\big).$$

The first-order conditions form a system of two differential equations with boundary conditions $s_1(\underline{v}) = s_0(\underline{v}) = \underline{v}$ and $s_1(\bar{v}) = s_0(\bar{v})$, their equations (1)–(2). The system is intractable in general. Under conditions that cover this model, an equilibrium in monotone pure strategies nevertheless exists (Reny and Zamir, 2004). The inversion below assumes that bidders play such an equilibrium and that each bid distribution is continuous and strictly increasing. Conditioning on a bidder's bid is then the same as conditioning on her value. With independent values it reduces to the asymmetric IPV system of Proposition 14.76, studied by Maskin and Riley (2000), and with one type it reduces to (15.30).

Inversion. Let B_1^* be the highest bid among the other type-1 bidders and B_0 the highest type-0 bid. Define $G_{B_1^*, B_0 | b_1}(X, Y \mid x) = \mathbb{P}(B_1^* \leq X,\ B_0 \leq Y \mid b_1 = x)$. Since bids are strictly increasing in values,

$$G_{B_1^*, B_0 | b_1}(X, X \mid x) = F_{y_1^*, y_0 | v_1}\big(s_1^{-1}(X),\ s_0^{-1}(X) \mid s_1^{-1}(x)\big).$$

The total derivative in the common threshold X is

$$\frac{d}{dX} G_{B_1^*, B_0 | b_1}(X, X \mid x) = \frac{\partial F_{y_1^*, y_0 | v_1}}{\partial y_1^*} \frac{1}{s_1'\big(s_1^{-1}(X)\big)} + \frac{\partial F_{y_1^*, y_0 | v_1}}{\partial y_0} \frac{1}{s_0'\big(s_0^{-1}(X)\big)}.$$

This is exactly the bracket in the type-1 first-order condition. Substituting gives

$$v_1 = \xi_1(b_1; \boldsymbol{G}) \equiv b_1 + \frac{G_{B_1^*, B_0 | b_1}(b_1, b_1 \mid b_1)}{\frac{d}{dX} G_{B_1^*, B_0 | b_1}(X, X \mid b_1)\big|_{X = b_1}}, \tag{15.39}$$

their equation (4). The weak type's inverse $\xi_0(b_0; \boldsymbol{G})$ is the same expression with (B_1, B_0^*) in place of (B_1^*, B_0), their equation (5). Two features distinguish (15.39) from (15.32). The conditioning distribution is trivariate, since it involves the bidder's own bid and the highest bid of each type. The denominator is a total derivative and not a density.

Proposition 15.34 (Campo et al., 2003, Proposition 1)**.** *The asymmetric APV model is identified. Let $\boldsymbol{G}$ have support $[\underline{b}, \bar{b}]^n$. It can be rationalized by an asymmetric APV model with $F \in \mathcal{P}$ if and only if two conditions hold.*

(i) $\boldsymbol{G} \in \mathcal{P}$.

(ii) $\xi_1(\cdot; \boldsymbol{G})$ *and* $\xi_0(\cdot; \boldsymbol{G})$ *are strictly increasing on* $[\underline{b}, \bar{b}]$*, with* $\xi_1(\bar{b}; \boldsymbol{G}) = \xi_0(\bar{b}; \boldsymbol{G})$.

The rationalizing distribution is $F(v_1, v_0) = \boldsymbol{G}\big(\xi_1^{-1}(v_1; \boldsymbol{G}), \xi_0^{-1}(v_0; \boldsymbol{G})\big)$.

The proof follows that of Proposition 15.31. The common upper endpoint in (ii) reflects the boundary condition $s_1(\bar{v}) = s_0(\bar{v})$. Identification is nonparametric and requires neither solving nor approximating the equilibrium. Because $\mathcal{P}$ contains the distributions that are exchangeable across all n bidders, the symmetric model is nested and can be tested against the asymmetric one.

Estimator. The conditioning on b_1 drops out of the ratio in (15.39), which equals

$$\frac{\mathbb{P}(B_1^* \le b_1,\ B_0 \le b_1,\ b_1 = b_1)}{\mathbb{P}(B_1^* = b_1,\ B_0 \le b_1,\ b_1 = b_1) + \mathbb{P}(B_1^* \le b_1,\ B_0 = b_1,\ b_1 = b_1)}, \tag{15.40}$$

where each "=" denotes a density (Campo et al., 2003, eq. (6)). With T auctions of a given configuration (n_1, n_0), the numerator is estimated by

$$\hat{G}_1(x, y, z) = \frac{1}{h_{G1} T} \sum_{t=1}^{T} \frac{1}{n_1} \sum_{i=1}^{n_1} \mathbf{1}(B_{1it}^* \le x)\, \mathbf{1}(B_{0t} \le y)\, \mathcal{K}\left(\frac{z - B_{1it}}{h_{G1}}\right).$$

The two terms of the denominator replace one indicator at a time by a kernel:

$$\hat{D}_{11}(x, y, z) = \frac{1}{h_{g1}^2 T} \sum_{t=1}^{T} \frac{1}{n_1} \sum_{i=1}^{n_1} \mathcal{K}\left(\frac{x - B_{1it}^*}{h_{g1}}\right) \mathbf{1}(B_{0t} \le y)\, \mathcal{K}\left(\frac{z - B_{1it}}{h_{g1}}\right),$$

$$\hat{D}_{12}(x, y, z) = \frac{1}{h_{g1}^2 T} \sum_{t=1}^{T} \frac{1}{n_1} \sum_{i=1}^{n_1} \mathbf{1}(B_{1it}^* \le x)\, \mathcal{K}\left(\frac{y - B_{0t}}{h_{g1}}\right) \mathcal{K}\left(\frac{z - B_{1it}}{h_{g1}}\right).$$

The pseudo-value of a type-1 bid is $\hat{V}_{1it} = B_{1it} + \frac{\hat{G}_1(B_{1it}, B_{1it}, B_{1it})}{\hat{D}_{11}(B_{1it}, B_{1it}, B_{1it}) + \hat{D}_{12}(B_{1it}, B_{1it}, B_{1it})}$, their equation (7), and type 0 is symmetric. The second step estimates bivariate densities of pairs of values within and across types (Campo et al., 2003, eqs. (9)–(11)). Because bid data are skewed, the authors work with $d = \ln(1 + b)$. If $D = \ln(1 + B)$, densities in b equal densities in d divided by $1 + b$. Then the markdown in b is $(1 + b)$ times the markdown in d, and

$$v = b + (1 + b)\frac{G_D}{g_D} = e^d \left(1 + \frac{G_D}{g_D}\right) - 1,$$

which is their equation (12). They use triweight kernels, rule-of-thumb bandwidths of the form $c\,(n_1 T)^{-\frac{1}{5}}$ and $c\,(n_1 T)^{-\frac{1}{6}}$ with $c = 2.978 \times 1.06\,\hat{\sigma}$, and trimming within one bandwidth of the boundaries (Campo et al., 2003, pp. 188–189).

Unobserved tract heterogeneity. Tracts differ in observed characteristics Z and unobserved characteristics W. Without restrictions, variation in W cannot be separated from variation in private values. Campo et al. (2003, Section 3.2) impose the following.

Assumption 15.35 (Campo et al., 2003, Section 3.2)**.** (i) The numbers of bidders of each type are deterministic functions of tract characteristics, $n_1 = n_1(Z, W)$ and $n_0 = n_0(Z, W)$. (ii) Conditional on (Z, n_1, n_0), values do not depend on W: $F(\cdot \mid Z, W) = F(\cdot \mid Z, n_1, n_0)$.

Part (i) holds in entry models in which firms decide to participate before learning their values. Part (ii) says that the bidder configuration is a sufficient statistic for the unobserved tract characteristics. Estimation conditional on (n_1, n_0) is then valid. The same idea, using an endogenous count as a control for unobservables, underlies the instrumental approach of Haile et al. (2003) in Section 15.6.2. It also has a cost. Under Assumption 15.35 the value distribution of joint bidders may differ between $(2, 0)$ and $(1, 1)$ auctions because the tracts differ. A comparison of the marginal densities of a type across configurations therefore tests for unobserved heterogeneity. A comparison of joint and solo densities within the $(1, 1)$ configuration tests for asymmetry.

The asymmetric pure common value model. Pure common values had been the standard model for offshore leases. Campo et al. (2003) derive a sharp restriction for two bidders. The tract has common value V. Bidder $i \in \{0, 1\}$ receives a signal σ_i, and the signals are independent given V but not identically distributed. Let $V(\sigma_1, \sigma_0) = \mathbb{E}[V \mid \sigma_1, \sigma_0]$. Bidder 1 wins when $\sigma_0 \le s_0^{-1}(b_1)$, so her first-order condition is

$$-F_{\sigma_0|\sigma_1}\big(s_0^{-1}(b_1) \mid \sigma_1\big) + \big[V\big(\sigma_1, s_0^{-1}(b_1)\big) - b_1\big] \frac{f_{\sigma_0|\sigma_1}\big(s_0^{-1}(b_1) \mid \sigma_1\big)}{s_0'\big(s_0^{-1}(b_1)\big)} = 0,$$

their equation (14). The argument leading to (15.32) turns it into

$$V\big(\sigma_1, s_0^{-1}(b_1)\big) = b_1 + \frac{G_{b_0|b_1}(b_1 \mid b_1)}{g_{b_0|b_1}(b_1 \mid b_1)} = \xi_1(b_1; \boldsymbol{G}), \qquad V\big(s_1^{-1}(b_0), \sigma_0\big) = \xi_0(b_0; \boldsymbol{G}), \tag{15.41}$$

their equations (16)–(17). The right sides are the same as in the APV model with two bidders. Only the interpretation of the left sides changes. A bivariate distribution of (b_1, b_0) is *quasi-symmetric* if $\mathbb{P}(b_1 \le b_0 \mid b_1 \le b,\ b_0 \le b) = \mathbb{P}(b_1 \ge b_0 \mid b_1 \le b,\ b_0 \le b)$ for every b. Exchangeable distributions are quasi-symmetric, but not conversely.

Proposition 15.36 (Campo et al., 2003, Proposition 2)**.** *If observed bids are equilibrium bids of an asymmetric pure common value model with two bidders, their joint distribution is quasi-symmetric. Quasi-symmetry is equivalent to $\xi_1(b; \boldsymbol{G}) = \xi_0(b; \boldsymbol{G})$ for every b. The asymmetric pure common value model is observationally equivalent to an asymmetric APV model with a quasi-symmetric value distribution and identical equilibrium strategies.*

Proof. At a common bid b, bidder 1's signal is $s_1^{-1}(b)$ and bidder 0's is $s_0^{-1}(b)$. Both left sides of (15.41) then equal $V\big(s_1^{-1}(b), s_0^{-1}(b)\big)$, so $\xi_1(b) = \xi_0(b)$. To link this to quasi-symmetry, let

$G(x, y) = \mathbb{P}(b_1 \le x,\ b_0 \le y)$ with density g, and let $\partial_1 G$ and $\partial_2 G$ be its partial derivatives. Then $G_{b_0|b_1}(y \mid x) = \frac{\partial_1 G(x,y)}{g_{b_1}(x)}$ and $g_{b_0|b_1}(y \mid x) = \frac{g(x,y)}{g_{b_1}(x)}$, so

$$\xi_1(b) - b = \frac{\partial_1 G(b,b)}{g(b,b)}, \qquad \xi_0(b) - b = \frac{\partial_2 G(b,b)}{g(b,b)}.$$

Hence $\xi_1 = \xi_0$ if and only if $\partial_1 G(b,b) = \partial_2 G(b,b)$ for all b. Next,

$$\mathbb{P}(b_1 \le b_0 \le b) = \int^b \int^y g(x,y)\,dx\,dy = \int^b \partial_2 G(y,y)\,dy,$$
$$\mathbb{P}(b_0 \le b_1 \le b) = \int^b \partial_1 G(x,x)\,dx.$$

These two probabilities are equal for every b if and only if $\partial_1 G(b,b) = \partial_2 G(b,b)$ for every b. Ties have probability zero, so equal probabilities mean each is half of $G(b,b)$, which is quasi-symmetry. For the last claim, define private values $\tilde{v}_i = \xi_i(b_i)$. They form a quasi-symmetric distribution, and the common strategy ξ^{-1} satisfies both APV first-order conditions. □

Setting $b = \bar{b}$ gives $\mathbb{P}(b_1 \le b_0) = \frac{1}{2}$. Each bidder wins half of the time, however different their information. The same property holds in the extreme case with one perfectly informed bidder, where the uninformed bidder's mixed strategy replicates the informed bid distribution (Proposition 14.55). The proposition yields a simple test of the pure common value model with two bidders, whatever the asymmetry.

Setting and data. The federal government has auctioned oil and gas rights on the Outer Continental Shelf (OCS) since 1954. Campo et al. (2003) study wildcat sales in the Gulf of Mexico off Louisiana. Areas are divided into tracts, usually of 5,000 or 5,760 acres, sold simultaneously by first-price sealed bid. The reserve price of $15 per acre is not regarded as screening participation (their footnote 10). Joint bidding affected fewer than 20 percent of auctions before 1970 and more than 80 percent after. A typical joint bid involves two or three firms. From December 1975, the eight largest firms were barred from bidding jointly with each other (their footnote 11). The sample covers auctions from December 1972 to 1979. It excludes later years because the rules changed, and two early sales with unusual water depth (their footnote 12). The authors keep auctions with exactly two bidders. This gives 227 auctions: 60 with two joint bids, 55 with two solo bids and 112 with one of each. Bids are in 1972 dollars per acre. Table 15.8 reproduces their Table I.

Joint bids are higher on average than solo bids. Each type bids more when facing a joint bidder. A test of equal means of joint and solo bids in the 112 mixed auctions gives $t = 1.66$, a weak rejection at the 10 percent level (Campo et al., 2003, p. 190). Joint bidders won 63 of the 112 mixed auctions. This share exceeds one half at the 10 percent level in a one-sided test. The within-auction standard deviation is 70 to 98 percent of the total, and 98 percent in auctions with two joint bidders. So much of the variation across tracts is explained by the bidder configuration. In log-bid regressions, the three bidding-structure dummies are jointly significant. Equality of the 16 sale dummies is nearly accepted, and neither the 1973 oil shock nor the 1975 ban has a significant effect (Campo et al., 2003, p. 191).

Testing pure common values. By Proposition 15.36, the joint bidder should win half of the mixed auctions. The authors split the 112 mixed auctions in half. In the 56 auctions with both bids below $460 per acre, the joint bidder wins 28 times. In the 56 auctions with at least one bid

Table 15.8: Bids in two-bidder OCS wildcat auctions, 1972–1979 (dollars per acre)

	Obs.	Mean	Std. dev.	Minimum	Maximum	Within s.d.
All bids	454	687.30	1,431.31	19.51	20,751.32	1,258.91
Joint bids	232	837.32	1,717.54	21.46	20,751.32	
Solo bids	222	532.53	1,033.20	19.51	11,019.08	
Joint vs. joint	120	875.13	2,056.12	33.94	20,751.32	2,011.99
Joint vs. solo	112	796.83	1,266.32	21.46	6,377.94	
Solo vs. joint	112	603.28	1,226.61	19.51	11,019.08	
Solo vs. solo	110	456.45	788.19	20.80	7,009.10	747.43

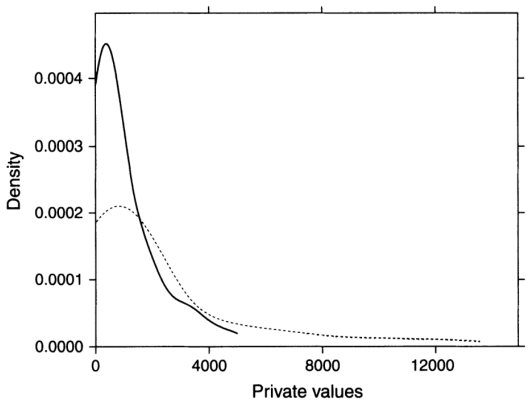
Notes. Bids in 1972 dollars per acre. "Joint vs. solo" means joint bids in auctions whose other bidder is solo. The within standard deviation is computed within auctions. Source: Campo et al. (2003, Table I).

above \$460, it wins 35 times. Quasi-symmetry requires a winning probability of one half in each subset. In the second subset, $t = 1.87$ rejects (Campo et al., 2003, p. 195). As a check, the share $\frac{35}{56} = 0.625$ has standard error $\sqrt{\frac{0.25}{56}} = 0.067$ under the null, which reproduces $t = 1.87$. The pure common value model is rejected for these auctions. A general model with values $U(\sigma_i, V)$ is not rejected, since it is not identified (Laffont and Vuong, 1996).

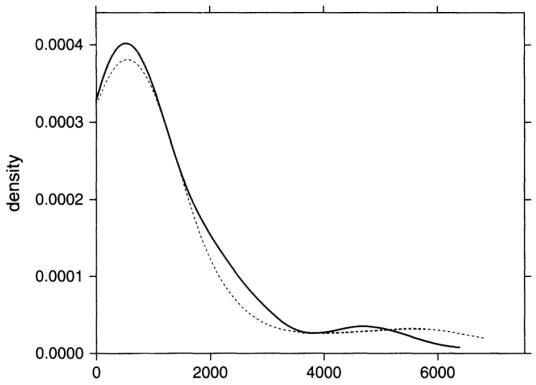
Results with one type. The $(2, 0)$ and $(0, 2)$ configurations are symmetric APV models, estimated as in Section 15.5.1. Three and six auctions are trimmed. Both estimated inverse bid functions are increasing, so the APV model is not rejected. The function for joint bidders facing joint bidders lies to the right of that for solo bidders facing solo bidders. For the same value, a joint bidder facing a joint bidder bids more. The value distribution of joint bidders first-order stochastically dominates that of solo bidders in a one-sided Kolmogorov-Smirnov test. The trimmed pseudo-values have mean \$2,195.14 for joint bidders and \$1,027.90 for solo bidders (their footnote 19). The test of Blum et al. (1961) rejects independence of the two values in every case. The statistic is 6.57 on bids and 4.69 on trimmed pseudo-values for joint pairs. For solo pairs it is 9.52 and 6.92 (Campo et al., 2003, p. 197).

Results with both types. In the $(1, 1)$ case the starred maxima are void, and the inversions reduce to $\xi_{10}(b_1) = b_1 + \frac{G_{b_0|b_1}(b_1|b_1)}{g_{b_0|b_1}(b_1|b_1)}$ and its mirror image (Campo et al., 2003, eqs. (18)–(19)). After trimming 21 auctions, 91 remain. Both estimated inverse functions increase. The solo bidder's function lies to the right of the joint bidder's, especially above \$500 per acre. For the same value, a solo bidder bids more aggressively. This again contradicts quasi-symmetry. The value densities of the two types are close (Figure 15.12, panel b). Trimmed pseudo-values average \$1,208.73 for joint and \$1,161.62 for solo bidders (their footnote 21). A Kolmogorov-Smirnov test does not reject equal distributions (their footnote 22). Asymmetry in values is weak. The weak bidder's lighter shading, that is, its more aggressive bidding, is the response that Proposition 14.76 predicts (Campo et al., 2003, p. 199). It does not produce inefficient allocations in the sample. Each type also adapts to its rival. A joint bidder bids more aggressively against a joint bidder, and a solo bidder bids slightly more aggressively against a joint bidder.

Unobserved heterogeneity and rents. Under Assumption 15.35, comparing a type's value density across configurations detects unobserved tract heterogeneity. Kolmogorov-Smirnov statistics are 0.1917 for joint bidders in $(2, 0)$ against $(1, 1)$ auctions and 0.0965 for solo bidders in $(0, 2)$ against $(1, 1)$ auctions (Campo et al., 2003, p. 200). The authors read the first as a clear rejection. Tracts that attract two joint bidders are more valuable than tracts that attract one bidder of



(a) Symmetric configurations: joint vs. joint (dashed), solo vs. solo (solid)



(b) Mixed configuration: joint (dashed), solo (solid)

Figure 15.12: Estimated marginal densities of private values in OCS wildcat auctions, dollars per acre. The horizontal axes differ across panels. In symmetric auctions the joint bidders' values are far more dispersed than the solo bidders'. In mixed auctions the two densities are close. The contrast between panels points to unobserved tract heterogeneity across configurations. Source: Campo et al. (2003), Figures 2 and 4.

each type. The differences in Table 15.8 thus reflect both asymmetry and tract heterogeneity, with heterogeneity the larger force. Winners' informational rents (15.38) average 65.07 percent across 197 winners (their Table II). They are 65.50 percent for joint and 64.59 percent for solo winners. So the government captures about 35 percent of the winner's willingness to pay. In dollars, joint winners earn $1,954.42 per acre and solo winners $1,151.40, because joint winners have higher values (Campo et al., 2003, p. 201).

Interpretation and critiques. Asymmetry between joint and solo bidders is weak. A ban on joint bidding would therefore change little if participation stayed the same. The authors argue that joint bidding raised revenue by increasing participation. The paper's contribution is methodological. It shows that the indirect approach handles asymmetric bidders whose equilibrium cannot be computed, and it gives a usable test of pure common values. The limits are severe in practice. The trivariate objects in (15.39) force the analysis to two-bidder auctions. With three bidders only 18 to 60 auctions would be available per configuration (their footnote 16). Types are binary and the configuration is taken as exogenous to values given the tract. The private value assumption for oil leases is contested. Hendricks et al. (2003) find bidding on earlier OCS auctions more consistent with common values (Section 15.6.4).

15.5.4 Asymmetric independent private values with all bids

Independence simplifies the inversion and lowers data requirements. Let bidder j's bid have distribution G_j and density g_j. With independent values, bids are independent, so

$G_{M_i|B_i}(m \mid b) = \prod_{j \neq i} G_j(m)$. Differentiating the product,

$$g_{M_i|B_i}(m \mid b) = \sum_{k \neq i} g_k(m) \prod_{j \neq i,k} G_j(m),$$

$$\frac{G_{M_i|B_i}(b \mid b)}{g_{M_i|B_i}(b \mid b)} = \frac{\prod_{j \neq i} G_j(b)}{\sum_{k \neq i} g_k(b) \prod_{j \neq i,k} G_j(b)} = \left[\sum_{j \neq i} \frac{g_j(b)}{G_j(b)} \right]^{-1}.$$

The inverse bid function is therefore

$$v_i = \xi_i(b_i) = b_i + \left[\sum_{j \neq i} \frac{g_j(b_i)}{G_j(b_i)} \right]^{-1}, \tag{15.42}$$

the inverse form of (14.77). Each value depends on its own bid and on the univariate distributions of rivals' bids. When all bids and bidder identities are observed, each F_i is identified by $F_i(v) = G_i(\xi_i^{-1}(v))$ (Athey and Haile, 2007, Theorem 3.1(ii)).

Estimation must condition on the set of opponents, because a change in their identities changes the strategy being inverted. With fully bidder-specific distributions, each set of bidders is treated separately. This requires many auctions with the same bidder set. A practical compromise groups bidders into a few types, with exchangeability within a type, as with joint and solo bidders or loggers and mills (Athey and Haile, 2007, Section 3.2.2). All auctions with the same number of bidders of each type can then be pooled. Asymmetry can also come from bidder covariates, such as the distance from a contractor's plant to the project. With discrete covariates this is the approach by types again. With continuous covariates the bid distributions are estimated conditional on them by kernel or sieve methods. The timber study of Section 15.9 applies (15.42) with parametric bid distributions.

Flambard and Perrigne (2006) apply the procurement version nonparametrically to snow removal contracts in Montreal (Hortaçsu and Perrigne, 2021, p. 102). In a low-bid auction bidder i wins when every rival bids more, and the same steps give

$$c_i = b_i - \left[\sum_{j \neq i} \frac{g_j(b_i)}{1 - G_j(b_i)} \right]^{-1}.$$

Firms are classified by their location relative to the job, and participation, winning probabilities and bid distributions differ across the classes. The estimated cost difference between the classes is about 6.5 percent. It leads to an inefficient allocation in 24 percent of the auctions. A subsidy to the weak, high-cost firms that restores symmetry would raise the share of contracts they win by 61 percent. With a cost of public funds taken into account, the overall procurement cost would fall by 1.34 percent under exogenous participation.

Equilibrium imposes testable restrictions. With independence and a common support of values, Theorem 15.29 requires bids to be independent, each ξ_i to be increasing, and all ξ_i to share the same upper endpoint. The last restriction comes from the common support. It can fail in a valid equilibrium if supports differ. Athey and Haile (2007, Section 5.1) give an example, which we verify. Let $n = 2$ with bid distributions $G_1(b) = b$ and $G_2(b) = b^2$ on $[0, 1]$. Then (15.42) gives

$$\xi_1(b) = b + \frac{G_2(b)}{g_2(b)} = b + \frac{b}{2} = \frac{3}{2}b, \qquad \xi_2(b) = b + \frac{G_1(b)}{g_1(b)} = 2b.$$

The implied value distributions are $F_1(v) = G_1(\frac{2}{3}v) = \frac{2}{3}v$ on $[0, \frac{3}{2}]$ and $F_2(v) = G_2(\frac{v}{2}) = \frac{v^2}{4}$ on $[0, 2]$. Each strategy is a best response. Bidder 1 maximizes $(v - b)b^2$, so $v = \frac{3}{2}b$, and bidder 2 maximizes $(v - b)b$, so $v = 2b$. Yet $\xi_1(1) = \frac{3}{2} \neq 2 = \xi_2(1)$. Equivalently, the densities of the highest rival bid differ at the top, $g_{M_1}(1) = g_2(1) = 2$ and $g_{M_2}(1) = g_1(1) = 1$, so the boundary condition (15.29) fails. Allowing supports to differ across bidders restores identification in such cases. If the lower ends of the supports also differ, some bidders may never win, and little can be learned about them (Athey and Haile, 2007, Section 5.1).

15.6 Common Values: Limits of Identification and Tests

With common values, information about each bidder's value is dispersed among the bidders. Learning a rival's signal would change a bidder's estimate of her own value (Definition 14.8). Winning then carries bad news, the winner's curse of Section 14.3.4. Many policy questions turn on the joint distribution of signals and values. Examples are the optimal reserve price, the revenue ranking of formats, and whether restricting entry raises revenue. This section first shows how little bids reveal about that distribution. It then shows that exogenous variation in competition still allows private values to be tested against common values. Next it presents a positive identification result for procurement with interdependent costs (Somaini, 2020). It ends with the evidence of Hendricks and Porter (1988) on an auction with an informed bidder.

15.6.1 What bids can and cannot reveal

Let bidder i observe a signal S_i about her value V_i. The primitive is the joint distribution $F_{S,V}$ of signals and values. In the pure common value model $V_i = V_0$ for all i. We focus on symmetric models. Let $Y_i = \max_{j \neq i} S_j$ and define the *pivotal expected value*

$$v(s, y; n) = \mathbb{E}\left[V_i \mid S_i = s,\ Y_i = y;\ n\right],$$

the expected value of a bidder whose signal is s and whose strongest rival has signal y. The dimension count is discouraging. The primitive governs $2n$ random variables, or $n + 1$ with pure common values, yet an auction reveals at most n bids (Athey and Haile, 2007, Section 7.1).

Signals have only ordinal meaning. Any strictly increasing relabeling of a signal leaves behavior unchanged. Athey and Haile (2002, eq. (8)) use this freedom to impose the normalization

$$v(s, s; n) = \mathbb{E}\left[V_i \mid S_i = \max_{j \neq i} S_j = s;\ n\right] = s. \tag{15.43}$$

In the second-price auction the equilibrium bid is $v(s, s; n)$ (Proposition 14.51). Under (15.43) it becomes $b(s) = s$, so bids reveal signals. In the first-price auction, the first-order condition of (14.68) holds with the pivotal expected value on the left:

$$v(s_i, s_i; n) = b_i + \frac{G_{M|B}(b_i \mid b_i)}{g_{M|B}(b_i \mid b_i)} \tag{15.44}$$

(Athey and Haile, 2007, eq. (7.2)). The right side is the same functional of bids as in the APV model. All bids therefore identify the joint distribution of the random variables $v(S_i, S_i; n)$, $i = 1, \ldots, n$, and nothing more.

Proposition 15.37 (Laffont and Vuong, 1996)**.** *Fix n and suppose the reserve price does not bind. Every symmetric affiliated value model of the first-price auction with a strictly increasing equilibrium is observationally equivalent to a symmetric APV model. Its private values are $\tilde{V}_i = v(S_i, S_i; n)$.*

Proof. Bids are strictly increasing transformations of affiliated, exchangeable signals, so $\boldsymbol{G}$ is symmetric and affiliated. By (15.44), $\xi(b; \boldsymbol{G}) = v\big(\beta^{-1}(b), \beta^{-1}(b); n\big)$, which is strictly increasing in b. At $b = \beta(s)$ the ratio in (15.44) equals $v(s, s; n) - \beta(s)$, which vanishes at $\underline{s}$ because $\beta(\underline{s}) = v(\underline{s}, \underline{s}; n)$ by (14.65). Both conditions and the boundary condition of Proposition 15.31 hold, so an APV structure rationalizes $\boldsymbol{G}$. Its values are $\xi(B_i; \boldsymbol{G}) = v(S_i, S_i; n)$. □

Conclusions drawn from bids with a fixed set of bidders and no reserve price therefore rest on a maintained assumption of private or common values. Different maintained assumptions can justify a wide range of reserve prices as optimal (Athey and Haile, 2007, Section 7.1). Second-price and ascending auctions do no better.

Proposition 15.38 (Athey and Haile, 2002, Corollary 2)**.** *Consider the symmetric common value model of the second-price sealed-bid auction.*

(i) The distribution of signals $F_{\boldsymbol{S}}$ is not identified from bids unless all bids are observed.

(ii) The joint distribution $F_{\boldsymbol{S},\boldsymbol{V}}$ is not identified from bids.

Proof. Under (15.43) bids equal signals. Part (i) is then Theorem 15.9 applied to the exchangeable vector $\boldsymbol{S}$. For (ii), take two joint distributions with the same $F_{\boldsymbol{S}}$ and different conditional laws of $\boldsymbol{V}$ given $\boldsymbol{S}$, both satisfying (15.43). In both, $b(s) = s$, so the distributions of bids coincide. □

Ascending auctions are harder still. A normalization like (15.43) can hold only in the initial phase, before anyone exits. After each exit, bidders revise their planned exit prices in ways that depend on $F_{\boldsymbol{S},\boldsymbol{V}}$. With $n > 2$ there is also a continuum of symmetric equilibria in undominated strategies (Bikhchandani et al., 2002). Even the most restrictive common value model fails.

Proposition 15.39 (Athey and Haile, 2002, Theorem 8)**.** *In an ascending auction, assume pure common values, independent and identically distributed signals, and the equilibrium of Milgrom and Weber (1982). With n fixed, the model is not identified from the observed bids, even up to a normalization of signals.*

Proof. Take $n = 3$ and signals uniform on $[0, 1]$. Let $s^{(1:3)} \le s^{(2:3)} \le s^{(3:3)}$ be the ordered signals. Model A has $V_0 = \frac{s_1+s_2+s_3}{3}$. Model B has $\hat{V}_0 = \frac{s^{(1:3)}}{3} + \frac{s^{(2:3)}}{6} + \frac{s^{(3:3)}}{2}$. In the Milgrom-Weber equilibrium each bidder initially plans to exit at the expected value given that all signals equal her own. In both models

$$\mathbb{E}[V_0 \mid S_1 = S_2 = S_3 = s] = s = \frac{s}{3} + \frac{s}{6} + \frac{s}{2},$$

so the first exit occurs at $B^{(1:3)} = s^{(1:3)}$ in both. Its distribution is $1 - (1 - b)^3$. The first exit reveals $s^{(1:3)}$. Each remaining bidder then plans to exit at the expected value given her own signal y, the revealed signal s, and a remaining rival with signal y. In Model A this is $\frac{s+2y}{3}$. In Model B it is $\frac{s}{3} + \frac{y}{6} + \frac{y}{2} = \frac{s+2y}{3}$. The second exit therefore has the same conditional distribution given $B^{(1:3)}$ in both models. The winner never exits, so the joint distribution of observed bids is the same in both models. □

The two models differ in economically relevant ways. The optimal reserve price differs between them (Athey and Haile, 2002, footnote 38). In Model B a bidder's value depends less on her rivals' signals when her own signal is the highest. This lowers the participation threshold for any reserve price and changes the seller's objective (Athey and Haile, 2007, Section 7.1).

Identification with more structure. One route adds structure. In the symmetric *mineral rights model*, signals are independent given the common value. Li et al. (2000) add separability. For each n there are known constants C and $D > 0$ such that, under (15.43), $S_i = C + D(V_0 + A_i)$, with $(V_0, A_1, \ldots, A_n)$ mutually independent and the A_i identically distributed (Athey and Haile, 2002, p. 2126). Then (15.44) reads

$$C + D\,(v_0 + a_i) = b_i + \frac{G_{M|B}(b_i \mid b_i)}{g_{M|B}(b_i \mid b_i)}.$$

All bids identify the joint distribution of $(V_0+A_1, \ldots, V_0+A_n)$. When the characteristic functions do not vanish, the deconvolution argument of Lemma 15.50 separates the distributions of V_0 and A_i. The argument fails when some bids are missing. Bids then reveal order statistics $V_0 + A^{(i:n)}$, which are dependent even though the A_i are independent.

Li et al. (2000) apply this structure to wildcat leases of the Outer Continental Shelf (Hortaçsu and Perrigne, 2021, p. 129). They estimate two versions. In the conditionally independent private values version, each bidder's value is its signal $S_i = V_0 A_i$, with V_0 independent of the A_i, so logs are additive as above. In the pure common value version, the pivotal expected value is log-linear in the log signal, and the model is identified only up to location and scale. In the first version the recovered values are multiple indicators of V_0, a measurement-error problem that deconvolution solves. The estimates show little affiliation. The variance of $\ln V_0$ is only 9.2 percent of the variance of $\ln A_i$, so idiosyncratic factors explain most of the variation in values.

Identification with ex post values. The other route adds data. In offshore oil auctions the oil extracted is metered, and in scaled timber sales the harvested volume is recorded. Such data measure the realized common value v_0 (Athey and Haile, 2007, Section 7.2.2). Define the conditional mean of the ex post value given the bid and the highest rival bid,

$$\vartheta(b, b'; n) = \mathbb{E}\left[V_0 \mid B_i = b,\ M_i = b';\ n\right]. \tag{15.45}$$

It is identified without any behavioral assumption, since V_0, B_i and M_i are all observed. With monotone bidding, $\mathbb{E}[V_0 \mid S_i = Y_i = s; n] = \vartheta(b, b; n)$ at $b = \beta(s; n)$. Equation (15.44) then yields the overidentifying restriction

$$\vartheta(b, b; n) = b + \frac{G_{M|B}(b \mid b)}{g_{M|B}(b \mid b)}. \tag{15.46}$$

Hendricks et al. (2003) proposed this test of equilibrium bidding. They estimate the left side by a bivariate local linear regression of ex post values on (B_i, M_i) and the right side from bids. Ex post values also measure the winner's curse. Two natural measures are

$$\mathbb{E}[V_0 \mid S_i = s] - \mathbb{E}[V_0 \mid S_i = Y_i = s] \quad \text{and} \quad \mathbb{E}[V_0 \mid S_i = s] - \mathbb{E}[V_0 \mid S_i = s,\ Y_i \le s],$$

equations (7.5)–(7.6) of Athey and Haile (2007). In bid terms they are $\mathbb{E}[V_0 \mid B_i = b] - \vartheta(b, b; n)$ and $\mathbb{E}[V_0 \mid B_i = b] - \mathbb{E}[V_0 \mid B_i = b,\ M_i \le b]$. The second uses only winning bids.

A positive value of the second measure does not reject private values (Athey and Haile, 2007, footnote 86). The interpretation of the measured ex post value as V_0 presumes common values.

Suppose values are independent and private and the measure equals the winner's value $\max_j V_j$. Then $\mathbb{E}[\max_j V_j \mid V_i = v] - \mathbb{E}[\max_j V_j \mid V_i = v,\ \max_{k\neq i} V_k \le v] = \mathbb{E}[\max_j V_j \mid V_i = v] - v > 0$. A noisy measure $\tilde{V}_0 = \lambda_0 + \lambda_1 V_0 + \eta$ with $\mathbb{E}[\eta \mid \boldsymbol{S}] = 0$ can still be used. The ex post analogue of (15.43) is then $\lambda_0 + \lambda_1 s$, which identifies λ_0 and λ_1 (Athey and Haile, 2007, eq. (7.11)).

Hendricks et al. (2003) take both ideas to wildcat leases of the Outer Continental Shelf, where ex post estimates of tract value measure V_0 (Hortaçsu and Perrigne, 2021, p. 126). Actual competition is low relative to potential entry, so they build a data-driven measure of the number of potential bidders. They estimate the expected ex post value given the bid, the level of competition and tract characteristics, and then add the condition that every rival bid lies below the bid. The difference is the second measure above. The winner's curse is about 107 percent of the average winning bid when competition is low, and it falls to 75 percent when competition is high. A second test compares conditional expectations of ex post values with the pivotal expected values recovered from bids by the indirect approach, as in (15.46). The recovered pivotal values rise with the bid, as rationalization requires, and bidders appear to overestimate tract values when competition is low. The authors conclude that bidding is consistent with common values and that bidders lower their bids to correct for the winner's curse.

15.6.2 Testing private against common values

Early tests regressed bids on the number of bidders (Gilley and Karels, 1981; Paarsch, 1992). The idea was that competition raises bids under private values, while a severe winner's curse could lower them under common values. The idea fails twice. In first-price auctions, bids can rise or fall with n under both paradigms (Pinkse and Tan, 2005). In ascending auctions the winner's value is censored. The distribution of each observed order statistic shifts with n even without a winner's curse, so the regression confounds the two effects (Athey and Haile, 2007, Section 8). The valid tests below isolate the winner's curse with an exact restriction from probability theory.

Lemma 15.40 (Recurrence relation, Athey and Haile, 2002, eq. (9))**.** *Let $X_1, \dots, X_n$ be exchangeable with continuous marginal distributions, and let $F_{(r:k)}$ be the distribution of the r-th lowest of $X_1, \dots, X_k$. Then for all x and all $r \le n-1$,*

$$\frac{n-r}{n} F_{(r:n)}(x) + \frac{r}{n} F_{(r+1:n)}(x) = F_{(r:n-1)}(x). \tag{15.47}$$

Proof. Draw an index J uniformly from $\{1, \dots, n\}$, independently of $\boldsymbol{X}$, and delete X_J. By exchangeability, the remaining $n-1$ variables have the same joint law as $(X_1, \dots, X_{n-1})$. So the r-th lowest of them, call it $\tilde{X}$, has distribution $F_{(r:n-1)}$. Let R_J be the rank of X_J among all n variables. Because J is uniform and independent of $\boldsymbol{X}$, R_J is uniform on $\{1, \dots, n\}$ and independent of the order statistics $X^{(1:n)}, \dots, X^{(n:n)}$. If $R_J > r$, deleting X_J leaves the r lowest variables intact, so $\tilde{X} = X^{(r:n)}$. This event has probability $\frac{n-r}{n}$. If $R_J \le r$, one of the r lowest is removed, so $\tilde{X} = X^{(r+1:n)}$. This event has probability $\frac{r}{n}$. Hence

$$F_{(r:n-1)}(x) = \mathbb{P}(\tilde{X} \le x) = \frac{n-r}{n} \mathbb{P}\big(X^{(r:n)} \le x\big) + \frac{r}{n} \mathbb{P}\big(X^{(r+1:n)} \le x\big).$$

□

As a check, let $n = 2$, $r = 1$, and let the X_i be independent with distribution F. Then $\frac{1}{2}[1 - (1-F)^2] + \frac{1}{2}F^2 = \frac{1}{2}(2F - F^2 + F^2) = F = F_{(1:1)}$. Under private values the number of bidders does not change values, so the distributions of value order statistics obey (15.47) across

n. Under common values the winner's curse breaks the relation in a known direction. The direction comes from the following result. It assumes exogenous participation in the sense of Section 15.1.1, so adding a bidder leaves the joint distribution of the incumbents' signals and values unchanged.

Lemma 15.41 (Athey and Haile, 2007, Lemma 8.1)**.** *Suppose participation is exogenous. With private values, $v(s,s;n) = v(s,s;n+1)$ for all s. With symmetric common values, $v(s,s;n) > v(s,s;n+1)$ for all s.*

Proof. With private values $v(s,s;n) = \mathbb{E}[V_i \mid S_i = s]$, which does not depend on n. With common values, fix bidder i, an incumbent rival m, and an entrant j. By symmetry,

$$\begin{aligned} v(s,s;n) &= \mathbb{E}\left[V_i \mid S_i = s,\ S_m = s,\ S_k \le s\ \forall k \neq i,m\right] \\ &= \mathbb{E}\Big[\mathbb{E}\left[V_i \mid S_i = s,\ S_m = s,\ S_k \le s\ \forall k \neq i,m,\ S_j\right]\Big] \\ &> \mathbb{E}\left[V_i \mid S_i = s,\ S_m = s,\ S_k \le s\ \forall k \neq i,m,\ S_j \le s\right] = v(s,s;n+1). \end{aligned}$$

The second line is the law of iterated expectations over the entrant's signal. With common values the inner expectation is strictly increasing in S_j. Restricting S_j to $S_j \le s$ removes its highest realizations and strictly lowers the mean. The last equality is the definition of v with $n+1$ bidders, since the event says that the strongest of i's n rivals has signal s. □

Winning against more rivals is worse news. With twenty bidders, having the highest signal implies a more biased signal than with two. Figure 15.13 illustrates Lemma 15.41 in a Gaussian mineral rights model.

Theorem 15.42 (Athey and Haile, 2002, Theorem 9)**.** *In a second-price sealed-bid or ascending auction with exogenous participation, the symmetric private value model is testable against the symmetric common value alternative. It suffices to observe the transaction price $B^{(m-1:m)}$ in auctions with $m \ge 2$ bidders and the bids $B^{(m-1:n)}, \dots, B^{(n-1:n)}$ in auctions with $n > m$ bidders.*

Proof. Take a second-price auction and $m = n-1$. Each bidder bids $b(s;n) = v(s,s;n)$. Under private values $b(s;n)$ does not depend on n. Bids are then a fixed increasing transformation of exchangeable signals, so they are exchangeable. Applying (15.47) with $r = n-2$ gives

$$\frac{2}{n}\mathbb{P}\big(B^{(n-2:n)} \le b\big) + \frac{n-2}{n}\mathbb{P}\big(B^{(n-1:n)} \le b\big) = \mathbb{P}\big(B^{(n-2:n-1)} \le b\big). \tag{15.48}$$

Under common values, $b(s;n) < b(s;n-1)$ by Lemma 15.41. Let $\sigma_k(b)$ be the signal that bids b in a k-bidder auction, so $\sigma_n(b) > \sigma_{n-1}(b)$. Using (15.47) for signals,

$$\begin{aligned} \frac{2}{n}\mathbb{P}\big(B^{(n-2:n)} \le b\big) + \frac{n-2}{n}\mathbb{P}\big(B^{(n-1:n)} \le b\big) &= \frac{2}{n}F_{(n-2:n)}\big(\sigma_n(b)\big) + \frac{n-2}{n}F_{(n-1:n)}\big(\sigma_n(b)\big) \\ &= F_{(n-2:n-1)}\big(\sigma_n(b)\big) \\ &> F_{(n-2:n-1)}\big(\sigma_{n-1}(b)\big) = \mathbb{P}\big(B^{(n-2:n-1)} \le b\big), \end{aligned}$$

where $F_{(r:k)}$ now refers to signals. A test of the equality (15.48) against this first-order stochastic dominance tests private against common values. In the ascending auction, private values again imply (15.48) and hence the recurrence in means, $\mathbb{E}[B^{(n-2:n-1)}] = \frac{2}{n}\mathbb{E}[B^{(n-2:n)}] + \frac{n-2}{n}\mathbb{E}[B^{(n-1:n)}]$. Under common values the top losing bidder in an $(n-1)$-bidder auction exits later in expectation than she would with an extra rival. This yields the strict inequality $\mathbb{E}[B^{(n-2:n-1)}] > \frac{2}{n}\mathbb{E}[B^{(n-2:n)}] + \frac{n-2}{n}\mathbb{E}[B^{(n-1:n)}]$ in every symmetric separating equilibrium (Athey and Haile, 2002, eqs. (13)–(17)). □

The ascending-auction part is notable because it holds whatever equilibrium is played. The relevant transaction price is the same in all symmetric separating equilibria, and Milgrom-Weber bids are maximal among them (Bikhchandani et al., 2002). One caveat applies. Losing bids in real ascending auctions may understate willingness to pay (Theorem 15.11), and this alone could mimic a winner's curse. Three extensions follow.

Theorem 15.43 (Athey and Haile, 2002, Theorems 10–11 and Corollary 4)**.** *Suppose participation is exogenous.*

(i) Asymmetric bidders. *Consider a second-price auction. Suppose bids $B^{(m-1:n)}, \dots, B^{(n-1:n)}$ are observed in auctions with $n \geq 3$ bidders, and transaction prices in auctions whose bidders form subsets of size $m < n$. Then the unrestricted private value model is testable against common values.*

(ii) First-price auctions. *If the top two bids are observed in auctions with n and $n-1$ bidders, $n \geq 3$, the symmetric APV model is testable against symmetric common values.*

(iii) Reserve prices. *Consider first-price, second-price or ascending auctions with a reserve price. Suppose $B^{(j:n)}$ and $B^{(j+1:n)}$ are observed in n-bidder auctions and $B^{(j:n-1)}$ in $(n-1)$-bidder auctions, for some $2 \leq j < n$. Then the symmetric private value model is testable.*

Proof sketch. (i) A random subsample of size m drawn from any n random variables is exchangeable (Athey and Haile, 2002, proof of Theorem 10). The recurrence therefore holds for averages of order-statistic distributions over subsets of bidders. (ii) Let $F_{v,(k:m)}$ be the distribution of $v(S^{(k:m)}, S^{(k:m)}; m)$ in m-bidder auctions. By Proposition 15.33 and (15.44), the top two bids identify $F_{v,(n-1:n)}$, $F_{v,(n:n)}$ and $F_{v,(n-1:n-1)}$. Under private values these are distributions of value order statistics, so by (15.47) with $r = n-1$,

$$\frac{1}{n} F_{v,(n-1:n)}(t) + \frac{n-1}{n} F_{v,(n:n)}(t) = F_{v,(n-1:n-1)}(t) \quad \text{for all } t.$$

Under common values $v(s, s; n)$ is still increasing in s, so the variables $v(S_i, S_i; n)$ are exchangeable and obey the recurrence with n held fixed. By Lemma 15.41, $v(s, s; n) < v(s, s; n-1)$, so the left side strictly exceeds the right side. (iii) With a reserve price, participants' values are draws from the distribution truncated at the reserve. Truncation preserves exchangeability, so the recurrence still holds under private values (Athey and Haile, 2002, proof of Corollary 4). In a first-price auction the relation applies to the values recovered from the bids. □

When all bids of a first-price auction are observed, the test can use the whole distribution of pivotal expected values. Let $F_{v,n}$ denote the distribution of the random variable $v(S_i, S_i; n)$, which (15.44) identifies.

Proposition 15.44 (Athey and Haile, 2007, Corollary 8.1 and Haile et al., 2003)**.** *Suppose participation is exogenous. Under private values, $F_{v,n}$ does not depend on n. Under symmetric common values, $F_{v,n}(t) < F_{v,n+1}(t)$ for all t in the interior of the supports.*

The result follows from Lemma 15.41, since $v(S_i, S_i; n)$ falls with n for every signal. Haile et al. (2003) build a two-step test on it. The first step computes pseudo-values $\hat{v}_{it}$ separately for each n, as in (15.36). The second step compares their empirical distributions across n. Two statistics are proposed. The first compares quantile-trimmed means

$$\hat{\mu}_{n,\tau} = \frac{1}{nT_n} \sum_{t:\, n_t = n} \sum_{i=1}^{n} \mathbf{1}\big(b_{it} \in [b_\tau, b_{1-\tau}]\big)\, \hat{v}_{it},$$

where b_τ is the τ-th quantile of bids in n-bidder auctions. The null hypothesis is that the $\mu_{n,\tau}$ are equal across n, and the alternative is that they decrease. Trimming at the same quantiles for every n fixes the set of signals behind each mean. Trimming on a fixed range of bids would compare different signals and could create or hide a winner's curse. The vector of trimmed means is asymptotically normal with a diagonal covariance matrix, which permits a one-sided likelihood ratio test. The second statistic is a smoothed multi-sample one-sided Kolmogorov-Smirnov statistic, $\sum_n \sup_v [\hat{F}_{\hat{v},n+1}(v) - \hat{F}_{\hat{v},n}(v)]$, with cutoffs obtained by subsampling (Athey and Haile, 2007, Section 8.1). Both tests must account for the estimation error in the pseudo-values.

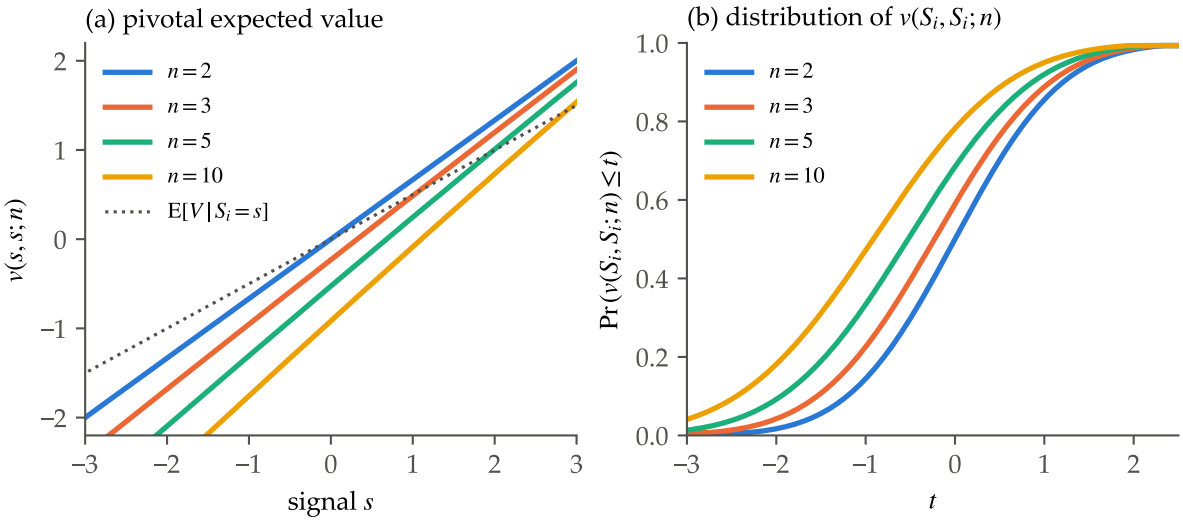


Figure 15.13: The winner's curse and the number of bidders in a Gaussian mineral rights model: $V_0 \sim N(0,1)$ and $S_i = V_0 + e_i$ with independent $e_i \sim N(0,1)$. Panel (a): the pivotal expected value $v(s,s;n)$ falls with n for every signal (Lemma 15.41). The dotted line is $\mathbb{E}[V_0 \mid S_i = s] = \frac{s}{2}$, which does not depend on n. Panel (b): the distribution of $v(S_i,S_i;n)$, the object compared across n in the test of Haile et al. (2003). Under private values the four curves would coincide. Our computation by numerical integration, with no random numbers (script `cv_winners_curse.py`).

Endogenous participation. Exogenous variation in n is a strong assumption. A binding reserve price or a bid-preparation cost truncates the set of participating types. Haile et al. (2003) adjust for truncation and compare the distributions on their common support (Athey and Haile, 2007, Section 8.2). Unobservables that move both participation and values are harder. If more valuable tracts attract more bidders, that variation can mask the winner's curse. Unobserved heterogeneity also threatens identification of $F_{v,n}$ itself (Section 15.7). Haile et al. (2003) propose an instrumental approach that builds on Assumption 15.35. Let the number of bidders be $n_t = \chi(Z_t, \omega_t)$, where Z_t is observed and ω_t is an unobserved index of the auction, the unobserved heterogeneity of Section 15.7. Assume (i) Z_t is independent of signals and values, and (ii) χ is weakly increasing in Z_t and strictly increasing in ω_t. Strict monotonicity in ω_t makes (n_t, Z_t) a sufficient statistic for ω_t. The pivotal expected value of a bidder whose signal s leads to the bid b is then identified conditional on (n_t, Z_t):

$$v(s,s;n,z) = b + \frac{\mathbb{P}\big(M_{it} \le b \mid B_{it} = b,\ Z_t = z,\ n_t = n\big)}{\frac{\partial}{\partial m}\mathbb{P}\big(M_{it} \le m \mid B_{it} = b,\ Z_t = z,\ n_t = n\big)\big|_{m=b}}.$$

Pooling pseudo-values across n for each z, the distribution of pivotal values must be the same

for all z under private values. It shifts with z under common values. In timber auctions they use the number of sawmills and logging firms near a sale as the instrument (Athey and Haile, 2007, Section 8.2). Strict monotonicity in a scalar unobservable is the price of the approach. It also requires the unobservable to be discrete, because n_t is.

Binding reserve prices. A reserve price offers a different test (Hendricks et al., 2003). With reserve r in a symmetric first-price auction, a bidder participates if her signal exceeds the threshold $s^* = \inf\{s : \mathbb{E}[V_i \mid S_i = s,\ Y_i \le s] \ge r\}$. The marginal participant bids r and wins only when no rival participates. Her pivotal expected value is $v(s^*, s^*; n)$. Under private values the two conditional expectations coincide, so $v(s^*, s^*; n) = r$. Under common values $\mathbb{E}[V_i \mid S_i = s^*,\ Y_i \le s^*] < \mathbb{E}[V_i \mid S_i = Y_i = s^*]$, so $v(s^*, s^*; n) > r$ (Athey and Haile, 2007, eqs. (8.7)–(8.8)). The inverse bid function at the bottom of the bid support, $\lim_{b \downarrow r} \left[b + \frac{G_{M|B}(b|b)}{g_{M|B}(b|b)} \right]$, should equal r under private values and exceed it under common values. With private values the markdown vanishes at the reserve, so rival bids are dense just above r (compare Theorem 15.27). With common values the markdown stays positive, because even the marginal participant bids below her pivotal value. Bids just above r are then relatively sparse, an implication of the reserve price already noted by Milgrom and Weber (1982). Hill and Shneyerov (2013) develop a formal test based on the tail of the bid distribution near the reserve.

Evidence from timber, oil and procurement auctions. The tests have been applied in several markets, and the answer depends on the market (Hortaçsu and Perrigne, 2021, Sections 2.3, 3.2 and 4.1). In Forest Service first-price sales in the western half of the United States, the tests of Haile et al. (2003) find no evidence of common values in scale sales. We report the results of the 2006 revision of that working paper, as summarized by Hortaçsu and Perrigne (2021, pp. 93–94). The evidence is mixed in lump-sum sales, where the case for common values was stronger. Compiani et al. (2020) extend the test to endogenous entry and unobserved heterogeneity and apply it to Outer Continental Shelf leases (pp. 126–127). Private information is multiplicatively separable into a function of observed and unobserved heterogeneity and an idiosyncratic base value. Bids then decompose into the same function times a *homogenized bid* that depends only on the number of bidders and the signal. The number of bidders depends on observables and rises weakly with the unobservable. An instrument shifts entry but not signals or values, and in the application it is the number of neighbor firms. Under private values the joint distribution of signals and values does not depend on the number of bidders, while common values order it by stochastic dominance. The authors conclude in favor of common values. Ignoring unobserved heterogeneity would produce an ordering contrary to common values, a misspecification of the kind studied in Section 15.7. For policy, the seller would not gain from limiting competition to soften the winner's curse. A second-price auction, which exploits the linkage principle (Proposition 14.62), would raise revenue only slightly.

Hong and Shum (2002) quantify the winner's curse in procurement with a parametric model of affiliated values (pp. 104–105). Under common values more bidders have two effects on bids. A competitive effect lowers them, and a winner's-curse effect raises them, so bids can be U-shaped in the number of bidders. The model follows the log-additive specification of Wilson, with multiplicative decompositions of costs and signals. The relative standard deviations of the common component, the private component and the signal noise measure how common the costs are. In New Jersey Department of Transportation auctions, highway work behaves like common values, while bridge work and road paving mix private and common values. Allowing for unobserved heterogeneity, road paving looks like independent private costs and highway work like affiliated private values. For highway work, halving the number of bidders

would lower the procurement cost by 15 percent. For the other two kinds of work, more competition lowers the cost, so the competitive effect dominates.

Table 15.9 collects the tests of this subsection. Each one replaces the unattainable goal of identifying $F_{S,V}$ by a restriction that private values impose and common values violate.

Table 15.9: Tests of private against common values

Format	Data and variation	Restriction under private values	Source
Second-price or ascending	Price with m bidders, upper bids with $n > m$. Exogenous n	Recurrence (15.47) holds (in means for ascending). Common values give dominance	Athey and Haile (2002, Thm. 9)
Second-price, asymmetric	Bids with n bidders, prices with subsets of bidders	Recurrence for random subsamples	Athey and Haile (2002, Thm. 10)
First-price	Top two bids with n and $n-1$ bidders	Recurrence for identified $v(S, S; n)$	Athey and Haile (2002, Thm. 11)
First-price	All bids, exogenous n	$F_{v,n}$ invariant to n. It falls in n under common values	Haile et al. (2003)
First-price	All bids, instrument for n	Pivotal values invariant to the instrument	Haile et al. (2003)
First-price	All bids, instrument for entry, unobserved heterogeneity	Joint law of signals and values invariant to n	Compiani et al. (2020)
First-price	Binding reserve price	Inverse bid function equals r at the bottom	Hendricks et al. (2003)
First-price	All bids and ex post values	Overidentifying restriction (15.46)	Hendricks et al. (2003)
First-price, two bidders	Bids and identities	Quasi-symmetry rejects asymmetric pure common values	Campo et al. (2003)

15.6.3 Interdependent costs: Somaini (2020)

Question. Most empirical work picks one of two polar models. Under private costs there is no winner's curse. Under pure common costs every bidder would incur the same cost, so the allocation cannot be inefficient. Intermediate models had received little attention, largely because Laffont and Vuong (1996) showed that any bid distribution rationalized by interdependent costs is also rationalized by private costs. Somaini (2020) asks whether richer variation in competitive conditions restores identification in procurement auctions. The variation comes from continuous bidder-specific cost shifters, such as each firm's distance to the project. The test of Haile et al. (2003) uses discrete variation in n. Continuous shifters vary competition in more directions.

Primitives. A buyer procures a project by first-price (low-bid) sealed bid from n risk-neutral bidders, with no reserve price. Bidder i's cost is C_i and her private information is a scalar signal S_i. Signals are normalized to have uniform marginals, so their joint distribution F_S is a copula. Each bidder has a public cost shifter w_i, and $\boldsymbol{w} = (w_1, \ldots, w_n)$. Somaini writes x_i for w_i and conditions on auction characteristics throughout. Bidder i's *full-information cost* is

$$c_i(\boldsymbol{s}_{-i}, s_i, w_i) = \mathbb{E}\left[C_i \mid \boldsymbol{S} = \boldsymbol{s},\ \boldsymbol{w}\right].$$

For risk-neutral bidders, the payoff-relevant primitives are F_S and the functions c_i. They are coarser than the joint distribution of costs and signals. They suffice for counterfactuals that change the rules, the reserve price or subsidies (Somaini, 2020, Section I).

Assumption 15.45 (Somaini, 2020, Assumptions A1–A3 and A7)**.** (A1) Signals are independent of cost shifters: $F_{S|\boldsymbol{w}} = F_S$. (A2) Signals are scalar, and F_S has a continuously differentiable bounded density f. (A3) Rivals' shifters are excluded from a bidder's full-information cost: $\mathbb{E}[C_i \mid \boldsymbol{S}, \boldsymbol{w}] = c_i(\boldsymbol{S}_{-i}, S_i, w_i)$. (A7) For every $\boldsymbol{w}$, the data are generated by repeated play of the same Bayes-Nash equilibrium in monotone pure strategies.

The model nests the standard cases. Private costs mean c_i does not depend on $\boldsymbol{s}_{-i}$. Independent private costs add independence of signals, and affiliated private costs allow affiliation. Pure common costs mean $c_i = c_j$ for all i, j. Bidders may also be asymmetric in any way. Assumptions A1 and A3 define what makes an observable a cost shifter. For distance, they rule out a firm having lower costs when a rival is nearby. They also rule out a firm regarding a nearby rival's signal as more informative. Equilibria in monotone pure strategies exist when signals are affiliated (Reny and Zamir, 2004). Somaini shows that without a binding reserve price they are strictly increasing (Somaini, 2020, Proposition 1).

First-order condition. Let $s_j(b) = \beta_j^{-1}(b)$ be the signal at which rival j bids b. A low bid wins, so bidder i wins with bid b when $\boldsymbol{S}_{-i} \geq \boldsymbol{s}_{-i}(b)$ componentwise. Her expected profit is

$$\Pi_i(b; s_i) = \int_{\boldsymbol{\tau} \geq \boldsymbol{s}_{-i}(b)} \big(b - c_i(\boldsymbol{\tau}, s_i, w_i)\big) f(\boldsymbol{\tau} \mid s_i)\, d\boldsymbol{\tau}.$$

Differentiating in b gives one term from the margin b and one boundary term for each rival:

$$\mathbb{P}\big(\boldsymbol{S}_{-i} \geq \boldsymbol{s}_{-i}(b) \mid s_i\big) - \sum_{j \neq i} s_j'(b) f\big(s_j(b) \mid s_i\big) \mathbb{P}\big(\boldsymbol{S}_{-ij} \geq \boldsymbol{s}_{-ij}(b) \mid s_i, s_j(b)\big) \times \Big[b - \mathbb{E}\big(C_i \mid s_i,\, s_j(b),\, \boldsymbol{S}_{-ij} \geq \boldsymbol{s}_{-ij}(b)\big)\Big] = 0.$$

Let $D_i(b)$ be the sum of the weights $s_j'(b) f(s_j(b) \mid s_i) \mathbb{P}(\boldsymbol{S}_{-ij} \geq \boldsymbol{s}_{-ij}(b) \mid s_i, s_j(b))$. It equals the absolute derivative of the win probability in the bid. Let $\pi_j^{(i)}(b)$ be rival j's weight divided by $D_i(b)$. Rearranging,

$$b - \frac{\mathbb{P}\big(\boldsymbol{S}_{-i} \geq \boldsymbol{s}_{-i}(b) \mid s_i\big)}{D_i(b)} = \sum_{j \neq i} \pi_j^{(i)}(b)\, \mathbb{E}\Big(C_i \mid s_i,\ S_j = s_j(b),\ \boldsymbol{S}_{-ij} \geq \boldsymbol{s}_{-ij}(b),\ w_i\Big), \tag{15.49}$$

equation (5) of Somaini (2020). The left side is marginal revenue, the bid minus a markup. The right side is the expected cost conditional on the bid being *pivotal*, that is, tying with at least one rival for the lowest bid. The weight $\pi_j^{(i)}$ is the probability of tying with rival j given a tie with at least one rival.

Identification. The argument has three steps. First, monotone strategies imply that the copula of bids equals the copula of signals. With uniform signals, $s_i = H_{B_i|\boldsymbol{w}}(b_i)$, the marginal distribution of i's bid given $\boldsymbol{w}$. Hence $F_S(\boldsymbol{s}) = H_{\boldsymbol{B}|\boldsymbol{w}}\big(Q_{B_1|\boldsymbol{w}}(s_1), \ldots, Q_{B_n|\boldsymbol{w}}(s_n)\big)$, where Q denotes a quantile function (Somaini, 2020, Lemma 1 and Proposition 3). By A1, the bid copula must not vary with $\boldsymbol{w}$, a testable implication. Nonparticipation is recorded as an infinite bid.

Second, the left side of (15.49) is identified as in (15.32), because conditioning on the signal is conditioning on the bid. With $M_i = \min_{j \neq i} B_j$,

$$\xi_i(b_i, \boldsymbol{w}) = b_i - \frac{\mathbb{P}(M_i \geq b_i \mid B_i = b_i, \boldsymbol{w})}{\left| \frac{\partial}{\partial m} \mathbb{P}(M_i \geq m \mid B_i = b_i, \boldsymbol{w}) \right|_{m = b_i}}. \tag{15.50}$$

The right side is the limit as $\varepsilon \downarrow 0$ of $\mathbb{E}\big(C_i \mid S_i = s_i,\ \boldsymbol{S}_{-i} \in L_\varepsilon(b_i, \boldsymbol{w}),\ w_i\big)$. Here $L_\varepsilon(b, \boldsymbol{w})$ is the set of rival signals for which i wins with bid b but loses with $b + \varepsilon$. It is the difference of two rectangles, each identified from the marginal bid distributions.

Third, variation in rivals' shifters moves these sets. With two bidders the pivotal event is a single point, and (15.49) becomes

$$\xi_1(b_1, \boldsymbol{w}) = c_1\big(H_{B_2|\boldsymbol{w}}(b_1),\ H_{B_1|\boldsymbol{w}}(b_1),\ w_1\big), \tag{15.51}$$

equation (8) of Somaini (2020). Holding w_1 fixed and varying (w_2, b_1) evaluates $c_1(\cdot, \cdot, w_1)$ at different pairs of signals. A3 ensures that w_2 moves the evaluation point without shifting c_1 itself. The rival's shifter works like an instrument for the rival's signal.

With three bidders the pivotal set is L-shaped (Figure 15.14). One bid gives one equation in two unknowns, the expected costs conditional on tying with bidder 2 or with bidder 3. Different rival shifters $\boldsymbol{w}'$ produce another L-shaped set stacked on the first, with s_1 and w_1 fixed. Under A1, the expected cost over the union is a probability-weighted average with identified weights. Stacking ever finer L-shaped sets covers the rectangle $\{S_2 \geq s_2,\ S_3 \geq s_3\}$. The limit identifies $\mathbb{E}(C_1 \mid s_1,\ S_2 \geq s_2,\ S_3 \geq s_3,\ w_1)$, the expected cost conditional on winning. Differentiating twice recovers the full-information cost:

$$\frac{\partial^2}{\partial s_2\, \partial s_3} \Big[\mathbb{E}\big(C_1 \mid s_1, S_2 \geq s_2, S_3 \geq s_3, w_1\big) \mathbb{P}\big(S_2 \geq s_2, S_3 \geq s_3 \mid s_1\big) \Big] \\ = c_1(s_2, s_3, s_1, w_1)\, f_{S_2, S_3 | S_1}(s_2, s_3), \tag{15.52}$$

equation (10) of Somaini (2020). The two minus signs from differentiating the lower limits cancel.

Theorem 15.46 (Somaini, 2020, Theorem 4)**.** *Under Assumption 15.45, the full-information cost $c_i(\boldsymbol{s}_{-i}, s_i, w_i)$ is identified for all $\boldsymbol{s} \geq \boldsymbol{s}^*$ if the observables exhibit sufficient variation and nonvanishing competition for bidder i at $(\boldsymbol{s}^*, w_i)$.*

Sufficient variation has a precise meaning (Somaini, 2020, Definition 1). For every $\boldsymbol{s} \geq \boldsymbol{s}^*$ there must be rival shifters $\boldsymbol{w}_{-i}$ and a finite bid b with $H_{B_j|\boldsymbol{w}}(b) = s_j$ for every bidder j. The bid b is then bidder i's equilibrium bid at signal s_i. Nonvanishing competition bounds the number of L-shaped sets needed, by requiring rivals to bid in any interval $[b, b']$ with nonvanishing probability (Definition 2). Equilibrium observables of first-price auctions typically exhibit nonvanishing competition. A bounded set of shifters suffices for signals bounded away from zero (Somaini, 2020, Propositions 5–6). Identification at extreme signals may need shifters with unbounded support.

Three limits deserve mention (Somaini, 2020, Section III.C). Binding reserve prices can reduce the variation that shifters generate. Entry costs paid after learning signals are hard to distinguish from full-information costs that rise sharply as rivals' signals approach the top. A random entry cost unobserved by the econometrician violates A7, so Theorem 15.46 does not apply. Finally, the identified primitives cannot evaluate counterfactuals in which bidders act after learning more, such as resale or subcontracting once costs are known.

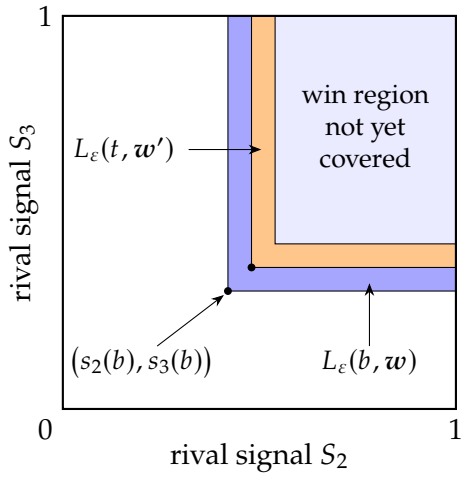

Figure 15.14: Pivotal sets with three bidders in a procurement auction, drawn in the space of bidder 1's rivals' signals. Bidder 1 wins with bid b when both rival signals exceed the thresholds $s_2(b)$ and $s_3(b)$. The blue L-shaped set $L_\varepsilon(b, \boldsymbol{w})$ contains the rival signals for which bidder 1 wins with b but loses with $b + \varepsilon$. The first-order condition identifies the expected cost on this set. Different rival shifters $\boldsymbol{w}'$ and a bid t produce the stacked orange set $L_\varepsilon(t, \boldsymbol{w}')$, holding bidder 1's signal and shifter fixed. Stacking such sets fills the light rectangle. Our drawing, after Somaini (2020, Figures 1–2).

Setting and data. The Michigan Department of Transportation (MDOT) awards about 1,050 highway contracts a year, worth about $1.2 billion in total, by first-price sealed bid. On each monthly letting date, 150 to 200 firms bid on 50 to 70 contracts (Somaini, 2020, p. 3844). Contracts are advertised at least 45 days ahead. There is no formal reserve price, but the agency may reject all bids if the lowest exceeds 110 percent of the engineer's estimate. From 2001 to 2010 the lowest bid exceeded that level in 11 percent of cases, and 15 percent of these were rejected (p. 3845). The study focuses on hot-mixed asphalt paving. The mix must be compacted while hot, above 135°C, so trucking time from a firm's plant matters for cost and quality. Distance from the plant to the project is the cost shifter. Of 10,522 auctions from January 2001 to December 2010, 3,851 required asphalt prequalification, and 1,925 had it as the only requirement. These form the sample (p. 3846).

In the sample the median engineer's estimate is $633,000 and the median lowest bid $586,000. Auctions have 3.04 participants on average. The median normalized winning bid, $\frac{\text{lowest bid}}{\text{estimate}} - 1$, is −6.8 percent. The second-lowest bid exceeds the lowest by 8.2 percent on average. The median participant is 38 km from the project and the median winner 22 km (Table 1). The average winning bid falls with the number of participants, but the average bid does not (Table 2). Somaini reads this as evidence against the symmetric independent private cost model with exogenous participation.

Econometric model. Signals are mapped to standard normals, $\zeta_i = \Phi^{-1}(S_i)$, with $\boldsymbol{\zeta} \sim N(0, \Sigma)$ and a factor structure $\Sigma = LL^\top + \Lambda$. Let Z_t be auction characteristics. The Gaussian information structure implies

$$\mathbb{E}\big(C_i \mid \boldsymbol{\zeta}, Z_t, w_i\big) = \alpha_{ic} + Z_t \alpha_{i0} + \alpha_{i1} w_i + \alpha_{i2} \sum_{j \neq i} \tilde{\sigma}_{ij} \zeta_j + \nu_i \zeta_i, \tag{15.53}$$

where $\tilde{\sigma}_{ij}$ is the (i, j) element of $-\Sigma^{-1}$, nonnegative under affiliation (Somaini, 2020, eq. (11)). Here Φ is the standard normal distribution function. One parameter per bidder, α_{i2}, measures

interdependence. Private costs are $\alpha_{i2} = 0$, interdependent costs are $\alpha_{i2} > 0$, and $\alpha_{i2} < 0$ would falsify the model. Substituting (15.53) into (15.49) gives the estimating equation

$$B_i = \alpha_{ic} + Z_t\alpha_{i0} + \alpha_{i1}W_i + \alpha_{i2}\,k_i(B_i, \boldsymbol{W} \mid H) + \iota_i(B_i, \boldsymbol{W} \mid H) + \nu_i\zeta_i, \tag{15.54}$$

equation (12). The term ι_i is the markup from market power, the second term of (15.50). The term $\alpha_{i2}k_i$ is the markup from the winner's curse, where

$$k_i = \sum_{j\neq i} \tilde{\sigma}_{ij}\left[\pi_j^{(i)}\zeta_j(b) + \sum_{k\neq i,j} \pi_k^{(i)}\,\mathbb{E}\big(\zeta_j \mid \zeta_k = \zeta_k(b),\ \boldsymbol{\zeta}_{-ik} \geq \boldsymbol{\zeta}_{-ik}(b)\big)\right]$$

depends only on the bid distribution H. A bidder knows that she wins only when rivals have drawn high signals.

Estimator and instruments. Let $\nu_{i\tau}$ be the τ-th quantile of $\alpha_{ic}+\nu_i\zeta_i$. Since signals are independent of shifters, (15.54) implies the quantile moment $\mathbb{E}[\mathbf{1}(B_i - Z_t\alpha_{i0} - \alpha_{i1}W_i - \alpha_{i2}k_i - \iota_i - \nu_{i\tau} \leq 0) - \tau \mid \boldsymbol{W}] = 0$. Nonparticipation censors bids. Only signals below a participation cutoff yield finite bids, and the cutoff has probability $\phi_i(\boldsymbol{W} \mid H)$. The moment conditional on participation replaces τ by $\min\big(\frac{\tau}{\phi_i(\boldsymbol{W}|H)}, 1\big)$ (Somaini, 2020, eqs. (13)–(14)). The parameters are estimated by instrumental variable quantile regression (Chernozhukov and Hansen, 2006). The instrument for k_i is its projection on the bidder's own covariates and rivals' distances. Rivals' distances are excluded from own cost by A3, and they move the pivotal sets and hence k_i. The first stage estimates the marginal bid distributions with cubic B-splines in the project's latitude, longitude and the bid, and the copula by simulated maximum likelihood. The markups ι_i and k_i come from spline estimates of win and tie probabilities. Standard errors come from 200 bootstrap samples of the 1,925 auctions (p. 3850).

Results. The analysis covers 19 frequent bidders, with the remaining firms grouped as a fringe bidder. The Akaike criterion selects two factors. The first factor creates correlations of 0.11 to 0.29 among one group of firms and explains up to 20 percent of their signal variance. The second explains up to 25 percent for another group (pp. 3854–3855). For bidder 1, the full-information cost at the 25th percentile of its own signal and the median of rivals' signals is 73 percent of the engineer's estimate for projects within 10 km. The interdependence coefficient α_{i2} is 0.500 (s.e. 0.190) for bidder 1, 0.350 (0.118) for bidder 2 and −0.025 (0.092) for bidder 3 (Table 5). Table 15.10 reproduces the effects of own and rivals' signals. A one standard deviation increase in bidder 1's own signal raises its full-information cost by 10 percentage points of the estimate. The same increase in a rival's signal raises it by 4 points on average and 7 at most (p. 3857). Rivals' signals matter, but less than one's own. Private costs are rejected for bidders 1 and 2. They cannot be rejected for bidders 3 and 9.

Counterfactuals. Somaini simulates restricting participation to the N bidders with the lowest median cost in 250 randomly drawn auctions. Three models are compared: the estimated common-cost model (CC), an affiliated private cost model that sets $\alpha_{i2} = 0$ (APC), and an independent private cost model that also sets $L = 0$ (IPC). Inviting more bidders lowers procurement costs in all three models. Going from two to seven invitees lowers costs by 5.48 percentage points under IPC, 5.00 under APC and 4.40 under CC (p. 3862). The bidder with the lowest median cost bids more aggressively with more rivals under IPC and APC. Under CC it bids less aggressively, because the winner's curse worsens. Table 15.11 decomposes the cost saving. The competitive and sampling effects lower costs. Affiliation and the winner's curse raise them. The winner's curse is strong enough to make the first invitee bid higher when competition grows, but not strong enough to make restricting entry profitable for the buyer.

Table 15.10: Effect of signals on full-information costs, Michigan highway procurement

	Own signal		Competitor (mean)		Competitor (maximum)

Table 15.11: Decomposition of the effect of inviting more bidders on procurement costs

Invitees	3 vs. 2	4 vs. 2	5 vs. 2	6 vs. 2	7 vs. 2	8 vs. 2	9 vs. 2	10 vs. 2
Competitive	1.98	2.52	2.71	2.79	2.92	2.95	2.97	2.97
Affiliation	−0.45	−0.57	−0.51	−0.50	−0.59	−0.61	−0.63	−0.64
Winner's curse	−1.52	−2.21	−3.06	−3.37	−3.65	−3.84	−3.95	−3.96
Sampling	2.83	3.88	4.91	5.38	5.71	5.95	6.08	6.10
Total	2.84	3.63	4.05	4.30	4.40	4.45	4.47	4.47

Notes. Cost savings relative to inviting two bidders, with 100 equal to average procurement cost with two invitees. The competitive effect is the fall in the average bid of the first invitee under IPC. The affiliation effect is the difference in that fall between APC and IPC, and the winner's curse effect the difference between CC and APC. The sampling effect is the difference between the first invitee's bid reduction and the fall in procurement cost under CC. Source: Somaini (2020, Table 8, top panel).

Interdependence also affects reserve prices. It lowers the probability of awarding the contract by as much as 0.1 when the reserve is about 90 percent of the estimate (p. 3864). Suppose MDOT must set one reserve for all contracts. With a willingness to pay of 100 percent of the estimate, the optimal reserve is 86 percent. With a willingness to pay of 150 percent, it is 125 percent. These reserves succeed with probabilities 0.67 and 0.99 and yield surpluses of 12 and 57 percent of the estimate. Auction-specific reserves would add less than 1 percent of the estimate (p. 3867). The 110 percent rule is consistent with a willingness to pay above 140 percent of the estimate.

Assessment. The paper gives the first nonparametric identification result for asymmetric interdependent-cost auctions with dependent signals. Identification comes from continuous variation in competitive conditions, which is richer than variation in the number of bidders. The estimates place Michigan paving between the polar paradigms, much closer to private costs. The application relies on strong structure. The Gaussian form summarizes interdependence by one parameter per bidder and makes costs additively separable in rivals' signals. Distance must satisfy A1 and A3, which fails if a nearby rival's signal is more informative. Participation is handled through censoring at a cutoff, and signals are scalar. Infrequent bidders are pooled into one fringe bidder. These restrictions buy precision in a sample of 1,925 auctions.

15.6.4 An auction with an informed bidder: Hendricks and Porter (1988)

Question. Hendricks and Porter (1988) test the equilibrium predictions of a common value auction with asymmetric information. The setting is the federal sale of drainage leases on the Outer Continental Shelf. A drainage tract is adjacent to a tract on which oil or gas has been found. Firms owning adjacent tracts, the *neighbor* firms, learn about the drainage tract from their own drilling. Other firms rely on seismic surveys and public information. The data include ex post production, so the authors can measure who earns rents and test whether bidding accounts for the winner's curse.

Theory. The model of Wilson (1967) and Engelbrecht-Wiggans et al. (1983) is developed in Proposition 14.55. One informed bidder observes a private and a public signal and forms the estimate H of the common value. The uninformed bidders observe only the public signal. In equilibrium the informed bidder bids $\mathbb{E}[H \mid H \leq h]$ above a cutoff, bids the reserve price below it, and abstains below the reserve. The uninformed bidders randomize so that the highest uninformed bid has the same distribution as the informed bid above the reserve. Hendricks and Porter (1988, pp. 870–871) list seven predictions.

(1) No neighbor bid is less frequent than no non-neighbor bid.

(2) The neighbor wins at least half of the tracts that receive a bid, by (14.59).

(3) Non-neighbors earn zero expected profit. They lose on tracts where no neighbor bids and gain where one does.

(4) The neighbor earns an information rent.

(5) Without a cost difference between bidders, the informed bid and the highest uninformed bid have approximately the same distribution given public information.

(6) The neighbor's strategy does not depend on the number of non-neighbors.

(7) The neighbor's bid increases in the public signal when a higher signal is good news.

Prediction (6) is convenient, because only participating non-neighbors are observed. Their number causes no selection bias in the neighbor's bid equation.

Setting and data. The sample covers federal tracts off Louisiana and Texas sold between 1959 and 1969 in 8 drainage sales, 144 tracts in all (Hendricks and Porter, 1988, p. 871). It excludes 25 tracts on which the high bid was rejected, for lack of data. The winning bid, the bonus, is paid at the sale. The government also receives a royalty of one sixth of revenues. A reserve price of $25 per acre applied on most drainage leases. The government rejected the high bid on 7 percent of wildcat and 15 percent of drainage tracts. The authors compute ex post discounted revenues and costs from production through 1980, real wellhead prices and drilling cost surveys, discounting at 5 percent a year. Table 14.1 summarizes the sample. Drainage tracts had an average winning bid of $5.76 million, net profit of $4.63 million and value of $13.51 million, with 2.73 bidders on average. The government captured 66 percent of the value of drainage tracts against 77 percent for wildcat tracts (p. 866).

Of the 144 drainage tracts, 114 were adjacent to previously leased federal tracts, and these form the sample. Neighbor firms are the owners of adjacent federal tracts. Of the 114 tracts, 40 had one neighbor firm and 74 had more (their Figure 1). Yet only 16 of the 74 received more than one neighbor bid (p. 872). The authors therefore assume that neighbor firms coordinate and submit at most one serious bid. Joint bidding was legal, and neighbors may already have formed a joint venture to manage production from the common pool. The empirical analogues are the largest neighbor bid B_I and the largest non-neighbor bid B_U, each set to the reserve price when no such bid is made. The numbers of neighbor and non-neighbor bids are N_I and N_U. The ex post gross profitability of the tract, π_t, proxies the neighbor's private information. The public information is the number of neighbor tracts N^{tr}, the ex post gross profit of the adjacent tract V^{adj}, and acreage (their Table 2).

Estimating equations. For tract t and bidder type $i \in \{I, U\}$, let

$$Y_{it} = W_{it}\boldsymbol{\theta}_i + \varepsilon_{it}, \qquad \ln \frac{B_{it}}{r_t} = \begin{cases} Y_{it} & \text{if } Y_{it} \geq 0, \\ 0 & \text{otherwise,} \end{cases}$$

where r_t is the reserve price and W_{it} a row of regressors. The errors $(\varepsilon_{It}, \varepsilon_{Ut})$ are bivariate normal with variances σ_I^2 and σ_U^2, covariance σ_{IU} and correlation ρ_{IU}. Bids are lognormal and censored at the reserve. Only tracts with at least one bid are observed. Tracts fall into three sets: Ω_{++} with bids of both types, Ω_{+0} with only neighbor bids, and Ω_{0+} with only non-neighbor bids. Let $Z(a, c; \rho)$ be the probability under a standard bivariate normal with correlation ρ that both components fall below a and c, the probability of no bid. The log-likelihood is $\sum_{\Omega_{++}} l_{1t} + \sum_{\Omega_{+0}} l_{2t} + \sum_{\Omega_{0+}} l_{3t}$, with

$$l_{1t} = -\ln(2\pi) - \frac{1}{2}\ln|\Sigma| - \frac{1}{2}\boldsymbol{\varepsilon}_t^{\top}\Sigma^{-1}\boldsymbol{\varepsilon}_t - \ln\left[1 - Z\left(-\frac{W_{Ut}\boldsymbol{\theta}_U}{\sigma_U}, -\frac{W_{It}\boldsymbol{\theta}_I}{\sigma_I}; \rho_{IU}\right)\right],$$

$$l_{2t} = \ln\Phi\left(\frac{-W_{Ut}\boldsymbol{\theta}_U - \frac{\sigma_{IU}}{\sigma_I^2}\varepsilon_{It}}{\sqrt{\sigma_U^2 - \frac{\sigma_{IU}^2}{\sigma_I^2}}}\right) - \ln\sigma_I + \ln\phi\left(\frac{\varepsilon_{It}}{\sigma_I}\right) - \ln\big[1 - Z(\cdot)\big],$$

and l_{3t} symmetric to l_{2t} (Hendricks and Porter, 1988, p. 873). Here Φ and ϕ are the standard normal distribution function and density. In l_{2t} the first term is the probability that the non-neighbor latent bid is negative given the neighbor's residual. The next two terms are the

density of the neighbor bid. The last term in each contribution conditions on at least one bid, which corrects for sample selection.

Participation and returns. No neighbor bid was made on 19 tracts and no non-neighbor bid on 35. So at least one neighbor bid on 83 percent of tracts and at least one non-neighbor on 68 percent (p. 874), as prediction (1) requires. Table 15.12 reproduces the returns by winner type. The neighbor won 59 of the 114 tracts, 52 percent, as prediction (2) requires. It won 62 percent of the 95 tracts it bid on, the figure the authors report (p. 874). Its share of tract value was about 44 percent, against an average firm share of 23 percent on wildcat tracts (prediction 4). Non-neighbor winners earned about zero on average, −0.42 million. They lost on tracts with no neighbor bid and gained on tracts with one, as prediction (3) requires. Neighbors appear able to identify the tracts likely to contain oil.

Table 15.12: Tracts won by neighbor and non-neighbor firms, OCS drainage sales 1959–1969

Panel A. Wins by type of firm (Table 3)

	Neighbor wins		Non-neighbor wins		
	A	Total	B	C	Total
Number of tracts	35	59	19	36	55
Tracts drilled	23	47	18	33	51
Productive tracts	16	36	12	19	31
Average winning bid	3.28	6.04	2.15	6.30	4.87
	(0.56)	(2.00)	(0.67)	(1.31)	(0.92)
Average gross profits	10.05	12.75	−0.54	7.08	4.45
	(3.91)	(3.21)	(0.47)	(2.95)	(1.99)
Average net profits	6.76	6.71	−2.69	0.78	−0.42
	(3.02)	(2.69)	(0.86)	(2.64)	(1.76)

Panel B. Single and multiple neighbor tracts (Table 4)

	Single	Multiple neighbors, by neighbor bids		
	neighbor	1	≥ 2	Total
Number of tracts	40	48	15	74
Tracts with no neighbor bid	8			11
Neighbor wins	19	29	11	40
Neighbor's average winning bid	4.795	2.615	17.193	6.624
	(1.444)	(0.697)	(9.953)	(2.885)
Neighbor's average gross profits	13.601	4.670	32.597	12.350
	(5.608)	(2.148)	(11.506)	(3.965)
Neighbor's average net profits	8.806	2.055	15.404	5.725
	(4.762)	(1.690)	(10.963)	(3.297)

Notes. Millions of 1972 dollars. Standard deviations of the sample means in parentheses. In Panel A, column A is tracts with no non-neighbor bid, column B tracts with no neighbor bid, and column C tracts on which a neighbor bid but a non-neighbor won. Gross profits exclude the bonus, and net profits deduct it. The authors give 17 (p. 867), 16 (p. 872) and 15 (Table 4) as the number of tracts with more than one neighbor bid. Panel B reproduces Table 4. Source: Hendricks and Porter (1988, Tables 3 and 4).

The model also predicts a mass point of neighbor bids at the reserve price, from informed types between the reserve and the cutoff. The authors find none. They suggest that firms feared the government would reject reserve-price bids, as it did on 25 drainage tracts. The reserve also explains why non-neighbors drilled tracts on which no neighbor bid. Drilling is rational if expected net profit given no neighbor bid is below the reserve but positive once the bid is

sunk. Panel B checks the coordination assumption. On single and multiple neighbor tracts alike, the neighbor won about half of the tracts. Net profits on multiple neighbor tracts are not significantly lower, so competition among neighbors did not dissipate rents. Valuable multiple neighbor tracts attracted more than one neighbor bid and earned higher net profits. The authors suggest "shadow" bids submitted to make bidding look competitive to the government (p. 875).

Information structure. Regressions of π_t on bids and participation test whether non-neighbors have payoff-relevant private information (their Table 5). With neighbor variables and public information, the R^2 is 0.640. Adding non-neighbor variables raises it to 0.699. Non-neighbor variables and public information alone give 0.154. The neighbor bid enters with coefficient 3.55 (t-statistic 3.90) and its square with -0.023 (-2.57). The F-statistic for the six non-neighbor variables is 3.22 with $(6, 98)$ degrees of freedom. The authors compare it with 3.71 as the 5 percent point and do not reject. They add that most of the non-neighbor explanatory power comes from the interaction with the neighbor bid. By standard tables the 5 percent point of $F(6, 98)$ is about 2.19, so the statistic would reject at conventional levels (our calculation).

Bid distributions. Prediction (5) concerns the joint distribution of (B_I, B_U) given public information. In the unrestricted bivariate model the two equations have similar coefficients and residual standard deviations, 2.02 and 2.66. Equal coefficients are not rejected: the likelihood ratio statistic is 10.58, below 11.07, the 5 percent point of $\chi^2(5)$. The residual correlation is 0.10 (t-statistic 0.94), so no omitted public variable appears to drive both bids (their Table 6). Adding tract profitability changes the picture. The coefficient on π_t is 0.091 (t-statistic 4.30) in the neighbor equation and 0.028 (0.79) in the non-neighbor equation. Equal coefficients are now rejected at 1 percent, with statistic 19.84 (their Table 7). Non-neighbors appear to have no information correlated with profitability beyond the public variables. Their bids are "noisier," with residual standard deviation 2.62 against 1.60 for neighbors. The informed bid rises with π_t and with V^{adj} and does not depend on N_U (prediction 6). The highest non-neighbor bid rises with N_U, as an order statistic should. Where N_U is excluded, it falls with the number of neighbor tracts (their Table 8).

A competitive alternative. Section IV of the paper estimates a model in which neighbors bid independently, each with a private signal. The likelihood treats each neighbor's bid and the highest non-neighbor bid as censored normal latent variables (Hendricks and Porter, 1988, p. 880). Two results contradict competitive bidding (their Table 9). First, each neighbor's bid falls with the number of neighbor firms, with coefficient -0.758 (t-statistic -3.96). For lognormal signals the competitive bid should first rise with the number of bidders. Citing Smiley (1979), the authors place the turning point at four bidders or more in their data (Hendricks and Porter, 1988, p. 880). Only ten tracts had four or more neighbor firms. Phantom bids, below the serious bid, are consistent with the pattern. Second, the number of neighbor firms lowers the highest non-neighbor bid by less than it lowers neighbor bids. Under competition among neighbors the less informed non-neighbors should react more, because their winner's curse worsens more.

Interpretation, critiques and contribution. The evidence supports the informed-bidder model with coordinated neighbors. Neighbors shade their bids well below their estimates and earn high returns. Non-neighbors bid cautiously, avoid the winner's curse and break even on average. The analysis has limits. Bidders are risk neutral, tracts are analyzed one at a time, and coordination among neighbors is assumed. The proxy for private information is ex post profitability, which measures the neighbor's estimate with error. The censored lognormal model is a statistical description of bids and is not derived from the equilibrium. The sample has only

114 tracts. The missing mass point at the reserve contradicts the model, and Hendricks et al. (1994) later model a random reservation price for that reason. In their model the reservation price is correlated with the tract value, and values are affiliated. Uninformed bidders are then less likely to participate and, when they do, tend to bid high, while informed bidders tend to bid low. The informed bid distribution stochastically dominates the uninformed one within the support of the reservation price and coincides with it above. The data support these predictions (Hortaçsu and Perrigne, 2021, p. 125).

The paper sits in a sequence of studies of the same leases (Hortaçsu and Perrigne, 2021, pp. 124–125). It built on the comparison of wildcat and drainage tracts by Hendricks et al. (1987). Bids, profits and net profits per acre are much larger on drainage tracts. The highest bid and the profit per acre are positively correlated on drainage tracts and negatively on wildcat tracts. Most large firms would have earned more by bidding less, a sign that they did not fully correct for the winner's curse. Hendricks et al. (1989) then focus on rejections. The government rejects the highest bid on 18 percent of drainage tracts and 9 percent of wildcat tracts, and rejected drainage bids are larger. They also note that neighbor firms rarely compete, although a drainage tract can have up to eight neighbors. The paper's lasting contribution is to show that ex post values let the econometrician see adverse selection. It confirmed subtle equilibrium predictions in a field setting and led to the tests of Hendricks et al. (2003) based on (15.46).

15.7 Unobserved Auction Heterogeneity

Objects sold in different auctions differ, and bidders usually know more about the differences than the econometrician does. A paving contractor visits the site and sees the curvature of the road and the state of the surface. A used-car dealer inspects each car for rust and dents. Such features shift every bidder's value in the same direction, and they are common knowledge among the bidders. When the econometrician cannot condition on them, the methods of Sections 15.4 and 15.5 attribute their effect to private information. This section shows what goes wrong and develops three remedies. They are deconvolution with several bids per auction, parametric mixtures, and control functions built from the seller's reserve price.

15.7.1 The problem

Let ω_t be a scalar characteristic of auction t that all bidders, and the seller, observe but the econometrician does not. We call ω_t *unobserved auction heterogeneity*. The two workhorse specifications are additive and multiplicative,

$$V_{it} = \omega_t + A_{it} \qquad \text{or} \qquad V_{it} = \omega_t A_{it}, \tag{15.55}$$

where A_{it} is bidder i's *idiosyncratic private component*. In procurement we write costs as $C_{it} = \omega_t A_{it}$ in the same way.

Assumption 15.47 (Unobserved auction heterogeneity)**.** (i) In each auction, $\omega_t, A_{1t}, \ldots, A_{nt}$ are mutually independent, $\omega_t \sim F_\omega$ and $A_{it} \sim F_{A_i}$, and auctions are independent. (ii) Each bidder observes ω_t, its own A_{it} and the number of bidders n_t. The econometrician observes bids and n_t but neither ω_t nor A_{it}. (iii) For each ω_t, bidders play the unique equilibrium of the game with that common component.

The same equation (15.55) with bidders who observe only their own sums V_{it} describes a *conditionally independent private values* model. It is a special case of affiliated private values

when the densities f_{A_i} are log-concave (Athey and Haile, 2007, Section 6.1.2). The two models differ only in what bidders know. With unobserved heterogeneity, bidder i knows that its rivals' values are centered on ω_t, so its uncertainty about the competition is the dispersion of the A_{jt} alone.

The information that is common knowledge among the bidders in auction t is the pair (Z_t, ω_t) of observed covariates and unobserved heterogeneity. In a private values first-price auction, the first-order condition (14.68) holds conditionally on it (Athey and Haile, 2007, Section 6.1.2),

$$v_{it} = b_{it} + \frac{G_{M|B}(b_{it} \mid b_{it}; n_t, Z_t, \omega_t)}{g_{M|B}(b_{it} \mid b_{it}; n_t, Z_t, \omega_t)}. \tag{15.56}$$

An econometrician who does not observe ω_t cannot estimate the conditional distribution that enters the markdown. Pooling auctions with different ω_t replaces it with a mixture over ω_t. The markdown is a nonlinear function of ω_t, so even its average is not identified without further structure (Athey and Haile, 2007, Section 6.1.2, citing Hendricks et al., 2003).

Athey and Haile (2007, Section 6.1.2) separate three questions.

(i) *Can unobserved heterogeneity be told apart from other sources of correlated bids?* In an ascending auction a bidder drops out at its value whether or not it observes ω_t. Unobserved heterogeneity is then observationally equivalent to correlated private values. In a first-price auction, any bid distribution that satisfies the conditions of Theorem 15.29 can be rationalized by affiliated private values without heterogeneity. The choice between the two models must rest on institutional knowledge.

(ii) *Is the joint law of $(\omega, A_1, \ldots, A_n)$ identified under heterogeneity?* In first-price auctions it is, under separability and independence, as we show below. In ascending auctions it requires additional variation, such as bidder covariates (Theorem 15.8).

(iii) *Which primitives does a question need?* In ascending and second-price auctions bidding is in dominant strategies, so the joint law $F_{\boldsymbol{V}}$ of values answers every counterfactual. First-price counterfactuals depend on beliefs, and beliefs vary with ω_t. They require the joint law of the components, $F_{\omega,\boldsymbol{A}}$. The joint law of values $F_{\boldsymbol{V}}$ is not enough.

Ignoring ω_t has a predictable effect on first-price estimates. Bids from auctions with high and low ω_t are pooled, so the estimated bid distribution is too dispersed. Each bidder appears to face a field of rivals that is more spread out than the one it faces in fact. The estimated markdown $\frac{G(b)}{(n-1)g(b)}$ is then too large, and so are estimated markups and the estimated dispersion of values (Krasnokutskaya, 2011, pp. 294–295).

Example 15.48 (Pooling bids across heterogeneous auctions)**.** Let $n = 4$, $V_{it} = \omega_t A_{it}$, $A_{it} \sim U[1,2]$ and $\ln \omega_t \sim N(0, 0.3^2)$. At $\omega = 1$ the game is a symmetric IPV auction with $F_A(a) = a - 1$ on $[1,2]$. The Riley-Samuelson bid (14.29) with no reserve price is

$$\alpha(a) = a - \frac{\int_1^a (t-1)^3\,dt}{(a-1)^3} = a - \frac{a-1}{4} = \frac{3a+1}{4}.$$

By Lemma 15.49(b) below, the bid at ω is $\beta(v;\omega) = \omega\,\alpha\left(\frac{v}{\omega}\right) = \frac{3v+\omega}{4}$. The markdown relative to value, $\frac{v-\beta(v;\omega)}{v} = \frac{a-\alpha(a)}{a} = \frac{a-1}{4a}$, does not depend on ω. Its average is

$$\mathbb{E}\left[\frac{A-1}{4A}\right] = \frac{1}{4}\left(1 - \mathbb{E}\left[\frac{1}{A}\right]\right) = \frac{1}{4}(1 - \ln 2) \approx 0.077.$$

We simulated 200 samples of $T = 500$ such auctions and applied the GPV estimator of Section 15.4 to the pooled bids (seed 15701, script `uh_bias.py`). The median estimate of the average markdown is 0.184, with 5th and 95th percentiles of 0.174 and 0.193 across samples. The estimated inverse bid function in Figure 15.15(a) has slope 1.47 over the central bids, against the true slope $\frac{4}{3}$. The estimated value density in panel (b) roughly tracks the marginal density of $V = \omega A$ but is more spread out. Computed over the plotted range $[0.4, 3.6]$, its variance is 0.376 against 0.300 for V. On the full support the exact variance of V is $e^{0.18} \cdot \frac{7}{3} - \left(1.5e^{0.045}\right)^2 = 0.332$. The estimated density has a long upper tail, from bids where $\hat{g}$ is small, which raises its full-support variance to about 1.4. The interquartile range is less sensitive to that tail. It is 0.97 for the pseudo-values (median across samples) against 0.73 for V. Both are far more dispersed than the distribution F_A, with interquartile range 0.5, that each bidder faces once it has seen ω_t.

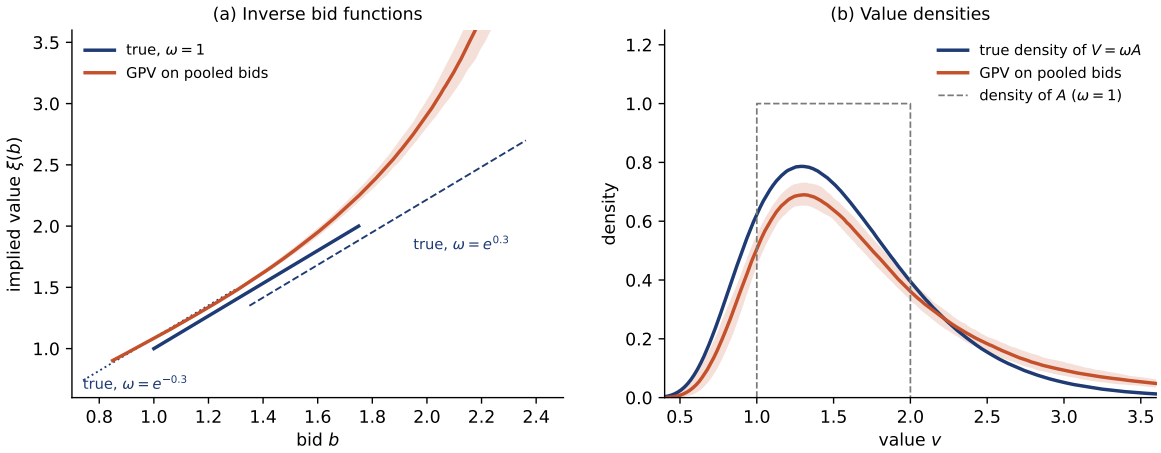

Figure 15.15: GPV applied to bids pooled across auctions with unobserved heterogeneity (our simulation, seed 15701). Design of Example 15.48: $n = 4$, $V = \omega A$, $A \sim U[1, 2]$, $\ln \omega \sim N(0, 0.3^2)$, $T = 500$ auctions, 200 samples. Panel (a): true inverse bid functions at three values of ω and the median GPV estimate from pooled bids with a 5–95 percent band. Panel (b): the true marginal density of V, the density of A that bidders face at $\omega = 1$, and the median GPV estimate with its band. The true average markdown is 0.077 and the median estimate is 0.184.

15.7.2 Separability and homogenization

Equilibrium bidding inherits the additive or multiplicative structure of values. This property drives every method in this section.

Lemma 15.49 (Separability, after Athey and Haile, 2007, eqs. (6.4)–(6.5), and Krasnokutskaya, 2011, Proposition 1)**.** *Let Assumption 15.47 hold with no binding reserve price. Let* $(\alpha_1, \ldots, \alpha_n)$ *be the equilibrium bid functions of the* normalized game*, the game with* $\omega = 0$ *in the additive case and* $\omega = 1$ *in the multiplicative case.*

(a) In a first-price auction with additive values, $\beta_i(v; \omega) = \omega + \alpha_i(v - \omega)$.

(b) In a first-price procurement auction with multiplicative costs $C_i = \omega A_i$, $\beta_i(c; \omega) = \omega\, \alpha_i\left(\frac{c}{\omega}\right)$. *In a first-price auction with multiplicative values* $V_i = \omega A_i$, *likewise* $\beta_i(v; \omega) = \omega\, \alpha_i\left(\frac{v}{\omega}\right)$.

(c) The homogenized bids $B^0_{it} = B_{it} - \omega_t$ *in case (a) and* $B^0_{it} = \frac{B_{it}}{\omega_t}$ *in case (b) equal* $\alpha_i(A_{it})$. *They are independent of* ω_t *and of each other, and they have the bid distributions of the normalized game.*

Proof. We prove (b), the case used in the application below. Suppose bidders $j \neq i$ use $\beta_j(c;\omega) = \omega\,\alpha_j\big(\frac{c}{\omega}\big)$ in the game with common component ω. A bidder with cost $C_j = \omega A_j$ then bids $\omega\,\alpha_j(A_j)$. Bidder i wins with bid b when every rival bids more,

$$\mathbb{P}\big(i \text{ wins} \mid b\big) = \mathbb{P}\big(\omega\,\alpha_j(A_j) > b \;\; \forall j \neq i\big) = \mathbb{P}\Big(\alpha_j(A_j) > \frac{b}{\omega} \;\; \forall j \neq i\Big) \equiv P_i^0\Big(\frac{b}{\omega}\Big),$$

where $P_i^0(a')$ is bidder i's probability of winning with bid a' in the normalized game. A bidder with cost $c = \omega a$ who bids b earns

$$(b - \omega a)\,P_i^0\Big(\frac{b}{\omega}\Big) = \omega\Big(\frac{b}{\omega} - a\Big)P_i^0\Big(\frac{b}{\omega}\Big).$$

Choosing b is the same as choosing $a' = \frac{b}{\omega}$ to maximize $(a'-a)P_i^0(a')$. That is bidder i's problem in the normalized game, and its solution is $a' = \alpha_i(a)$. Hence the best response is $b = \omega\,\alpha_i(a) = \omega\,\alpha_i\big(\frac{c}{\omega}\big)$, and the profile is an equilibrium of the game with ω. By Assumption 15.47(iii) it is the equilibrium. The sale auction with $V_i = \omega A_i$ follows word for word, with $(v-b)$ in place of $(b-c)$ and win probabilities $\mathbb{P}\big(\omega\,\alpha_j(A_j) < b\;\forall j \neq i\big)$. Part (a) follows from the same argument with $b - \omega$ in place of $\frac{b}{\omega}$ and $(v-\omega)$ in place of a. For (c), $B_{it}^0 = \alpha_i(A_{it})$ is a function of A_{it} alone, and the A_{it} are independent of ω_t and of each other. □

The argument needs the whole game to scale with ω. A reserve price that does not move with ω breaks it, which is one reason the application below relies on a nonbinding reserve. If the number of bidders responds to ω_t through entry, part (c) holds only conditional on n_t, and n_t itself carries information about ω_t.

Homogenization with observed covariates. Separability is useful even when all heterogeneity is observed. Section 15.2.4 homogenized transaction prices in ascending auctions, where bids equal values. Athey and Haile (2007, Section 6.1.1), following Haile et al. (2003), carry the idea over to first-price bids. Suppose, as in Theorem 15.7(ii), that $V_{it} = g_0(Z_t) + A_{it}$ with A_{it} independent of Z_t and the normalization $g_0(z_0) = 0$. Lemma 15.49(a) with $\omega_t = g_0(Z_t)$ gives $\beta_i(v;n,z) = g_0(z) + \beta_i\big(v - g_0(z);n,z_0\big)$. Bids therefore satisfy the regression

$$b_{it} = \kappa(n_t) + g_0(z_t) + \varepsilon_{it}, \qquad \varepsilon_{it} = \beta_i(V_{it} - g_0(z_t);n_t,z_0) - \kappa(n_t), \qquad \mathbb{E}[\varepsilon_{it} \mid z_t, n_t] = 0, \tag{15.57}$$

where $\kappa(n)$ is an intercept for n-bidder auctions, as in Section 15.2.4. Ordinary least squares on all bids estimates g_0. The homogenized bids $\hat{b}_{it} = b_{it} - \hat{g}_0(z_t)$ estimate the bids that would have been placed at z_0. The GPV estimator applied to them, separately for each n, recovers $F_V(\cdot;z_0)$, and then $F_V(v;z) = F_V\big(v - g_0(z);z_0\big)$ for every z. The first stage uses all $\sum_n nT_n$ bids, so a flexible parametric g_0 converges at the parametric rate. As in the ascending case, it leaves the nonparametric asymptotics of the second stage unchanged. The multiplicative case works the same way in logs. Athey and Haile (2007, eqs. (6.7)–(6.9)) also describe sieve and finite-mixture specifications of the bid distribution. These let covariates affect bids more flexibly, at the cost of a priori structure, and covariate effects are then recovered only indirectly.

Why unobserved heterogeneity needs more. With ω_t unobserved, the analogue of (15.57) is $\ln b_{it} = \ln\omega_t + \ln B_{it}^0$. The term $\ln\omega_t$ is an auction fixed effect that cannot be subtracted. The structure nevertheless suggests a remedy. Two bids from the same auction are two noisy measurements of the same $\ln\omega_t$, with independent errors $\ln B_{it}^0$. This is the repeated-measurement problem of the measurement-error literature (Li and Vuong, 1998), and deconvolution solves it (Athey and Haile, 2007, Section 6.1.2 and footnote 51).

15.7.3 Identification by deconvolution: Krasnokutskaya (2011)

Question and model

Krasnokutskaya (2011) asks how much of the variation in contractors' costs is private information, and how far IPV and APV estimators err when bidders share cost information that the econometrician lacks. The answer matters for markups, for the efficiency of first-price procurement, and for any policy evaluated with an estimated cost distribution. Her abstract states that accounting for unobserved heterogeneity "has important implications for the evaluation of the distribution of rents, efficiency, and optimal auction design" (p. 293). We cite the published article by page. Some material appears only in the 2004 working paper (Krasnokutskaya, 2004), which we mark WP. Its application used a different sample and reported different headline numbers. We give the published numbers and say where the WP figures differ.

There are n bidders of two observable types, n_1 of type 1 and $n_2 = n - n_1$ of type 2. Bidder i's cost of the project in auction t is $C_{it} = \omega_t A_{it}$. The maintained assumptions are the following (pp. 296–297).

(D1) $\omega_t, A_{1t}, \dots, A_{nt}$ are mutually independent. A_{it} has distribution F_k for a type-k bidder, and the supports $[\underline{\omega}, \bar{\omega}]$ and $[\underline{a}, \bar{a}]$ lie in $(0, \infty)$.

(D2) The densities f_1, f_2 are continuously differentiable and strictly positive on the interior of the support.

(D3) $\mathbb{E}[A_{it}] = 1$ for type-1 bidders.

(D4) The number of bidders is common knowledge, and there is no binding reserve price.

(D1) is the identifying assumption. (D2) delivers existence and uniqueness of the equilibrium. (D3) fixes the scale, since (ω, A) and $(c\,\omega, \frac{A}{c})$ produce the same costs. For each ω the game is an asymmetric IPV procurement auction. Krasnokutskaya attributes the existence of a unique equilibrium in strictly monotone, differentiable strategies to McAdams and others (p. 297). By Lemma 15.49(b), $B_{it} = \omega_t\, \alpha_{k(i)}(A_{it})$, where $k(i)$ is bidder i's type. This is her Proposition 1, which she notes also holds for additive components (p. 298, footnote 3).

Let G_k^0 and g_k^0 be the distribution and density of the homogenized bid $B^0 = \alpha_k(A)$ of a type-k bidder, and write $-k$ for the other type. In the normalized game a type-k bidder with cost a who bids b^0 wins with probability $P_k^0(b^0) = \big(1 - G_k^0(b^0)\big)^{n_k - 1}\big(1 - G_{-k}^0(b^0)\big)^{n_{-k}}$. Its first-order condition is $P_k^0(b^0) + (b^0 - a)P_k^{0\prime}(b^0) = 0$, so that $a = b^0 + \frac{P_k^0(b^0)}{P_k^{0\prime}(b^0)}$ with

$$\frac{P_k^{0\prime}(b^0)}{P_k^0(b^0)} = -\frac{(n_k - 1)\, g_k^0(b^0)}{1 - G_k^0(b^0)} - \frac{n_{-k}\, g_{-k}^0(b^0)}{1 - G_{-k}^0(b^0)}.$$

Substituting gives the inverse bid function in terms of homogenized bid distributions (her eq. (1) and condition (W6), pp. 298 and 302),

$$a = \xi_k(b^0) \equiv b^0 - \frac{\big(1 - G_k^0(b^0)\big)\big(1 - G_{-k}^0(b^0)\big)}{(n_k - 1)\, g_k^0(b^0)\big(1 - G_{-k}^0(b^0)\big) + n_{-k}\, g_{-k}^0(b^0)\big(1 - G_k^0(b^0)\big)}. \tag{15.58}$$

This is the asymmetric procurement condition of Section 14.13, applied to the normalized game. It would identify F_k immediately if homogenized bids were observed. They are not, because ω_t is not.

Kotlarski's lemma

Deconvolution rests on a characterization result for sums of independent random variables. We write $\mathrm{i} = \sqrt{-1}$ for the imaginary unit and $\varphi_Y(t) = \mathbb{E}\big[e^{\mathrm{i}tY}\big]$ for the *characteristic function* of a random variable Y (Appendix B).

Lemma 15.50 (Kotlarski, 1966, and Athey and Haile, 2007, Lemma 6.1)**.** *Let Y_1, Y_2, Y_3 be mutually independent random variables with finite means and characteristic functions $\varphi_1, \varphi_2, \varphi_3$ that never vanish. Let $Q_1 = Y_1 + Y_3$ and $Q_2 = Y_2 + Y_3$, and let $\Psi(t_1, t_2) = \mathbb{E}\big[e^{\mathrm{i}(t_1 Q_1 + t_2 Q_2)}\big]$ be their joint characteristic function, with partial derivative Ψ_1 in its first argument.*

(i) The joint distribution of (Q_1, Q_2) determines the distributions of Y_1, Y_2, Y_3 up to location.

(ii) Under the normalization $\mathbb{E}[Y_1] = 0$,

$$\varphi_3(t) = \exp\Big(\int_0^t \frac{\Psi_1(0,u)}{\Psi(0,u)}\,du\Big), \qquad \varphi_1(t) = \frac{\Psi(t,0)}{\varphi_3(t)}, \qquad \varphi_2(t) = \frac{\Psi(0,t)}{\varphi_3(t)}. \tag{15.59}$$

Proof. Step 1. By independence,

$$\Psi(t_1,t_2) = \mathbb{E}\big[e^{\mathrm{i}t_1 Y_1}\, e^{\mathrm{i}t_2 Y_2}\, e^{\mathrm{i}(t_1+t_2)Y_3}\big] = \varphi_1(t_1)\,\varphi_2(t_2)\,\varphi_3(t_1+t_2).$$

Step 2. Finite means make each φ_j differentiable, with $\varphi_j'(0) = \mathrm{i}\,\mathbb{E}[Y_j]$. Differentiating in t_1,

$$\Psi_1(t_1,t_2) = \varphi_1'(t_1)\varphi_2(t_2)\varphi_3(t_1+t_2) + \varphi_1(t_1)\varphi_2(t_2)\varphi_3'(t_1+t_2).$$

Step 3. At $t_1 = 0$, use $\varphi_1(0) = 1$ and $\varphi_1'(0) = \mathrm{i}\,\mathbb{E}[Y_1] = 0$:

$$\Psi_1(0,u) = \varphi_2(u)\,\varphi_3'(u), \qquad \Psi(0,u) = \varphi_2(u)\,\varphi_3(u).$$

Step 4. Since $\varphi_2(u) \neq 0$, dividing gives $\frac{\Psi_1(0,u)}{\Psi(0,u)} = \frac{\varphi_3'(u)}{\varphi_3(u)}$. Let $L(t) = \int_0^t \frac{\varphi_3'(u)}{\varphi_3(u)}du$. Then

$$\frac{d}{dt}\Big[\varphi_3(t)e^{-L(t)}\Big] = e^{-L(t)}\Big(\varphi_3'(t) - \varphi_3(t)\frac{\varphi_3'(t)}{\varphi_3(t)}\Big) = 0,$$

and $\varphi_3(0)e^{-L(0)} = 1$. Hence $\varphi_3(t) = e^{L(t)}$, the first formula in (15.59). *Step 5.* Setting $t_2 = 0$ and then $t_1 = 0$ in Step 1 gives $\Psi(t,0) = \varphi_1(t)\varphi_3(t)$ and $\Psi(0,t) = \varphi_2(t)\varphi_3(t)$, which yield the other two formulas. *Step 6.* A characteristic function determines its distribution (Lévy's inversion theorem), which proves (ii). Without the normalization, Step 3 adds $\mathrm{i}\,\mathbb{E}[Y_1]$ to the ratio, so φ_3 is recovered up to the factor $e^{\mathrm{i}t\mathbb{E}[Y_1]}$. Adding a constant to Y_3 and subtracting it from Y_1 and Y_2 leaves (Q_1, Q_2) unchanged, which proves (i). □

The proof uses Step 4 to avoid taking logarithms of a complex function. The idea is simple. With two measurements sharing one component, the covariation of Q_1 and Q_2 isolates the shared part, and the marginals then reveal the rest.

Example 15.51 (Normal components)**.** Let $Y_1 \sim N(0, \sigma_1^2)$, $Y_2 \sim N(\mu_2, \sigma_2^2)$ and $Y_3 \sim N(\mu_3, \sigma_3^2)$. Then

$$\ln \Psi(t_1,t_2) = \mathrm{i}\mu_2 t_2 + \mathrm{i}\mu_3(t_1+t_2) - \tfrac{1}{2}\big[\sigma_1^2 t_1^2 + \sigma_2^2 t_2^2 + \sigma_3^2(t_1+t_2)^2\big],$$

so $\frac{\Psi_1(0,u)}{\Psi(0,u)} = \mathrm{i}\mu_3 - \sigma_3^2 u$. Integrating from 0 to t gives $\varphi_3(t) = \exp\big(\mathrm{i}\mu_3 t - \tfrac{1}{2}\sigma_3^2 t^2\big)$, the $N(\mu_3, \sigma_3^2)$ characteristic function. Here $\sigma_3^2 = \mathrm{Cov}(Q_1, Q_2)$ and $\mu_3 = \mathbb{E}[Q_1]$. In the normal case means and covariances suffice. In general the lemma uses the entire joint distribution of the two measurements.

Identification

Theorem 15.52 (Krasnokutskaya, 2011, Theorem 1)**.** *Let (D1)–(D4) hold, and suppose the characteristic functions of* $\ln \omega$ *and of* $\ln B^0$ *for each type never vanish. Then* F_ω *is identified from the joint distribution of any two bids* $(B_{i_1 t}, B_{i_2 t})$ *submitted in the same auction. The distribution* F_k *is identified from the same joint distribution if at least one of the two bidders has type* k*. In particular, a pair formed by a type-1 and a type-2 bidder identifies* F_ω*,* F_1 *and* F_2 *(p. 299).*

Proof. Step 1 (separate the common component). By Lemma 15.49(b),

$$\ln B_{i_1 t} = \ln \omega_t + \ln B^0_{i_1 t}, \qquad \ln B_{i_2 t} = \ln \omega_t + \ln B^0_{i_2 t},$$

with $\ln \omega_t$, $\ln B^0_{i_1 t} = \ln \alpha_1(A_{i_1 t})$ and $\ln B^0_{i_2 t} = \ln \alpha_2(A_{i_2 t})$ mutually independent by (D1). Bounded supports give finite means. Apply Lemma 15.50 with $Y_3 = \ln \omega$, $Y_1 = \ln B^0_1$ and $Y_2 = \ln B^0_2$, under the location normalization $\mathbb{E}[\ln B^0_1] = 0$. The distributions of $\ln \omega$, $\ln B^0_1$ and $\ln B^0_2$ are identified, and since the logarithm is strictly increasing, so are F_ω, G^0_1 and G^0_2.

Step 2 (invert the normalized game). With G^0_1, G^0_2 and their densities known, (15.58) identifies ξ_1 and ξ_2. These are strictly increasing in equilibrium, so $F_k(a) = G^0_k\big(\xi_k^{-1}(a)\big)$, as in Laffont and Vuong (1996) for asymmetric IPV.

Step 3 (impose the scale). The location normalization in logs is a scale normalization in levels. Rescaling all homogenized bids by c rescales ξ_k, and hence A, by c, and rescales ω by $\frac{1}{c}$. The unique c with $\mathbb{E}[A] = 1$ for type 1 implements (D3). □

Several remarks qualify the result. First, realizations are not identified. The n bids of an auction are n equations in the $n + 1$ unknowns $\omega_t, A_{1t}, \ldots, A_{nt}$ (p. 300). Distributions are identified, but no individual cost is. Second, a single bid per auction would not suffice. The distribution of $\ln B = \ln \omega + \ln B^0$ alone has many decompositions into independent parts. Third, the nonvanishing condition is taken from Athey and Haile (2007, Lemma 6.1). Krasnokutskaya's appendix argues instead that bounded supports make the characteristic functions entire, so that their zeros form a countable set (p. 320, Lemma A1). Fourth, when both bidders in the pair have the same type, the pair identifies F_ω and that type's F_k.

Testable restrictions and extensions

The model has overidentifying content when three or more bids are observed (Section 3.2). Ratios of bids eliminate ω_t,

$$\ln \frac{B_{i_1 t}}{B_{i_3 t}} = \ln B^0_{i_1 t} - \ln B^0_{i_3 t}, \qquad \ln \frac{B_{i_2 t}}{B_{i_3 t}} = \ln B^0_{i_2 t} - \ln B^0_{i_3 t}.$$

Now $-\ln B^0_{i_3 t}$ plays the role of the common component. Applying Lemma 15.50 to the ratios uses only independence across bidders, and not independence of ω and $\boldsymbol{A}$. Her Proposition 2 lists three implications. (W1) If bidders i_1 and i_3 have the same type, the distributions of $\ln B^0_{i_1}$ and $\ln B^0_{i_3}$ recovered from the ratios coincide. (W2) The distributions recovered from the ratios coincide with those recovered from the pair $(\ln B_{i_1}, \ln B_{i_2})$, which holds only if ω is independent of $\boldsymbol{A}$. (W3) For four distinct bidders, $\frac{B_{i_1}}{B_{i_2}}$ and $\frac{B_{i_3}}{B_{i_4}}$ are independent. Independence of the private components implies (W1) and (W3), and independence of ω and $\boldsymbol{A}$ adds (W2) (pp. 301–302). (W1) and (W2) need three bids per auction, and (W3) needs four.

Her Proposition 3 collects restrictions that every model with unobserved heterogeneity imposes on the data (p. 302). (W4) The functions in (15.59) are characteristic functions of real random variables, and the two individual components they describe have the same support. (W5) They do not depend on which pair of bidders is used. (W6) Each ξ_k in (15.58) is strictly increasing, the restriction that Guerre et al. (2000) pointed out without heterogeneity. If a model with unobserved heterogeneity generated the data, (W4)–(W6) hold. The WP also presents them as sufficient. It adds that a degenerate distribution of $\ln \omega$, its condition (W7), marks IPV data (WP, Proposition 4).

Two limits of the result deserve emphasis. The first concerns APV. Both models make bids in the same auction dependent, but heterogeneity makes them conditionally independent, while APV makes them affiliated. By results related to de Finetti's theorem, the set of affiliated distributions is larger than the set of conditionally independent ones. Some APV bid distributions therefore cannot come from unobserved heterogeneity (p. 302). Restriction (W3) gives a practical test. Under heterogeneity, ratios of distinct pairs of bids from the same auction are independent. Many APV distributions violate this, among them the truncated multivariate normal for a large set of parameters (p. 303). The test has no power against a small set of affiliated distributions. The WP took a different view. It conjectured that heterogeneity with affiliated components is not identified, and it read the heterogeneity model as attributing the least private information consistent with the data (WP, Section 6). Second, the multiplicative form ties the mean and the dispersion of costs together. The extension $C_{it} = \omega_{1t} + \omega_{2t} A_{it}$, with independent ω_1, ω_2 and $\boldsymbol{A}$, lets the two vary separately. The WP's Theorem 1a identifies all distributions from four bids per auction. Kotlarski's argument is applied to the logs of differences of bids to recover the scale component ω_2, and then to differences and levels to recover the rest (WP, Appendix A). The published article leaves this model to a separate note by the author (p. 319).

Estimation

The estimator follows the proof (Section 4.1 and Appendix A.2). Estimation is carried out within a cell of auctions with the same (n, n_1) and the same discrete covariates. Let T_0 be the number of auctions in the cell.

Step 1: deconvolution. The joint characteristic function of a type-1 and a type-2 log bid and its derivative are estimated by averages over auctions and over all such pairs of bidders,

$$\hat{\Psi}(t_1, t_2) = \frac{1}{T_0} \sum_{t=1}^{T_0} \frac{1}{n_1 n_2} \sum_{i:\, k(i)=1} \sum_{j:\, k(j)=2} e^{\mathrm{i}(t_1 \ln b_{it} + t_2 \ln b_{jt})},$$

$$\hat{\Psi}_1(t_1, t_2) = \frac{1}{T_0} \sum_{t=1}^{T_0} \frac{1}{n_1 n_2} \sum_{i:\, k(i)=1} \sum_{j:\, k(j)=2} \mathrm{i} \ln b_{it}\ e^{\mathrm{i}(t_1 \ln b_{it} + t_2 \ln b_{jt})}.$$

Plugging these into (15.59) gives $\hat{\varphi}_{\ln \omega}$, $\hat{\varphi}_{\ln B_1^0}$ and $\hat{\varphi}_{\ln B_2^0}$. Densities follow from a truncated inverse Fourier transform with the damping factor of Diggle and Hall (1993) and Li et al. (2000),

$$\hat{f}_{\ln \omega}(y) = \frac{1}{2\pi} \int_{-T_c}^{T_c} \left(1 - \frac{|t|}{T_c}\right) e^{-\mathrm{i}ty}\, \hat{\varphi}_{\ln \omega}(t)\, dt, \tag{15.60}$$

and likewise for $\ln B_k^0$. We call the truncation constant T_c to keep T for the number of auctions. A change of variables gives $\hat{f}_\omega(w) = \frac{1}{w} \hat{f}_{\ln \omega}(\ln w)$. The damping factor tames the oscillating

tails that truncation produces (pp. 324–325). She chooses T_c by matching the first two moments of each component (p. 325). The targets come from a type-1 and a type-2 log bid in the same auction. Under the normalization $\mathbb{E}[\ln B_1^0] = 0$ they are

$$\mathbb{E}[\ln \omega] = \mathbb{E}[\ln B_1],$$
$$\operatorname{Var}(\ln \omega) = \frac{1}{2}\big[\operatorname{Var}(\ln B_1) + \operatorname{Var}(\ln B_2) - \operatorname{Var}(\ln B_1 - \ln B_2)\big] = \operatorname{Cov}(\ln B_1, \ln B_2),$$

together with $\mathbb{E}[\ln B_2^0] = \mathbb{E}[\ln B_2] - \mathbb{E}[\ln B_1]$ and $\operatorname{Var}(\ln B_k^0) = \operatorname{Var}(\ln B_k) - \operatorname{Var}(\ln \omega)$ (p. 325, footnote 34). For each candidate T_c she computes the moments of the estimated densities and picks the T_c that minimizes the squared deviations from the targets, scaled by the target variances. In the application this gives $T_c = 50$ (p. 325). Support bounds are estimated from the extremes of log bids and of differences of log bids (p. 321). A bias correction of the kind proposed by Horowitz and Markatou improves small-sample performance (p. 304, footnote 15, and p. 325). The WP also rescales bids into $[0, 2\pi]$ before estimation (WP, pp. 16–17).

Step 2: inversion. With $\hat{g}_k^0$ and $\hat{G}_k^0(a) = \int_{\underline{\hat{a}}}^{a} \hat{g}_k^0$ in hand, evaluate (15.58) on a grid of homogenized bids to obtain $\hat{\xi}_k$ (p. 304, Step 6). Invert it to get the normalized bid function $\hat{\alpha}_k = \hat{\xi}_k^{-1}$. The distribution of the private component is then

$$\hat{F}_k(a) = \hat{G}_k^0\big(\hat{\xi}_k^{-1}(a)\big),$$

the sample analogue of Step 2 of the proof (Steps 7–8). Finally, rescale so that $\mathbb{E}[A] = 1$ for type 1 (Step 9). The WP instead drew pseudo homogenized bids from $\hat{g}_k^0$, computed pseudo costs $\hat{\xi}_k(\tilde{b}_\ell^0)$, and smoothed them with the triweight kernel $\mathcal{K}(u) = \frac{35}{32}(1-u^2)^3\mathbf{1}(|u| \le 1)$. Its bandwidth was $2.978 \times 1.06\,\hat{\sigma}\,L^{-\frac{1}{6}}$, with $\hat{\sigma}$ the standard deviation of $\ln(1 + \text{bids})$ (WP, p. 17).

Two derived objects summarize the results (p. 305, Steps 10–11). The density of total cost is $f_{C_k}(c) = \int f_k\big(\frac{c}{u}\big)\frac{1}{u} f_\omega(u)\,du$. The *expected inverse bid function* averages, over the values of ω consistent with the bid b, the cost of a type-k bidder who bids b,

$$\bar{\xi}_k(b) = \int u\,\xi_k\Big(\frac{b}{u}\Big) f_\omega(u \mid b)\,du, \qquad f_\omega(u \mid b) = \frac{f_\omega(u)\,\mathbf{1}\big(\frac{b}{\bar{a}} \le u \le \frac{b}{\underline{a}}\big)}{\int_{\frac{b}{\bar{a}}}^{\frac{b}{\underline{a}}} f_\omega(y)\,dy}.$$

Here $[\underline{a}, \bar{a}]$ is the support of the homogenized bids. The truncation removes values of ω that cannot produce the bid b given the bounded supports.

Properties. Her Proposition 4 shows that $\hat{F}_\omega$ and $\hat{F}_k$ are uniformly consistent under (D1)–(D4) and (D5) (p. 305). Condition (D5) requires the characteristic functions of $\ln\omega$ and $\ln B_k^0$ to be *ordinary smooth* of order $\varkappa > 1$ in the sense of Fan (1991), that is, $d_0|t|^{-\varkappa} \le |\varphi(t)| \le d_1|t|^{-\varkappa}$ as $|t| \to \infty$. The rate for the deconvolved densities is taken from Li and Vuong (1998) (p. 322). Deconvolution estimators converge slowly, so large samples are needed (Athey and Haile, 2007, Section 6.1.2). Confidence intervals come from the bootstrap (p. 305).

Figure 15.16 shows the estimator at work in a simulation of our own. Two features stand out. Pairs of bids recover two distributions with opposite skewness that a single bid would blur into one symmetric-looking density. The bands are wide even with 1,000 auctions and four bids each, which illustrates the slow rates.

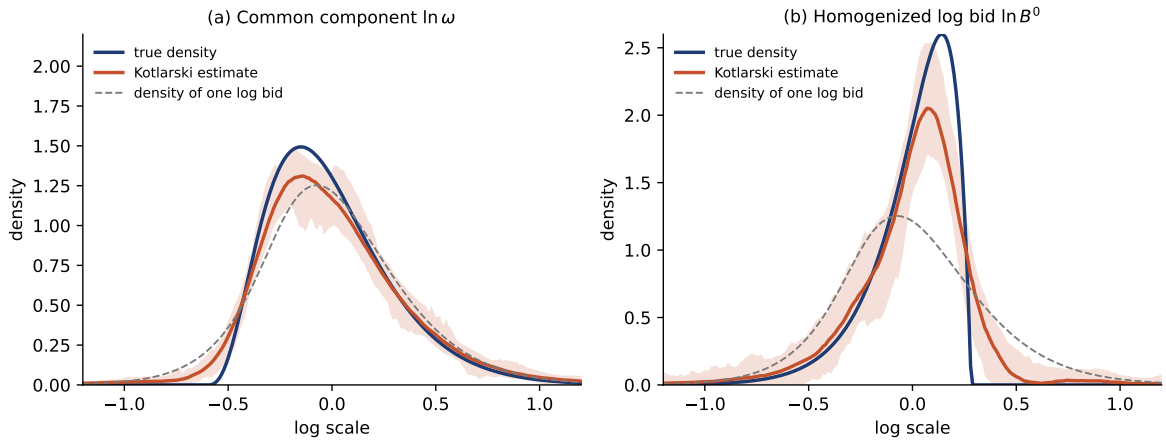

Figure 15.16: Deconvolution of log bids with (15.59) and the damped inverse (15.60) (our simulation, seed 15703). $T = 1{,}000$ auctions with four bidders of one type. $\ln \omega$ is a standardized Gamma(4) variable scaled to standard deviation 0.3, and $\ln B^0$ is a reflected standardized Gamma(2) variable scaled to standard deviation 0.2. Characteristic functions average over all ordered pairs of bids. T_c is chosen by Krasnokutskaya's moment criterion on the grid $3, 4, \ldots, 25$, and the largest value is usually chosen. Lines show the median over 200 samples, bands the 5–95 percent range. The dashed curve is the density of a single log bid.

Monte Carlo evidence

The published Monte Carlo study is reported in figures only (Section 4.3, pp. 306–309). Costs are multiplicative, $C = \omega A$, with distributions shaped like the estimated ones. Each sample has two bidders of each type, as in the data, and $T = 250$, 200 or 150 auctions, so each private component is estimated from 500, 400 or 300 bids. The 5–95 percent bands of the estimated distributions contain the true ones except in the smallest samples, where the bands are wide and miss small parts of the true functions (p. 306).

The WP ran a more detailed study with tables, which we report next. Its design is additive, $C = \omega + A$, with symmetric bidders (WP, Section 4.4). A is uniform with mean zero and variance 0.33. ω follows a power distribution with exponent 3 and mean 10.5, with variances chosen so that bid functions have closed forms. Each sample has $T = 400$ auctions with two bidders, and each experiment is replicated 500 times. Five cases are studied (WP, Table 1b). Case 1 has independent costs. Case 2 has unobserved heterogeneity with $\mathrm{Var}(\omega) = 0.04$ or 0.34. Case 3 is APV, with bidders who observe only C. Cases 4 and 5 add correlation among private components or between private and common components. The estimator behaves as theory predicts (WP, Table 2b). With independent costs the estimated $\mathrm{Var}(\omega)$ is 0.013, with interval $[0.01, 0.02]$, close to degenerate. The estimated markup is 0.362 against a true 0.38. With heterogeneity, the estimated variances of A are 0.321 and 0.318 against 0.33. The estimated variances of ω are 0.0362 and 0.335 against 0.04 and 0.34. Markups are 0.082 and 0.092 against 0.09. WP Table 3b prints a true markup of 0.03 for $\mathrm{Var}(\omega) = 0.34$, so the two tables of the paper disagree (see the notes to Table 15.13). With APV data the procedure misreads the information structure. The estimated markup is 0.18 against a true 0.47 in case 3a, and 0.33 against 0.21 in case 3b. With correlated components, the variance of ω is overstated and that of A understated. The bias is negligible when the correlation is about 5 percent of $\mathrm{Var}(A)$ (WP, pp. 19–20).

The second experiment applies IPV and APV estimators to data with heterogeneity. Table 15.13 reproduces the results. As $\mathrm{Var}(\omega)$ grows, both misspecified procedures understate

mean costs, overstate their variance, and overstate markups. Krasnokutskaya reports that the bias becomes significant once the correlation of costs reaches about 0.3 (WP, p. 21). Their bid functions are flatter than the truth, and the IPV estimate is especially flat at the low end. A known common component produces a bid distribution with thin tails, which IPV reads as extreme shading at the bottom.

Table 15.13: Misspecified estimators applied to data with unobserved heterogeneity (Krasnokutskaya 2004 working paper, Table 3b, not in the published article)

$\mathrm{Var}(\omega)$	Procedure	$\mathbb{E}(C)$	$\mathrm{Var}(C)$	$\mathbb{E}$(markup)
0.04	True model	10.5	0.37	0.09
	UH	[10.44, 10.59]	[0.32, 0.41]	[0.078, 0.095]
	APV	[10.37, 10.48]	[0.35, 0.44]	[0.097, 0.12]
	IPV	[10.41, 10.5]	[0.34, 0.44]	[0.95, 0.11]
0.34	True model	10.5	0.67	0.03
	UH	[10.28, 10.64]	[0.63, 0.72]	[0.02, 0.038]
	APV	[8.31, 9.57]	[0.89, 1.02]	[0.042, 0.55]
	IPV	[8.85, 9.84]	[0.83, 0.96]	[0.4, 0.52]
1	True model	10.5	1.33	0.01
	UH	[10.15, 10.76]	[1.27, 1.43]	[0.008, 0.014]
	APV	[7.6, 8.8]	[2.01, 2.27]	[0.033, 0.047]
	IPV	[8.1, 9.2]	[1.86, 2.05]	[0.31, 0.044]

Notes. Additive design $C = \omega + A$, two symmetric bidders, 400 auctions, 500 replications. UH, APV and IPV denote estimators that assume unobserved heterogeneity, affiliated private values and independent private values. Brackets give 5th and 95th pointwise percentiles of the estimator. Entries are reproduced as printed. Four markup intervals look like decimal-point typos in the source: $[0.95, 0.11]$, $[0.042, 0.55]$, $[0.4, 0.52]$ and $[0.31, 0.044]$. The true markup at $\mathrm{Var}(\omega) = 0.34$ is printed as 0.03 here and as 0.09 in WP Table 1b.

Application: Michigan highway maintenance

Setting. The Michigan Department of Transportation allocates road work by first-price sealed-bid auctions (Section 5.1, pp. 306–307). It advertises a project 4 to 10 weeks before the letting, with a short description of location, completion time and tasks. Firms can obtain a detailed description. The department prepares an *engineer's estimate* from the work required for each task, priced with winning bids on similar past projects and deflated. Federal law requires the winning bid to be below 110 percent of this estimate, unless the state justifies an exception in writing. Bids and even winning bids above the threshold appear in the data, so Krasnokutskaya treats the reserve as nonbinding. Following the literature, she assumes bidders know how many rivals they face (pp. 309–310).

Data. The sample covers maintenance projects with bituminous resurfacing as the main task, let between February 1997 and December 2003, a total of 3,947 projects (p. 310). For each project she observes the letting date, completion time, location, tasks, the identities and bids of all bidders, and the engineer's estimate. Two arguments support the model. Resurfacing jobs are precisely specified and simple, which favors private values. Their costs depend on elevation, curvature, traffic and the age of the surface, which contractors see on site visits and the researcher does not. Firms differ mainly in size, which every participant observes, so she

allows two observable types. A bidder is *regular* if it won at least $10 million of projects in each year of the data and has at least 100 employees (p. 310). She notes that this matches the industry's definition of a large bidder (footnote 19). All other bidders are *fringe*. The WP used a different definition, which the published one replaces. There a regular bidder submits at least 12 bids per year, ranks in the top 10 percent of firms by employment and works in three or more specializations (WP, Section 5.2).

The number of bidders ranges from 1 to 11. More than 85 percent of projects have 2 to 6 bidders, and the mean is 3.4 with standard deviation 1.3. About 75 percent of engineer's estimates lie between $100,000 and $1,000,000, with 5 percent below and 20 percent above (p. 310). Table 15.14 reproduces her descriptive table. The gap between the estimate and the winning bid grows with the number of bidders. *Money left on the table* is the gap between the two lowest bids relative to the estimate. It averages 7 percent and falls from 11 to 4 percent as the number of bidders rises (p. 311).

Table 15.14: Michigan highway maintenance auctions: descriptive statistics by number of bidders (Krasnokutskaya 2011, Table 1, and WP Table 1c)

Number of bidders	Overall	1	2	3	4	5	6
Number of observations	3,947	71	673	1,126	1,026	365	192
Engineer's estimate	12.80	13.34	10.27	12.60	13.90	12.90	16.40
	(2.35)	(2.88)	(1.41)	(3.02)	(2.26)	(1.79)	(3.39)
Winning bid	11.10	14.12	10.00	11.80	12.90	11.80	15.20
	(2.32)	(3.05)	(1.50)	(2.89)	(2.25)	(1.66)	(3.35)
Money left on the table	0.07	NA	0.11	0.08	0.07	0.05	0.04
	(0.05)	NA	(0.08)	(0.06)	(0.06)	(0.05)	(0.04)
Number of regular bidders	1.92	0.79	1.43	1.65	2.07	2.16	2.29
	(1.06)	(0.41)	(0.62)	(0.72)	(0.98)	(1.21)	(1.32)

Notes. Means with standard deviations in parentheses. The engineer's estimate and the winning bid are in hundreds of thousands of dollars. Money left on the table is the difference between the lowest and second-lowest bids divided by the engineer's estimate. The overall column includes projects with 7 to 11 bidders. The published Table 1 prints the columns for 2 to 6 bidders as shown. Its overall column is misprinted, with 1.175 and 4.660 in every row, and its one-bidder column prints the overall values. We take these two columns from WP Table 1c.

Evidence of heterogeneity. Krasnokutskaya first tests for heterogeneity (Section 5.2, p. 311). She conditions on a linear index of observables estimated by ordinary least squares. The index contains the engineer's estimate, duration, highway type, year, month and district dummies, and the number of tasks. The tests run within cells defined by the main task and the number of bidders (Appendix A.3). The first test asks whether two bids from the same auction are independent given the index, which is the null of IPV against heterogeneity. The second asks whether two ratios built from four distinct bids are independent, restriction (W3). This is the null of heterogeneity against APV. For resurfacing projects with four regular bidders, the p-values are 0.03 and 0.52. IPV is rejected at the 5 percent level, and heterogeneity is not rejected against APV. The test sample has 370 auctions with estimates between $350,000 and $750,000 (footnote 21). Table 15.15 reproduces the index regressions.

The WP looked at the same correlation more directly. Its regressions of log bids in four-bidder resurfacing projects are reproduced in Table 15.16 (WP, Table 2c). Bids rise with the engineer's estimate, distance to the site and the firm's backlog ("load remaining"), and fall

Table 15.15: Linear index of log bids on observables (Krasnokutskaya 2011, Table 2)

	Test subsample	Estimation subsample
Constant	0.375	0.327
	(0.010)	(0.012)
Engineer's estimate	0.8413	0.8113
	(0.028)	(0.025)
Duration	0.0011	0.0015
	(0.0013)	(0.0011)
Tasks	0.0014	0.0012
	(0.0007)	(0.0009)
$(n_{\text{regular}}, n_{\text{fringe}})$	(4,0)	(2,2)
Number of projects	370	226
R^2	33%	17%

Notes. Ordinary least squares estimates of the mean of the log bid, with the figures in parentheses as printed. Variables are labeled as in the source, which does not say whether the engineer's estimate enters in logs. The test subsample is used for the specification tests and the estimation subsample for the deconvolution.

with the number of potential bidders. Fringe firms bid more. Adding auction dummies raises R^2 from 0.857 to 0.914. The random-effects estimates attribute $\rho = 0.48$ of the residual variance of log bids to the auction level. The printed variance components imply a smaller share, $\frac{0.16}{0.16+0.22} \approx 0.42$. The text reports R^2 values of 0.81 and 0.89 for the same regressions (WP, p. 25), which also differ from the table. Common variation across bids in an auction that observables do not explain is the signature of unobserved heterogeneity.

Correlated bids could have other sources. Common values are unlikely, she argues, because simple maintenance projects carry little project-level uncertainty. Collusion is harder to rule out, since each test assumes a particular scheme (p. 311). Following Porter and Zona (1993), if only the winning bid reflected a cost, the losing bids would be phony. She recovers the regular and fringe bid distributions from the winning bid alone with the method of Athey and Haile (2002). These match the distributions estimated from losing bids, which she reads as evidence against collusion (p. 312).

Results. Estimation uses the 226 projects with an engineer's estimate between $300,000 and $580,000, a completion time of 3 to 6 months, and two regular and two fringe bidders (p. 312). Results for other cells are described as qualitatively similar. Residual variation in observables is removed by homogenization in logs, as in Section 15.7.2. She regresses log bids on the observables of Table 15.15 and deconvolves the residuals. Costs are then $C_{it} = e^{z_t'\theta}\,\omega_t A_{it}$, and the fitted scaling factor $e^{z_t'\theta}$ is added back for the variance decomposition and the comparisons (p. 312, footnote 22).

Table 15.17 collects the main numbers (pp. 313–316). The heterogeneity component ω has mean 0.98 and standard deviation 0.204. The *common component* $e^{z'\theta}\omega$, which combines the observed and the unobserved parts, has mean $392,000 and standard deviation $78,890. The private components of the two types are similar. The fringe mean is 1.06, against the normalized regular mean of 1, and the standard deviations are 0.14 (regular) and 0.13 (fringe). Fringe firms thus have higher but slightly less dispersed costs. A test of equal private-component distributions gives a p-value of 0.69 (p. 314). The text says that this rejects equality at the 10

Table 15.16: Regressions of log bids, four-bidder resurfacing projects (Krasnokutskaya 2004 working paper, Table 2c, selected rows)

	OLS	Auction dummies	Random effects
Log (estimate)	0.9100	0.9300	0.8800
	(0.0530)	(0.1400)	(0.1300)

	(0.0157)	(0.0127)	(0.0144)
Number of potential bidders	−0.1100	−0.1330	−0.1100
	(0.0310)	(0.0230)	(0.0290)
Fringe (dummy)	0.2500	0.2800	0.2200
	(0.1100)	(0.1200)	(0.1000)
Constant	0.1750	0.1620	0.1680
	(0.0580)	(0.0520)	(0.0480)
R^2	0.857	0.914	0.917 (overall)

Notes. Dependent variable $\ln B$. 947 bids. Standard errors in parentheses. Omitted rows are length and dummies for marking, landscaping and signs. All columns include district and regular-bidder dummies. Coefficients on auction-level variables in the auction-dummies column are reproduced as printed. Random effects: R^2 within 0.00, between 0.934, $\sigma_u^2 = 0.16$, $\sigma_\varepsilon^2 = 0.22$, $\rho = 0.48$ as printed, although $\frac{\sigma_u^2}{\sigma_u^2+\sigma_\varepsilon^2} = 0.42$. These regressions are not in the published article.

percent level, which a p-value of 0.69 does not support.

To split the variance of costs, she uses the exact identity for independent factors,

$$\operatorname{Var}(\omega A) = \mathbb{E}[\omega^2]\mathbb{E}[A^2] - (\mathbb{E}\omega)^2(\mathbb{E}A)^2 = (\mathbb{E}\omega)^2 \operatorname{Var}(A) + (\mathbb{E}A)^2 \operatorname{Var}(\omega) + \operatorname{Var}(\omega)\operatorname{Var}(A),$$

and drops the last, second-order term (p. 314). She attributes $(\mathbb{E}\omega)^2 \operatorname{Var}(A)$ to private information and $(\mathbb{E}A)^2 \operatorname{Var}(\omega)$ to common knowledge. Both terms are invariant to the normalization, since $(\omega, A) \mapsto (c\,\omega, \frac{A}{c})$ leaves each unchanged (footnote 25). For homogenized costs the private term accounts for almost 31 percent of the variance, and for 31.3 percent of the exact variance (footnote 26). For total costs, including the observed scaling factor, it accounts for 34.4 percent (footnote 27). The rounded moments of regular bidders reproduce these shares. For homogenized costs,

$$\frac{(\mathbb{E}\omega)^2 \operatorname{Var}(A)}{(\mathbb{E}\omega)^2 \operatorname{Var}(A) + \operatorname{Var}(\omega)} = \frac{0.98^2 \times 0.14^2}{0.98^2 \times 0.14^2 + 0.204^2} = \frac{0.0188}{0.0188 + 0.0416} \approx 0.31.$$

For total costs in thousands of dollars, the same ratio is $\frac{392^2 \times 0.14^2}{392^2 \times 0.14^2 + 78.89^2} = \frac{3{,}012}{3{,}012 + 6{,}224} \approx 0.33$, close to the reported 34.4 percent. Private information therefore explains about a third of the variation in costs, the 34 percent that Hortaçsu and Perrigne (2021, p. 103) report for this article. The other two thirds is information that all bidders share and the econometrician does not see.

The WP reported different figures from a different sample, and the published estimates supersede them. Its sample had 487 larger and longer projects, with estimates between \$500,000 and \$900,000 and durations of 6 to 9 months (WP, p. 25). Its common component had mean \$654,000 and standard deviation \$31,700, and its private components had standard deviations 0.22 and 0.23. Its text gave a private share of "almost 15%" (WP, p. 26), while its abstract and conclusion gave 25 percent. Neither figure follows from its own moments. With $\mathbb{E}\omega = 654$, $\sqrt{\operatorname{Var}(\omega)} = 31.7$ and $\sqrt{\operatorname{Var}(A)} = 0.22$, the private term is $654^2 \times 0.22^2 \approx 20{,}700$ and the common term is $31.7^2 \approx 1{,}005$, a private share near 95 percent.

Normalized markups $\frac{b-c}{c}$ range from 0.1 to 25 percent for regular bidders, with an average of 8.4 percent. For fringe bidders they range from 0.1 to 18 percent, with an average of 6.1 percent (p. 314). Fringe firms thus have higher costs, slightly less dispersed costs and lower markups than regular firms, as Hortaçsu and Perrigne (2021, p. 103) summarize. To measure inefficiency she draws pseudo-samples of costs for 250 auctions with three bidders each, as printed. She computes bids from the estimated bid functions and records how often the lowest bid does not come from the lowest cost. Over 1,000 repetitions the probability of an inefficient outcome averages 5 percent, with a 95 percent range of $[3.6, 6.2]$. The misallocation raises the cost of procurement by 2 percent, with range $[1.3, 2.8]$ (p. 314). The WP's figure of 28 percent, with range $[26.6, 30.3]$, came from pseudo-samples of two regular and two fringe costs in its own sample (WP, pp. 25–28). It is superseded.

The IPV and APV estimators of Guerre et al. (2000) and Li et al. (2002), applied to the same data, give larger markups and more dispersed costs (pp. 314–316). The average markup of regular bidders is 14 percent under APV and 19 percent under IPV, against 8.4 percent under heterogeneity. For fringe bidders the figures are 12.2, 16.5 and 6.1 percent. The variance of costs estimated under heterogeneity is 18 percent lower than under APV and 22 percent lower than under IPV. Figure 15.17 shows why. Both misspecified bid functions lie above the heterogeneity estimate, and their confidence bands meet its band only near the top of the support. The misspecified estimators read common variation in bids as private information. They therefore infer lower costs and larger markups from the same bids.

Reserve prices. The estimates feed a design exercise (pp. 316–317). To avoid the complications of asymmetric auctions, she uses the estimates for regular bidders only and treats bidders as

Table 15.17: Michigan resurfacing auctions: estimates under unobserved heterogeneity (UH), APV and IPV (Krasnokutskaya 2011, Section 5.3, with the superseded WP estimates)

	Published article			WP (2004)
	UH	APV	IPV	UH
Average markup $\frac{b-c}{c}$, regular bidders	8.4%	14%	19%	7.5%
Average markup $\frac{b-c}{c}$, fringe bidders	6.1%	12.2%	16.5%	6%
Probability of an inefficient allocation	5% [3.6, 6.2]			28% [26.6, 30.3]
Cost increase from misallocation	2% [1.3, 2.8]			
Cost variance under UH relative to column		18% lower	22% lower	
Common component, mean (s.d.)	\$392,000 (\$78,890)			\$654,000 (\$31,700)
Heterogeneity component ω, mean (s.d.)	0.98 (0.204)			
Private component A, s.d. regular, fringe	0.14, 0.13			0.22, 0.23
Private component A, fringe mean (regular = 1)	1.06			1.2
Private share of variance, homogenized costs	31%			
Private share of variance, total costs	34.4%			15% or 25%

Notes. Published estimates use 226 projects with two regular and two fringe bidders, engineer's estimates between \$300,000 and \$580,000 and durations of 3 to 6 months. Brackets give 95 percent ranges over 1,000 simulated pseudo-samples. The WP used 487 projects with estimates between \$500,000 and \$900,000 and durations of 6 to 9 months. Its private share is 15 percent in the text and 25 percent in the abstract, and neither follows from its printed moments (see text). The WP also reported inefficiency rates of 34 and 38 percent under IPV and APV and extra markups of \$61,000 and \$33,000. Its cost variances under UH were 35 and 25 percent below IPV and APV (WP, pp. 25–28).

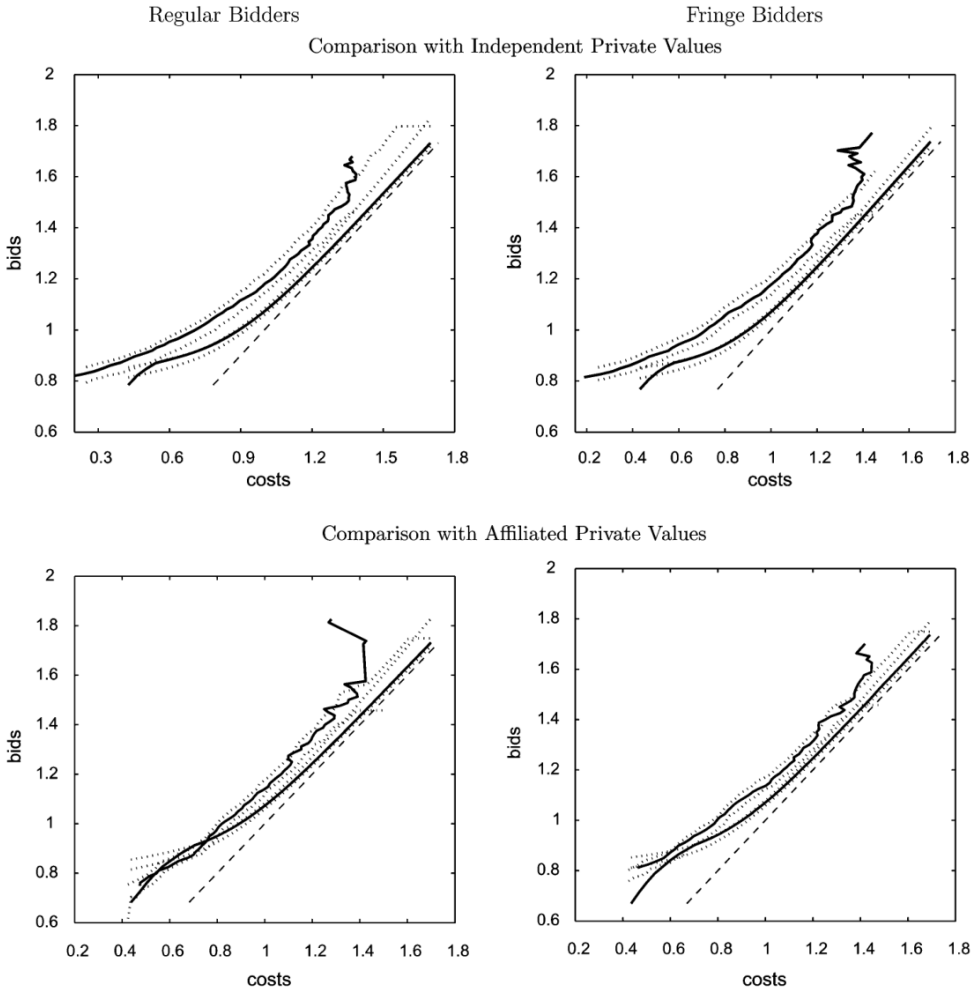

Figure 15.17: Expected bid functions, bids against costs in homogenized units, for regular (left) and fringe (right) bidders. The top row compares the heterogeneity estimate with IPV, and the bottom row compares it with APV. In each panel the dashed line is the diagonal. The lower solid line is the estimate under unobserved heterogeneity, and the upper solid line is the misspecified estimate. Dotted lines are pointwise 95 percent bootstrap bands. Source: Krasnokutskaya (2011), Figure 5.

symmetric. The government minimizes the expected cost of procurement. If no bid falls below the maximum acceptable price r, the project waits. Waiting costs c_0, which combines the cost of delay and the expected cost of completing the work later. In the notation of Section 14.13.4, c_0 plays the role of the buyer's value u_0. Suppose first that the government observes ω. Costs then have the distribution $F_C(c \mid \omega) = F_1\left(\frac{c}{\omega}\right)$ and density $f_C(c \mid \omega) = \frac{1}{\omega} f_1\left(\frac{c}{\omega}\right)$. The virtual cost (14.115) is

$$J(c \mid \omega) = c + \frac{F_C(c \mid \omega)}{f_C(c \mid \omega)} = c + \omega \frac{F_1(\frac{c}{\omega})}{f_1(\frac{c}{\omega})} = \omega J_1\left(\frac{c}{\omega}\right), \qquad J_1(a) = a + \frac{F_1(a)}{f_1(a)}.$$

The optimal maximum price solves $J(r^* \mid \omega) = c_0$, so that

$$r^*(\omega) = \omega J_1^{-1}\left(\frac{c_0}{\omega}\right).$$

The reserve does not scale with ω, because c_0 is fixed in dollars. This benchmark is case (a) of her four candidates. In case (b) the government does not observe ω. It chooses one reserve that minimizes the expected cost averaged over F_ω. Cases (c) and (d) use the cost distributions estimated under IPV and APV. Each candidate is evaluated under the heterogeneity model. Since c_0 is not observed, she reports results for several values.

Table 15.18 reproduces her Table 4 for projects with an engineer's estimate of $400,000. Reserves based on IPV estimates raise the expected cost above the benchmark by 8.3 to 20.6 percent of c_0, which she rounds to 9 to 20 percent. Relative to the benchmark cost, the increase is 10 to 35 percent. The reserve of case (b) costs only about 1 percent of c_0, or 1 to 2 percent of the benchmark. APV-based reserves do worse still. Both misspecified models also imply too low a probability that any bid is submitted. For c_0 of at least 150 percent of the mean cost, which she regards as the realistic range, accounting for heterogeneity saves at least 16 percent of the benchmark cost (p. 317). This is large next to markups of only 6 to 8 percent of costs.

Tests of the assumptions and robustness. Her Table 3 reports tests of the restrictions of Proposition 2 (pp. 317–318). The ratio test (W3) of Section 5.2 gives a p-value of 0.52. Independence of the private components from ω gives 0.81 (bootstrap) and 0.75 (subsampling). Independence of the private components across bidders gives 0.43 and 0.63. The text adds a p-value of 0.63 for the test of part 1 of Proposition 2. None of the tests rejects. One robustness check addresses dynamics. Capacity constraints would link bids across auctions and bias the estimated joint characteristic function. She re-estimates the model on projects for which every regular bidder's backlog lies between 30 and 75 percent of the largest backlog observed in the data. The sample shrinks and the estimates are less precise, but the variance decomposition and the biases from misspecification are similar (pp. 318–319). The WP adds a fit check. Pseudo-bids simulated from the estimated model reproduce the estimated densities of actual bids, with the largest gap near the mode (WP, p. 28, Figure 3c).

Assessment

Krasnokutskaya's paper gave the first nonparametric identification result for first-price auctions with unobserved heterogeneity. It turned the repeated-measurement idea into an auction estimator, and it quantified how IPV and APV estimators err. In Michigan resurfacing, private information explains only about a third of cost variation, 34 percent of the variation in total costs (p. 319). The remaining two thirds is common knowledge among bidders. Ignoring it raises the estimated average markup of regular bidders from 8.4 percent to 14 percent (APV) or

Table 15.18: Optimal reserve prices under alternative models (Krasnokutskaya 2011, Table 4)

		Unobserved heterogeneity			
c_0		Benchmark (a)	Expected (b)	IPV (c)	APV (d)

Notes. Projects with an engineer's estimate of \$400,000, regular bidders treated as symmetric. c_0 is the cost of not awarding the project today, in hundreds of thousands of dollars. (a) The government observes ω. (b) One reserve minimizes the cost averaged over F_ω. (c), (d) Reserves computed from IPV and APV estimates. All candidates are evaluated under the heterogeneity estimates. Intervals in parentheses as printed.

19 percent (IPV). Reserve prices based on the misspecified models would raise procurement costs by 10 to 63 percent of the benchmark. The asymmetry between regular and fringe firms matters less, with inefficient awards in 5 percent of auctions at a cost of 2 percent. Hortaçsu and Perrigne (2021, p. 103) summarize the published findings in the same terms. The WP's figures differ, with a 28 percent inefficiency rate and a private share of 15 or 25 percent, and the published article replaces them.

The approach has four limits. First, heterogeneity must be scalar and enter by a known separable form, and the two-dimensional extension needs four bids. Second, independence of ω and $\boldsymbol{A}$ and across bidders is essential. Her tests do not reject it (Table 3), but they have limited power, and the model leaves no room for affiliation among the private components. Third, estimation is cell by cell in (n, n_1) and covariates, with slow rates, and the published estimates rest on 226 projects. Athey et al. (2011, footnote 22) give this reason for not using the method on timber data. "[O]ne would want to estimate the model separately for each vector of participants (n_L, n_M) and we simply don't have the data to do this." Fourth, the number of bidders is taken as exogenous. Entry that responds to ω_t would violate (D1), and Krasnokutskaya leaves participation to separate work.

Krasnokutskaya and Seim (2011) add participation in later work on California highway procurement, where small firms receive a bid preference (Hortaçsu and Perrigne, 2021, p. 123). They estimate an entry model of the Levin and Smith (1994) type with cost asymmetries. Entry costs are 2.2 to 3.9 percent of the engineer's estimate for small firms and 3.1 to 3.3 percent for large firms. The state aims to award 25 percent of procurement spending to small firms. With fixed participation, reaching the goal would require a 50 percent bid discount, at a very modest increase in cost. With endogenous participation a 20 percent discount suffices, but the total procurement cost rises by 3.2 percent. Section 14.13.4 discusses the theory of such preferences.

Later work relaxes separability. Hu et al. (2013) identify nonseparable heterogeneity from three bids per auction (as described by Roberts, 2013, p. 5). Asker (2010) applies the deconvolution to knockout bids in a stamp cartel (Section 13.8.4).

15.7.4 Parametric approaches

A parametric first step trades flexibility in the distributions for flexibility in how covariates and heterogeneity enter. Athey et al. (2011) specify Weibull bid distributions conditional on a Gamma-distributed multiplicative component, which integrates out in closed form (Section 15.9, Proposition 15.61). Values then follow from the first-order condition at any ω, as in Theorem 15.52. The parametric form lets heterogeneity affect types differently and keeps estimation feasible with many participant configurations (Athey and Haile, 2007, Section 6.1.2). Roberts and Sweeting (2013) estimate values with heterogeneity in values and entry costs by simulated maximum likelihood with importance sampling (as described by Roberts, 2013, p. 6). Hong and Shum (2002) model the median of the bid distribution as a normal random variable whose mean depends on the number of bidders (as described by Krasnokutskaya, 2011, p. 296). Finite mixtures of parametric distributions offer a middle ground (Athey and Haile, 2007, eqs. (6.7)–(6.9)). In all of these, identification of the heterogeneity distribution leans on functional form.

15.7.5 Reserve prices as a control for quality: Roberts (2013)

Idea. Every method so far uses only bidders' behavior. Roberts (2013) uses the seller's behavior. A seller who knows the object well probably observes what the bidders observe. If the reserve price rises with the unobserved quality, then reserve prices reveal it. The logic is that of a control function, close to the use of investment as a proxy for productivity by Olley and Pakes (1996). Roberts (2013) credits the suggestion to Athey and Haile, and Athey and Haile (2007, footnote 56) point to restrictions from the seller's side as a direction worth exploring. His motivating evidence is old. In the eggplant data of Laffont et al. (1995), winning bids and reserve prices move in tandem across auctions (Roberts, 2013, p. 7, citing their Appendix figure, reproduced in Figure 15.6b).

Model. In auction t there are N_t bidders with symmetric independent private values. Observed characteristics Z_t and the scalar ω_t are known to the seller and the bidders, and the econometrician observes only Z_t. Values are drawn from $F_V(\cdot \mid Z_t, \omega_t)$, which may depend on ω_t in any way, but not on N_t. The seller sets the reserve price $r_t = m(Z_t, \omega_t)$ with the same function m in every auction. The bidders counted in N_t include those with values below r_t.

Assumption 15.53 (Roberts, 2013, Assumption S1)**.** For every z, $m(z, \omega)$ is strictly increasing in ω.

Reserves need not be optimal. Monotonicity is nevertheless what optimal reserves deliver under weak conditions. Recall the virtual valuation (14.48) and write it conditionally on ω as $\psi(t \mid \omega) = t - \frac{1-F_V(t|\omega)}{f_V(t|\omega)}$. The optimal reserve solves $\psi(r^* \mid \omega) = v_0$, where v_0 is the seller's value (Corollary 14.47).

Proposition 15.54 (Roberts, 2013, Proposition 1)**.** *If V and ω are affiliated and $\psi(t \mid \omega)$ is increasing in t for every ω, the optimal reserve price is increasing in ω.*

Proof. Take $\omega_1 < \omega_2$. By Proposition 14.13, affiliation gives the monotone likelihood ratio property. For $v_1 < v_2$, $\frac{f_V(v_2|\omega_1)}{f_V(v_1|\omega_1)} \le \frac{f_V(v_2|\omega_2)}{f_V(v_1|\omega_2)}$, strictly under strict affiliation. Integrating over $v_2 > v_1$ gives $\frac{1-F_V(v_1|\omega_1)}{f_V(v_1|\omega_1)} < \frac{1-F_V(v_1|\omega_2)}{f_V(v_1|\omega_2)}$, so the inverse hazard rises with ω and $\psi(t \mid \omega_2) < \psi(t \mid \omega_1)$ for every t. Let r_1 solve $\psi(r_1 \mid \omega_1) = v_0$. Then $\psi(r_1 \mid \omega_2) < v_0$. Since $\psi(\cdot \mid \omega_2)$ is increasing, the solution r_2 of $\psi(r_2 \mid \omega_2) = v_0$ satisfies $r_2 > r_1$. □

The second result is the identification theorem. Partition $Z = (Z_0, Z_1)$.

Proposition 15.55 (Roberts, 2013, Proposition 2)**.** *Let Assumption 15.53 hold. Suppose (i) there is a value z_1^* such that $m(z_0, z_1^*, \omega) = \omega$ for all z_0 and ω, and (ii) ω is independent of Z_1 conditional on Z_0. Then $F_V(v \mid Z, \omega)$ is identified for $v \ge m(Z, \omega)$ from transaction prices and reserve prices in first-price and second-price (or ascending) auctions. With N known and unsold auctions recorded, the probability of no sale also identifies the mass $F_V\big(m(Z, \omega) \mid Z, \omega\big)$.*

Proof. Step 1 (the law of ω). By (i) and (ii),

$$\mathbb{P}(r_t \le u \mid Z_0 = z_0, Z_1 = z_1^*) = \mathbb{P}(\omega_t \le u \mid Z_0 = z_0, Z_1 = z_1^*) = F_{\omega|Z_0}(u \mid z_0).$$

Step 2 (the function m). For any z_1, monotonicity and (ii) give

$$F_{\omega|Z_0}(u \mid z_0) = \mathbb{P}\big(m(z_0, z_1, \omega_t) \le m(z_0, z_1, u) \mid z_0, z_1\big) = F_{r|Z}\big(m(z_0, z_1, u) \mid z_0, z_1\big),$$

so $m(z_0, z_1, u) = F_{r|Z}^{-1}\big(F_{r|Z}(u \mid z_0, z_1^*) \mid z_0, z_1\big)$ is identified. *Step 3 (realizations).* Since m is strictly increasing in ω, each observed (r_t, Z_t) reveals $\omega_t = m^{-1}(Z_t, r_t)$. *Step 4 (values).* Treat (Z_t, ω_t) as observed covariates. For fixed (Z, ω) the reserve $m(Z, \omega)$ is fixed, so transaction prices are censored at it. Apply the truncated inversions of Proposition 15.13 in second-price and ascending auctions and of Theorem 15.27 in first-price auctions. They identify $F_V(\cdot \mid Z, \omega)$ on $[m(Z, \omega), \infty)$. Take an ascending auction with N known, for instance. The second-highest value is at most $v \ge m(Z, \omega)$ exactly when the car goes unsold or sells at a price of at most v. The probability of this event is $\Lambda_{N-1:N}\big(F_V(v \mid Z, \omega)\big)$, which is then inverted. □

Roberts (2013, Proposition 2) states the result without the restriction $v \ge m(Z, \omega)$, and his proof cites Athey and Haile (2002, Theorems 1 and 6), which assume no binding reserve. Below the reserve, no bid is recorded and the data carry no information about $F_V(\cdot \mid Z, \omega)$, as in Theorem 15.27. The reserve does bind in his data, since 107 of 1,117 cars in one subsample go unsold.

The normalization (i) holds in many functional forms, for example $r = z\,\omega$ or $r = z + \omega$ at a suitable z (Roberts, 2013, footnote 6). Unlike Theorem 15.52, the result allows values to depend on ω in any way and needs only the transaction price. It requires instead that the reserve depend on nothing that the bids do not reflect.

Setting and data. The data come from a wholesale used-car auction house in Suwon, South Korea, which held weekly auctions between October 10, 2001 and November 27, 2002 (Roberts, 2013, Section 3). Only registered dealers may bid, and more than 380 were registered. The house charges the seller $50 per car and collects 2.2 percent of the price from each side if the car sells. Sellers set reserve prices, usually with guidance from the house. Dealers receive car descriptions three days ahead and inspect the cars for three hours or more before the auction. The format is a button auction with reentry. The price rises by $30 every three seconds while at least two buttons are pressed, and bidders cannot see when rivals drop out. Of 28,334 passenger cars, Roberts studies 4,943 automatic five-passenger sedans. Hyundai, Daewoo and

Kia account for 42, 39 and 18 percent of auctions. The average winning bid is \$3,661.83, the average reserve \$3,361.26, and 5.37 bidders bid on the average car (Roberts, 2013, Table 1). Among bids, only the transaction price is recorded, together with the identities of the winner and the runner-up and the number of bidders.

Evidence for the assumptions. Several facts support the model (Roberts, 2013, pp. 13–19). In regressions of the log winning bid on car characteristics and dummies, R^2 rises from 0.903 to 0.979 when the log reserve is added. The log reserve alone gives 0.966 (Table 2). The residuals of winning bids and of reserves, after both are regressed on characteristics, have correlation 0.890, against a raw correlation of 0.983. For 107 unsold cars among 1,117 auctioned between October 10 and December 27, 2001, the same residual correlations are 0.942 for the highest bid and 0.943 for the average bid. The reserve does not predict failure to sell. Its coefficient in a logit is 0.232 with standard error 0.263 (Table 4). Moving the reserve from its 25th to its 75th percentile raises the failure probability by about 2 percentage points. Reserves do not rise with the number of bidders, which a signaling model of reserves would predict (Cai et al., 2007). About four of the roughly five bidders per car bid above the reserve, so the co-movement is not mechanical. Bidders look symmetric. Three quarters of them buy 17 or fewer cars over 59 auction days.

Estimation. For Hyundai Sonatas, Roberts specifies $m(Z_1, \omega) = \mu(X; \vartheta) + \omega$ with $\mathbb{E}[\omega X] = 0$ (p. 19). Here X collects age and mileage. The function μ is quadratic in them, including their interaction. The residual of this regression estimates ω_t. The distribution of transaction prices P_t given $Z = (Z_1, \hat{\omega})$ is estimated by a kernel estimator of a conditional distribution (his eq. (3)),

$$\hat{F}_{P|Z=z}(v) = \frac{\sum_{t=1}^{T} \tilde{\mathcal{K}}_1\left(\frac{v - P_t}{h}\right) \mathcal{K}_2\left(\frac{z - Z_t}{h}\right)}{\sum_{t=1}^{T} \mathcal{K}_2\left(\frac{z - Z_t}{h}\right)},$$

where $\tilde{\mathcal{K}}_1$ is the integral of a kernel $\mathcal{K}_1$. Gaussian kernels and Silverman's bandwidth are used. Bid increments are ignored, so the transaction price is the second-highest of N values, and $\hat{F}_V(v \mid z) = \Lambda^{-1}_{N-1:N}\left(\hat{F}_{P|Z=z}(v)\right)$ (his eq. (2), our (15.1)). By Proposition 15.55, this inversion is valid for v at or above the reserve, and only if unsold auctions enter $\hat{F}_{P|Z}$ as described in Step 4. Roberts does not treat the reserve as a censoring point. Since about four of the roughly five bidders per car bid above the reserve, the censoring mainly affects the lower tail of the estimated value distribution. Consistency with a generated regressor follows from conditions in Matzkin (2003). Roberts pools months with similar numbers of unique bidders, whose average is 62.6. He drops auctions with more than eight bidders, which keeps over 92 percent of them, and sets $N = 8$. The restricted sample has 454 Sonatas, with mean winning bid \$3,574.38, mean reserve \$3,320.22, mean age 84.10 months and 4.83 unique bids per car (Table 5). In this sample the adjusted R^2 of the log winning bid rises from 0.773 to 0.971 with the reserve, and the residual correlation is 0.9343 against a raw 0.9835.

Results. Figure 15.18 shows estimated value distributions for a seven-year-old Sonata with 100,000 km. Ignoring heterogeneity produces a much more dispersed distribution. Controlling for it, the distributions at the 10th, 50th and 90th percentiles of ω are ordered by first-order stochastic dominance. Their means are \$1,919.61, \$2,426.20 and \$2,971.17, with bootstrap 95 percent intervals [1,904.37, 1,937.11], [2,406.88, 2,448.65] and [2,946.99, 2,999.08] (p. 22). With $N = 7$ the means are \$2,168.82, \$2,542.19 and \$3,146.35, and with $N = 9$ they are \$1,871.81, \$2,326.22 and \$2,788.02 (footnote 9). A parametric alternative with lognormal values and a Poisson number of bidders gives \$1,758.45, \$2,184.41 and \$2,864.57, with an estimated mean of 8.84 bidders (footnote 10).

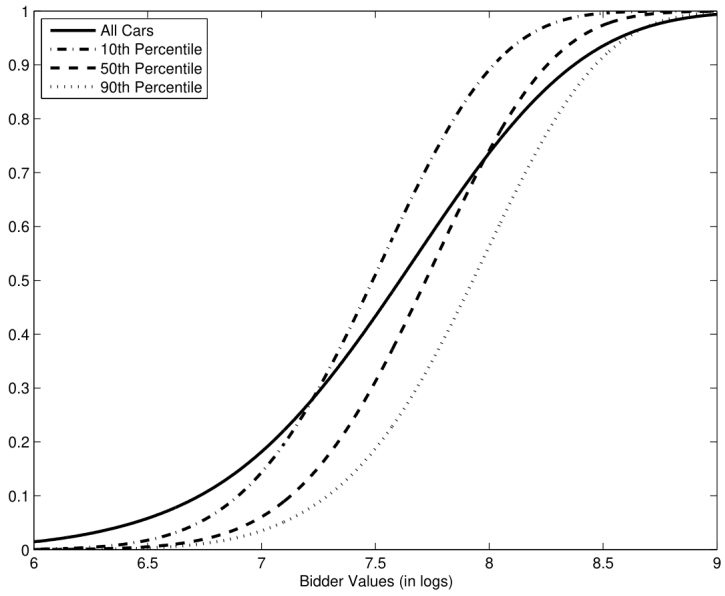

Figure 15.18: Estimated value distributions (log values) for seven-year-old automatic Hyundai Sonatas with 100,000 km. Solid line: ignoring unobserved heterogeneity. Other lines: controlling for it at the 10th, 50th and 90th percentiles of ω. Source: Roberts (2013), Figure 1 (June 2013 working-paper version).

Counterfactuals. Roberts asks how much of the attainable value sellers capture and through which channels. He sets the seller's value to $v_0 = \gamma r$ for $\gamma \in \{0, 0.25, 0.5, 0.75\}$ and simulates revenues with $N = 8$. Table 15.19 reproduces his Table 6. Ignoring heterogeneity overstates the dispersion of values and pushes the estimated optimal reserve up. A sufficient condition is hazard rate dominance. Let λ_C and λ_{NC} be the hazard rates of the value distributions estimated with and without the control, and suppose $\lambda_C(r) > \lambda_{NC}(r)$ for all r. The optimal reserve with the control solves $r_C = v_0 + \frac{1}{\lambda_C(r_C)} < v_0 + \frac{1}{\lambda_{NC}(r_C)}$, so $\psi_{NC}(r_C) < v_0$. Regularity then gives $r_{NC} > r_C$ (Roberts, 2013, footnote 13). With actual reserves, the mean seller captures between 88.42 and 92.23 percent of the value of the optimal auction with the same bidders, depending on γ. Using the "optimal" reserves computed while ignoring heterogeneity would lower the mean share to between 85.53 and 88.93 percent. The text summarizes the first result as "around 94%" (p. 25), above every mean and median in the table. The figure is close to the 90th-percentile column, 93.08 to 94.51 percent. The text also says that 90 percent of sellers achieve more than 83 percent, which matches the 10th percentile of 83.69 at $\gamma = 0$.

Table 15.20 reproduces Table 7, which decomposes the value of the platform with $\gamma = 0$. Let π_r^N denote revenue with N bidders and reserve r. The first row is the gain $\pi_{r=r^*}^{N+1} - \pi_{r=0}^{N}$ from one more bidder together with an optimal reserve. The next rows split the gain into the extra bidder, $\pi_{r=0}^{N+1} - \pi_{r=0}^{N}$, and the reserve, $\pi_{r=r^*}^{N+1} - \pi_{r=0}^{N+1}$. The extra bidder dominates, as the theorem of Bulow and Klemperer (1996) suggests (Proposition 14.48). With four bidders, the extra bidder is worth $\frac{94.49}{5.51} \approx 17.1$ times as much as the optimal reserve when heterogeneity is controlled for, and $\frac{81.89}{18.11} \approx 4.5$ times as much when it is not. With five bidders the ratios are 26.1 and 5.1. The text reports 17.5 and 4.6 "when there are five bidders" (p. 26), close to our ratios for $N = 4$, where the extra bidder makes five. Ignoring heterogeneity overstates the role of reserves and understates the role of competition.

Assessment. Roberts showed that seller behavior can carry information about what the

Table 15.19: Optimal reserve prices and the share of value captured by sellers (Roberts 2013, Table 6)

	Difference in optimal reserve		Actual reserves (%)				Reserves ignoring UH (%)

Notes. $v_0 = \gamma r$, with r the observed reserve. "Overall" is the average difference across all cars, and "Median" the average for cars with ω within half a standard deviation of its median. The paper's column header, and its definition on p. 24, write the difference as $R^*_C - R^*_{NC}$. The table note describes it as the optimal reserve ignoring heterogeneity minus the optimal reserve controlling for it. The text and its footnote 13 say that ignoring heterogeneity raises the optimal reserve. The positive entries agree with the note, which we follow. The remaining columns give the percentage of the value of the optimal auction captured with actual reserves and with the "optimal" reserves that ignore heterogeneity. Bootstrap standard errors (100 repetitions) in parentheses, in percentage points for percentages.

Table 15.20: Channels through which sellers gain from the auction house (Roberts 2013, Table 7)

N	2	3	4	5	6	7
Controlling for unobserved heterogeneity

Notes. $\gamma = 0$. Shares are $\frac{\pi^{N+1}_{r=0} - \pi^N_{r=0}}{\pi^{N+1}_{r=r^*} - \pi^N_{r=0}}$ and $\frac{\pi^{N+1}_{r=r^*} - \pi^{N+1}_{r=0}}{\pi^{N+1}_{r=r^*} - \pi^N_{r=0}}$. Revenues from 10,000 simulations. Bootstrap standard errors (100 repetitions) in parentheses, in percentage points for percentages.

econometrician misses. The method needs only transaction and reserve prices, and it lets values depend on ω without separability. Its requirements are strong in other directions. Heterogeneity must be scalar and enter both the reserve and the bids. The seller may have no private information that bidders value, and the reserve may respond to nothing that bidders ignore. All sellers must use one reserve rule, which the auction house's guidance makes plausible. Bidders must be symmetric, and the number of potential bidders must be assumed. The estimates of the reserve function are parametric. Within these limits, the paper adds the seller as a second source of information about unobserved quality, and it measures the Bulow-Klemperer comparison in a real market.

15.7.6 Comparing the approaches

Table 15.21 summarizes the approaches. They differ in the data they demand and in the restrictions they place on how heterogeneity enters. The number of bidders can itself serve as a control when it is a sufficient statistic for the heterogeneity (Campo et al., 2003, Section 3.2). It can also serve as an instrument when participation depends on an excluded variable (Haile et al., 2003), as discussed in Section 15.6.

Table 15.21: Approaches to unobserved auction heterogeneity

Approach	Data required	Restrictions	What is identified	Practical cost
Homogenization (Section 15.7.2)	Bids and observed covariates	All heterogeneity observed. Separable covariate effect	$F_V(\cdot \mid z)$ and the covariate effect g_0	Low
Deconvolution (Krasnokutskaya, 2011)	At least two bids per auction, bidder types	Scalar ω, separable. Components ω and A_i mutually independent	F_ω and each F_k, not realizations	High: cell by cell, slow rates
Parametric mixture (Athey et al., 2011)	All bids	Parametric bid laws. Heterogeneity ω independent of covariates	Parameters, then $F_k(\cdot \mid \omega)$ for any ω	Moderate
Reserve-price control (Roberts, 2013)	Transaction and reserve prices	Reserve strictly increasing in scalar ω. No seller private information	m, F_ω, realizations of ω, $F_V(\cdot \mid z, \omega)$ above the reserve	Moderate. N assumed
n as control or instrument (Campo et al., 2003; Haile et al., 2003)	Bids, n, excluded shifters of participation	n sufficient for ω, or monotone in it	Value distributions given the control	Moderate
Three bids (Hu et al., 2013)	At least three bids per auction	Heterogeneity may enter values nonseparably	Model primitives with nonseparable heterogeneity	High

15.8 Entry, Participation, Dynamics and Risk Aversion

The identification results so far treat the set of bidders as given, each auction as a separate game, and bidders as risk neutral. This section relaxes each assumption in turn. The theory of entry is in Section 14.11, and the timber application, where entry costs are estimated, is in Section 15.9.

15.8.1 Potential and actual bidders

Following Athey and Haile (2007, Section 6.3), let $\mathcal{N}$, with $|\mathcal{N}| = N$, be the set of potential bidders, those who draw signals and decide whether to bid. Let $\mathcal{A} \subseteq \mathcal{N}$, with $|\mathcal{A}| = n$, be the set of actual bidders, those who place a bid. These are the objects of Section 15.4.7, now written as sets. Both sets can vary across auctions. The set of potential bidders varies when acquiring a signal is costly. The set of actual bidders varies, for a given $\mathcal{N}$, when a reserve price binds or bidding is costly. The consequences for equilibrium and for identification depend on two questions. Do bidders know who participates? Does the econometrician observe $\mathcal{N}$, $\mathcal{A}$, or only n?

15.8.2 Selection by a reserve price or a bid cost

A binding reserve price selects bidders with values above r. In ascending auctions with independent private values, participants' values are draws from the truncated distribution, and observing $\mathcal{N}$ restores F_V above r (Proposition 15.13). In first-price auctions, the inversion with a reserve and an unknown number of potential bidders is (15.24) (Theorem 15.27). Athey and Haile (2007, Section 6.3.1) extend the first-price results to private values with correlation. Suppose bidders do not know $\mathcal{A}$ when they bid, which is natural because participation depends on private information. The distribution of the highest rival bid then mixes over the possible participant sets,

$$G_{M_i|B_i}(m \mid b; \mathcal{N}) = \mathbb{P}\big(\mathcal{A} = \{i\} \mid i \in \mathcal{A}, B_i = b\big) + \sum_{\mathcal{A}' \ni i,\, |\mathcal{A}'|>1} \mathbb{P}\Big(\mathcal{A} = \mathcal{A}',\ \max_{k \in \mathcal{A}', k \neq i} B_k \leq m \,\Big|\, B_i = b\Big).$$

Each piece is observable, so the first-order condition (14.68) still maps each bid to a value. Two results follow (Athey and Haile, 2007, Theorems 6.4–6.5). First, for each $\mathcal{A}$, the joint distribution of values of participants above r is identified from r, all bids and bidder identities. Second, each marginal $F_{V_i}(v)$ is identified for $v \geq r$, since $F_{V_i}(r) = \mathbb{P}(i \notin \mathcal{A})$ is observed when $\mathcal{N}$ is. Nothing can be learned about correlation among values below r. A cost of preparing a bid acts like a reserve price, since only bidders with high enough values bid (Athey and Haile, 2007, footnote 60, citing Samuelson, 1985 and Haile et al., 2003).

15.8.3 Costly signal acquisition and the entry cost

In the model of Levin and Smith (1994), firms pay K to learn their values and then bid (Section 14.11). In the symmetric equilibrium firms randomize, so the set of entrants $\tilde{\mathcal{N}}$ varies exogenously. Entrants learn who else entered before bidding. If the reserve price lies below every value, it binds only when a single firm enters, and that firm bids the reserve. The randomization is useful twice. It creates exogenous variation in the number of bidders, which the tests of Section 15.6 require. It also identifies the entry cost.

Proposition 15.56 (Entry costs, Athey and Haile, 2007, Section 6.3.2)**.** *Suppose entry generates exogenous variation in $\tilde{\mathcal{N}}$ and the reserve lies below the support of values. Suppose the econometrician observes the entrants and all their bids. Under IPV the winning bid suffices.*

(i) Each entrant's expected gross profit $\pi_i(\mathcal{A})$ in (14.105) is identified for every participant set $\mathcal{A}$ with $|\mathcal{A}| \geq 2$ that occurs with positive probability.

(ii) For any firm that randomizes, the entry cost is identified by (14.104), $K = \sum_{\mathcal{A} \ni i} \mathbb{P}\big(\tilde{\mathcal{N}} = \mathcal{A} \mid i \in \tilde{\mathcal{N}}\big)\, \pi_i(\mathcal{A})$.

In the symmetric IPV first-price auction with n entrants,

$$\pi(n) = \mathbb{E}_B\Big[\frac{G_n(B)^n}{(n-1)\,g_n(B)}\Big], \qquad \hat{\pi}(n) = \frac{1}{nT_n}\sum_{t:\,n_t=n}\sum_{i=1}^{n}\frac{\hat{G}_n(b_{it})^n}{(n-1)\,\hat{g}_n(b_{it})}, \tag{15.61}$$

where G_n and g_n are the bid distribution and density in n-bidder auctions.

Proof. (i) Exogenous variation in $\tilde{\mathcal{N}}$ means that bids in auctions with participant set $\mathcal{A}$ are equilibrium bids for that set. The first-order condition identifies the value behind each bid (Sections 15.4 and 15.5). Then $\pi_i(\mathcal{A})$ is the expectation, over i's bids, of the margin times the probability of winning, both functions of observables. (ii) A firm that randomizes is indifferent, so its expected gross profit from entry equals K. The probabilities of each participant set are observed. For the formula, a bidder who bids b against $n-1$ symmetric rivals wins with probability $G_n(b)^{n-1}$ and has margin $\xi(b) - b = \frac{G_n(b)}{(n-1)g_n(b)}$ by (15.9). Its expected profit is

$$\big(\xi(b)-b\big)G_n(b)^{n-1} = \frac{G_n(b)}{(n-1)g_n(b)}\,G_n(b)^{n-1} = \frac{G_n(b)^n}{(n-1)g_n(b)}.$$

Averaging over the bid distribution gives (15.61). The sample analogue replaces G_n and g_n by the GPV estimates. □

Example 15.57 (Recovering the entry cost)**.** Take uniform values on $[0,1]$ and no reserve. In n-bidder auctions bids are uniform on $[0,c]$ with $c = \frac{n-1}{n}$, so $G_n(b) = \frac{b}{c}$ and $g_n = \frac{1}{c}$. Then

$$\pi(n) = \int_0^c \Big(\frac{b}{c}\Big)^n \frac{c}{n-1}\,\frac{db}{c} = \frac{c}{n-1}\int_0^1 u^n\,du = \frac{c}{(n-1)(n+1)} = \frac{1}{n(n+1)},$$

which matches Lemma 14.79. A lone entrant pays the reserve and earns $\pi(1) = \mathbb{E}[V] = \frac{1}{2}$, where $\mathbb{E}[V]$ is identified from bids in auctions with two or more entrants. Suppose there are $N = 5$ potential entrants and the observed entry probability is 0.816. The number of rival entrants is binomial, so $K = \sum_{n=1}^{5}\binom{4}{n-1}0.816^{n-1}0.184^{5-n}\pi(n) = 0.050$. This inverts the forward calculation of Example 14.82.

The entry cost is identified in dollars. Entry models that draw inferences solely from entry decisions cannot recover the level of entry costs in this way. In auctions the bids reveal post-entry profits, so the level of K is identified (Athey and Haile, 2007, Section 6.3.2). With asymmetric bidders there can be several type-symmetric entry equilibria. Since the estimated $\pi_i(\mathcal{A})$ do not depend on the equilibrium selected, all equilibria of the entry game can be computed for given entry costs. Their number can thus be checked in the data, as Athey et al. (2011) do (Proposition 14.84, Section 15.9). Entry may also be selective. In the model of Samuelson (1985), firms know their values before they decide to enter, so only firms with high values pay K. More generally, firm i observes a signal S_i of its value V_i before entry and enters when S_i exceeds a threshold $\bar{s}$. In a symmetric equilibrium the threshold makes the marginal entrant indifferent,

$$\mathbb{E}\big[\pi(V_i;\tilde{\mathcal{N}}) \mid S_i = \bar{s}\big] = K,$$

where $\pi(V_i;\tilde{\mathcal{N}})$ is the post-entry profit of a firm with value V_i when the set of entrants is $\tilde{\mathcal{N}}$. The model of Levin and Smith (1994) is the case in which S_i is independent of V_i, and that of Samuelson (1985) the case $S_i = V_i$ (Hortaçsu and Perrigne, 2021, p. 92, footnote 9). With selective entry the bids of entrants reveal the distribution of values conditional on entry, not

the distribution in the population of potential bidders. Identification then rests on exogenous variation in the number of potential bidders or in entry costs (Marmer et al., 2013; Gentry and Li, 2014; Roberts and Sweeting, 2013). Gentry and Li (2014) give conditions under which models of selective entry are identified (Hortaçsu and Perrigne, 2021, footnote 8).

Estimates of entry costs. Table 15.22 collects entry-cost estimates from timber and procurement auctions, as summarized by Hortaçsu and Perrigne (2021, Sections 2.2, 2.6.3, 3.3 and 3.10). The estimates are small relative to the value of the objects sold, but they matter for policy because participation responds to them. Athey et al. (2011) find median logger entry costs of \$2,870 in the Northern forests and \$5,056 in California (Section 15.9). Their benchmark is the median expected profit of a mill in a sealed sale, about \$45,000 gross of entry costs (their footnote 26). The logger entry costs are thus $\frac{2,870}{45,000} \approx 6.4$ and $\frac{5,056}{45,000} \approx 11.2$ percent of that profit, the ratios that Hortaçsu and Perrigne (2021, p. 91) report. Because loggers randomize their entry, a logger's entry cost equals its own expected gross profit from entry by construction. The informative benchmark is therefore the profit of the stronger bidders, the mills, who always enter. Li and Zheng (2012) estimate both entry models on first-price timber sales of the Michigan Department of Natural Resources (p. 91). The entry cost means different things in the two models. Under selective entry it is a cost of preparing a bid, while under the Levin-Smith model it also covers learning one's value. The models also differ in their reserve-price advice. Under selective entry the optimal reserve solves the usual condition (14.51), while under the Levin-Smith model it equals the seller's value, as in Proposition 14.81. The entry cost is about 6.8 percent of a bidder's value under selective entry and 9.5 percent under the Levin-Smith model. A Bayes factor, the ratio of the marginal likelihoods of the two estimated models, favors selective entry.

Li and Zhang (2015) add affiliated private values and asymmetries in values and entry costs that arise from the distance between a bidder and the tract (pp. 91–92). They parameterize the joint distributions with copulas and solve the asymmetric auctions numerically. In sealed-bid sales of the Oregon Department of Forestry, values show little dependence and entry costs show more. Their merger counterfactual shows that entry matters for policy. Ignoring entry, a merger of two bidders lowers the welfare of the merging bidders and the payoff of the others, whichever pair merges. With entry, the merging bidders gain when the two bidders with the largest hauling distances merge, and they lose slightly when the two closest bidders merge. The effects on the other bidders go the opposite way.

Roberts and Sweeting (2016) study the 1984 federal buyout of timber contracts that firms had bought at the prices of the late-1970s timber boom and could no longer afford (p. 92). Their model nests both entry models. Each firm sees a noisy signal of its value, enters above a threshold signal, and then bids in a second-price auction. To avoid multiple equilibria, mills and loggers share the signal distribution and the entry cost, and their value distributions differ only in the mean. Entry is selective to a moderate degree, and mills have higher values. The entry cost is 2.7 percent of the bid on average. Without the bailed-out firms, revenue would have been 11.1 percent lower, because most of them were high-value mills and values are dispersed. A Levin-Smith model would instead predict higher revenue after the exit of an entrant. An additional bidder is worth more to the seller than an optimal reserve price, as the result of Bulow and Klemperer (1996) suggests (Proposition 14.48).

Procurement auctions show similar magnitudes. In highway mowing contracts of the Texas Department of Transportation, only 28 percent of planholders bid (Li and Zheng, 2009). The Levin-Smith model fits better than the selective model by a mean squared error criterion (Hortaçsu and Perrigne, 2021, p. 105). More planholders affect bids through a positive entry effect and a negative competition effect. The total effect on bids is negative when competition

Table 15.22: Estimated entry costs in auction studies (as summarized by Hortacsu and Perrigne 2021)

Study	Auctions	Entry model	Entry cost
Athey et al. (2011)	USFS timber, North and California	Levin-Smith, asymmetric	Logger entry cost: 6.4% and 11.2% of the median mill profit
Li and Zheng (2012)	Michigan DNR timber, first-price	Samuelson and Levin-Smith	6.8% (selective) and 9.5% (nonselective) of value
Roberts and Sweeting (2016)	USFS timber, 1980s	Signals, nests both	2.7% of the bid
Roberts and Sweeting (2013)	USFS timber, ascending	Signals, selective	2% of the average winning bid
Li and Zheng (2009)	Texas DOT highway mowing	Levin-Smith preferred	14% of the cost estimate, 8% of the winning bid
Krasnokutskaya and Seim (2011)	California highway procurement	Levin-Smith, asymmetric	2.2–3.9% (small firms), 3.1–3.3% (large firms) of the estimate

Notes. Entry costs as fractions of the quantity named in the last column. USFS: United States Forest Service. DNR: Department of Natural Resources. DOT: Department of Transportation. Sources are the summaries of Hortaçsu and Perrigne (2021, pp. 91, 92, 100, 105 and 123), except the ratios for Athey et al. (2011), which we recompute from their p. 246 and footnote 26.

is low and positive when it is high. The authors conclude that encouraging more potential bidders is not a desirable policy for the agency.

15.8.4 Bidders uncertain about the competition

In sealed-bid auctions, bidders may not know how many rivals they face. In second-price auctions this does not affect private values bidding. With common values it does, and Athey and Haile (2002, Theorem 12) show that the test of private against common values in Section 15.6 survives. Suppose bidders do not know n. They observe instead a public signal η, unobserved by the econometrician, that is strictly affiliated with n. The symmetric private values model remains testable against symmetric common values from transaction prices in m-bidder auctions and bids $B^{(m-1:n)}, \dots, B^{(n-1:n)}$ in auctions with $n > m$ bidders.

In first-price auctions uncertainty about n changes bidding even with private values. Suppose η is observed by the econometrician as well, and let $\tilde{\pi}(n \mid \eta)$ be the probability of n bidders given η. The first-order condition is (15.56) with the rival-bid distribution mixed over n (Athey and Haile, 2002, eq. (22)). Fixing η, the winning bid satisfies (Athey and Haile, 2002, eq. (23))

$$\mathbb{P}\big(B^{\text{win}} \le b \mid \eta\big) = \sum_{n \ge 2} \tilde{\pi}(n \mid \eta)\, \mathbb{P}(B_i \le b \mid \eta)^n .$$

The right side is strictly increasing in $\mathbb{P}(B_i \le b \mid \eta)$, and $\tilde{\pi}(n \mid \eta)$ is observed. The winning-bid distribution therefore identifies $\mathbb{P}(B_i \le b \mid \eta)$, hence the rival-bid distribution, and then F_V through the first-order condition. If η is unobserved by the econometrician, the problem becomes one of unobserved heterogeneity (Section 15.7).

When bidders know nothing about the realized set of entrants, the rival-bid distribution $G_{M_i|B_i}$ averages over entrant sets and does not depend on the realized $\mathcal{N}$ (Athey and Haile, 2007, eqs. (6.21)–(6.22)). The two informational assumptions have testable implications. If

bidders know $\mathcal{N}$, a lone entrant bids the reserve price with probability one. If they do not, the distribution of a bidder's bid does not vary with the realized $\mathcal{N}$.

Internet auctions raise a related problem. Bidders arrive at different times, and some never bid because the price already exceeds their value. The number of bidders is then unobserved, which defeats the inversion of Section 15.2. Song (2004) shows that two order statistics suffice, as summarized by Athey and Haile (2007, Lemma 6.2). Let $Y^{(N:N)}$, $Y^{(N-1:N)}$ and $Y^{(N-2:N)}$ be the three highest of $N \geq 3$ independent draws from F_Y, with N random and unobserved. Then F_Y is determined by the joint law of $\left(Y^{(N-1:N)}, Y^{(N-2:N)}\right)$. Given $Y^{(N-2:N)} = y_0$, the two highest draws are an i.i.d. sample of two from the truncated distribution $\frac{F_Y(\cdot)-F_Y(y_0)}{1-F_Y(y_0)}$, whatever N is. The lower of two draws identifies its parent (Theorem 15.4), and letting y_0 fall to the bottom of its support recovers F_Y. With eBay data, the method uses auctions whose bidding histories make it nearly certain that the second- and third-highest submitted bids equal the corresponding values (Athey and Haile, 2007, Section 6.3.4).

15.8.5 Dynamics and capacity: Jofre-Bonet and Pesendorfer (2003)

Question and model

Highway paving contractors bid repeatedly, and a contract won today ties up machines and crews for months. Jofre-Bonet and Pesendorfer (2003), henceforth JBP, ask how such capacity constraints shape bidding, costs and efficiency. They develop an estimator for a dynamic auction game that never solves for an equilibrium. Their abstract states the finding. In this market "previously won uncompleted contracts reduce the probability of winning further contracts."

Time is discrete with an infinite horizon (JBP, Section 2). In each period one contract with characteristics s_0, drawn i.i.d., is let by first-price sealed bid. There are n_r *regular* bidders who stay forever and a varying number of *fringe* bidders who live one period. Regular bidder i's state s_i lists the remaining size and time to completion of each project it won recently, and $s = (s_1, \ldots, s_{n_r})$. After s_0 is revealed, each bidder learns its cost privately. Costs are independent across bidders conditional on states, with distribution $F(\cdot \mid s_0, s_i, s_{-i})$. There is a public reserve price r and a secret reserve price drawn from a known distribution, which acts like one more rival bid. The state moves deterministically, $s' = \mathcal{T}(s_0, s, j)$, where j is the identity of the winner and $j = 0$ means no award. Bidders discount the future with factor δ, which in this subsection is a discount factor and not a mean utility. The solution concept is a Markov perfect equilibrium in strategies $b(c, s_0, s_i, s_{-i})$ that are symmetric conditional on states.

Bidder i's ex ante value function, which we write $\mathcal{V}_i$ to keep it apart from the values V_{it}, satisfies (JBP, eq. (2.1))

$$\mathcal{V}_i(s) = \mathbb{E}_{s_0} \int \max_b \left\{ (b-c)\mathbb{P}(i \text{ wins} \mid b) + \delta \sum_{j=0}^{n} \mathbb{P}(j \text{ wins} \mid b)\, \mathcal{V}_i\big(\mathcal{T}(s_0, s, j)\big) \right\} f(c \mid s_0, s_i, s_{-i})\, dc. \tag{15.62}$$

The first-order condition

Write G_j and g_j for the distribution and density of rival j's bid given the state, including fringe bidders and the secret reserve. Let $h_j = \frac{g_j}{1-G_j}$ be its hazard and $H_i(b) = \sum_{j \neq i} h_j(b)$. Bidder i wins

with probability $P_i(b) = \prod_{j\neq i}\big(1 - G_j(b)\big)$. Rival j wins when bidder i bids b if j's bid lies below b and below every other rival's bid. This has probability $P_j(b) = \int_{\underline{b}}^{b} g_j(x)\prod_{l\neq i,j}\big(1 - G_l(x)\big)dx$, where $\underline{b}$ is the lower end of the bid support. The derivatives are

$$P_i'(b) = -P_i(b)H_i(b), \qquad P_j'(b) = g_j(b)\prod_{l\neq i,j}\big(1 - G_l(b)\big) = P_i(b)\,h_j(b),$$

so that $P_i' + \sum_{j\neq i} P_j' = 0$, as it must be because someone always wins. Differentiating the objective in (15.62) with respect to b and writing $\mathcal{V}_i^j = \mathcal{V}_i(\mathcal{T}(s_0, s, j))$,

$$P_i(b) + (b - c)P_i'(b) + \delta\Big[P_i'(b)\mathcal{V}_i^i + \sum_{j\neq i} P_j'(b)\mathcal{V}_i^j\Big] = 0.$$

Substitute the derivatives and divide by $P_i(b)$:

$$1 - (b - c)H_i(b) - \delta\sum_{j\neq i} h_j(b)\big[\mathcal{V}_i^i - \mathcal{V}_i^j\big] = 0.$$

Solving for the cost gives the inverse bid function (JBP, eq. (3.1)),

$$c = \xi_i(b) \equiv b - \frac{1}{H_i(b)} - \delta\sum_{j\neq i}\frac{h_j(b)}{H_i(b)}\Big[\mathcal{V}_i\big(\mathcal{T}(s_0, s, j)\big) - \mathcal{V}_i\big(\mathcal{T}(s_0, s, i)\big)\Big]. \tag{15.63}$$

The markdown has two parts. The first, $\frac{1}{H_i(b)}$, is the static markdown of Section 14.13. The second is the loss in future value from winning today rather than letting rival j win, weighted by j's share of the hazard. With capacity constraints, winning raises backlog and lowers continuation value, so the second term raises the bid above its static level. For fringe bidders $\mathcal{V} = 0$ and the condition is static. At the reserve the first term vanishes, but the second does not, so a regular bid need not equal cost there.

The value function in terms of bids

The key step expresses $\mathcal{V}_i$ through bid distributions alone. Substitute the first-order condition into (15.62). The margin times the win probability plus the term in $\mathcal{V}_i^i$ is

$$(b - c)P_i + \delta P_i\mathcal{V}_i^i = \frac{P_i}{H_i} + \delta P_i\sum_{j\neq i}\frac{h_j}{H_i}\big(\mathcal{V}_i^j - \mathcal{V}_i^i\big) + \delta P_i\mathcal{V}_i^i = \frac{P_i}{H_i} + \delta\sum_{j\neq i} P_i\frac{h_j}{H_i}\mathcal{V}_i^j,$$

using $\sum_{j\neq i}\frac{h_j}{H_i} = 1$. Change the variable of integration from the cost to bidder i's bid, so that $f(c)\,dc = dG_i(b)$. Write $dG^{(i)}(b) = P_i(b)\,dG_i(b)$ for the probability that i wins with a bid near b. Then (JBP, Proposition 1)

$$\mathcal{V}_i(s) = \mathbb{E}_{s_0}\Big[\int\frac{1}{H_i(b)}\,dG^{(i)}(b) + \delta\sum_{j\neq i}\Big(\mathbb{P}(j\text{ wins}) + \int\frac{h_j(b)}{H_i(b)}\,dG^{(i)}(b)\Big)\mathcal{V}_i\big(\mathcal{T}(s_0, s, j)\big)\Big], \tag{15.64}$$

where $\mathbb{P}(j\text{ wins}) = \int P_j(b)\,dG_i(b)$. The weights in parentheses sum to one over j, since $\sum_{j\neq i}\int\frac{h_j}{H_i}dG^{(i)} = \mathbb{P}(i\text{ wins})$. JBP write the second integral as $\int\frac{h_i}{H_i}\,dG^{(j)}$, which is the same object

because $P_i h_j g_i = h_i\, g_j \prod_{l \neq j}(1 - G_l)$. Equation (15.64) is linear in the vector of values on a grid of states. With $m_i(s)$ the first term and $Q_{ij}(s)$ the transition weights, $\boldsymbol{\mathcal{V}}_i = \boldsymbol{m}_i + \delta \sum_{j \neq i} \boldsymbol{Q}_{ij} \boldsymbol{\mathcal{V}}_i$, so $\boldsymbol{\mathcal{V}}_i = (\boldsymbol{I} - \delta \boldsymbol{Q}_i)^{-1} \boldsymbol{m}_i$ with $\boldsymbol{Q}_i = \sum_{j \neq i} \boldsymbol{Q}_{ij}$ (JBP, eq. (3.3)). This is the GPV idea extended to dynamics. Bid distributions summarize beliefs, so the first-order condition and the value function follow without solving the game.

Identification and estimation

Given δ, the cost distribution is identified on the interval from the bottom of its support to $\xi_i(r)$, the cost at which bidding the reserve is optimal. The pair (δ, F) is not identified (JBP, Proposition 2). The non-identification of the discount factor parallels single-agent dynamic models. Estimation is parametric (JBP, Section 3.3). For regular bidders, $\ln(b + 1)$ has a Weibull density with a lower endpoint common to all bidders. Its scale depends on states and contract characteristics through symmetric functions of rivals' characteristics. Fringe bids have a beta density on the interval from the lower bound to r. Regular bids are observed only below r, so the likelihood is

$$\mathcal{L} = \prod_t \left[\prod_{i=1}^{n_r} g(b_{it} \mid \theta_{it})^{o_{it}} \left(1 - G(r_t \mid \theta_{it})\right)^{1 - o_{it}} \prod_{j=n_r+1}^{n_t} g_f(b_{jt} \mid \theta_t) \right],$$

with $o_{it} = 1$ if regular bidder i bids in auction t. The value function is computed on 50 states drawn from the observed states, with expectations over 50 contracts drawn from the data and a quadratic approximation off the grid. Costs follow from (15.63), and $F(c \mid \cdot) = G\big(\xi^{-1}(c) \mid \cdot\big)$.

Data and reduced-form evidence

The data are California Department of Transportation highway contracts with bids from May 1996 to May 1999 (JBP, Section 4). Of 2,566 advertised projects, 2,207 were awarded, 343 were cancelled or postponed, and 16 drew no bids. The awarded contracts were worth $4,661.73 million in total. They drew 10,289 bids, 4.63 per contract on average, and 1,466 bids that violated the reserve were dropped. The regular bidders are the 10 largest firms by dollar value won with at least 80 bids. They win 25 percent of the dollar value and 17 percent of contracts. *Backlog* is the dollar value of uncompleted work from contracts won earlier, standardized by each firm's mean and standard deviation. As the number of bidders rises from 1 to 9 or more, the low bid moves from 11 percent above the engineer's estimate to 14 percent below it (JBP, Table II).

Reduced-form regressions on 22,230 bidder-contract observations point to capacity constraints (JBP, Table III). In a probit of bid submission, the backlog coefficient is −0.0835 (standard error 0.015). In Tobit and Heckman regressions of $\ln\left(1 + \frac{r - \text{bid}}{\text{estimate}}\right)$, where a negative sign means a higher bid, it is −0.0383 (0.007) and −0.0127 (0.004). These are the specifications without firm effects. A constrained bidder is about 50 percent less likely to bid than an unconstrained one. Raising backlog from −1 to 1 raises the bid by 2.5 to 7.6 percent (JBP, p. 1466). Distance to the project discourages bidding and raises bids, with probit and Tobit coefficients of −0.5193 (0.023) and −0.2536 (0.012).

Results

The parametric bid distributions fit the fringe bids closely. Predicted fringe bids average 78.01 percent of the reserve with standard deviation 11.71, against 77.72 and 11.53 in the data. The

predicted probability of a regular bid is 5.97 percent against 5.96 percent. Predicted regular bids are somewhat too high, 82.36 against 79.03 percent of the reserve (JBP, pp. 1471–1474). Bids of a bidder with backlog 2 first-order stochastically dominate those at backlog −2, and unconstrained bidders are about twice as likely to bid.

The authors impose an annual discount factor of 0.8, with a contract offered about every 12 hours. The average discounted value of bidder 3 is $25 million, and other regular bidders range from $7 million to $73 million. Raising the discount factor to 0.9 roughly doubles these values. Backlog lowers bidder 3's value by about 35 percent over the range shown. For the average bidder, the value is about 39 percent higher at backlog −2 than at backlog 2 (JBP, pp. 1477–1478).

Markups are large. The median markup of bidder 3 is 26.0 percent of the bid and the mean 35.6 percent. Across all regular bids the median is 32.6 percent and the mean 40.3 percent. The dynamic term in (15.63) accounts for 64.2 percent of bidder 3's markup and 55.9 percent across regular bidders. With $\delta = 0.9$, the median markup across regular bids rises to 45.9 percent and the dynamic share to 69.8 percent (JBP, pp. 1479–1480). Capacity matters for the buyer as well. When every regular bidder's backlog is −2 the average price is $539,845, against $657,016 at backlog 2, a difference of about 18 percent (JBP, p. 1481). Moving from backlog 2 to −2 requires a 114 percent increase in regular bidders' capacity.

Table 15.23 reproduces the efficiency analysis. For each observed contract, the authors compare the winner with the firm that minimizes the current cost plus the discounted expected future cost. An inefficient firm wins 32 percent of the time. The average loss is 13 percent of the engineer's estimate, or $305,500 per contract (JBP, p. 1483). Nearly all of the loss comes from current costs, and inefficiency is about equally likely whether a regular or a fringe bidder wins.

Table 15.23: Estimated efficiency losses (Jofre-Bonet and Pesendorfer 2003, Table V)

	Engineer's estimate (thousands of dollars)					
	[0, 100]	(100, 400]	(400, 1000]	(1000, 5000]	> 5000	Overall
All contracts						
Number of contracts	49	893	525	545	184	2,196
Probability of an inefficiency	0.02	0.52	0.17	0.24	0.11	0.32
Average efficiency loss	0.04	0.08	0.14	0.17	0.19	0.13
Contracts won by a regular bidder						
Number of contracts	1	90	94	147	42	374
Probability of an inefficiency	0.00	0.20	0.55	0.38	0.27	0.36
Average efficiency loss	0.36	0.29	0.29	0.22	0.24	0.25
Contracts won by a fringe bidder						
Number of contracts	48	803	431	398	142	1,822
Probability of an inefficiency	0.02	0.56	0.08	0.19	0.06	0.31
Average efficiency loss	0.04	0.06	0.11	0.15	0.18	0.10

Notes. Efficiency losses as a fraction of the engineer's estimate. The benchmark selects, in the current auction only, the firm that minimizes current cost plus discounted expected future cost, with first-price auctions thereafter. This gives a lower bound on the efficiency loss.

Assessment

The paper's contribution is methodological. It showed that the two-step logic of Guerre et al. (2000) extends to dynamic games. Bid distributions estimated in a first step deliver both the continuation values and the costs, through a linear system and a first-order condition.

Computation is light because no equilibrium is ever solved. The authors relate the idea to Hotz and Miller (1993). Two-step estimators of dynamic oligopoly models later built on the same principle. Bajari et al. (2007) estimate policy functions and state transitions first and recover the structural parameters from equilibrium conditions second (p. 1331). They cite JBP as an analysis of repeated auctions built on first-order conditions, one of the techniques designed for continuous choices (p. 1333, footnote 5).

The results rest on assumptions that the data cannot test, as the authors stress. The discount factor is not identified, and the markup estimates move with it. Bid distributions are parametric. A Weibull-beta mixture fits regular bids better, but it violates the monotone bid hazard that the model requires, so the authors keep the Weibull (JBP, p. 1474). There is no unobserved heterogeneity, the mirror image of Krasnokutskaya's assumption of no dynamics. Strategies are symmetric conditional on states, which the evidence supports for most but not all firms. Inferred costs that would be negative at the bottom of the bid range are set to zero. Markups of a third of the bid are large, though the authors note that money left on the table averages 9 percent of the bid. Athey and Haile (2007, Section 9) place the paper among several sources of dynamics in auctions. These include tacit collusion in repeated auctions, private information that persists over time, learning by doing and capacity constraints. They note that the dynamics created by persistent private information had not been studied empirically, and they use this model to illustrate the case of capacity.

15.8.6 Risk aversion

Risk neutrality is natural when stakes are small relative to wealth, but many auctions involve large stakes (Athey and Haile, 2007, Section 6.4). In an ascending auction with private values, bidding one's value remains a dominant strategy under any risk preference. F_V is then identified whenever it is under risk neutrality, and risk preferences are not identified at all.

In a first-price auction risk aversion changes bids. With a common utility function $\mathcal{U}$, $\mathcal{U}(0) = 0$, and $\ell(s) = \frac{\mathcal{U}(s)}{\mathcal{U}'(s)}$ as in (14.38), the first-order condition is (14.39),

$$v = \xi(b; n, \ell) \equiv b + \ell^{-1}\Big(\frac{G(b)}{(n-1)\,g(b)}\Big) \tag{15.65}$$

(Athey and Haile, 2007, eqs. (6.24)–(6.25)). Campo et al. (2011) show that independent bids can be rationalized if and only if $\xi(\cdot; n, \ell)$ is increasing for some admissible ℓ (as summarized by Athey and Haile, 2007, Section 6.4.1, who cite the 2002 working paper). Risk aversion thus enlarges the set of bid distributions that equilibrium can explain. It also destroys identification with a single n. Take constant relative risk aversion (CRRA), $\mathcal{U}(x) = x^{1-\varsigma}$ with $0 \le \varsigma < 1$. Then $\ell(s) = \frac{s}{1-\varsigma}$ and $\ell^{-1}(z) = (1-\varsigma)z$. Suppose bids are rationalized by ς and values $V = \xi(B; n, \varsigma)$. For any $\tilde{\varsigma} \in (\varsigma, 1)$,

$$\xi(b; n, \tilde{\varsigma}) = b + (1-\tilde{\varsigma})\frac{G(b)}{(n-1)g(b)} = \frac{\tilde{\varsigma}-\varsigma}{1-\varsigma}\,b + \frac{1-\tilde{\varsigma}}{1-\varsigma}\,\xi(b; n, \varsigma),$$

a positive combination of two increasing functions. So $\tilde{\varsigma}$ rationalizes the same bids, with values $\tilde{V} = \xi(B; n, \tilde{\varsigma}) \le V$. More risk-averse bidders shade less, so the same bids correspond to lower values. Any degree of risk aversion above the smallest one that rationalizes the data fits equally well.

Identification needs exclusion restrictions or other data (Athey and Haile, 2007, Section 6.4). Exogenous variation in the number of bidders changes the lotteries bidders face without

changing values. Let $b_n(\alpha)$ be the α-quantile of bids in n-bidder auctions. Bid functions are strictly increasing, so $b_n(\alpha)$ is the bid of the α-quantile value $v(\alpha)$, and $G_n(b_n(\alpha)) = \alpha$. Writing $z_n(\alpha) = \frac{\alpha}{(n-1)\, g_n(b_n(\alpha))}$, (15.65) gives, for all n,

$$v(\alpha) = b_n(\alpha) + \ell^{-1}\big(z_n(\alpha)\big). \tag{15.66}$$

For two numbers of bidders $n_1 < n_2$, subtracting gives $b_{n_2}(\alpha) - b_{n_1}(\alpha) = \ell^{-1}\big(z_{n_1}(\alpha)\big) - \ell^{-1}\big(z_{n_2}(\alpha)\big)$ for every α. Tracing α over $(0,1)$ restricts ℓ^{-1} at many points, which is the basis of the identification result of Guerre et al. (2009). Under constant relative risk aversion,

$$1 - \varsigma = \frac{b_{n_2}(\alpha) - b_{n_1}(\alpha)}{z_{n_1}(\alpha) - z_{n_2}(\alpha)}$$

must hold with the same ς at every α, an overidentifying restriction (Athey and Haile, 2007, Section 6.4.1). Other routes exist. A bidder covariate that shifts wealth or the value of winning plays the same role. Campo et al. (2011) combine constant relative risk aversion with a parametric restriction at one quantile of the value distribution. If the value distribution is known from other data, such as ascending auctions with the same bidders, first-price bids identify the utility function directly (Athey and Haile, 2007, footnote 74). With asymmetric bid distributions, risk preferences that differ across bidders with a common value distribution can be identified from a few quantiles under a parametric family (Athey and Haile, 2007, Section 6.4.2).

Empirical magnitudes. Timber auctions have supplied most of the estimates (Hortaçsu and Perrigne, 2021, Section 2.4). Many sales are scale sales, in which bids are per unit of estimated volume but payments follow the harvested volume. The winner then bears volume risk, which makes risk preferences relevant (p. 94). Campo et al. (2011) estimate the semiparametric model on USFS first-price sales in the western United States. Utility is CRRA, and a parametric quantile restriction exploits variation in covariates and in the number of potential bidders. The estimated coefficient of relative risk aversion is 0.278, that is, $\varsigma = 0.278$ in the notation above (p. 95). Under CRRA, risk aversion acts like an increase in competition and lowers bidders' information rents. The simulated optimal reserve price is about 19 percent below the risk-neutral one. Bidding is already aggressive, so the seller needs a smaller reserve to extract rents.

Lu and Perrigne (2008) use the route of Athey and Haile (2007, footnote 74). Ascending sales identify the value distribution, because risk aversion does not affect bids there, and first-price sales then identify utility. With the same USFS data, they estimate a concave utility function that is neither CRRA nor constant absolute risk aversion (CARA), although CRRA fits better than CARA. They also find some dependence of values on the number of bidders (p. 95). Grundl and Zhu (2019) combine the deconvolution of Section 15.7.3 with the exclusion restriction of Guerre et al. (2009), in USFS sales from the Southern states (pp. 95–96). Allowing for unobserved heterogeneity, they find risk neutrality. Ignoring it, they estimate CRRA coefficients from 0.57 to 0.85. The intuition is that risk aversion raises the dispersion of bids. Without heterogeneity in the model, bids that vary little with n relative to their dispersion are read as evidence of risk aversion. The direction of the bias depends on the correlation between heterogeneity and n, which their results suggest is positive.

Risk aversion is a candidate explanation for evidence that sealed-bid auctions raise more revenue, since it favors the first-price format (Proposition 14.40). Athey et al. (2011, pp. 234–235) argue against it in their timber data. In the cases considered by Matthews (1987), risk aversion would lower participation in sealed-bid auctions, which "runs contrary to our findings" (Section 15.9).

15.9 Open versus Sealed Bidding in Timber Auctions: Athey, Levin and Seira (2011)

This section studies one application from beginning to end. Athey et al. (2011), whom we abbreviate ALS, ask whether a seller should sell by open ascending auction or by first-price sealed bid. Their answer uses nearly every tool of this chapter. The sealed-bid model is the asymmetric private values model, inverted through first-order conditions as in Sections 15.4 and 15.5. Bids within an auction are correlated, so the model contains unobserved auction heterogeneity of the kind studied in Section 15.7. Bidders choose whether to pay to participate, and entry costs are recovered from an indifference condition as in Section 15.8. The equilibrium theory comes from Sections 14.10 to 14.12. We follow the order of a full case study: question, institutions, data, model, reduced-form evidence, structural estimation, validation, counterfactuals and assessment.

15.9.1 The question

The choice between open and sealed bidding arises in sales of timber, oil leases, art, real estate and financial assets, and in procurement. Theory identifies conditions under which either format is better for efficiency or revenue. Evidence is scarce, because most markets operate under a single set of rules (Athey et al., 2011, p. 207). ALS ask three questions. Which format attracts more bidders? Which format raises more revenue? Does the allocation of the object depend on the rules?

The stakes are large in the timber market. Logging and milling form a $100 billion a year industry in the United States, and about 30 percent of timberland is publicly owned. During the period ALS study, the federal government sold about $1 billion of timber a year (Athey et al., 2011, p. 208).

Revenue equivalence (Proposition 14.43) is the benchmark. With risk-neutral bidders whose private values are independent draws from one distribution, both formats yield the same expected revenue for a fixed set of participants. The equivalence survives costly entry. If loggers and mills drew values from the same distribution, the two formats would have the same expected entry, the same allocation and the same expected revenue (Athey et al., 2011, Section II.D). Any systematic difference between the formats must therefore come from a departure from the benchmark. Candidates include asymmetric bidders, collusion, common values, correlated values and risk aversion.

Two departures pull in opposite directions. Sealed bidding favors weak bidders, because strong bidders shade their bids more (Proposition 14.76, after Maskin and Riley, 2000). Weak bidders then earn more from participating and enter more often, an effect stressed by Klemperer (2004). The price of this advantage is an inefficient allocation. The open auction allocates efficiently among participants, but a bidding ring is self-enforcing in it (Proposition 14.87). The first chief of the Forest Service, Gifford Pinchot, chose sealed bids for that reason, "thereby preventing the customary collusion between bidders" (Pinchot, 1998, p. 209), as quoted by Athey et al. (2011, footnote 2). A century later, Marshall and Marx (2012, ch. 10, p. 207) still list sealed instead of ascending bids first among the measures an auctioneer can take against rings (Section 15.10). Theory gives no general revenue ranking, even with fixed participation (Athey et al., 2011, p. 215). The comparison is quantitative, and it needs a model estimated from data.

The Forest Service timber program is a good test case. It uses both formats in the same forests, and for some sales it chose the format at random (Athey et al., 2011, p. 207).

15.9.2 Institutions

A sale begins when the Forest Service identifies a tract of timber and organizes a *cruise*, a survey that estimates the merchantable timber on the tract. The sale is announced at least 30 days before the auction. The announcement states the auction format, the estimated volume and logging costs, the tract characteristics and a reserve price (Athey et al., 2011, p. 218). The reserve price follows a formula. It starts from the cruise estimates of timber value and costs and adds a fixed margin for profit and risk. Some sales are restricted to firms with fewer than 500, or fewer than 25, employees. ALS exclude these small-business sales.

Before the auction, firms may cruise the tract themselves and prepare bids. The recording rules differ by format (Athey et al., 2011, p. 219). In a sealed-bid sale the Forest Service records each bidder's identity and bid. In an open auction each firm must submit a qualifying bid before the sale, typically equal to the reserve price. The Forest Service records every qualifying firm and the highest bid each one offers. Entry is therefore observed in both formats, including firms that never bid actively in an open auction. Open auctions are conducted by outcry and the price can rise in jumps. ALS know of no evidence that jump bidding mattered much, but it complicates inference from recorded open bids (Athey et al., 2011, footnote 3), as Theorem 15.11 makes precise.

After the auction the winner has a set period, typically one to four years in the sample, to harvest the timber. In a *scale sale* the winner pays per unit of timber removed, so revenue can differ from the winning bid times the cruise volume. In a *lump-sum sale* the winner pays the bid. For scale sales ALS have limited harvest data and use the bid price as a proxy for revenue (Athey et al., 2011, p. 219).

The format itself has a history (Athey et al., 2011, pp. 210 and 221–226). Sealed bidding was used early in the twentieth century and has remained almost universal in the Southeast. Open auctions gained favor elsewhere, especially in the Pacific Northwest, on the argument that they let local mills respond directly to competition. In 1976 Congress mandated sealed bidding, but the regulations allowed forest managers to use open auctions if they could justify the choice. The format therefore continued to vary across places and times. Schuster and Niccolucci (1994) document from interviews that for a subset of Northern sales the format was chosen at random. In some instances it was decided by picking colored balls out of a sock (their p. 90, as cited by ALS, p. 226). ALS analyze the 378 sales that Schuster and Niccolucci identify as randomized and obtain very similar estimates of the effect of sealed bidding (reported in their Online Appendix).

15.9.3 Data

The unit of observation is a timber sale. The Northern sample covers sales held from 1982 to 1990 in the Kootenai and Idaho Panhandle National Forests. These neighboring forests on the Idaho-Montana border have the largest timber programs of the Forest Service's Northern region. The California sample covers sales held from 1982 to 1989 (Athey et al., 2011, p. 218). In California the format varies more systematically with sale size, which makes tract differences harder to control for. Prices are in 1982 dollars per thousand board feet of timber, abbreviated mbf.

For every sale ALS know the identity and bid of each participant and the characteristics in the sale announcement. These include the reserve price and the Forest Service estimates of volume, selling value, and logging, manufacturing and road-building costs. They also include the timber density, the contract length, salvage and scale-sale indicators and a Herfindahl index

of species concentration. Market conditions are measured by monthly United States housing starts and county counts of logging firms and sawmills (Athey et al., 2011, p. 226).

Mills and loggers. ALS classify bidders as *mills*, which have manufacturing capacity, and *loggers*, which do not (Athey et al., 2011, p. 219). Other groupings, by number of employees or number of auctions entered, turn out to be similar. The theory requires mills to be the stronger bidders, and the data agree. A regression of log per-unit sealed bids on a mill dummy and auction fixed effects gives a coefficient of 0.248 in the North, with a t-statistic of roughly 8 (Athey et al., 2011, p. 220). Mill bids are thus about 25 percent higher than logger bids in the same auction. An entering mill wins more often than an entering logger, 28 percent against 21 percent. In California mill bids are just over 12 percent higher with auction fixed effects.

Two explanations for the mill advantage are cost differences and double marginalization. A logger who wins must sell the logs to a mill, which may charge a margin over its processing costs. ALS give an example (Athey et al., 2011, footnote 10). Suppose all bidders agree that the timber is worth \$100,000 net of costs, and that a winning logger must pay a \$20,000 margin to one of two local mills. Each logger values the contract at \$80,000. Each mill values it at \$90,000, since it expects to collect the margin with probability one half if a logger wins.

Observed sale characteristics explain much of the variation in bids. Regressing individual log sealed bids on sale characteristics and a logger dummy gives an R^2 of 0.62 in the North and 0.71 in California. Regressing the average bid of each sale on sale characteristics gives 0.72 and 0.69 (Athey et al., 2011, footnote 9).

Potential bidders. The entry model needs the number of potential bidders of each type. For loggers, ALS count the distinct logging companies that entered an auction in the same area over the previous year. The area is the forest district in the North and the forest in California (Athey et al., 2011, p. 221 and footnote 11). The count contains measurement error, because firms enter and exit and bidder names are recorded with varying spellings. For mills the model itself supplies the answer. In the estimated equilibrium every potential mill enters, so the number of potential mills equals the number of entering mills.

Choice of format and trimming. Format choice is related to observables, so ALS model it. A logit of a sealed-bid dummy on the sale characteristics, potential-competition measures and dummies for year, quarter, location and species gives their Table II. Sale size enters as a step function with 10 steps that roughly correspond to deciles (Athey et al., 2011, p. 227). Smaller sales are more often sealed, and the effect is much stronger in California. The coefficient on the largest volume category (over 90 hundred mbf) is −2.479 (s.e. 0.583) in the North and −9.833 (0.930) in California. The pseudo-R^2 is 0.19 in the North (N = 1,233 sales) and 0.66 in California (N = 2,064). Location dummies are jointly significant in both regions (Table II).

The fitted probability of sealed bidding is the *propensity score*. Some open sales look unlike any sealed sale, and their propensity score is close to zero. ALS keep only sales with a propensity score between 0.075 and 0.925 (Athey et al., 2011, p. 227). This drops 154 open and 8 sealed sales in the North. In California it keeps only about one third of the sales: 707 of 2,064, by the counts in their Table I. Table 15.24 reports the selected samples. They contain 1,071 Northern sales (732 open, 339 sealed) and 707 California sales (325 open, 382 sealed).

The selected samples show the pattern the theory predicts. Sealed sales attract more loggers (3.23 against 2.75 in the North, 3.01 against 1.95 in California) and slightly fewer mills. Loggers win more sealed sales. Sealed tracts remain smaller even after trimming, while reserve prices per unit are similar. In the full Northern sample the average winning bid is 69.45 dollars per mbf in sealed sales and 61.82 in open sales (Table I). The text on p. 221 of the paper reverses these two numbers. The table agrees with the rest of the paper, so we follow it.

Table 15.24: Summary statistics for the selected samples (means, standard deviations in parentheses)

	Northern forests		California forests	
	Open	Sealed	Open	Sealed
Number of sales	732	339	325	382
Auction outcomes				
Winning bid (dollars per mbf)	63.27 (44.91)	69.42 (46.63)	85.10 (102.93)	80.39 (63.20)
Entrants	4.13 (2.44)	4.40 (2.83)	3.72 (2.24)	4.27 (2.76)
Loggers entering	2.75 (2.46)	3.23 (2.57)	1.95 (1.89)	3.01 (2.35)
Mills entering	1.38 (1.68)	1.17 (1.74)	1.77 (1.77)	1.26 (1.57)
Fraction loggers entering	0.64 (0.39)	0.76 (0.33)	0.55 (0.39)	0.73 (0.31)
Logger wins auction	0.59 (0.49)	0.68 (0.47)	0.50 (0.50)	0.67 (0.47)
Appraisal variables				
Volume (hundred mbf)	23.02 (34.30)	14.65 (25.50)	23.77 (24.14)	11.24 (12.45)
Reserve price (dollars per mbf)	25.68 (25.46)	26.64 (24.44)	37.31 (49.64)	33.26 (32.28)
Selling value (dollars per mbf)	253.04 (130.67)	259.35 (125.33)	233.41 (143.15)	239.72 (119.74)
Contract length (months)	22.19 (16.35)	15.94 (13.38)	16.23 (10.34)	11.97 (6.78)
Potential competition				
Active loggers	19.91 (9.71)	19.47 (8.86)	10.11 (6.86)	11.29 (6.62)
Active mills	5.25 (2.20)	5.79 (2.48)	5.42 (3.54)	5.48 (2.85)

Notes. Selected-sample columns of Athey et al. (2011, Table I). The selected sample keeps sales whose propensity score lies between 0.075 and 0.925. An active logger or mill is a firm that bid in the same forest district (North) or forest (California) in the prior 12 months. In the published table, panel (a) is titled "California Sales" and panel (b) "Northern Sales," but each panel's notes and sample sizes identify the other region. We assign regions by the notes and sample sizes, which match Table V of the paper.

15.9.4 The model and its predictions

The theory is developed in Sections 14.10 to 14.12. We restate it in the notation of this chapter. There are N_L potential loggers and N_M potential mills, with $\boldsymbol{N} = (N_L, N_M)$. Each potential bidder pays a cost K to gather information and enter. A bidder who enters learns its private value v_i, an independent draw from F_L or F_M with continuous density on $[r, \bar{v}_k]$. Mills are strong in the reverse hazard rate order (Definition 14.73),

$$\frac{f_M(v)}{F_M(v)} \geq \frac{f_L(v)}{F_L(v)} \qquad \text{for all } v.$$

Bidders decide on entry independently but learn the set of participants $\boldsymbol{n} = (n_L, n_M)$ before bidding (Athey et al., 2011, Section II.A).

In the sealed auction, a participant with value v_i facing the participant set $\boldsymbol{n}$ solves (Athey et al., 2011, eq. (1))

$$\pi_i^{\mathrm{s}}(v_i; \boldsymbol{n}) = \max_{b \geq r} (v_i - b) \prod_{j \in \boldsymbol{n} \setminus i} G_j(b; \boldsymbol{n}), \qquad G_j(b; \boldsymbol{n}) = F_j\big(\beta_j^{-1}(b; \boldsymbol{n})\big). \tag{15.67}$$

The first-order condition, together with the boundary condition $\beta_i(r; \boldsymbol{n}) = r$, characterizes the bid functions (Athey et al., 2011, eq. (2)),

$$\frac{1}{v_i - b_i} = \sum_{j \in \boldsymbol{n} \setminus i} \frac{g_j(b_i; \boldsymbol{n})}{G_j(b_i; \boldsymbol{n})}. \tag{15.68}$$

Solving for the value gives the inverse bid function, the asymmetric version of (15.9),

$$v_i = \xi_i(b_i; \boldsymbol{n}) \equiv b_i + \left[\sum_{j \in \boldsymbol{n} \setminus i} \frac{g_j(b_i; \boldsymbol{n})}{G_j(b_i; \boldsymbol{n})} \right]^{-1}. \tag{15.69}$$

With type-symmetric strategies the sum has $n_L - 1$ logger terms and n_M mill terms for a logger, and n_L logger terms and $n_M - 1$ mill terms for a mill, as in (14.83) and (14.84).

In the open auction each participant bids up to its value, so $\beta_i(v; \boldsymbol{n}) = v$. A participant who plans to drop out at b wins when every rival value lies below b and then pays the larger of the highest rival value $V_{-i} \equiv \max_{j \in \boldsymbol{n} \setminus i} V_j$ and the reserve price. Its expected profit is (Athey et al., 2011, eq. (3))

$$\pi_i^{\mathrm{o}}(v_i; \boldsymbol{n}) = \max_{b \geq r} \Big(v_i - \mathbb{E}\big[\max\{V_{-i}, r\} \;\big|\; V_j \leq b \;\forall j \in \boldsymbol{n} \setminus i \big] \Big) \prod_{j \in \boldsymbol{n} \setminus i} F_j(b) = \mathbb{E}\Big[\big(v_i - \max\{V_{-i}, r\} \big)^+ \Big]. \tag{15.70}$$

The second equality holds because the maximum is attained at $b = v_i$. Let $\pi_L^\tau(\boldsymbol{n})$ and $\pi_M^\tau(\boldsymbol{n})$ be the expected profits of a participating logger and mill in format $\tau \in \{\mathrm{o}, \mathrm{s}\}$, averaged over its own value. The ex ante payoff from entry is (14.100), a weighted sum of $\pi_i^\tau(\boldsymbol{n})$ over participant sets with binomial weights. A type-symmetric entry equilibrium (Definition 14.83) has all loggers enter with probability p_L and all mills with probability p_M.

The theory yields five predictions that organize the empirical work.

(P1) *Homogeneous benchmark.* If $F_L = F_M$, both formats have the same entry, allocation and expected revenue.

(P2) *Uniqueness.* If $\pi_M^{\mathrm{s}}(n_L, n_M + 1) > \pi_L^{\mathrm{s}}(n_L, n_M)$ for all (n_L, n_M), each format has a unique type-symmetric entry equilibrium, with $p_L = 0$ or $p_M = 1$ (Proposition 14.84). The empirically relevant case is $p_M = 1$ and $0 < p_L < 1$, since ALS observe logger entry in more than 85 percent of sales and always more potential than actual logger entrants (p. 214). Their later count is less absolute, with more potential than actual entrants in 99 percent of Northern sales and 95 percent of California sales (p. 245, Section 15.9.6).

(P3) *Entry and allocation.* Relative to sealed bidding, open bidding has less logger entry, the same mill entry in the relevant case, and a lower probability that a logger wins (Proposition 14.85).

(P4) *Revenue and efficiency.* There is no general revenue ranking. The sealed auction is inefficient even for fixed participants, while the open auction is efficient.

(P5) *Collusion.* If participating mills cooperate perfectly in open auctions, then in the relevant case entry and the allocation are unchanged and only prices fall (Proposition 14.89). The price falls only when two or more mills participate, by the amount in (14.109).

Prediction (P5) is the source of the collusion test in Section 15.9.7. A sale with zero or one participating mill carries no information about mill collusion.

What the model leaves out. ALS abstract from common values and risk aversion (Athey et al., 2011, Section II.F). Bidders may hold private estimates of timber quality and volume, which creates a common value component, and they may be risk averse. ALS give two reasons for the omission. The format differences they find are qualitatively unlike those that common values or risk aversion would generate, as we show in Section 15.9.5. Including either feature would also complicate the analysis substantially. They further assume that bidders learn

their values only after paying K, and they restrict attention to type-symmetric equilibria, a convenient assumption that permits point identification of entry costs. Pure-strategy entry equilibria would yield bounds on entry costs instead, an approach they pursue in Athey et al. (2013). Finally, the model assumes independent entry decisions, which rules out bid rotation. ALS check this by testing whether the entry of pairs of firms is negatively correlated given sale characteristics. A handful of pairs show significant negative correlation, but for the vast majority negative correlation is rejected (Athey et al., 2011, footnote 5).

15.9.5 Reduced-form evidence

Before estimating the model, ALS measure the effect of the format on outcomes directly. For an outcome Y, such as logger entry or the log price, they write (Athey et al., 2011, eq. (5))

$$Y = f(\text{SEALED}, Z, \boldsymbol{N}, \varepsilon). \tag{15.71}$$

Here SEALED equals one for a sealed sale and zero for an open sale. The vector Z collects the observed sale characteristics, $\boldsymbol{N}$ the measures of potential competition, and ε is an unobservable. The object of interest is the average effect of sealed bidding,

$$\Delta_Y = \mathbb{E}_{Z,\boldsymbol{N},\varepsilon}\big[f(1, Z, \boldsymbol{N}, \varepsilon) - f(0, Z, \boldsymbol{N}, \varepsilon)\big]. \tag{15.72}$$

In the language of program evaluation (Appendix A), $f(1,\cdot)$ and $f(0,\cdot)$ are the potential outcomes under the two formats, and Δ_Y is the average treatment effect.

Assumption 15.58 (Selection on observables)**.** (i) *Unconfoundedness.* SEALED is independent of ε conditional on $(Z, \boldsymbol{N})$. (ii) *Overlap.* $0 < e(Z, \boldsymbol{N}) < 1$, where $e(Z, \boldsymbol{N}) = \mathbb{P}(\text{SEALED} = 1 \mid Z, \boldsymbol{N})$ is the propensity score.

Part (i) holds by design for the randomized sales, provided Z includes the administrative unit that randomized, since assignment probabilities differed across forest districts (Athey et al., 2011, p. 229). It holds for the other sales if managers chose the format using the Forest Service appraisal or a rule based on recorded covariates. If a manager used a deterministic rule, such as open bidding above a volume threshold, the format would not vary given Z. A logit that does not reproduce the rule exactly would then estimate intermediate propensity scores near the threshold. Identification would come from discontinuities in outcomes, as in a regression discontinuity design (Athey et al., 2011, footnote 13). Part (ii) is the reason for the trimming in Section 15.9.3. Sales with propensity scores near zero or one have no comparable sales in the other format.

ALS use three estimators of Δ_Y. The first is ordinary least squares (Athey et al., 2011, eq. (6)),

$$Y_t = \Delta_Y \,\text{SEALED}_t + Z_t \boldsymbol{\kappa}_Z + \boldsymbol{N}_t \boldsymbol{\kappa}_N + \varepsilon_t, \tag{15.73}$$

which imposes a constant effect. The second interacts SEALED_t with each covariate and averages the implied effects over the sample. The third is a *matching estimator*. For each sale t let $\mathcal{J}_4(t)$ be the four sales of the opposite format whose estimated propensity scores are closest to $\hat{e}(Z_t, \boldsymbol{N}_t)$. The average $\hat{Y}_t = \frac{1}{4}\sum_{s \in \mathcal{J}_4(t)} Y_s$ imputes the outcome that sale t would have had under the other format. With T sales in all, (Athey et al., 2011, eq. (7))

$$\hat{\Delta}_Y = \frac{1}{T}\sum_{t \,\in\, \text{sealed}} \big(Y_t - \hat{Y}_t\big) + \frac{1}{T}\sum_{t \,\in\, \text{open}} \big(\hat{Y}_t - Y_t\big). \tag{15.74}$$

Each term compares a sale's realized outcome with its imputed counterfactual, with the sign arranged so that every term estimates the sealed outcome minus the open outcome. Under Assumption 15.58, conditioning on the scalar propensity score balances the covariates (Appendix A), so matching on $\hat{e}$ is enough. ALS compute robust standard errors following Abadie and Imbens (2006). Matching on many covariates with a bias correction gives somewhat larger effects of sealed bidding. ALS report the propensity-score estimates because they are conservative and in line with the regressions (Athey et al., 2011, footnote 14). Median regressions give similar results (footnote 15).

Table 15.25: Effect of sealed bidding on sale outcomes

Dependent variable	(1) ln(logger entry)	(2) ln(mill entry)	(3) Loggers per entrant	(4) Logger wins	(5) ln(price)	(6) ln(price) with entry
A. Northern sales (N = 1,071)						
OLS, no interactions	0.089	−0.014	0.056	0.039	0.094	0.055
	(0.036)	(0.030)	(0.016)	(0.026)	(0.038)	(0.032)
OLS with interactions	0.097	−0.010	0.058	0.038	0.099	0.060
	(0.036)	(0.031)	(0.016)	(0.027)	(0.039)	(0.033)
Matching	0.100	0.018	0.052	0.034	0.118	0.091
	(0.048)	(0.053)	(0.029)	(0.039)	(0.064)	(0.055)
B. California sales (N = 707)						
OLS, no interactions	0.101	−0.026	0.058	0.036	0.027	−0.026
	(0.045)	(0.038)	(0.020)	(0.036)	(0.051)	(0.040)
OLS with interactions	0.099	−0.022	0.056	0.035	0.026	−0.037
	(0.044)	(0.038)	(0.020)	(0.035)	(0.050)	(0.039)
Matching	0.106	−0.123	0.097	0.107	−0.038	0.005
	(0.062)	(0.067)	(0.034)	(0.051)	(0.127)	(0.087)

Notes. Reproduced from Athey et al. (2011, Table III). Each entry is the estimated effect of sealed bidding, with robust standard errors in parentheses. Regressions include the sale controls of their Table II. These are the reserve price, appraisal estimates, contract length per unit volume, species Herfindahl, density, salvage and scale indicators, housing starts, volume categories, and year, quarter, location and species dummies. Column (6) also controls for the numbers of entering mills and loggers. The matching estimator uses the four closest matches on the estimated propensity score, with standard errors following Abadie and Imbens (2006).

Table 15.25 reproduces the results. Sealed bidding raises logger entry by about 10 percent in both regions, and all six estimates in column (1) are significant (Athey et al., 2011, p. 230). With roughly three entering loggers per sale, this is two or three additional loggers per 10 sales. A log coefficient c corresponds to a proportional change of $e^c - 1$, so the Northern OLS estimate of 0.089 means 9.3 percent (our calculation). Mill entry shows no significant effect, except for the California matching estimate, which suggests lower mill entry under sealed bidding. The share of loggers among entrants is 5 to 6 percentage points higher in sealed sales. Loggers are 3 to 4 percentage points more likely to win, but these estimates are imprecise, especially in California (p. 232).

The price results differ sharply between regions. In California the sealed-bid price effect is small and insignificant, and it turns negative once entry is controlled for. In the North sealed prices are about 10 percent higher, and the estimates are significant. The average winning bid in the North is just over \$134,000, so a 10 percent difference is about \$13,000 per sale, or about \$14 million over the sample (p. 232). With the numbers of entrants as controls, the effect falls to about 6 percent (s.e. 3 percent) in the regressions and 9 percent by matching. The

same regressions suggest that an additional mill raises the winning bid by about 19 percent and an additional logger by about 12 percent (pp. 232–233). The numbers of entrants may be endogenous if bidders see tract features that the data omit. ALS tried instrumenting entry with potential-competition measures, but the estimates were highly sensitive to the choice of instruments (footnote 17).

Alternative explanations. ALS consider three alternatives to their model (Athey et al., 2011, pp. 233–234). The first is selection on unobservables. If managers sold more valuable tracts by sealed bid, entry and revenue would be higher in sealed sales for that reason alone. This story fits poorly with the fact that larger, and so more valuable, tracts are more often sold by open auction. If managers chose sealed bidding when they expected more interest from loggers, the entry results would follow. That choice contradicts industry perceptions and the Forest Service's own guidelines, which instruct managers to use sealed bidding when a sale is not expected to be competitive. The second alternative is common or affiliated values. In the standard symmetric models these imply lower prices in sealed auctions (Proposition 14.64), the opposite of the Northern evidence. The third is risk aversion. Symmetric risk-averse bidders generate higher sealed-bid revenue, but in the cases studied by Matthews (1987) risk aversion lowers participation in sealed auctions, the opposite of the entry evidence. Either feature could matter only as part of a more complicated story.

The reduced-form evidence matches the theory qualitatively. It cannot say whether a reasonable parameterization matches it quantitatively. It also cannot separate competitive from collusive open bidding, because prediction (P5) says that collusion leaves entry and allocation unchanged. Both questions need the structural model.

15.9.6 Structural estimation

Why only sealed bids. ALS estimate every primitive from the sealed-bid sales alone. Three arguments support this choice. The model has unobserved heterogeneity, so values are correlated across bidders within an auction. Values are then not identified from open-auction bids (Theorem 15.9), as ALS note in their footnote 18. Losing bids in open outcry auctions need not equal values, and Theorem 15.11 shows what can be learned without that assumption. Finally, estimating from sealed bids alone turns every prediction about open auctions into an out-of-sample test, in two senses. The open tracts were not used in estimation, and the open auction is a different game from the one used in estimation (Athey et al., 2011, p. 235).

Information and equilibrium. Let Z be the sale characteristics observed by bidders and by us. Let ω be a characteristic known to participants but not recorded in the data, the unobserved heterogeneity of Section 15.7. ALS write X for Z and u for ω.

Assumption 15.59 (Structure of the timber model)**.**

(i) Potential bidders know $(Z, \boldsymbol{N})$. They decide whether to pay the entry cost $K(Z, \boldsymbol{N})$.

(ii) A participant learns the participant set $\boldsymbol{n}$, the characteristic ω and its own value.

(iii) Values are independent across bidders conditional on $(Z, \omega, \boldsymbol{N})$, with distributions $F_L(\cdot \mid Z, \omega, \boldsymbol{N})$ and $F_M(\cdot \mid Z, \omega, \boldsymbol{N})$.

(iv) Sealed-bid data come from a type-symmetric entry equilibrium with competitive bidding, in which mills enter with probability one and loggers with probability $p_L(Z, \boldsymbol{N}) \in (0, 1)$.

(v) A lone bidder bids the reserve price. With two or more bidders the reserve price does not bind.

(vi) Auctions are independent of one another. The characteristic ω is independent of $(Z, \boldsymbol{N}, \boldsymbol{n})$.

Part (ii) has a useful implication. Bidders learn ω only after entering, so entry decisions cannot depend on ω, which makes the independence of ω and $\boldsymbol{n}$ in part (vi) consistent with the timing. Part (iv) gives $N_M = n_M$ in every sale. For N_L ALS use the count of active loggers. It strictly exceeds the number of entering loggers in 99 percent of Northern sales and 95 percent of California sales, as mixed-strategy entry requires (Athey et al., 2011, p. 245). Part (v) follows Haile (2001), who discusses why Forest Service reserve prices are typically nonbinding. Its cost is that fitted bid distributions put a small probability on bids below the reserve. A model with values distributed above the reserve fit the data poorly, possibly because the reserve formula tracks bidder values poorly (Athey et al., 2011, footnote 20).

The Gamma-Weibull bid distributions. Given $(Z, \boldsymbol{N}, \boldsymbol{n})$, the joint distribution of bids in an auction combines three distributions. Two are the logger and mill bid distributions. The third is the distribution of ω, which generates the correlation among bids. ALS parameterize all three. For $k \in \{L, M\}$ (Athey et al., 2011, eq. (8)),

$$G_k(b \mid Z, \omega, \boldsymbol{N}, \boldsymbol{n}) = 1 - \exp\left(-\omega\left(\frac{b}{\lambda_k(Z, \boldsymbol{N}, \boldsymbol{n})}\right)^{\rho_k(\boldsymbol{n})}\right), \tag{15.75}$$

a Weibull distribution with scale λ_k and shape ρ_k, both depending on the bidder's type. They are parameterized as

$$\ln \lambda_k(Z, \boldsymbol{N}, \boldsymbol{n}) = Z\boldsymbol{\theta}^{\lambda}_{Z} + \boldsymbol{N}\boldsymbol{\theta}^{\lambda}_{N} + \boldsymbol{n}\boldsymbol{\theta}^{\lambda}_{n,k} + \theta^{\lambda}_{0,k}, \tag{15.76}$$

$$\ln \rho_k(\boldsymbol{n}) = \boldsymbol{n}\boldsymbol{\theta}^{\rho}_{n,k} + \theta^{\rho}_{0,k}. \tag{15.77}$$

ALS write β and γ for the coefficient vectors and θ for the variance of ω. We write $\boldsymbol{\theta}^{\lambda}$ and $\boldsymbol{\theta}^{\rho}$ for the coefficients, because β denotes bid functions in this book, and σ^2_{ω} for the variance. The shape ρ_k is unrelated to the pass-through rate of earlier chapters. The counts n_L and n_M enter as $\min\{n_L, 5\}$ and $\min\{n_M, 5\}$, because the effect of an additional bidder should fade as the number of bidders grows. The mill distribution has a separate effect for a single participating mill, since theory suggests that a lone mill may behave quite differently. The heterogeneity ω follows a Gamma distribution with mean one and variance σ^2_{ω}. ALS chose a specification more parsimonious than their regressions to limit overfitting in out-of-sample predictions (Athey et al., 2011, footnote 21).

Two features of (15.75) deserve comment. First, ALS parameterize the bid distributions and leave the value distributions implied. This is the parametric version of the two-step approach of Section 15.4: fit the bids, then infer values from first-order conditions. ALS note a limitation shared by all two-step methods. Nothing forces the value distributions implied for different participant sets $\boldsymbol{n}$ to coincide, as theory requires (their footnote 21). Second, theory implies a bounded bid support while the Weibull is unbounded. ALS therefore truncate the very upper tail of the fitted distributions (their footnote 23).

The following representation shows how ω creates correlation.

Lemma 15.60 (A representation of Gamma-Weibull bids)**.** *Under* (15.75)*, bid i in an auction with heterogeneity ω can be written*

$$B_i = \lambda_{k(i)}\left(\frac{E_i}{\omega}\right)^{\frac{1}{\rho_{k(i)}}},$$

where $E_1, \dots, E_n$ are independent standard exponential random variables, independent of ω.

Proof. Fix ω and drop the subscript $k(i)$. For $b > 0$, the event $\{B_i \le b\}$ equals $\{E_i \le \omega(\frac{b}{\lambda})^{\rho}\}$, because the map $e \mapsto \lambda(\frac{e}{\omega})^{\frac{1}{\rho}}$ is strictly increasing. Hence

$$\mathbb{P}(B_i \le b \mid \omega) = 1 - \exp\Big(-\omega\Big(\frac{b}{\lambda}\Big)^{\rho}\Big),$$

which is (15.75). Independence of the E_i gives conditional independence of the bids. □

Taking logs, $\ln B_i = \ln \lambda_{k(i)} + \frac{1}{\rho_{k(i)}}(\ln E_i - \ln \omega)$. A high ω lowers every bid in the auction, and a low ω raises them all. This common shift is the within-auction correlation that ALS observe in the data.

Proposition 15.61 (The auction likelihood)**.** *Let auction t have participants $\boldsymbol{n}_t$ with $|\boldsymbol{n}_t| \ge 2$ and bids $b_1, \dots, b_{|\boldsymbol{n}_t|}$. Write λ_i and ρ_i for the scale and shape of bidder i's type, $z_i = (\frac{b_i}{\lambda_i})^{\rho_i}$ and $a = \sigma_\omega^{-2}$. Without upper-tail truncation, the joint density of the bids given $(Z_t, \boldsymbol{N}_t, \boldsymbol{n}_t)$ is*

$$\ell_t = \prod_{i \in \boldsymbol{n}_t} \left[\frac{\rho_i}{\lambda_i} \Big(\frac{b_i}{\lambda_i}\Big)^{\rho_i - 1} \right] \cdot \frac{\Gamma\big(|\boldsymbol{n}_t| + a\big)\, a^a}{\Gamma(a)\, \big(\sum_{i \in \boldsymbol{n}_t} z_i + a\big)^{|\boldsymbol{n}_t| + a}}. \tag{15.78}$$

Proof. Step 1 (conditional density). Differentiating (15.75) in b gives the density of one bid given ω,

$$g_i(b_i \mid \omega) = \omega\, \frac{\rho_i}{\lambda_i} \Big(\frac{b_i}{\lambda_i}\Big)^{\rho_i - 1} e^{-\omega z_i}.$$

Step 2 (independence given ω). By Lemma 15.60 the bids are independent given ω, so their joint density given ω is the product,

$$\prod_{i \in \boldsymbol{n}_t} g_i(b_i \mid \omega) = \omega^{|\boldsymbol{n}_t|} \prod_{i \in \boldsymbol{n}_t} \left[\frac{\rho_i}{\lambda_i} \Big(\frac{b_i}{\lambda_i}\Big)^{\rho_i - 1} \right] \exp\Big(-\omega \sum_{i \in \boldsymbol{n}_t} z_i\Big).$$

Step 3 (the Gamma density). A Gamma variable with mean one and variance σ_ω^2 has shape $a = \sigma_\omega^{-2}$ and rate a, so its density is

$$h(\omega) = \frac{a^a}{\Gamma(a)}\, \omega^{a-1} e^{-a\omega}, \qquad \omega > 0.$$

Step 4 (integrate out ω). By part (vi) of Assumption 15.59, ω is independent of $(Z, \boldsymbol{N}, \boldsymbol{n})$. The unconditional density is the integral of the product of Steps 2 and 3. Collecting powers of ω, the integral that remains is

$$\int_0^\infty \omega^{|\boldsymbol{n}_t| + a - 1} \exp\Big(-\omega\Big(\sum_i z_i + a\Big)\Big) d\omega = \frac{\Gamma(|\boldsymbol{n}_t| + a)}{\big(\sum_i z_i + a\big)^{|\boldsymbol{n}_t| + a}},$$

by the identity $\int_0^\infty u^{c-1} e^{-ud}\, du = \frac{\Gamma(c)}{d^c}$ for $c, d > 0$. Multiplying by the bid-specific factors and by $\frac{a^a}{\Gamma(a)}$ gives (15.78). □

The estimator maximizes $\sum_t \ln \ell_t$ over $(\boldsymbol{\theta}^\lambda, \boldsymbol{\theta}^\rho, \sigma_\omega^2)$ on the sealed sales with two or more bidders. ALS present their likelihood in an Online Appendix that we do not reproduce. Equation (15.78) is our derivation for the untruncated model. With upper-tail truncation the conditional densities must be renormalized, and the integral over ω then loses this closed form in general. The factor a^a equals $(\sigma_\omega^2)^{-\sigma_\omega^{-2}}$, the form often written in software.

Corollary 15.62 (Within-auction correlation of log bids)**.** *For two bidders $i \neq j$ in the same auction, without truncation,*

$$\operatorname{Corr}(\ln B_i, \ln B_j \mid Z, \boldsymbol{N}, \boldsymbol{n}) = \frac{\psi_1(a)}{\psi_1(a) + \frac{\pi^2}{6}},$$

where ψ_1 is the trigamma function, the second derivative of $\ln\Gamma$. The correlation does not depend on the scales, the shapes or the types of the two bidders.

Proof. By Lemma 15.60, $\ln B_i = \ln \lambda_i + \frac{1}{\rho_i}(\ln E_i - \ln \omega)$, with E_i, E_j and ω mutually independent. A standard exponential has $\operatorname{Var}(\ln E) = \psi_1(1) = \frac{\pi^2}{6}$. A Gamma variable with shape a has $\operatorname{Var}(\ln \omega) = \psi_1(a)$, whatever its rate. Therefore

$$\operatorname{Cov}(\ln B_i, \ln B_j) = \frac{\psi_1(a)}{\rho_i \rho_j}, \qquad \operatorname{Var}(\ln B_i) = \frac{\psi_1(a) + \frac{\pi^2}{6}}{\rho_i^2}.$$

Dividing the covariance by the product of the standard deviations, the factors ρ_i and ρ_j cancel. □

The symbol ψ_1 is unrelated to the virtual value of (14.48). With the estimates in Table 15.26, $\sigma_\omega^2 = e^{-0.502} = 0.605$ in the North and $e^{-0.416} = 0.660$ in California. The implied correlations are 0.33 and 0.36 (our calculation, script `als_calcs.py`). Unobserved heterogeneity thus accounts for about a third of the variance of log bids given the observables and the participant set.

Identification. Given the parametric forms, the scale and shape coefficients are identified by the marginal distributions of logger and mill bids across sales with different characteristics and participant sets. The variance σ_ω^2 is identified by the within-auction covariance of bids, as Corollary 15.62 makes explicit. Theorem 15.52 shows that two bids per auction identify the heterogeneity distribution nonparametrically when it enters multiplicatively and independently. ALS use a parametric version instead for a practical reason. A semiparametric estimator would need to be run separately for each participant configuration (n_L, n_M), and the data are too few for that (Athey et al., 2011, footnote 22). ALS also report that without heterogeneity they estimate implausibly high bid margins, in line with the findings of Krasnokutskaya (2011) for highway procurement (p. 236). An affiliated private values model could also rationalize correlated bids. In the baseline symmetric model, however, affiliation implies higher prices in open auctions, contrary to their data (footnote 19).

Estimates. Table 15.26 reproduces the main rows. Three findings stand out (Athey et al., 2011, p. 238). First, mill bids dominate logger bids although the specification does not impose it. The mill dummy in the scale equation is 0.284 in the North and 0.160 in California. On average, mill bids are roughly 25 percent higher in the North and 15 percent higher in California. Second, bids rise with the number of competitors, as the independent private values model predicts. The coefficients on the capped counts of mill and logger entrants in the scale equation are positive. Bids could fall with competition if values were affiliated or had a common component. Third, σ_ω^2 is significant in both regions, so the heterogeneity is needed. In the entry logit, the reserve price and the number of active loggers lower each logger's entry probability. The latter sign is natural, since a logger facing more potential rivals expects less profit.

Fit. The model implies that each bid factors as $b_{it} = \exp(Z_t \boldsymbol{\theta}_Z^\lambda + \boldsymbol{N}_t \boldsymbol{\theta}_N^\lambda)\, e_{it}$, where the distribution of e_{it} depends only on the participant set (Athey et al., 2011, p. 238). ALS compute sealed-bid residuals $\hat{e}_{it} = b_{it} \exp(-Z_t \hat{\boldsymbol{\theta}}_Z^\lambda - \boldsymbol{N}_t \hat{\boldsymbol{\theta}}_N^\lambda)$ and compare their moments with those the

Table 15.26: Gamma-Weibull bid distributions and logger entry, sealed-bid sales (selected rows)

Notes. Selected rows of Athey et al. (2011, Table IV), standard errors in parentheses. Both equations also include road costs, species Herfindahl, timber density, salvage and scale dummies, and dummies for forest district (North) or forest (California), year and species. Bid distributions are estimated by maximum likelihood on sales with two or more bidders, and the entry logit by maximum likelihood on all sealed sales. The paper labels the shape equation $\ln(p)$ and the variance $\ln(\theta)$. Table V of the paper lists 1,492 and 1,630 sealed bids, a count that includes sales with a single bidder.

fitted model predicts. Table 15.27 shows a close match. Figure 15.19 compares the kernel-smoothed density of the residuals with the density implied by the model. ALS also run the conditional Kolmogorov test of Andrews (1997). It compares the observed bids with bids simulated from the fitted model given $(Z, \boldsymbol{N})$, using a parametric bootstrap. The test does not reject the Gamma-Weibull model even at the 20 percent level in either region (p. 241).

Table 15.27: Moments of sealed-bid residuals, data and fitted model

	Northern sales		California sales	
	Data	Model	Data	Model
Mean	2.16	2.12	25.9	25.6
Standard deviation	1.18	1.21	12.6	13.6
Between-auction standard deviation	0.94	0.97	9.7	10.8
Within-auction standard deviation	0.75	0.70	8.5	8.1

Notes. From the text of Athey et al. (2011, p. 238). The residual is the bid divided by the fitted covariate index $\exp(Z_t \hat{\boldsymbol{\theta}}_Z^{\lambda} + \boldsymbol{N}_t \hat{\boldsymbol{\theta}}_N^{\lambda})$. The two regions have different scales because the index omits the region-specific constants.

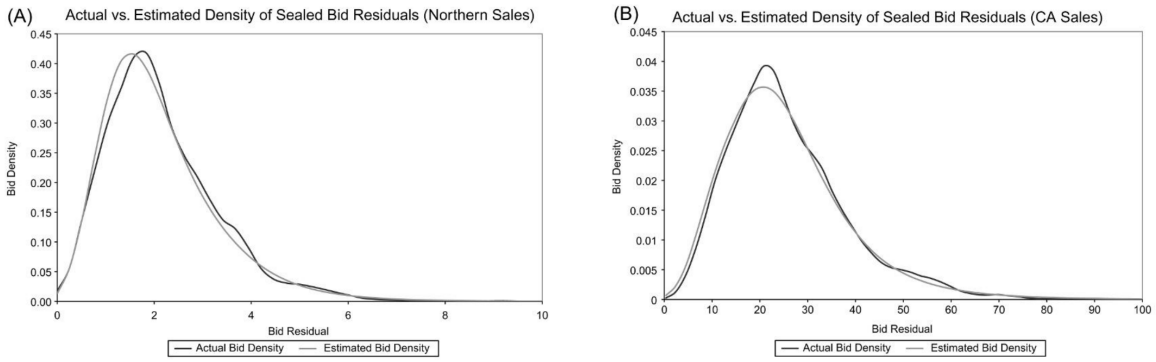

Figure 15.19: Actual (dark) and model-implied (light) densities of sealed-bid residuals, Northern sales (A) and California sales (B). Residuals are bids divided by the fitted covariate index, and the actual density is smoothed with a kernel. Source: Athey et al. (2011), Figure I.

Recovering values. Each sealed bid must be optimal against the rivals' bid distributions. Given $(Z, \omega, \boldsymbol{N}, \boldsymbol{n})$, the value behind a bid is given by (15.69) (Athey et al., 2011, eq. (9)). For the Weibull distribution the reverse hazard rate has a closed form. Differentiating (15.75),

$$g_k(b \mid \omega) = \omega \rho_k b^{\rho_k - 1} \lambda_k^{-\rho_k} \exp\left(-\omega \left(\frac{b}{\lambda_k}\right)^{\rho_k}\right).$$

Dividing by G_k and multiplying numerator and denominator by $\exp(\omega(\frac{b}{\lambda_k})^{\rho_k})$,

$$\frac{g_k(b \mid \omega)}{G_k(b \mid \omega)} = \frac{\omega \rho_k b^{\rho_k - 1} \lambda_k^{-\rho_k}}{\exp\left(\omega(\frac{b}{\lambda_k})^{\rho_k}\right) - 1}. \tag{15.79}$$

Truncating the upper tail divides g_k and G_k by the same constant, so (15.79) is unchanged below the truncation point. If ω were observed, each bid would map into a value, and the value distributions would follow as in Section 15.4. As Krasnokutskaya (2011) observed, we

can still recover the value distributions for any value of ω, because the bid functions are strictly increasing (Athey et al., 2011, eq. (10)):

$$F_k(v \mid Z, \omega, \boldsymbol{N}) = G_k\big(\xi_k^{-1}(v \mid Z, \omega, \boldsymbol{N}, \boldsymbol{n}) \,\big|\, Z, \omega, \boldsymbol{N}, \boldsymbol{n}\big). \tag{15.80}$$

The parameterization implies a scaling property that ALS exploit (Athey et al., 2011, p. 243). Write $s = \exp(Z\boldsymbol{\theta}_Z^\lambda + \boldsymbol{N}\boldsymbol{\theta}_N^\lambda)$, the part of the scale common to both types, and $\lambda_k = s\tilde{\lambda}_k(\boldsymbol{n})$. Then $G_k(b) = \tilde{G}_k(\frac{b}{s})$, where $\tilde{G}_k$ is the distribution at $s = 1$. Differentiating, $g_k(b) = \frac{1}{s}\tilde{g}_k(\frac{b}{s})$, so the reverse hazard rates scale as $\frac{g_k}{G_k}(b) = \frac{1}{s}\frac{\tilde{g}_k}{\tilde{G}_k}(\frac{b}{s})$. Substituting into (15.69),

$$\xi_i(b) = b + s\left[\sum_{j\in\boldsymbol{n}\setminus i} \frac{\tilde{g}_j}{\tilde{G}_j}\Big(\frac{b}{s}\Big)\right]^{-1} = s\,\tilde{\xi}_i\Big(\frac{b}{s}\Big).$$

Values, bids and therefore profits all scale with s. Profits need to be computed for a single value of $(Z, \boldsymbol{N})$ and then rescaled, which makes the many simulations below feasible.

A second property shows how the shape parameters govern market power.

Proposition 15.63 (A floor on margins in the Weibull model)**.** *Under* (15.75)*, for every bid $b > 0$, every ω and every participant set,*

$$\frac{\xi_i(b) - b}{\xi_i(b)} \;\geq\; \frac{1}{1 + \sum_{j\in\boldsymbol{n}\setminus i}\rho_j},$$

with equality in the limit $b \to 0$.

Proof. Let $x_j = \omega(\frac{b}{\lambda_j})^{\rho_j} > 0$. By (15.79), $\frac{g_j}{G_j}(b) = \frac{\rho_j}{b}\cdot\frac{x_j}{e^{x_j}-1}$. Since $e^x - 1 > x$ for $x > 0$, each factor $\frac{x_j}{e^{x_j}-1}$ lies in $(0,1)$ and tends to one as $x_j \to 0$. Hence $\sum_j \frac{g_j}{G_j}(b) < \frac{1}{b}\sum_j \rho_j$, and by (15.69)

$$\xi_i(b) - b > \frac{b}{\sum_j \rho_j}, \qquad \text{so} \qquad \xi_i(b) > b\,\frac{1 + \sum_j \rho_j}{\sum_j \rho_j}.$$

Write $m = \xi_i(b) - b$. The margin $\frac{m}{b+m}$ increases in m, so it exceeds its value at $m = \frac{b}{\sum_j \rho_j}$, which is $\frac{1}{1+\sum_j \rho_j}$. As $b \to 0$, every $x_j \to 0$ and the inequality becomes an equality. □

The proposition is our derivation, not a result in ALS. It shows that the shapes, which measure how concentrated bids are, discipline the markdowns. With the Northern estimates and two loggers and two mills, $\rho_L = e^{1.134+2(0.016)+2(0.015)} = 3.31$ and $\rho_M = 3.56$. Every logger bid in that configuration then carries a margin of at least $\frac{1}{1+3.31+2(3.56)} = 0.088$ (our calculation). ALS estimate the median profit margin across all bids, averaging over ω, at 9.5 percent in the North and 10.0 percent in California, similar for mills and loggers (Athey et al., 2011, p. 243). The paper does not state the formula for its margin, so the comparison is only indicative. Margins of this size suggest that sealed bidding is quite competitive.

Figure 15.20 shows the recovered primitives for a sale with average covariates, $\omega = 1$ and two participants of each type. ALS compute the bid functions by inverting ξ_k for the fitted bid distributions. The mill value distribution is shifted well to the right of the logger distribution. The mill bid function lies below the logger bid function, so mills bid less than loggers at any given value (p. 243). This is property (i) of Proposition 14.76, the result of Maskin and Riley (2000), now found in estimated primitives.

Checking uniqueness. Prediction (P2) needs $\pi_M^{\mathrm{s}}(n_L, n_M + 1) > \pi_L^{\mathrm{s}}(n_L, n_M)$. ALS compute the profits by simulation (Athey et al., 2011, pp. 243–245).

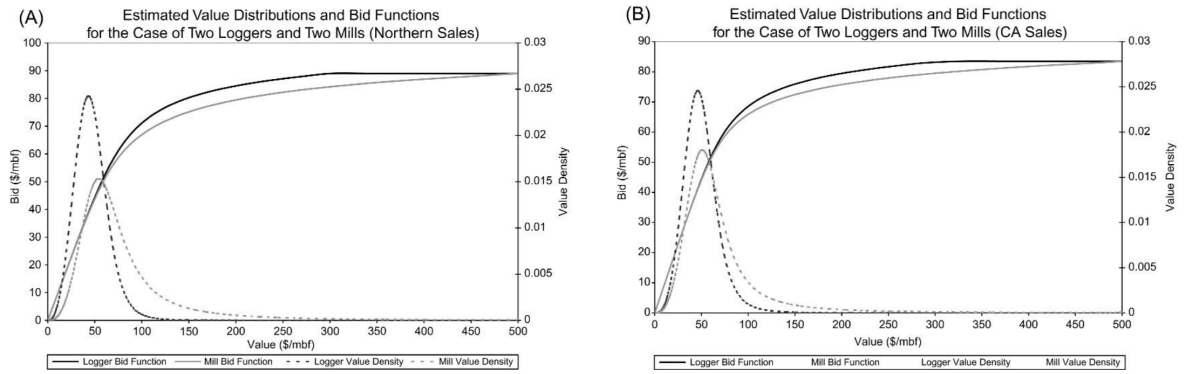

Figure 15.20: Estimated value densities (dashed, right axis) and equilibrium bid functions (solid, left axis) for a sale with average covariates, $\omega = 1$, two loggers and two mills, Northern sales (A) and California sales (B). Dark curves are loggers and light curves are mills. The mill value density lies to the right, and the mill bid function lies below the logger bid function. Source: Athey et al. (2011), Figure II.

(1) Draw ω from the estimated Gamma distribution.

(2) For each participant, draw a bid from $\hat{G}_L(\cdot \mid \omega)$ or $\hat{G}_M(\cdot \mid \omega)$.

(3) Convert each bid into a value with $\hat{\xi}_k$ from (15.69) and (15.79).

(4) Identify the winner, the highest bidder, and record its profit $v - b$. Losers earn zero.

(5) Repeat 5,000 times for each configuration with up to 8 mills and 25 loggers, and average.

The inequality holds for all configurations and every tract in the sample (p. 245). By Proposition 14.84, the estimated model has a unique type-symmetric entry equilibrium for every tract, whatever the entry cost. In that equilibrium, if loggers enter with positive probability, every mill enters.

Entry costs. ALS observe loggers entering 85 percent of Northern sales and 88 percent of California sales (p. 245). Since potential exceeds actual logger entry almost everywhere, loggers must randomize, and a randomizing logger is indifferent. For format τ, (Athey et al., 2011, eq. (11))

$$\Pi_L^\tau(Z, \boldsymbol{N}) = \sum_{n_L=1}^{N_L} \pi_L^\tau(Z, \boldsymbol{N}, \boldsymbol{n})\, \mathbb{P}\big[\boldsymbol{n} \mid Z, \boldsymbol{N}, i \in \boldsymbol{n}, \tau\big] = K(Z, \boldsymbol{N}), \tag{15.81}$$

with $n_M = N_M$. This is the general condition (14.97) and the identification argument of Proposition 15.56. Given that logger i enters, each of the other $N_L - 1$ potential loggers enters independently with probability $p^\tau(Z, \boldsymbol{N})$, so (Athey et al., 2011, eq. (12))

$$\mathbb{P}\big[n_L \mid Z, \boldsymbol{N}, i \in \boldsymbol{n}, \tau\big] = \binom{N_L - 1}{n_L - 1} p^\tau(Z, \boldsymbol{N})^{n_L - 1} \big(1 - p^\tau(Z, \boldsymbol{N})\big)^{N_L - n_L}. \tag{15.82}$$

For sealed sales the entry probability is a logit (Athey et al., 2011, eq. (13)),

$$p^{\mathrm{s}}(Z, \boldsymbol{N}) = \frac{\exp(Z\boldsymbol{\gamma}_Z + \boldsymbol{N}\boldsymbol{\gamma}_N)}{1 + \exp(Z\boldsymbol{\gamma}_Z + \boldsymbol{N}\boldsymbol{\gamma}_N)}, \tag{15.83}$$

where ALS write α for $\boldsymbol{\gamma}$. In sale t the number of entering loggers is binomial with $N_{L,t}$ trials

and success probability $p_t = p^{\mathrm{s}}(Z_t, \boldsymbol{N}_t)$. Up to a constant, the log-likelihood is

$$\ln L(\gamma) = \sum_{t \in \text{sealed}} \Big[n_{L,t} \ln p_t + \big(N_{L,t} - n_{L,t}\big) \ln(1 - p_t) \Big]. \tag{15.84}$$

Let $\boldsymbol{x}_t = (Z_t, \boldsymbol{N}_t)$ be the row of regressors. For the logit, $\frac{\partial \ln p_t}{\partial \gamma} = (1 - p_t)\boldsymbol{x}_t^\top$ and $\frac{\partial \ln(1-p_t)}{\partial \gamma} = -p_t \boldsymbol{x}_t^\top$. The score is therefore

$$\frac{\partial \ln L}{\partial \gamma} = \sum_t \Big[n_{L,t}(1 - p_t) - (N_{L,t} - n_{L,t}) p_t \Big] \boldsymbol{x}_t^\top = \sum_t \big(n_{L,t} - N_{L,t} p_t \big) \boldsymbol{x}_t^\top .$$

The maximum likelihood estimator sets the sum of observed minus expected entrants, weighted by the covariates, to zero. The estimates are the entry columns of Table 15.26.

The entry cost then follows without further estimation. ALS combine the simulated profits $\hat{\pi}_L^{\mathrm{s}}(Z, \boldsymbol{N}, \boldsymbol{n})$ with $\hat{p}^{\mathrm{s}}(Z, \boldsymbol{N})$ in (15.81) and (15.82), and set $\hat{K}(Z, \boldsymbol{N}) = \hat{\Pi}_L^{\mathrm{s}}(Z, \boldsymbol{N})$ for each tract. The median entry cost is \$2,870 (s.e. \$325) in the North and \$5,056 (s.e. \$673) in California (Athey et al., 2011, p. 246). Cruising a tract can cost several thousand dollars, so these figures are plausible. For comparison, the median expected profit of a mill in a sealed sale is roughly \$45,000 gross of entry costs (footnote 26). The median entry costs are thus about 6.4 and 11.2 percent of that profit, the ratios reported by Hortaçsu and Perrigne (2021, p. 91) (Table 15.22). Two checks support the specification. If loggers entered with probability zero in some tracts, the data would contain significantly more sales without logger entry than the binomial model predicts, and they do not (footnote 25). Under pure-strategy entry, revealed preference gives fairly tight bounds on entry costs that are similar to the point estimates (footnote 26).

Figure 15.21 illustrates the logic and anticipates the open-auction prediction. The logger's entry payoff falls with the probability that other loggers enter. A logger earns less in an open auction for any participant set, so the open curve lies below the sealed curve. With the cost K fixed, the equilibrium entry probability is lower under open bidding.

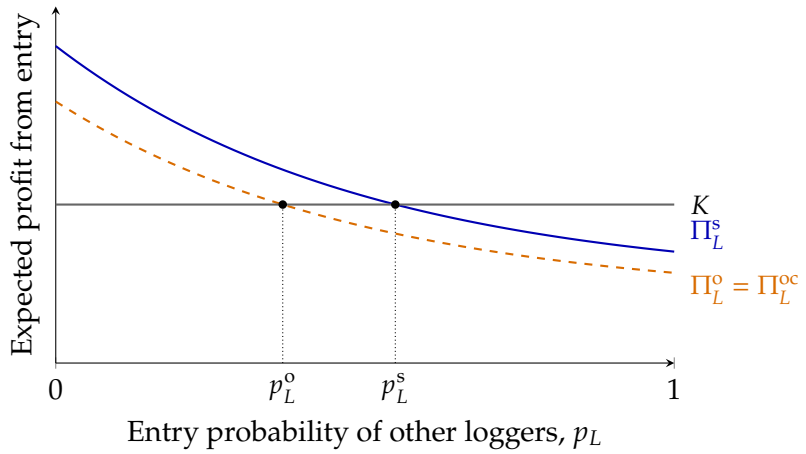

Figure 15.21: Logger entry in the type-symmetric equilibrium with $p_M = 1$ (schematic, not estimated). The entry payoff of a logger falls in the entry probability of the other loggers. Indifference with the entry cost K pins down p_L^{s} in sealed auctions and the lower p_L^{o} in open auctions. Mill collusion in open auctions leaves logger profits unchanged ($\Pi_L^{\mathrm{oc}} = \Pi_L^{\mathrm{o}}$), so it leaves logger entry unchanged.

15.9.7 Out-of-sample predictions and the competitiveness of open auctions

With the value distributions and entry costs in hand, ALS predict the outcome of every sale and compare the predictions with the data (Athey et al., 2011, pp. 247–248). The procedure has four parts.

(1) *Sealed sales.* The entry logit gives the distribution of entering loggers, and mill entry is known. The fitted bid distributions, integrated over ω, give bidding outcomes for each participant set. Combining the two gives outcomes conditional on the tract characteristics alone.

(2) *Open sales, competitive.* For each simulated auction, draw ω and draw a value for each participant from $\hat{F}_L(\cdot \mid Z, \omega, \boldsymbol{N})$ or $\hat{F}_M(\cdot \mid Z, \omega, \boldsymbol{N})$ via (15.80). Then record the price $P^{\text{o}} = \max\{V^{(n-1:n)}, r\}$, the second-highest participant value or the reserve price.

(3) *Open sales, collusive.* All participating mills except the one with the highest value drop out at once. The price is the second-highest value in the set formed by the top mill and the loggers, or the reserve price.

(4) *Open entry.* Mill entry equals the potential mill count. The logger entry probability p_L^{o} is the unique solution of $\hat{\Pi}_L^{\text{o}}(Z, \boldsymbol{N}; p_L) = \hat{K}(Z, \boldsymbol{N})$. Uniqueness holds because $\hat{\Pi}_L^{\text{o}}$ falls monotonically in p_L (Athey et al., 2011, footnote 27). By prediction (P5), the same p_L^{o} applies under collusion.

Standard errors come from a parametric bootstrap. ALS draw parameters from the estimated asymptotic distribution of the Table 15.26 estimates and repeat the whole calculation for each draw (p. 248). Column (2) of Table 15.28 conditions on the observed participants, and column (3) predicts entry as well.

In-sample fit. The sealed-bid rows measure fit, since these sales were used in estimation. In the North the average sale price is 69.4 dollars per mbf, against predictions of 69.9 with observed entry and 70.4 with predicted entry (Athey et al., 2011, p. 248). Average logger and mill bids and the share of sales won by loggers are also close. The largest discrepancy is in California, where the model overpredicts the sale price, 84.4 or 83.8 against 80.4, and the revenue.

Out-of-sample entry and allocation. The open-auction rows are the demanding test. The model predicts open-auction logger entry of 2.67 in the North against 2.75 observed, and 1.90 in California against 1.95 (Athey et al., 2011, p. 250). The model therefore explains the entry gap between formats, one of the main departures from revenue equivalence. It is less successful with allocation. It predicts that loggers win 54.4 percent of Northern open sales, or 56.0 percent with observed entry, against 59.0 percent observed. California shows a similar underprediction.

Out-of-sample prices and conduct. In California the competitive model predicts an open-auction price of 87.2 with observed entry and 86.7 with predicted entry, against 85.1 observed. The model reproduces the absence of a price difference between formats. The North is different. The competitive model predicts 67.9 or 67.8, and the fully collusive model 44.2 or 44.1. The observed average is 63.3. Accounting for sampling error, ALS reject both models at conventional levels. "Mildly cooperative" behavior by participating mills fits better than either extreme (pp. 250–251). A linear interpolation between the competitive and collusive predictions in column (2) gives a cooperation share of $\frac{67.9-63.3}{67.9-44.2} = 0.19$ (our calculation). ALS use 18 percent as the share that rationalizes Northern open prices in their welfare analysis.

Two robustness arguments strengthen the conclusion (p. 251). If sealed bidding were partly collusive, the inferred values would be higher, and open prices would look even less

Table 15.28: Actual outcomes and outcomes predicted by the estimated model

	N	(1) Actual	(2) Predicted, bidding only	(3) Predicted, bidding and entry
A. Northern sales				
Sealed-bid sales				
Average bid	1,492	59.6	58.2 (1.4)	57.4 (1.3)

Average mill bid	396	83.8	84.7 (2.7)	85.2 (2.7)
Average sale price	339	69.4	69.9 (1.4)	70.4 (1.6)
Average revenue (thousands)	339	111.4	108.1 (4)	109.9 (4.2)
Percent of sales won by loggers	339	68.1	68.0 (0.90)	65.0 (0.01)
Average logger entry	339	3.23		3.23 (0.09)
Open auction sales				
Average sale price, competition	732	63.3	67.9 (1.8)	67.8 (2.1)
Average sale price, collusion	732	63.3	44.2 (1.3)	44.1 (2.2)
Average revenue, competition	732	144.7	152.7 (6.8)	154.8 (7.9)
Average revenue, collusion	732	144.7	61.0 (2)	64.7 (5.0)
Percent of sales won by loggers	732	59.0	56.0 (0.01)	54.4 (0.02)
Average logger entry	732	2.75		2.67 (0.17)
B. California sales				
Sealed-bid sales				
Average bid	1,630	73.6	74.7 (2.3)	74.2 (2.3)
Average logger bid	1,150	64.0	63.6 (2.1)	62.3 (2.4)
Average mill bid	480	96.5	101.2 (3.5)	102.8 (3.8)
Average sale price	382	80.4	83.8 (2.1)	84.4 (2.4)
Average revenue (thousands)	382	103.1	110.7 (3.8)	111.9 (4.0)
Percent of sales won by loggers	382	66.8	66.4 (1.2)	62.6 (1.3)
Average logger entry	382	3.01		3.01 (0.07)
Open auction sales				
Average sale price, competition	325	85.1	87.2 (2.7)	86.7 (3.1)
Average sale price, collusion	325	85.1	46.1 (1.2)	51.0 (1.6)
Average revenue, competition	325	227.0	244.7 (9.7)	242.4 (10.9)
Average revenue, collusion	325	227.0	93.2 (2.6)	112.9 (5.6)
Percent of sales won by loggers	325	50.5	48.2 (1.1)	43.6 (1.8)
Average logger entry	325	1.95		1.90 (0.13)

Notes. Reproduced from Athey et al. (2011, Table V). Bids and prices in 1982 dollars per mbf, revenue in thousands of 1982 dollars. Column (1) shows average outcomes. Column (2) shows predictions for the same sales conditional on the observed entrants. Column (3) shows predictions of the equilibrium model of entry and bidding. Parametric bootstrap standard errors in parentheses, as printed (the paper prints a second standard error, 0.1, below the row for Northern sealed-bid logger entry). The standard errors for the percent of sales won by loggers appear in mixed units in the original.

competitive. ALS also examined the open sales whose predicted price lies far above the actual price and found no obvious pattern.

Where collusion should show up. Statistical detection of collusion is hard (Bajari and Ye, 2003), so ALS test a sharper implication of (P5). With zero or one participating mill the competitive and collusive models predict the same price. Any effect of mill collusion must appear in sales with two or more mills. Table 15.29 and Figure 15.22 split the Northern sales by mill participation.

Table 15.29: Actual and predicted sale prices by mill participation, Northern sales

	N	(1) Actual	(2) Predicted, bidding only	(3) Predicted, bidding and entry
Zero mills				
Sealed-bid sales	181	51.7	51.4	51.4
Open auction sales	321	49.8	50.5	47.1
One mill				
Sealed-bid sales	70	66.8	64.6	66.9
Open auction sales	150	50.0	52.2	59.5
Two or more mills				
Sealed-bid sales	88	108.1	112.1	112.2
Open auction sales	261	87.5	98.5	98.0

Notes. Reproduced from Athey et al. (2011, Table VI). Average sale prices in 1982 dollars per mbf. Predictions assume competitive bidding.

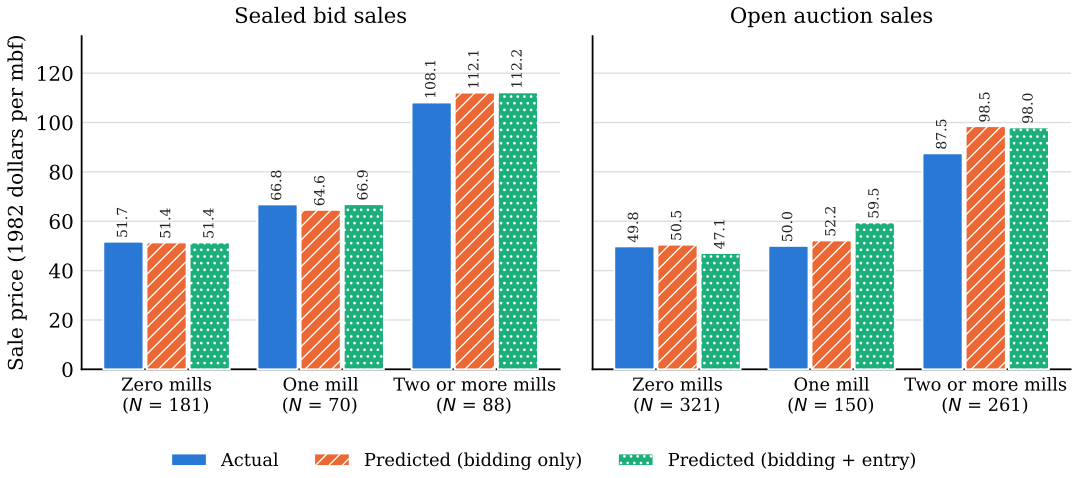

Figure 15.22: Actual and predicted competitive sale prices by mill participation, Northern sales. Drawn from the numbers in Athey et al. (2011, Table VI). With observed entry, the competitive model fits open prices with zero or one mill and overpredicts them with two or more mills.

With exogenous entry, column (2), the competitive model predicts open prices accurately with zero mills (50.5 against 49.8) and one mill (52.2 against 50.0). With two or more mills it predicts 98.5 against an observed 87.5, a shortfall of 11 percent (our calculation), as the collusion theory implies (Athey et al., 2011, p. 252). In sealed sales with two or more mills the shortfall is 4 percent. Column (3) is less sharp, because the model does not fit realized logger entry cell by cell. For open sales it predicts 3.31, 2.26 and 1.06 entering loggers in sales with zero, one and two or more mills, against 3.76, 3.32 and 1.77 observed (footnote 28). Column (2)

uses observed entry and isolates the bidding margin. Since the theory predicts identical entry under competition and collusion, that margin is where the two hypotheses differ.

15.9.8 Counterfactual comparison of formats

ALS finally take the estimates as the true primitives and ask what would happen if every tract were sold by one format (Athey et al., 2011, Section V.C). For each tract and format they compute expected entry, the expected price and revenue, the probability that a logger wins and the expected surplus. Surplus is the winner's value net of the entry costs sunk by all participants. Under exogenous entry, participation is fixed at its realized value. Under endogenous entry, both formats are solved for their entry equilibria. For open auctions they consider competitive mills and mills that cooperate 18 percent of the time. Table 15.30 reproduces the results.

Table 15.30: Counterfactual outcomes of sealed and open auctions

	(1) Sealed	(2) Open (competitive)	(3) Sealed − open (1) − (2)	(4) Open (partly collusive)	(5) Sealed − open (1) − (4)
A. Northern sales (N = 1,071)					
Exogenous entry					
Average sale price	68.56	68.53	0.03 (0.04)	64.58	3.98 (0.24)
Average revenue	138.33	138.64	−0.32 (0.06)	124.33	14.00 (1.22)
Average surplus	176.99	177.06	−0.08 (0.02)		
Percent won by loggers	60.14	59.68	0.46 (0.16)		
Endogenous entry					
Average sale price	69.68	68.19	1.49 (0.71)	64.11	5.57 (0.82)
Average revenue	143.04	139.87	3.17 (2.24)	125.32	17.72 (2.74)
Average surplus	156.53	156.84	−0.30 (2.70)		
Percent won by loggers	59.65	57.19	2.46 (0.00)		
Logger entry	3.10	2.76	0.34 (0.12)		
B. California sales (N = 707)					
Exogenous entry					
Average sale price	85.53	85.20	0.32 (0.07)	79.39	6.13 (0.39)
Average revenue	172.64	172.10	0.55 (0.13)	154.43	18.21 (1.36)
Average surplus	203.61	203.65	−0.04 (0.02)		
Percent won by loggers	58.21	57.81	0.40 (0.002)		
Endogenous entry					
Average sale price	88.36	83.76	4.60 (2.26)	78.55	9.81 (2.21)
Average revenue	182.38	168.20	14.18 (5.43)	152.83	29.55 (5.39)
Average surplus	181.82	170.58	11.24 (6.86)		
Percent won by loggers	55.84	52.66	3.18 (0.01)		

Notes. Reproduced from Athey et al. (2011, Table VII). Averages over all tracts in a region of model predictions. Prices in 1982 dollars per mbf, revenue and surplus in thousands of 1982 dollars. Exogenous entry uses the realized participants, and endogenous entry uses the equilibrium entry model. The partly collusive open auction has mills cooperating 18 percent of the time. Bootstrap standard errors in parentheses. The text of the paper (p. 253) states that with fixed participation sealed bidding raises Northern revenue by $320 per sale. The table prints a difference of −0.32 thousand, consistent with its columns (1) and (2).

A discrepancy in the source. With fixed participation, the text of ALS reports a sealed-bid revenue gain of "only $320 per sale in the Northern region and $546 in California" (p. 253). Table VII prints a Northern difference of −0.32 thousand dollars. The table's own columns

agree with the negative sign, since 138.33 − 138.64 = −0.31. For California the text and table agree, 0.55 thousand. We report the table and conclude that with fixed participation the Northern revenue difference is a few hundred dollars, of uncertain sign as printed.

Lessons. Four lessons emerge (Athey et al., 2011, pp. 253–255).

(i) *With fixed participation and competitive bidding, the format barely matters.* Revenue differences are a few hundred dollars per sale, and the logger win probability changes by less than one percentage point. The efficiency advantage of the open auction is under $100 per sale in both regions. The asymmetry between mills and loggers is substantial, yet its consequences for fixed participants are small.

(ii) *Entry magnifies the differences.* Both formats attract the same mills, but sealed bidding attracts three to four more loggers per 10 sales (0.34 more per sale in the North). Loggers win 2 to 4 percentage points more sales. The sealed-bid revenue advantage rises to roughly $3,000 per sale in the North and $14,000 in California, which is 2.3 and 8.4 percent of competitive open-auction revenue (our calculation).

(iii) *Efficiency comparisons are noisy.* The surplus difference stays small in the North. In California the point estimate even favors sealed bidding, although sealed bidding is known to be less efficient in equilibrium. The reason is that ALS estimate separate value distributions for each participant configuration, and these estimates are not identical. Expectations over stochastic logger entry weight the configurations differently across formats (footnote 29). Pooling the configurations would break the link between the value distribution and the estimated bid distribution through the first-order condition.

(iv) *Collusion dominates.* Suppose mills cooperate 18 percent of the time in open auctions. Open bidding then raises about $14,000 less per Northern sale than competitive sealed bidding with fixed participation, and over $17,000 less with entry effects. The California differences are larger, $18,210 and $29,550 in Table 15.30.

The revenue consequences of the format choice run mainly through the vulnerability of open auctions to collusion. Gains from extra logger entry come second, and efficiency losses are small.

15.9.9 Assessment

Contribution. ALS combine three features that earlier work had treated separately: asymmetric bidders, unobserved auction heterogeneity and endogenous participation (Athey et al., 2011, p. 255). Their entry model recovers entry costs in dollars from post-entry profits and observed entry rates. Earlier entry models in industrial organization infer profits relative to a normalized distribution of entry costs. Their main methodological idea is to use variation in the rules for validation. The parameters come from one game and are tested on another, which is a demanding out-of-sample check. The logic resembles the validation of conduct estimates against direct cost data in Chapter 3, with the second auction format in place of the cost data. The approach also yields a conduct test. Behavior in the format least prone to collusion serves as a benchmark for behavior in the format where collusion is suspected.

Limitations. Several assumptions deserve scrutiny.

- *Functional form.* The Weibull and Gamma forms and the independence of ω from Z are maintained hypotheses. They pass an informal moment check and a formal specification

test, but they drive the extrapolation to open auctions. Roberts (2013) argues that the reserve price itself carries information about ω (Section 15.7). ALS include the reserve price in Z, so this would violate the independence of ω and Z, and the large reserve-price coefficient in Table 15.26 may partly proxy for ω.

- *Competitive sealed bidding.* The benchmark assumes that sealed bidding is competitive. ALS argue that sealed collusion would only strengthen the conclusion, but a cartel operating in both formats would weaken the cross-format test.
- *Two types and a crude model of collusion.* Bidders are mills or loggers, and collusion is modeled as perfect mill cooperation in a fraction of sales. Partial cooperation, cooperation that depends on the identities of the mills, or coordinated entry would change the predictions.
- *Entry.* Point identification of entry costs relies on type-symmetric mixed strategies and on the measured number of potential loggers, which contains error. Values learned only after entry rule out selective entry.
- *Format selection.* In California the format varies strongly with size, and trimming keeps one third of the sales. Selection on unobservables remains a concern there.
- *Open auctions as button auctions.* Open predictions assume that the price equals the second-highest value. Jump bidding and bid increments break this equality (Theorem 15.11).
- *Two-step consistency.* Value distributions estimated separately by participant set need not coincide, which produces the anomalous California surplus estimate.

Follow-up work. Later studies of Forest Service sales build on this model (Hortaçsu and Perrigne, 2021, Section 2.6). Athey et al. (2013) evaluate small-business set-asides, sales reserved for firms with fewer than 500 employees. Their model keeps the entry and the mill-logger asymmetry of ALS and uses California's open and sealed sales. Opening the set-aside sales to large firms would cut the share of sales won by small firms by 51 percent. It would raise revenue by 6 percent and surplus by 21 percent (pp. 98–99). A bid subsidy of only 5 or 6 percent for small firms would keep their share of sales satisfactory. Prices would then rise by 4 percent and efficiency by 2 percent. Roberts and Sweeting (2013) let bidders receive signals of their values before entry, which makes entry selective. They compare the simultaneous open auction with a sequential mechanism. In it, entrants arrive one at a time, observe the earlier offers and may jump bid to deter later entry. With moderate selection and an entry cost of 2 percent of the average winning bid, the sequential mechanism raises revenue by 1.8 percent. A simultaneous auction with an optimal reserve raises it by 0.2 percent (pp. 99–100). Haile (2001) studies resale. When winners can resell in a secondary market, the values at which bidders drop out of an open auction rise with the number of bidders. Common values predict the reverse, through the winner's curse. He instruments the number of bidders with the number of sawmills in and near the county, and the evidence supports the model with resale (p. 100). The bounds of Aradillas-López et al. (2013) for correlated private values are applied to Oregon sales in Section 15.2.7.

15.10 Testing for Collusion with Auction Data

Auction data seem ideal for detecting collusion. The rules are known, every bid and bidder is often recorded, and the competitive benchmark is a fully specified game. Detection is

nonetheless hard. Porter and Zona (1993), in the working-paper version we follow, explain why.[1] Patterns often read as collusion can arise in competitive equilibria. Rotating winners are consistent with competition when firms face capacity constraints. Comparisons of winning bids with engineers' cost estimates can mislead, because the estimates may be inflated by past bids. Collusive schemes take many forms (Hendricks and Porter, 1989). A cartel might rotate a single bid among its members, or several members might submit higher *complementary bids*, also called *phantom bids*, to create the appearance of competition. No single test can detect every scheme. A cartel that includes every bidder could even choose complementary bids that pass any broadly applicable test. Its bids would mimic competitive bids for some plausible realization of costs (Porter and Zona, working paper, pp. 2–3).

Athey et al. (2011, p. 211) sort the empirical approaches into three groups. Table 15.31 summarizes them. The first group requires prior knowledge of the cartel's existence and structure and compares suspected members with other bidders. The second derives in-sample specification tests of the competitive model and treats collusion as the alternative. The third, which ALS introduce, uses behavior under one format as the benchmark for another.

Table 15.31: Approaches to detecting collusion with auction data

Approach	Maintained information	Implication tested	Examples
Suspected members versus others	Identity of a candidate cartel, bid levels and ranks	Determinants of non-winning cartel bids differ from those of the low cartel bid and of non-cartel bids	Porter and Zona (1993, 1999)
Specification tests of competition	Bidder and auction covariates	Conditional independence and exchangeability of bids	Bajari and Ye (2003)
Cross-format benchmark	A format presumed competitive	Prices in the suspect format fall short of predictions only where theory says collusion bites	Athey et al. (2011)
Records of a known cartel	Knockout bids and side payments	Structural values and damages from the cartel's internal bids	Asker (2010)
Super-plus factors	Bid histories, registrations, ownership after the sale	Transfers among bidders, no rivalry within a subset, prompt resale, close losing bids	Marshall and Marx (2012)

Porter and Zona: low cartel bids versus higher cartel bids. Porter and Zona study state highway paving contracts on Long Island in the early 1980s. A set of five firms, named in a bid-rigging conviction and related suits, forms a candidate cartel. Insiders described meetings that designated a serious bidder and its bid, after which other members submitted higher bids. The cartel did not rotate single bids. Several members bid on most jobs, which makes detection possible because ring behavior can be compared with that of non-members. Each competitive bidder in a low-bid procurement auction chooses its bid b to maximize $(b - c_{it})\Psi_{it}(b)$, where c_{it} is its cost on job t and $\Psi_{it}(b)$ its probability of submitting the lowest bid. The first-order condition is

$$\Psi_{it}(b) + (b - c_{it})\Psi'_{it}(b) = 0,$$

the procurement analog of (15.68). Costs are unobserved, so Porter and Zona approximate the

[1] We use NBER Working Paper 4013 (March 1992) for the description of the tests. The published estimates are discussed in Section 13.9.

equilibrium bid by a log-linear rule,

$$\ln B_{it} = \alpha_t + W_{it}\vartheta + \epsilon_{it}, \qquad \mathbb{E}[\epsilon_{it}] = 0, \qquad \operatorname{Var}(\epsilon_{it}) = \sigma_t^2. \tag{15.85}$$

Here α_t is a job effect, W_{it} are firm-job cost shifters such as capacity and backlog, and ϵ_{it} is private cost information whose variance differs by job. Ordinary least squares on competitive bids estimates ϑ, the job mean squared residual estimates σ_t^2, and feasible generalized least squares reweights the data.

The sharper test uses the ranking of bids. Let $X_{it} = -\frac{W_{it}}{\hat{\sigma}_t}$ be the deflated cost shifters with the sign reversed. If $-\epsilon_{it}$ is type I extreme value, the job effect cancels and the probability that firm i submits the lowest bid takes the logit form. The probability of the observed ranking $b_{r_1 t} < b_{r_2 t} < \cdots < b_{r_n t}$ is the rank-ordered logit

$$\mathbb{P}\left[b_{r_1 t} < \cdots < b_{r_n t}\right] = \prod_{m=1}^{n-1} \frac{\exp(\vartheta X_{r_m t})}{\sum_{l=m}^{n} \exp(\vartheta X_{r_l t})}. \tag{15.86}$$

The likelihood factors into the probability of the lowest bid and the probabilities of the ranks above it. Under correct specification and no phantom bidding, both parts carry the same coefficients. A likelihood ratio test applied to competitive bids checks the specification. The same test applied to cartel bids asks whether the low cartel bid and the higher cartel bids share determinants. Complementary bids are not meant to win, so their ranking need not reflect cost differences. Porter and Zona find that ranks and levels of non-cartel bids follow cost measures, while the ranks of higher cartel bids do not and differ from those of the low cartel bid. A Chow test of a common bid equation for cartel and competitive firms, estimated as in their Table 4, gives $F(76, 319) = 9.38$ (p. 33). For competitive bids, the likelihood ratio statistic for equal coefficients across ranks is 4.30 against a χ^2_6 distribution, a p-value of 0.64 (p. 33, estimates in Table 5). For cartel bids it is 8.94 against a χ^2_4 distribution, a p-value of 0.063 (p. 34, estimates in Table 6). The p-values are our computation. Page and table numbers refer to the NBER working-paper version of Porter and Zona (1993), and Section 13.9 reports the full estimates.

Bajari and Ye: independence and exchangeability. A second approach needs no list of suspects. In an independent private values model with symmetric bidders, bids are independent across bidders conditional on the covariates, and the joint distribution of bids is exchangeable (Athey and Haile, 2007, Section 5.5). Suppose values have the form $V_{it} = h(Z_{1t}, Z_{2i}, Z_{2(-i)}, A_{it})$, where Z_{1t} is an auction covariate, Z_{2i} a bidder covariate, $Z_{2(-i)}$ the rivals' covariates and A_{it} an idiosyncratic factor with an exchangeable distribution. Each bid then depends on $(Z_{1t}, Z_{2i}, Z_{2(-i)})$ and not on the bidder's identity. Two regression tests follow. Residuals from regressions of bids on covariates should be uncorrelated across bidders, and coefficients should be equal across bidders or classes of bidders. Bajari and Ye (2003) apply both tests to highway construction procurement. Collusion is the alternative. Rejection can also reflect omitted heterogeneity common to the bidders, the problem of Section 15.7.

The structural signature. ALS add a third approach with three steps. Estimate the model on the segment least prone to collusion, sealed sales. Predict outcomes where collusion is suspected, open sales. Then look where theory says collusion must appear, sales with two or more strong participants. The test exploits an implication of theory that a cartel cannot easily mask: a ring of mills cannot lower prices in sales where at most one mill participates. Its power comes from the structural model, which delivers the competitive benchmark for each cell.

Using a cartel's own records. When records of a cartel's internal knockout auctions survive, the cartel's bids can be modeled directly. Asker (2010) uses such records for a ring of stamp dealers to estimate values, the ring's gains and the harm to sellers and to non-members (Section 13.8).

Theory and enforcement. The theory of Section 14.12 explains why the format matters. In open and second-price auctions, a ring in which the highest-value member bids and the others abstain is self-enforcing within the auction (Propositions 14.87 and 14.89). In first-price auctions a ring needs the threat of future punishment, the repeated-game enforcement of Chapter 12. Optimal collusion in repeated first-price auctions with private information can take sophisticated forms. When the auctioneer reveals the winning bid but not the winner's identity, optimal collusion has every member bid the reserve price with equal chances of winning. Athey and Haile (2007, footnote 102) summarize this result of Athey et al. (2004a).

Marshall and Marx (2012, ch. 8) compare what a ring gains under each format, with independent private values and a fixed set of bidders. In an ascending auction the ring's highest-value member bids up to its value and the other members never raise a hand (pp. 171–172). The ring gains only when it holds the two highest values. It then wins at the highest value outside the ring instead of the second-highest value overall. A bidder outside the ring who wins pays what it would have paid without the ring, so the ring captures all of the gain (p. 176). In a first-price auction the ring's designated bidder faces fewer rivals and lowers its bid. Bidders outside the ring respond by lowering their bids as well, and the equilibrium is unique (pp. 174–175). The lower ring bid sometimes lets an outsider win when it would have lost under competition. Part of the collusive gain then leaks to bidders outside the ring, so the incentive to collude is typically weaker under sealed bidding (p. 176).

Example 15.64 (Ring gains in an ascending auction)**.** Let $n = 5$ bidders have values drawn independently from the uniform distribution on $[0, 1]$, with no reserve price, and let k of them form a ring. The m-th lowest of five uniform values has mean $\mathbb{E}[V^{(m:5)}] = \frac{m}{6}$. Let J be the number of top values that the ring holds in an unbroken run from the top. If $J \le 1$, the price is the second-highest value overall. If $J = j \ge 2$, the price is the highest value outside the ring, $V^{(5-j:5)}$. Ring members are a random subset, so for $k = 2$

$$\mathbb{P}(J \le 1) = 1 - \frac{2}{5} \cdot \frac{1}{4} = \frac{9}{10}, \qquad \mathbb{P}(J = 2) = \frac{2}{5} \cdot \frac{1}{4} = \frac{1}{10}.$$

The expected price is

$$\frac{9}{10} \cdot \frac{4}{6} + \frac{1}{10} \cdot \frac{3}{6} = 0.600 + 0.050 = 0.650,$$

against $\frac{4}{6} \approx 0.667$ without the ring. The ring wins when it holds the top value, which happens with probability $\frac{2}{5}$. Given that event, its member with the top value pays $\frac{4}{6}$ with probability $\frac{3}{4}$ and $\frac{3}{6}$ with probability $\frac{1}{4}$. The ring's expected surplus is therefore

$$\frac{2}{5}\left[\frac{5}{6} - \left(\frac{3}{4} \cdot \frac{4}{6} + \frac{1}{4} \cdot \frac{3}{6}\right)\right] = \frac{2}{5} \cdot \frac{5}{24} = \frac{1}{12} \approx 0.083.$$

Each member expects about 0.042, against $\frac{1}{30} \approx 0.033$ for a competitive bidder. Both numbers match the first rows of Table 15.32.

Table 15.32 shows both effects (pp. 181–182). A ring that does not include every bidder hurts the seller more under ascending bidding, and its members gain more there. Outside bidders gain nothing from a ring at an ascending auction, while at a first-price auction their

Table 15.32: Ring size and auction format with five uniform bidders (Marshall and Marx 2012, Table 8.1)

	Expected price		Surplus per ring member		Surplus per outsider	
Ring size k	Ascending	First price	Ascending	First price	Ascending	First price
1	0.667	0.667	0.033	0.033	0.033	0.033
2	0.650	0.651	0.042	0.035	0.033	0.037
3	0.600	0.609	0.056	0.041	0.033	0.049
4	0.467	0.506	0.083	0.057	0.033	0.086
5	0.000	0.000	0.167	0.167		

Notes. Values uniform on $[0, 1]$, reserve price zero. Ascending entries and the first-price entries for $k = 1$ are analytic. The other first-price entries come from Monte Carlo simulation with 100,000 draws, as reported by Marshall and Marx from earlier work of Marshall and coauthors.

surplus rises with the size of the ring. The authors caution that this ranking is not a general result (p. 181, footnote 21, citing Maskin and Riley, 2000). Leakage also shapes who joins (Section 8.3, pp. 176–180). At an ascending auction nothing leaks, so outsiders always want to join, and with symmetric bidders the ring wants everyone in. At a sealed-bid auction a weak bidder may prefer to stay out and bid against a ring whose depressed bids it can exploit. Membership also raises a sequencing problem (Section 8.3.2, pp. 179–180). The last bidder to join adds a large gain, because its entry removes all remaining competition. If that bidder were paid its contribution, every member would want to join last. Rings therefore fix the division of the gain before the auction, with equal shares for symmetric members and the average of each member's marginal contributions for asymmetric ones. Settling the split in advance also rules out conflicting claims and costly rent seeking after the auction (p. 180).

Auction design against rings. Marshall and Marx (2012, ch. 10) turn the comparison into design advice. Transparency helps a ring monitor its members (pp. 200–202). Rules written to curb favoritism by public officials announce the set of bidders before the sale and publish bids and identities after it, which serves rings as well. In early spectrum auctions of the Federal Communications Commission, bidders chose their increments and used the last three digits of their bids to signal to one another. Later designs fixed the increments and hid rivals' identities until the auction closed. A right of last refusal for an incumbent supplier lets the incumbent watch rivals' bids in real time, which deters deviations from a collusive agreement. Bidding under disguised identities, or shill bids, makes deviations harder for a ring to police, especially at sealed-bid auctions (pp. 202–205). With transparent registration a ring can suppress competition at an ascending auction. It does so with a scheme in which the winning member pays the ring the excess of the second-highest member report over the price. If identities are hidden during the bidding and registration is not transparent, payments from winning members alone cannot suppress all competition. Information about the object also matters. If bidders have more expertise than the seller, competitive bidding transfers the rents from that expertise to the seller, which gives bidders an extra reason to collude. The frequency of sales matters as well (p. 206). Regular, frequent sales make bid rotation and punishment easier, so an auctioneer worried about collusion may hold fewer sales of larger lots at irregular intervals. Finally, sealed bids leave a paper trail of losing bids, while ascending auctions often leave no record of who would have bid (pp. 206–207). The authors list six measures (p. 207). Use sealed instead of ascending bids. Limit information about rivals, outcomes and bids. Avoid rights of last refusal for incumbents. Allow multiple bids, some under disguised identities. Choose disclosure of the seller's information with collusion in mind. Hold auctions at long,

irregular intervals. The first measure is the choice that Pinchot made for the Forest Service (Section 15.9.1).

Plus factors for rings. A *plus factor* is evidence, beyond parallel prices, that supports an inference of collusion. Marshall and Marx (2012, ch. 12) focus on *super-plus factors*, patterns whose probability without a ring is close to zero (pp. 243–244). They stress those that a ring could not remove without changing how it works. Two apply to both formats. The first is transfers among bidders, such as cash settlements of a knockout or subcontracting and joint ownership arrangements that were not declared before the sale. The second is a divergence between observed prices and the prices predicted by a model estimated on a benchmark in which no ring is presumed to operate. This is the logic of the cross-format test of Athey et al. (2011), with sealed sales as the benchmark and open sales as the suspect segment.

At an ascending auction the ring's rule is simple: members do not bid while another member is active (pp. 244–246). The winner and the last underbidder, and any two bidders who compete directly, are then never both members. A subset of bidders who never bid against each other at meaningful prices is therefore a super-plus factor, although it may take many auctions to detect. Ascending auctions allocate efficiently, so a prompt resale to another bidder who was present suggests a post-auction knockout. Light attendance is not a super-plus factor, since rings may require members to attend. At a sealed-bid auction resale is weaker evidence, because asymmetric bidders can produce inefficient allocations that resale corrects (pp. 246–247). Nonwinning bids unrelated to values, the evidence that Porter and Zona (1993) use, are not substantive either, because a ring can rescale its losing bids freely. Close pairs of bids are more telling. Suppose the top member has value $100,000 and would bid $90,000 under competition, but the ring wants it to bid $50,000. A member with value $60,000 that expects less than $10,000 from the ring would then gain by bidding $50,001 through a shill. To deter this, the ring has its top member bid more, say $65,000, and has another member bid just below. The frequent closeness of two bids then reveals the ring. A sudden switch from ascending to sealed bidding is informative too (p. 248). A large price increase after the switch suggests that a ring operated at the ascending auctions. No change is not evidence of no ring, and risk aversion raises sealed-bid prices only modestly.

Shill bidding in Russian oil and gas auctions. The appendix to their chapter 12 studies ascending auctions for Russian oil and gas leases, which proceed only if at least two bidders register (pp. 248–255). The government sets a reserve price and the increments, and the lowest feasible bid is one increment above the reserve. The data cover 620 auctions from 2004 to 2007. They are complete for 121 auctions and partial for 499. The complete auctions are larger, with an average reserve of 71,503,769 rubles against 49,484,900. Five were canceled and one was awarded on criteria other than price, which leaves 115. Table 15.33 reproduces the distribution of winning bids. Auctions with six or more participants always end at least 20 increments above the reserve. In 34 of the 43 two-bidder auctions, 79 percent, the winning bid is one or two increments above the reserve. These 34 auctions have an average reserve of 27,515,294 rubles, less than half the average for all 620.

The identities point to shills (Table 12.3, pp. 251–253). The 34 auctions have 24 distinct winners, 26 distinct losers and 26 distinct ordered pairs. One bidder won six such auctions, always against the same opponent, which never won any of the 620 auctions. The authors classify 13 losing bidders as *pure shills*. Each bid at most once, never won a lease in the 620 auctions, and never took part in an auction without its winning partner. Two losers form a rotating pair, each winning against the other at one or two increments, and the remaining 11 are occasional shills. The registration rule explains the pattern. A license of interest to a single

Table 15.33: Winning bids in increments above the reserve, by number of participants (Marshall and Marx 2012, Table 12.2)

	Increments of the winning bid above the reserve					
Participants	1	2	3–19	20–99	100 or more	Auctions
2	53%	26%	9%	7%	5%	43
3	3%	9%	26%	41%	21%	34
4	8%	0%	15%	15%	62%	13
5	10%	10%	20%	10%	50%	10
6 or more	0%	0%	0%	33%	67%	15
Combined	23%	13%	15%	22%	28%	115

Notes. Subsample of 115 auctions with complete data, 2004–2007. Each row sums to 100 percent. Their Table 12.1 gives the same data as shares of all 115 auctions.

firm cannot be sold unless a second bidder registers, so the firm has an incentive to bring one along. The authors note that their own static model of semitransparent auctions leaves no role for shills in a well-functioning ring. Two pure shills did appear with their partners in auctions with more than two bidders, which suggests dynamic motives or a strategic auctioneer.

Evidence from timber sales. Forest Service timber sales have produced several studies of collusion (Hortaçsu and Perrigne, 2021, Section 2.5). Collusion was suspected in the 1970s and led to a congressional hearing in 1977, but few cases were prosecuted (p. 96). Baldwin et al. (1997) study Forest Service oral auctions. They compare order-statistic models of competitive and cooperative bidding, in which a winning ring member pays the highest value outside the ring. The supply of timber varied across years, and oversupply alone could depress bids. After controlling for supply conditions, collusion explains the low bids better (pp. 96–97). In British Columbia, sales are by first-price sealed bid. List et al. (2007) treat collusion as an unobserved treatment and test conditional independence and exchangeability of bids, in the spirit of Bajari and Ye (2003). They flag 130 suspect bidders, and the evidence of collusion is mixed (p. 97). Price (2008) studies the spatial proximity of bidders. Firms located in the same town or nearby bid 10 to 13 percent less, and exchangeability is rejected for firms in close proximity. Industry interviews suggest that distance does not create asymmetry in values. With the same data, Schurter (2020) shows that an asymmetric independent private values model with collusion is not identified when the colluders are unknown (pp. 97–98). An instrument that shifts competition but is independent of values given the reserve price restores identification. His test asks, bidder by bidder, whether estimated values are independent of the reserve. Seven firms fail it, and four of them do not bid competitively. Competitive bidding by these four firms would raise revenue by 3.2 percent, a moderate cost of collusion.

15.11 Divisible-Good Auctions: Bidding with Demand Schedules

Treasury bills, central bank loans and electricity are sold in auctions in which each bidder states a quantity for every price. The good is *divisible*, so any share of the supply can be allocated. Such auctions are also called *share auctions*, after the model of Wilson (1979). Each bid is a demand schedule, and the seller adds the schedules up to clear the market. This section gives a short treatment of the format. Its message is that the logic of Section 15.4 carries over. The

distribution of the market-clearing price, given a bidder's own schedule, takes the place of the distribution of rival bids. We set up the model, derive the first-order conditions under uniform and discriminatory pricing, and study one application of each.

15.11.1 The share auction with step bids

A perfectly divisible good is sold to N bidders. Quantities are measured as shares of the announced supply. The quantity sold, Q, may be random, because the seller can adjust it after seeing the bids. Its distribution is common knowledge. Bidder i observes a private signal s_i, and signals are independent across bidders. Winning the share q gives the bidder the gross utility

$$V(q, s_i) = \int_0^q v(u, s_i)\, du, \tag{15.87}$$

where the *marginal value* $v(q, s_i)$ is weakly decreasing in q and strictly increasing in s_i. Values are private, so v does not depend on rivals' signals (Kastl, 2011, p. 978 and Assumptions 2 and 6).

A bid is a *step function*. Bidder i submits K_i *bidpoints* (b_k, q_k), $k = 1, \dots, K_i$, with prices $b_1 > b_2 > \cdots > b_{K_i}$ and cumulative quantities $q_1 < q_2 < \cdots < q_{K_i}$. The bidder demands nothing at prices above b_1 and demands q_k at prices in $(b_{k+1}, b_k]$, with the convention $b_{K_i+1} = 0$ and $q_0 = 0$. The seller caps the number of bidpoints at $\bar{K}$, which is 10 in both applications below. Bidders use far fewer steps than the cap allows, so the steps are a feature of the data that a model must explain.

Let $y_j(p)$ be bidder j's demand at price p. The *residual supply* facing bidder i is the quantity left for it after its rivals' demands are met,

$$RS_i(p) = Q - \sum_{j \neq i} y_j(p). \tag{15.88}$$

It rises with p. It is random from i's point of view, because it depends on rivals' signals and on Q. The *market-clearing price* P^c is the highest price at which total demand weakly exceeds supply. Bids above P^c are filled in full. Demands exactly at P^c are scaled down in proportion until the supply is exhausted, a rule called *pro rata rationing on the margin*. Two payment rules are common. Under *uniform pricing* every unit won pays P^c. Under *discriminatory pricing*, also called pay-as-bid, each unit won pays the bid on that unit. A bidder then pays the area under its own step function up to the quantity it wins.

With continuous and strictly decreasing bid functions, as in Wilson (1979), residual supply crosses each demand curve at a single point and nobody is rationed. With steps, residual supply is itself a step function. It can cross bidder i's schedule in two ways. On a vertical segment, i receives exactly q_k at a price strictly between b_{k+1} and b_k. On a horizontal segment, the price equals one of i's bids and i is rationed. With private values and a continuous price grid, ties with positive probability are incompatible with equilibrium, except possibly at bids above the bidder's marginal value (Kastl, 2011, p. 984 and Appendix B). A bidder that expected a tie at a bid below its marginal value would gain by raising that bid slightly. A rationed bidder is then the only marginal bidder, and it receives the residual supply at its own bid.

15.11.2 Uniform pricing: Kastl (2011)

Question. Economists agree that governments should sell their securities by auction, but they disagree about the format. In a survey that Kastl (2011) cites, 39 of 42 countries used

discriminatory pricing and only 3 used uniform pricing (p. 974). Theory does not rank the two formats on revenue or on efficiency (Athey and Haile, 2007, Section 10). Kastl asks how to measure the performance of a uniform-price auction from bids when bidders submit only a few steps. His answer starts from the observation that steps change the first-order conditions, and with them the values that bids reveal.

The step first-order condition. Fix bidder i with signal s_i, its bid $\{(b_k, q_k)\}$ and its rivals' strategies. All probabilities and expectations below are over rivals' signals and the supply, given s_i and i's bid. Write A_k for the event $b_k > P^c > b_{k+1}$, in which residual supply crosses the vertical segment of i's schedule at q_k.

Proposition 15.65 (Step condition under uniform pricing)**.** *Assume private values and pro rata rationing on the margin. In any Bayesian Nash equilibrium, for almost every s_i, every step k at which a tie has probability zero satisfies*

$$\mathbb{P}(A_k)\big[v(q_k, s_i) - \mathbb{E}(P^c \mid A_k)\big] = q_k \, \frac{\partial \, \mathbb{E}\big[P^c \, \mathbf{1}\{b_k \geq P^c \geq b_{k+1}\}\big]}{\partial q_k}. \tag{15.89}$$

Equivalently,

$$v(q_k, s_i) = \mathbb{E}(P^c \mid A_k) + \frac{q_k}{\mathbb{P}(A_k)} \, \frac{\partial \, \mathbb{E}\big[P^c \, \mathbf{1}\{b_k \geq P^c \geq b_{k+1}\}\big]}{\partial q_k}. \tag{15.90}$$

Derivation. We give the argument for a step at which ties have probability zero, as they do when $b_k < v(q_k, s_i)$. Fix a realization of rivals' signals and of the supply. Let $P(q)$ be the inverse residual supply, the price at which RS_i equals q. Three events involve step k.

(i) On A_k, $b_{k+1} < P(q_k) < b_k$. Bidder i wins q_k at the price $P(q_k)$, and its payoff is $V(q_k, s_i) - P(q_k)\, q_k$.

(ii) On B_k, $q_{k-1} < RS_i(b_k) < q_k$. The price is b_k, and i is rationed to $RS_i(b_k)$.

(iii) On B_{k+1}, $q_k < RS_i(b_{k+1}) < q_{k+1}$. The price is b_{k+1}, and i is rationed to $RS_i(b_{k+1})$.

Raise q_k slightly and hold the other bidpoints fixed. On B_k and B_{k+1} the payoff does not depend on q_k, because i receives the residual supply. Only the boundaries of the three events move. On the boundary between A_k and B_k we have $P(q_k) = b_k$ and $RS_i(b_k) = q_k$, so the payoffs in (i) and (ii) coincide. The same holds on the boundary between A_k and B_{k+1}. Moving a boundary therefore has no first-order effect, and only the change inside A_k remains. Differentiating the payoff in (i) gives

$$\frac{\partial \, \mathbb{E}[\text{payoff}]}{\partial q_k} = \mathbb{E}\Big[\Big(v(q_k, s_i) - P(q_k) - q_k \, \frac{\partial P(q_k)}{\partial q_k}\Big)\mathbf{1}\{A_k\}\Big].$$

Set the derivative to zero and use $\mathbb{E}\big[P(q_k)\mathbf{1}\{A_k\}\big] = \mathbb{P}(A_k)\, \mathbb{E}(P^c \mid A_k)$:

$$\mathbb{P}(A_k)\big[v(q_k, s_i) - \mathbb{E}(P^c \mid A_k)\big] = q_k \, \mathbb{E}\Big[\frac{\partial P(q_k)}{\partial q_k} \, \mathbf{1}\{A_k\}\Big].$$

It remains to rewrite the right side. The event $b_k \geq P^c \geq b_{k+1}$ is the union of A_k, B_k and B_{k+1}. This union does not move with q_k, since a change in q_k only shifts states among the three events. Inside the union, P^c equals $P(q_k)$ on A_k and the constants b_k and b_{k+1} on the other two events. It is continuous across their boundaries. Hence

$$\frac{\partial \, \mathbb{E}\big[P^c \, \mathbf{1}\{b_k \geq P^c \geq b_{k+1}\}\big]}{\partial q_k} = \mathbb{E}\Big[\frac{\partial P(q_k)}{\partial q_k} \, \mathbf{1}\{A_k\}\Big].$$

Substituting gives (15.89), and dividing by $\mathbb{P}(A_k)$ gives (15.90). The regularity needed to differentiate under the expectation is established in Lemmas A2 to A4 of the appendix of Kastl (2011). □

At a step with $b_k \geq v(q_k, s_i)$ a tie can have positive probability, and the condition gains two terms that involve the rationed quantity (Kastl's eq. (2)). Kastl uses (15.90) at every step. From discussions with market participants, he argues that bidders ignore the effect of their demand on the rationed quantity. An alternative estimator that allows for ties gives qualitatively similar, somewhat larger estimates with large standard errors (Section 4.1 and Appendix B.1).

Interpretation. The left side of (15.90) is the value of the marginal unit. The right side is its expected marginal expenditure. It adds the expected price on the vertical segment and the expected rise in the clearing price on the q_k units already bought. The bidder is a buyer facing a random, upward-sloping residual supply curve, so the condition equates marginal value with marginal expenditure. Kastl reads it as marginal cost equal to marginal revenue for an oligopolist facing uncertain demand. The analogy extends the one of Section 14.13.3. There a single-object bidder chose a price, and the win probability played the role of quantity. Here the bidder chooses quantities directly, and residual supply plays the role of the demand curve. The second term on the right measures *quantity shading*. The bidder asks for less than the quantity at which its marginal value equals the expected price, because more demand raises the price on all of its units.

Steps versus smooth schedules. In Wilson's model with smooth schedules, the analog of (15.90) holds at every price on the schedule (Kastl's eq. (1)):

$$v\big(y(p), s_i\big) = p - y(p)\,\frac{H_x\big(p, y(p)\big)}{H_p\big(p, y(p)\big)}, \qquad H(p,x) = \mathbb{P}\big(x \leq RS_i(p)\big). \tag{15.91}$$

Here $H(p,x)$ is the probability that the clearing price is at most p when i demands x at p, and subscripts denote partial derivatives. Since H falls in x and rises in p, the markdown is nonnegative. Every bid then lies weakly below the marginal value. The step condition differs in one place. Its reference point is the expected clearing price on the segment, $\mathbb{E}(P^c \mid A_k)$, which lies below the bid b_k. Nothing in (15.90) therefore forces b_k below $v(q_k, s_i)$.

Corollary 15.66 (Bids above marginal values)**.** *Under uniform pricing with step bids, a bidder may optimally bid above its marginal value (Kastl, 2011, Corollary 1).*

Proof. Consider a bidder so small that its bid does not affect the distribution of P^c, which is continuous, and let $K_i = 1$. Ties then have probability zero, and the right side of (15.89) is zero. With $b_2 = 0$ the condition becomes

$$v(q_1, s_i) = \mathbb{E}\big(P^c \mid P^c < b_1\big).$$

Whenever P^c falls below b_1 with positive probability, the conditional mean lies strictly below b_1. Hence $b_1 > v(q_1, s_i)$. □

The intuition is that one step must serve every price below b_1. The bidder buys q_1 whenever the price falls below b_1, so it equates the marginal value of the last unit with the average price at which that unit is bought. The bid itself only decides whether the bidder buys at all. Exercise 8. shows that it equals the average value of the block, $\frac{V(q_1, s_i)}{q_1}$, which exceeds the marginal value of the last unit.

The corollary matters for counterfactuals. Solving for an equilibrium under another format is hard, so researchers often compare realized revenue with the revenue under *truthful bidding*, in which every bidder bids its marginal value schedule. With smooth schedules no bid exceeds value, so this revenue bounds uniform-price revenue from above. Athey and Haile (2007, Section 10) describe how the working-paper version of Hortaçsu and McAdams (2010) used such a bound for Turkish treasury auctions. With steps the bound fails, because bids can exceed values. Ignoring the steps also overstates values, since the smooth model adds the shading term to the bid instead of to $\mathbb{E}(P^c \mid A_k)$. Kastl argues that both errors bias comparisons toward the discriminatory format (Sections 5.2.3 and 5.2.4).

Identification and estimation. The bids are observed. Every unknown on the right of (15.90) is therefore a functional of the distribution of P^c given i's bid. That distribution depends on the joint distribution of rivals' bid functions and of the supply. Under private values, independence across bidders and symmetry within groups of bidders, rivals' bid functions are independent draws from a group distribution. The distribution of P^c can then be simulated by *resampling*, a method introduced in the working-paper version of Hortaçsu and McAdams (2010). The steps are as follows (Section 4.2.1).

1. Fix bidder i in auction t. Let g be its group and N_{tg} the number of bidders from group g.
2. Draw $N_{tg} - 1$ bid functions from group g, and N_{th} from each other group h, with replacement from the sample.
3. Combine the drawn schedules with a draw of the supply to form a residual supply curve, as in (15.88).
4. Intersect this curve with i's bid to obtain one clearing price.
5. Repeat steps 2 to 4 B times.

The simulated prices estimate $\mathbb{P}(A_k)$ and $\mathbb{E}(P^c \mid A_k)$. For the derivative, let $\mathcal{E}_k(q)$ be the expectation $\mathbb{E}\left[P^c \mathbf{1}\{b_k \geq P^c \geq b_{k+1}\}\right]$ when the k-th quantity of i's bid is set to q. Kastl repeats the simulation at $q_k - \varepsilon_n$ and uses the difference quotient

$$\frac{\hat{\mathcal{E}}_k(q_k) - \hat{\mathcal{E}}_k(q_k - \varepsilon_n)}{\varepsilon_n},$$

where $\varepsilon_n \to 0$ slowly enough as the sample grows. The estimators are consistent as the number of auctions grows (Proposition 2).

The two steps mirror those of Section 15.4. A first step estimates the distribution of rivals' behavior without solving for an equilibrium. A second step inverts a first-order condition bid by bid. Two features differ. First, the first step now estimates a distribution of residual supply curves instead of a scalar bid distribution. Second, the inversion recovers the marginal value only at the submitted quantities $q_1, \ldots, q_{K_i}$. Since v falls in q, between two steps it lies between the adjacent estimates. Beyond the last step it lies between zero and the last estimate. To the left of the first step it has no upper bound. Kastl builds upper and lower step-function envelopes from the point estimates for his counterfactuals. He caps values to the left of the first step at the first estimate and sets values beyond the last step to zero (Section 5.2.4).

Data. Kastl (2011) studies 28 uniform-price auctions of three-month Czech Treasury bills, held by the Czech National Bank between November 25, 1999 and December 14, 2000 (Section 5.1). Each bill has a face value of 1,000,000 Czech koruny (CZK), about $26,300. The data contain every bid, the announced supply, the clearing price and the final allocation. Table 15.34

reproduces the summary statistics. About 13 bidders are active in an auction. They may submit up to 10 bidpoints, but they submit 2.3 on average and never more than 9. Single demands range from 0.01 to 50 percent of the supply, and 50 percent is the most a bidder may request. Of the 16 bidder identities, seven are small and ask for less than 5 percent of the supply in every auction. The other nine are large. The government may keep part of the issue through a noncompetitive bid placed after it sees the bids. It kept up to 77 percent of the supply, mostly as announced in advance. The unannounced withdrawal exceeded 2 percent of the issue in only two auctions, so bidders face some uncertainty about the supply. Kastl argues that values are private, because there is virtually no secondary market and banks hold the bills to maturity.

Table 15.34: Czech Treasury bill auctions, 1999–2000 (Kastl, 2011, Table 1)

	Mean	Min	Max	Std. dev.
Active bidders per auction	13	10	16	1.4
Bidpoints per bidder	2.3	1	9	1.55
Price bid (CZK)	987,039	986,203	987,776	236.8
Yield of price bid (%)	5.30	4.99	5.65	0.10
Quantity bid (share of supply)	0.091	0.0001	0.5	0.11
Unannounced noncompetitive bid (share of supply)	0.0024	0	0.036	0.008
Clearing price (CZK)	986,994	986,463	987,173	174.71
Clearing yield (%)	5.32	5.22	5.54	0.08
Reference interest rate (%)	5.39	5.32	5.74	0.10
Revenue (million US dollars)	210	78.9	263.2	62.6

Notes. 28 auctions of three-month bills. An active bidder submits a nonzero bid. Price bids are per bill of face value CZK 1,000,000, and the lowest yield corresponds to the highest bid. Quantity bids are shares of the supply offered, across all steps. The unannounced noncompetitive bid is the government's unexpected withdrawal of supply. One US dollar was about 38 CZK.

An auction has too few bidders for resampling within it. Kastl pools four neighboring auctions of the same maturity, held within two months, and treats them as repetitions of one game. With 15 potential bidders per auction, 7 small and 8 large, the pool contains 60 bid functions (Section 5.2.1). A potential bidder that does not bid counts as submitting a zero bid. The government's withdrawal enters in two ways. Model M1 resamples the government's noncompetitive bid as a third group. Model M2 imposes a rule suggested by insiders. Supply is withdrawn if the market would not clear or if the clearing yield would exceed the reference interbank rate by more than one basis point (Section 5.1). Standard errors come from 500 bootstrap replications (Section 5.2.2).

Results. The estimates show that the steps matter. For bidder 1 in auction 52, the bid at the first step lies above the estimated marginal value, as Corollary 15.66 allows (Figure 4). The incentive to shade grows with the quantity demanded, so bids above value are more likely at small quantities. In 6 of the 28 auctions, realized revenue exceeded the revenue from truthful bidding of the upper envelope of estimated values (Tables 3 and 4). In the smooth model this could not happen. On average, the clearing price under truthful bidding is close to the actual one (Table 15.35). Bidders thus have little market power near the expected clearing price.

To judge the format without solving for a counterfactual equilibrium, Kastl estimates each bidder's expected surplus per bill. He uses the upper envelope of its values and the simulated distribution of P^c. If the bidders' total expected surplus is close to zero and the allocation is efficient, the format extracts almost all the surplus it could. Table 15.35 reports the averages. Since 25 CZK per bill correspond to one basis point of annual yield, the mechanism leaves

about 3 basis points unextracted on average (Section 5.2.5). Full extraction cannot be rejected in 19 of the 28 auctions, and misallocation costs about 2.5 basis points. Values from the smooth model raise the unextracted surplus to about 5 basis points. They overstate bidders' surplus by about 60 percent. Kastl concludes that switching formats is unlikely to bring economically significant gains. Bidders lose little by using few steps. For bidders who use one bidpoint, the implied lower bound on the cost of a second one ranges from $2 to $150 (Section 5.2.6).

Table 15.35: Performance of the Czech uniform-price auctions (Kastl, 2011, Tables 3 to 6)

	Estimate
Mean clearing price, actual (CZK)	986,994
Mean clearing price, truthful bidding of the upper envelope (CZK)	986,997.11
Mean clearing price, truthful bidding of the lower envelope (CZK)	986,958.71
Auctions with actual revenue above truthful upper-envelope revenue	6 of 28
Bidders' total expected surplus per bill, step model (CZK)	83.67
Bidders' total expected surplus per bill, smooth model (CZK)	133.45
Loss from misallocation (basis points)	2.50

Notes. Means over the 28 auctions under model M1. Surplus uses the upper envelope of estimated marginal values. At 25 CZK per basis point, 83.67 and 133.45 CZK are about 3.3 and 5.3 basis points of annual yield, and their ratio is 1.6. Under model M2 the total surplus is 77.73 CZK, the misallocation loss is 2.54 basis points, and the mean price under truthful upper-envelope bidding is CZK 986,998.54.

15.11.3 Discriminatory pricing: Cassola, Hortaçsu and Kastl (2013)

Question. On August 9, 2007, BNP Paribas froze three investment funds exposed to the American subprime mortgage market. The spread between unsecured and secured one-week interbank rates in the euro area then rose from about 4 basis points to well over 10. Banks' bids for central bank loans rose as well. Cassola et al. (2013), henceforth CHK, ask how the crisis changed individual banks' cost of short-term funds. They also ask how much of the rise in bids reflects higher values and how much is a strategic response to rivals' more aggressive bids. The answer matters for policy. Interbank loans are traded over the counter, and balance sheets are published rarely. Bids are therefore one of the few high-frequency measures of funding costs at the bank level (Section 1).

Setting. The European Central Bank (ECB) supplies liquidity through its main refinancing operations, weekly auctions of collateralized loans with a one-week maturity. A bank submits up to ten pairs of an interest rate and a quantity through its national central bank. The ECB finds the highest rate at which demand weakly exceeds supply. Bids at higher rates are filled, and demands at the marginal rate are rationed pro rata. Throughout the sample the format is discriminatory, so each winner pays its own bid rate. The bid is an interest rate, so a higher rate is a higher bid. After each auction the ECB publishes only aggregate outcomes, such as the marginal rate, the total allotment, the weighted average rate and the number of bidders (Section 3). After August 2007 the allotment deviated substantially from the announced benchmark, so the model treats supply as random.

Values. The marginal value of an ECB loan reflects the bank's outside options (Section 5.1). In a stylized version of the model, a bank needs a fixed amount of liquidity and can also borrow in the interbank market. Its last units can be borrowed against high-quality collateral at the bank's secured rate. The units beyond its collateral cost its unsecured rate. Units in between cost a

rate that depends on the haircuts applied to its other securities. The marginal value schedule therefore falls from the unsecured rate to the secured rate. A bank with weak collateral values ECB loans close to its unsecured rate.

Model. The model is the share auction of Section 15.11.1 with three additions. Bidders observe a vector ω_t of public information that the econometrician may not see, such as market rates and announcements. Signals are independent across bidders conditional on ω_t, and the marginal value is $v(q, s_i, \omega_t)$, which we abbreviate to $v(q, s_i)$. The supply is random, with a distribution known to bidders, and each bank submits at most 10 steps (Assumptions 1 to 6).

Proposition 15.67 (Step condition under discriminatory pricing)**.** *Assume private values and pro rata rationing on the margin. In any Bayesian Nash equilibrium of the discriminatory auction, for almost every s_i, every step $k < K_i$ at which $v(\cdot, s_i)$ is continuous satisfies*

$$v(q_k, s_i) = b_k + \frac{\mathbb{P}(b_{k+1} \geq P^c)}{\mathbb{P}(b_k > P^c > b_{k+1})} (b_k - b_{k+1}). \tag{15.92}$$

The last step satisfies $b_{K_i} = v(\bar{q}, s_i)$, where $\bar{q}$ is the largest quantity that bidder i can be allocated.

Derivation. Raise q_k by a small amount Δq and hold the other bidpoints fixed. This moves Δq units from step $k+1$, priced at b_{k+1}, to step k, priced at b_k. Three cases arise.

(i) If $P^c \geq b_k$, bidder i receives less than q_k, so the units at the end of step k are not won. The payoff does not change.

(ii) If $b_k > P^c > b_{k+1}$, residual supply cuts the vertical segment at q_k. The bidder now wins Δq more units and pays b_k for each, a gain of $\big[v(q_k, s_i) - b_k\big]\Delta q$.

(iii) If $P^c \leq b_{k+1}$, the bidder wins the Δq units with or without the change. It now pays b_k for them instead of b_{k+1}, a loss of $(b_k - b_{k+1})\Delta q$.

As in the derivation of Proposition 15.65, payoffs are continuous across the boundaries of these events, so moving the boundaries has no first-order effect. At an optimum the expected gain equals the expected loss:

$$\mathbb{P}(b_k > P^c > b_{k+1})\big[v(q_k, s_i) - b_k\big] = \mathbb{P}(b_{k+1} \geq P^c)\,(b_k - b_{k+1}).$$

Dividing by $\mathbb{P}(b_k > P^c > b_{k+1})$ gives (15.92). The last step has no lower step. Raising q_{K_i} adds units bought at b_{K_i} whenever $P^c < b_{K_i}$, so optimality requires

$$\mathbb{P}(P^c < b_{K_i})\big[v(q_{K_i}, s_i) - b_{K_i}\big] = 0.$$

Hence the last bid equals the marginal value at the end of the last step. □

Compare (15.92) with (15.90). In both formats, extra quantity at step k earns a surplus in the states where residual supply cuts the vertical segment. The cost differs. Under uniform pricing, more demand raises the clearing price on all inframarginal units. Under pay-as-bid, it raises the price paid on units that would have been won anyway at the lower step. The shading term in (15.92) is nonnegative, so $v(q_k, s_i) \geq b_k$ at every interior step. Bids therefore never exceed values under discriminatory pricing, while under uniform pricing they can (Corollary 15.66).

As the steps become fine, (15.92) converges to the condition for smooth schedules (CHK, footnote 16). Let $H(b, q)$ be the probability that $P^c < b$ when i demands q at the price b, and let H_b be its derivative in b. Set $b_{k+1} = b_k - \Delta b$. For small Δb,

$$\mathbb{P}(b_k > P^c > b_{k+1}) \approx H_b(b_k, q_k)\,\Delta b, \qquad \mathbb{P}(b_{k+1} \geq P^c) \approx H(b_k, q_k).$$

Substituting into (15.92) and letting $\Delta b \to 0$ gives

$$v(q, s_i) = b + \frac{H(b, q)}{H_b(b, q)}, \tag{15.93}$$

the condition for discriminatory auctions with smooth schedules (Athey and Haile, 2007, Section 10). It has the form of the inversion (15.9). In a first-price auction of one object, a bid b wins with probability $G(b)^{n-1}$. The ratio of this probability to its derivative is $\frac{G(b)}{(n-1)g(b)}$. In a divisible-good auction, the probability that the clearing price falls below the bid takes its place. CHK's condition for a step over which the marginal value is flat has the same form, with $\mathbb{P}(b_k > P^c)$ in place of H (Proposition 1(ii)).

Estimation. CHK use the resampling estimator of Section 15.11.2 with one change. Bids respond to public information ω_t that the econometrician may not observe, and such information moved fast after August 2007. Pooling auctions would mix different values of ω_t. With about 340 bidders per auction, CHK instead resample within a single auction, which holds ω_t fixed. They prove that the estimator of the clearing-price distribution is consistent as the numbers of bidders and of resamples grow (Proposition 2). Deviations of the allotment from the announced supply are resampled from their empirical distribution, separately before and after the turmoil (Section 5.3.2). Bidders may know which banks are in distress while the econometrician does not. With hundreds of bidders, drawing one fewer bidder from a group barely changes the simulated price distribution, so CHK estimate under ex ante symmetry (Section 5.3.1). Estimating auction by auction is a direct way to handle the unobserved heterogeneity of Section 15.7. It is feasible only because each auction has hundreds of bidders.

Data. CHK observe all bids in the 50 regular one-week refinancing auctions between January 4 and December 11, 2007, 32 of them before August 9 (Sections 4 and 6.2). An auction has on average 341 participating banks out of 733 identities, so about half of the potential bidders take part in a given week. Bids have 1.66 steps on average. The average bank demands about 1 billion euros at 3.94 percent. This rate is about 4 basis points above EONIA, an index of overnight unsecured interbank rates. Table 15.36 compares the periods before and after the turmoil. After August 9, bids have more steps, the supply is smaller, and bids are 10 basis points higher relative to EONIA.

Table 15.36: ECB one-week refinancing auctions before and after August 9, 2007 (Cassola, Hortaçsu and Kastl, 2013, Table II)

	Mean		Standard deviation	
	Before	After	Before	After
Bidders	348.6	328.1	20.88	34.37
Submitted steps	1.47	2.02	0.73	1.34
Price bid (%)	3.80	4.13	0.20	0.06
Spread of bid over EONIA (percentage points)	0.00	0.10	0.02	0.08
Quantity bid (share of supply)	0.004	0.005	0.009	0.014
Issued amount (billion euros)	292.34	202.19	1.42	4.51

Notes. 50 auctions in 2007, 32 of them before August 9. The price bid is an interest rate. EONIA is the euro overnight index average.

Results. *Shading*, the gap between a bank's marginal value and its bid, averaged 6.6 basis points over the whole sample, with a standard deviation of 20. It averaged about 4 basis points before

the turmoil, with a standard deviation of 11.5, and 11.2 basis points after it, with a standard deviation of 30.5. Uncertainty about where the auction would clear rose, and shading rose with it. Bank-by-bank regressions of shading on a turmoil dummy find a significant change for 99 banks. Shading fell by 2 basis points on average for 7 of them and rose by over 18 basis points on average for the other 92 (Section 6.1).

Values tell a more varied story. For the 482 banks that bid both before and after August 9, CHK regress each bank's quantity-weighted marginal value on a turmoil dummy. About two thirds of these banks show a significant increase in value. The other third show none, so the rise in their bids was purely a strategic response to their rivals. For almost 100 banks, values rose by more than 20 basis points (Section 6.2). The same regressions with bids in place of values find a significant increase for nearly every bank. Table 15.37 cross-tabulates the two classifications. They disagree for 101 of the 482 banks, or 21 percent. A placebo test splits the auctions before the turmoil into two halves. It finds disagreement for 39 of 443 banks, which suggests that the gap in Table 15.37 is not due to chance.

Table 15.37: Banks with a significant post-crisis increase, by values and by bids (Cassola, Hortaçsu and Kastl, 2013, Table III)

	Increase in bids	
Increase in values	Yes	No
Yes	326	5
No	96	55

Notes. The 482 banks that bid both before and after August 9, 2007. An increase is a significant positive coefficient on a turmoil dummy in a regression of the bank's quantity-weighted marginal value, or of its quantity-weighted bid.

The estimated values line up with other measures of bank health (Section 6.4). In a panel of 20 banks with credit default swap (CDS) data, a bank's CDS spread relative to the average raises its marginal value after the turmoil. The coefficient is 0.008, with a standard error of 0.001 (Table IV). A "bad" bank, with the highest relative CDS spread and the largest outstanding long-term ECB loans, is predicted to value funds at 4.57 percent. A "good" bank is predicted at 3.94 percent, a gap of over 60 basis points. CHK also use a cross-section of about 390 banks with balance-sheet data. The change in estimated values predicts the change from 2006 to 2007 in return on equity and in the cost-to-income ratio at the 5 percent level. Banks whose values rose more saw their return on equity fall and their cost-to-income ratio rise. The change in values also predicts return on assets at the 10 percent level when bids are included, while the change in bids predicts none of these measures (Table V). Values also show that reported interbank rates understated many banks' unsecured borrowing costs. Several auctions late in 2007 cleared above EURIBOR, the survey-based unsecured rate, although ECB loans are collateralized (Section 6.3).

Lessons. Bids are not values, even in pay-as-bid auctions in which every interior bid lies below value. Read at face value, the bids would label almost every bank as hit by the crisis, while a third of them were only responding to their rivals. The logic of Section 15.4 carries over to demand schedules. Observed rival schedules give the distribution of the clearing price conditional on a bidder's own bid. The first-order condition of the format then turns each step into a marginal value. The format matters for that inversion. Under uniform pricing a step bid can exceed the marginal value, and under discriminatory pricing it cannot.

15.12 What Auction Data Can and Cannot Tell Us

This chapter has asked one question in many settings. Which primitives can be recovered from which data, under which model? Table 15.38 collects the answers. Its rows are models and its columns are data configurations. Each cell states whether the primitives are identified and points to the result that says so. The last column lists the extra data or variation that restores identification or provides a test.

Four lessons stand out from the table and the case study.

The data matter as much as the model. Reading across a row shows how much the observables matter. The same symmetric affiliated private values model is unidentified from transaction prices and identified from all first-price bids. Reading down a column shows the reverse trade-off. With transaction prices alone we must assume independence, and with richer data we can relax it (Section 15.2). In this chapter, bidder identities, extra bids and exogenous variation in the number of bidders have each turned a negative result into a positive one. So have covariates, reserve prices, ex post values and a second auction format. When planning an empirical auction study, the first question is which of these the data contain.

First-order conditions recover private information. In a first-price auction the bidder's first-order condition maps a bid into a value. The markdown $\frac{G(b)}{(n-1)g(b)}$ is computed from the bid distribution alone. This is the auction analog of recovering marginal cost from a pricing first-order condition and estimated demand (Chapters 4 and 8). Auctions have one advantage over those settings. The seller writes the rules, so the game form is known, and conduct need not be estimated as a free parameter (Chapter 3). The price of this advantage is the equilibrium assumption, which must hold auction by auction.

Credibility comes from validation. Identification results say what the data could reveal under a model. They do not say whether the model is right. The timber study shows one way to earn credibility. Estimate on one segment, predict another that was not used in estimation, and examine the gaps where theory says they should and should not appear. Specification tests such as the conditional Kolmogorov test help, but out-of-sample predictions under different rules test the behavioral assumptions directly.

Open frontiers. Dynamic links between auctions, through capacity, learning or collusion, require models in which bidders look ahead (Section 15.8). Divisible-good auctions received only a short treatment in Section 15.11. Auctions of several different objects, in which bidders value packages, raise identification problems beyond the scope of this book (Athey and Haile, 2007, Section 10). Bidding that departs from equilibrium, through learning or behavioral biases, challenges the assumption that makes inversion possible. Athey and Haile (2007, Section 11) also stress that identification analysis matters beyond econometrics. In learning models such as self-confirming equilibrium, the question is whether players themselves can infer the primitives of the game from the outcomes they observe.

15.13 Bibliographic notes

Structural econometrics of auctions began with parametric models. Paarsch (1992) estimated parametric models with closed-form bid functions. Donald and Paarsch (1993, 1996) worked out the non-standard asymptotics that a parameter-dependent support creates. Laffont et al. (1995) introduced simulation and showed that revenue equivalence can serve as an estimation

Table 15.38: An identification map for single-object auctions

Model	Ascending or second price, transaction price only	Second price, all bids	First price, all bids	First price or Dutch, winning bid only	Extra data that restore identification or testability
Symmetric IPV	Identified from any one order statistic with known n (Thm. 15.4)	Identified, since bids equal values (Prop. 15.3)	Identified if and only if bids satisfy (C1) and (C2) (Thm. 15.19)	Identified with known n (Prop. 15.28)	Exogenous variation in n or a second order statistic makes the model testable (Thm. 15.4)
Asymmetric IPV	Identified with the winner's identity, by competing risks (Thm. 15.6)	Identified with bidder identities	Identified with bidder identities (Eq. (15.42))	Identified with the winner's identity (Prop. 15.28)	Identities or bidder classes. Exogenous participation for tests (Thm. 15.6)
IPV with observed covariates	$F(\cdot \mid z)$ identified. Additive index up to location (Thm. 15.7)	Identified given z	Identified given z, using homogenized bids (Lem. 15.49)	Identified given z (Prop. 15.28)	Bidder covariates with large support identify even correlated values (Thm. 15.8)
Symmetric APV	Not identified (Thm. 15.9)	Identified	Identified. Rationalizable if and only if G is affiliated and ξ increasing, given the boundary condition of Prop. 15.31	Not identified. Top two bids identify the law of the top two values (Prop. 15.33)	All bids, or bidder covariates (Thm. 15.8). Bounds on revenue with exogenous n (Sec. 15.2)
Asymmetric APV	Not identified (Thm. 15.9)	Identified with identities	Identified with identities (Prop. 15.34)	Not identified	All bids with identities. In practice $n = 2$ (Sec. 15.5)
Common values	Not identified. Pure common values not even up to normalization (Props. 15.38 and 15.39)	Signal law identified after normalization. Joint law of signals and values never (Prop. 15.38)	Pivotal expected value identified, joint law not. Observationally equivalent to APV for fixed n (Sec. 15.6)	Not identified	Exogenous n tests private against common values (Thm. 15.42, Prop. 15.44). Ex post values (Sec. 15.6)
IPV with unobserved heterogeneity	Not identified from one price per auction, a single convolution such as $\omega + A^{(n-1:n)}$ with many decompositions (remarks after Thm. 15.52)	Joint value law identified. With two or more bids and separable values, F_ω and F_A follow by deconvolution (Lem. 15.50)	Identified with two or more bids under separability (Lem. 15.49, Thm. 15.52). Parametric mixture (Prop. 15.61)	F_V identified above the reserve from transaction and reserve prices if the reserve rises with ω (Prop. 15.55)	Two bids per auction, reserve prices, or three bids without separability (Sec. 15.7)
Risk aversion	Bidding unaffected. Preferences not identified and not needed for these formats (Sec. 15.8.6)	Same as the price-only case	Not identified from one n. If a CRRA utility rationalizes the bids, so does any more risk-averse one (Sec. 15.8.6)	Not identified	Exogenous variation in n, a wealth or value shifter, a parametric restriction, or F_V from other formats (Sec. 15.8.6)
Costly entry	Entry cost identified once F is, from mixed-strategy indifference (Prop. 15.56)	Entry cost identified (Prop. 15.56)	Entry cost identified (Prop. 15.56, Eq. (15.81))	Identified under IPV (Prop. 15.56)	Observed potential bidders. Exogenous shifts of N or K for selective entry (Sec. 15.8)
Binding reserve price	F identified above r only (Prop. 15.13). The optimal reserve is recovered when it exceeds r (Prop. 15.14)	F identified above r	F above r, N and $F(r)$ identified (Thm. 15.27)	F identified above r	Observed potential bidders identify $F(r)$. Exogenous variation in r traces more of F (Sec. 15.2)
Open outcry with jump bids	Bounds on F and on the optimal reserve (Thm. 15.11)	Not applicable	Not applicable	Not applicable	Smaller increments tighten the bounds (Thm. 15.11)

Notes. IPV and APV denote independent and affiliated private values. "Identified" refers to the value distribution of the model, or to the joint law of values for correlated models. Unless stated otherwise, the number of bidders n is observed. Each cell names the result of this book that states or proves it.

device. The surveys of Hendricks and Paarsch (1995), Laffont (1997) and Perrigne and Vuong (1999) describe the field at that stage. Paarsch and Hong (2006) give a book-length treatment of the parametric and early nonparametric methods. Paarsch (1997) used a parametric model of British Columbia timber sales to estimate an optimal reserve price, an early policy application of the structural approach.

The indirect approach of Guerre et al. (2000) reorganized the field. It was extended to affiliated private values by Li et al. (2002) and to asymmetric bidders by Campo et al. (2003). Athey and Haile (2002) asked systematically which models are identified from which data, across formats, and Athey and Haile (2007) restate the whole literature in that framework. Their survey is the natural next step for a reader of this chapter. Haile and Tamer (2003) replaced the button model with weak behavioral restrictions, an early instance of partial identification in industrial organization. Aradillas-López et al. (2013) bound revenue and the optimal reserve price with correlated private values. Coey et al. (2017) tighten such bounds with observed bidder asymmetries, and Coey et al. (2019) use the bidder exclusion effect to bound the gain from an optimal reserve. Li and Perrigne (2003) study secret reserves in French timber sales. Most of these applications find observed reserve prices low relative to the estimated optimum.

On common values, Laffont and Vuong (1996) established the observational equivalence with affiliated private values, and Li et al. (2000) added structure under which the mineral rights model is identified. Haile et al. (2003) developed tests based on variation in the number of bidders, and Hendricks et al. (2003) used ex post values to test equilibrium bidding. Compiani et al. (2020) extended the tests to endogenous entry and unobserved heterogeneity and found common values in offshore oil leases. Hong and Shum (2002) measured the winner's curse in highway procurement. Somaini (2020) obtained identification with interdependent costs from continuous variation in competitors' cost shifters. Hendricks and Porter (1988) remains the leading field evidence on adverse selection in auctions, and Hendricks and Porter (2007) survey the empirical literature on auctions. Hortaçsu and Perrigne (2021) update that survey market by market, covering timber, procurement, offshore oil and online auctions. Their survey complements Athey and Haile (2007) on the applied side.

Unobserved heterogeneity is now a standard concern. Krasnokutskaya (2011) brought deconvolution to auctions. Her published application differs from that of the earlier working paper (Krasnokutskaya, 2004), and we report the published estimates. Roberts (2013) used reserve prices as a control, and Hu et al. (2013) relaxed separability with three bids per auction. Haile and Kitamura (2019) survey the identification results. Entry was modeled empirically by Athey et al. (2011) in the tradition of Levin and Smith (1994). Selective entry, in the spirit of Samuelson (1985), is studied by Marmer et al. (2013), Gentry and Li (2014) and Roberts and Sweeting (2013). Li and Zheng (2012) and Roberts and Sweeting (2016) estimate entry costs under both entry models with timber data. Jofre-Bonet and Pesendorfer (2003) extended the two-step logic to dynamic auctions with capacity constraints. Campo et al. (2011) and Guerre et al. (2009) studied risk aversion, and Lu and Perrigne (2008) and Grundl and Zhu (2019) estimated it from timber sales. On collusion, Porter and Zona (1993, 1999) and Bajari and Ye (2003) test competitive bidding directly, and Asker (2010) studies a cartel's internal records. Chapter 13 treats these studies in depth. Marshall and Marx (2012) analyze how the auction format shapes what a bidding ring gains, which designs make rings harder to sustain, and which patterns in bid records reveal them.

Section 15.11 gives a short treatment of divisible-good auctions, in which bidders submit demand schedules. The share auction model is due to Wilson (1979). Hortaçsu and McAdams (2010) introduced the resampling estimator of the distribution of the clearing price and compared pay-as-bid with uniform pricing in Turkish Treasury auctions. Kastl (2011) derived

the first-order conditions for step bids under uniform pricing and applied them to Czech Treasury bills. Cassola et al. (2013) used the discriminatory version to measure banks' funding costs in the auctions of the European Central Bank during the 2007 crisis. Athey and Haile (2007, Section 10) discuss identification in multi-unit and multi-object auctions more broadly.

15.14 Exercises

1. *Precision of estimators from ascending-auction data.* Parts (a) to (c) ask which order statistic is more informative, and parts (d) to (f) show that estimated bounds can cross. Consider the SIPV model of a second-price sealed-bid auction with n bidders. In each of T auctions, either the highest bid $B^{(n:n)}$ or the second-highest bid $B^{(n-1:n)}$ is recorded.

   (a) Use (15.1) to show that $\Lambda_{n:n}(x) = x^n$ and that F is identified from the highest bid by $F(v) = G_{B^{(n:n)}}(v)^{\frac{1}{n}}$.

   (b) Derive the delta-method variance of the estimator $\hat{F}(v) = \hat{G}_{B^{(n:n)}}(v)^{\frac{1}{n}}$, following the steps that led to (15.2). Show that its asymptotic variance per auction is $\frac{F^{2-n}(1-F^n)}{n^2}$, evaluated at $F = F(v)$.

   (c) Let values be uniform on $[0,1]$ and $n = 4$. Compare the asymptotic variances of the two estimators of $F(0.2)$, and the variance $\frac{F(1-F)}{n}$ of the estimator that uses all bids. Show that the second-highest bid is almost nine times as informative as the highest bid at this point. Explain the result in terms of how often a value near 0.2 becomes the highest or the second-highest of four.

   (d) Suppose now that the button model holds with $\Delta = 0$, so the bounds of Theorem 15.11 coincide with $F(v)$ at a point v. Two order statistics give estimators $\hat{a}_1$ and $\hat{a}_2$ of the upper bound, and one gives an estimator $\hat{c}$ of the lower bound. Treat $\hat{a}_1$, $\hat{a}_2$ and $\hat{c}$ as independent draws from $N\big(F(v), \sigma^2\big)$. Show that $\mathbb{E}\big[\min\{\hat{a}_1, \hat{a}_2\}\big] = F(v) - \frac{\sigma}{\sqrt{\pi}}$, so the estimated upper bound is biased downward.

   (e) Show that the estimated upper bound lies below the estimated lower bound with probability $\frac{2}{3}$. Note that the event is that $\hat{c}$ is not the smallest of three exchangeable draws.

   (f) Explain why replacing the minimum and maximum by smooth weighted averages, as Haile and Tamer (2003) do, reduces the problem. What does the example imply for reporting estimated bounds without inference?

2. *The GPV inversion with power bids.* Bids in a symmetric first-price auction with n bidders are i.i.d. with $G(b) = b^a$ on $[0,1]$, where $a > 0$.

   (a) Use (15.9) to show that $\xi(b) = q_a b$ with $q_a = \frac{a(n-1)+1}{a(n-1)}$.

   (b) Show that condition (C2) of Theorem 15.19 holds for every $a > 0$, both directly and by checking that $\frac{g}{G^n}$ is strictly decreasing as in Remark 15.20.

   (c) Use (15.10) to derive F. Show that values follow a power distribution on $[0, q_a]$ and that the result agrees with the bid function of Example 15.15.

   (d) Show that the relative markdown $\frac{v-b}{v}$ equals $\frac{1}{a(n-1)+1}$ for every bid. Compute it for $a = \frac{1}{2}$ with $n = 2$ and for $a = 2$ with $n = 4$, and explain why more concentrated bids imply smaller markdowns.

3. *The recurrence relation and the winner's curse.*

   (a) Verify Lemma 15.40 for three i.i.d. uniform draws, with $r = 1$ and $r = 2$, by computing each order-statistic distribution explicitly.

   (b) In a symmetric second-price auction with common values, the bid function $b(s; n)$ falls strictly in n (Lemma 15.41). Explain, without formulas, why the transaction price in $(n-1)$-bidder auctions is then stochastically larger than the mixture of order statistics on the left side of (15.48).

   (c) A researcher regresses winning bids from first-price auctions on the number of bidders and finds a negative coefficient. She concludes that values are common. Give two reasons why the conclusion does not follow, citing the results of Section 15.6.2.

4. *Risk aversion and exogenous variation in n.* Values are uniform on $[0, 1]$, and bidders have utility $\mathcal{U}(x) = x^a$ with $0 < a \le 1$. The symmetric first-price bid is then $\beta(v) = \frac{n-1}{n-1+a}\, v$, the solution of (14.40) for uniform values.

   (a) Write $c_n = \frac{n-1}{n-1+a}$. Show that bids in n-bidder auctions are uniform on $[0, c_n]$, that $b_n(\alpha) = c_n \alpha$, and that $z_n(\alpha) = \frac{\alpha c_n}{n-1}$ in the notation of (15.66).

   (b) Using only n-bidder auctions, show that the risk-neutral inversion (15.9) rationalizes the bids with values uniform on $\left[0, \frac{n}{n-1} c_n\right]$. Explain why this illustrates the non-identification result of Section 15.8.6.

   (c) For two numbers of bidders $n_1 < n_2$, show that $\frac{b_{n_2}(\alpha) - b_{n_1}(\alpha)}{z_{n_1}(\alpha) - z_{n_2}(\alpha)} = a$ for every α. Interpret this as the overidentifying restriction of Section 15.8.6.

5. *Recovering an entry cost.* There are $N_L = 6$ potential loggers. Mills always enter and their number is fixed. A participating logger's expected profit, estimated from bids as in Proposition 15.56, is $\pi_L(n_L) = \frac{40}{n_L + 1}$ thousand dollars when n_L loggers participate.

   (a) Write the indifference condition (15.81) for a logger who enters when each other potential logger enters with probability p.

   (b) Show that the ex ante entry profit $\Pi_L(p)$ falls strictly in p. Use first-order stochastic dominance of the binomial distribution in p.

   (c) The observed entry probability is $p = 0.5$. Show that the implied entry cost is $K \approx 9.55$ thousand dollars. Compute $\Pi_L(0)$ and $\Pi_L(1)$ and explain why any K between them is consistent with mixed entry.

   (d) Suppose a change in format lowers every $\pi_L(n_L)$ by 10 percent while K stays fixed. Explain, using Figure 15.21, why logger entry falls, and why mill collusion would not change it.

6. *Interpreting the timber evidence.* Answer in words, citing the results of this chapter.

   (a) Why does estimating the model from sealed-bid sales alone make the predictions for open auctions an out-of-sample test, in two distinct senses?

   (b) Why is a sale with a single participating mill uninformative about collusion among mills? Which pattern in Table 15.29 would have contradicted the collusion interpretation?

   (c) Why does ignoring unobserved heterogeneity inflate estimated markups? Relate your answer to Example 15.48 and to the finding of Athey et al. (2011) without heterogeneity.

(d) Should a seller in the Northern forests worry more about the inefficiency of sealed bidding or about collusion in open auctions? Use Table 15.30 to give a quantitative answer.

7. *What a ring gains at an ascending auction.* Five bidders have values drawn independently from the uniform distribution on $[0, 1]$, and there is no reserve price. A ring of k randomly chosen bidders operates as in Example 15.64. Its highest-value member bids up to its value, and the other members do not bid.

   (a) For $k = 3$, find the probability that the ring holds the two highest values and the probability that it holds the three highest values. Show that the expected price is 0.600.

   (b) Show that the expected surplus of each bidder outside the ring is $\frac{1}{30}$ for every $k < 5$. Use this result and $\mathbb{E}[V^{(5:5)}] = \frac{5}{6}$ to show that each ring member expects about 0.056 when $k = 3$.

   (c) In Table 15.32 the surplus of outside bidders at a first-price auction rises with k. Explain why, and explain why this leakage weakens the incentive to form a ring under sealed bidding.

   (d) Explain why a pair of bidders who never bid against each other across many ascending auctions is a super-plus factor, while light attendance at the auctions is not.

8. *Bidding with steps in a divisible-good auction.* A bidder has a strictly decreasing marginal value $v(q)$ on $[0, 1]$ and gross utility $V(q) = \int_0^q v(u)\,du$. It is a price taker. The clearing price P^c has a continuous distribution H with density h on $[0, 1]$, which the bidder's own bid does not affect.

   (a) Under uniform pricing the bidder submits one step (b, q). Explain why it wins q at the price P^c when $P^c < b$ and wins nothing otherwise. Write its expected payoff as an integral over the price. Show that the first-order condition for q is $v(q) = \mathbb{E}(P^c \mid P^c < b)$, as in Corollary 15.66. Show that the condition for b is $b = \frac{V(q)}{q}$, and conclude that $b > v(q)$.

   (b) Let $v(q) = 1 - q$ and let P^c be uniform on $[0, 1]$. Show that the optimal step has $q = \frac{2}{3}$ and $b = \frac{2}{3}$, while $v(\frac{2}{3}) = \frac{1}{3}$. Check the second-order conditions.

   (c) Under discriminatory pricing the bidder submits two steps, with $b_1 > b_2$ and $q_1 < q_2$. Write its expected payoff using $\mathbb{P}(P^c < b_2)$ and $\mathbb{P}(b_2 < P^c < b_1)$. Differentiate with respect to q_1 and q_2, and show that the results are (15.92) for $k = 1$ and $b_2 = v(q_2)$.

   (d) Explain why the condition in (c) implies $v(q_1) \geq b_1$, while the condition in (a) implies $b > v(q)$. Relate the difference to the use of truthful-bidding revenue as an upper bound in Section 15.11.2.

Appendix A

Econometric Toolkit

Every chapter of this book estimates something. Chapter 3 regresses prices on taxes and estimates conduct by instrumental variables. Chapter 8 minimizes a generalized method of moments (GMM) criterion that contains a simulated integral. Chapter 13 maximizes a likelihood with latent cartel regimes, and Chapter 15 estimates value densities with kernels. Chapter 11 compares merging and non-merging products before and after a merger. This appendix collects the econometric tools behind these exercises in one place. It develops each tool once, in general notation, and proves the results that the chapters rely on. Standard results that the book uses without relying on their proofs are stated with references to the textbooks listed in Section A.14.

The appendix assumes a first-year graduate sequence in econometrics, but it does not assume that the reader remembers it. Each section starts from definitions and then turns to worked applications drawn from the papers of the book, so that every tool is seen at work on data from industrial organization. When an application belongs to a chapter, the appendix gives the econometric point and a cross-reference, and the chapter gives the economics and the full tables. Several applications are recomputed here. We re-estimate the cigarette tax regression of Sumner (1981) with modern standard errors and replicate the Monte Carlo design of Guerre et al. (2000). We also study simulated designs for weak instruments, latent regimes, simulation estimators, clustering, kernels and staggered adoption.

Three styles of empirical work. We sort the uses of these tools into three broad styles. The division is ours, but it follows the history that Einav and Levin (2010, pp. 146–147 and 157–158) sketch. They describe how the field moved from cross-industry regressions to studies of single industries, and they weigh structural work against (quasi-)experimental designs. *Structural* work specifies demand, cost and conduct and estimates their parameters, as in the random coefficients model of Berry et al. (1995) (Chapter 8). Its tools are GMM, maximum likelihood and simulation, and its identification rests on instruments, equilibrium conditions and functional forms. *Design-based* work measures the effect of a discrete change by comparing exposed and unexposed units, as in merger retrospectives (Chapter 11). Its tools are differences in differences, event studies and instrumental variables, and its identification rests on assumptions about counterfactual outcomes. *Descriptive* or reduced-form work documents relations between market outcomes and market structure, as in the fare regressions of Borenstein (1989) (Chapter 9). Its main tools are least squares and instrumental variables, and its interpretation needs care because the regressors are themselves equilibrium outcomes. Many papers combine the three styles, and the same estimator often serves all of them.

Plan of the appendix. Section A.1 defines identification and shows how simultaneity and

selection defeat naive comparisons. Sections A.2 and A.3 develop least squares, panel data, systems of equations and instrumental variables, including weak instruments and specification tests. Sections A.4 to A.6 treat estimators defined by optimizing a criterion. They cover the general theory, the generalized method of moments, and maximum likelihood with latent variables. Section A.7 adds simulation to these estimators. Sections A.8 and A.9 turn to inference, with standard errors under dependence, the delta method and the bootstrap. Sections A.10 and A.11 develop nonparametric estimators of densities and regression functions, deconvolution and estimation under partial identification. Sections A.12 and A.13 cover the research designs of retrospective studies, namely differences in differences and financial event studies. Table A.1 lists, for each tool, the section that develops it, the chapters that use it and one example.

Table A.1: Econometric tools, where this appendix develops them, and where the book uses them

Tool	Section	Chapters	Example
Identification, simultaneity and selection	A.1	1, 3, 9	Supply and demand (Working, 1927), demand rotations (Bresnahan, 1982)
Least squares, panel data and systems	A.2	1, 3, 5	Two-way fixed effects for tax pass-through (Sumner, 1981)
Instrumental variables, weak instruments and specification tests	A.3	3, 5, 7, 9, 11	Co-location as an instrument for rival mergers (Dafny, 2009)
Extremum estimators and GMM	A.4, A.5	3, 4, 8	Demand and supply moments for automobiles (Berry et al., 1995)
Maximum likelihood and latent regimes	A.6	6, 13, 15	Switching regressions for a railroad cartel (Porter, 1983a; Ellison, 1994)
Simulation estimators	A.7	8, 10, 15	Simulated likelihood for newspaper demand (Gentzkow, 2007)
Clustered and HAC standard errors	A.8	3, 8, 11	Sumner's regression with state clusters (Table A.8)
Delta method and bootstrap	A.9	5, 8, 13	Bootstrapped counterfactuals for antibiotics (Chaudhuri et al., 2006)
Kernels, deconvolution and bounds	A.10, A.11	6, 13, 15	First-price auctions (Guerre et al., 2000), unobserved heterogeneity (Krasnokutskaya, 2011)
Differences in differences and panel event studies	A.12	3, 5, 9, 11	Consumer-product merger retrospectives (Ashenfelter and Hosken, 2010)
Financial event studies	A.13	9, 11	Entry by People Express (Whinston and Collins, 1992)

Conventions. Vectors are columns unless stated otherwise. The sample has n observations $w_1, \ldots, w_n$, where w_i collects the data of observation i. We write $\xrightarrow{p}$ for convergence in probability and $\xrightarrow{d}$ for convergence in distribution. A sequence X_n is $o_p(1)$ if $X_n \xrightarrow{p} 0$. It is $O_p(1)$, or *bounded in probability*, if for every $\epsilon > 0$ there is an M with $\mathbb{P}(\|X_n\| > M) < \epsilon$ for all large n. For a positive sequence a_n, $X_n = o_p(a_n)$ means $\frac{X_n}{a_n} = o_p(1)$, and $O_p(a_n)$ is defined in the same way. An event occurs *with probability approaching one* (w.p.a.1) if its probability tends to one as $n \to \infty$. Asymptotic statements are in n unless stated otherwise. Sometimes a different count

drives the asymptotics. In demand models estimated from market-level data it is the number of markets or products. It is the number of auctions L in the estimators of Section A.10, and the number of clusters C for clustered data (Section A.8.2).

The appendix uses generic notation, and several symbols have a local meaning that differs from their meaning in the chapters. The vector θ is a generic parameter with true value θ_0, estimator $\hat{\theta}$ and parameter space Θ. Elsewhere in the book θ is the conduct parameter, and we say so whenever that meaning appears here. A regressor vector x_i is a $K \times 1$ column, unlike the characteristics row x_{jt} of the demand chapters, and β is a generic coefficient vector. Instruments form an $L \times 1$ vector z_i, so L usually counts instruments or moments. The structure-conduct-performance examples of Sections A.1.3 and A.2.3 use the Lerner index L_k instead. The letter L is also the number of auctions in Sections A.10 and A.11 and the length of the event window in Section A.13. Each of these uses is defined where it appears. First-stage coefficients are written π, which is not profit. The matrices Ω and S usually denote covariance matrices of errors, scores or moments. The exceptions are the ownership matrix Ω_t in the supply moments of Section A.5.1 and Porter's parameter vector Ω in Section A.6.6. In Section A.8 the index c denotes a cluster, not marginal cost. Section A.12 uses τ_t for a period effect, while Section A.13 uses τ for a trading day.

A.1 Identification and the logic of empirical models

Every empirical claim in this book rests on an argument that the data, together with stated assumptions, pin down the object of interest. This section makes that argument precise. It defines identification, shows how simultaneity and selection defeat naive comparisons, and describes the Monte Carlo experiments that the book uses to study estimators.

A.1.1 Models, structures and identification

We separate four objects. The *observables* w are the variables in the data, such as prices, quantities and cost shifters. A *structure* S specifies every primitive of the economic model: demand and cost functions, the rule that determines conduct, and the joint distribution of the unobservables. Each structure implies a distribution of the observables, which we write $F_w(\cdot\,; S)$. A *model* $\mathcal{M}$ is the set of structures that satisfy the maintained assumptions. A *feature* $\psi = \psi(S)$ is any quantity we want to learn, such as a slope, an elasticity, a markup or a counterfactual price.

Definition A.1 (Identification)**.** Let $\mathcal{M}$ be a model and let $S_0 \in \mathcal{M}$ be the structure that generated the data.

(i) Two structures $S, S' \in \mathcal{M}$ are *observationally equivalent* if $F_w(\cdot\,; S) = F_w(\cdot\,; S')$.

(ii) The feature ψ is *point identified* at S_0 if $\psi(S) = \psi(S_0)$ for every $S \in \mathcal{M}$ that is observationally equivalent to S_0. It is *identified* in $\mathcal{M}$ if this holds at every $S_0 \in \mathcal{M}$.

(iii) The *identified set* of ψ at S_0 is

$$\Psi_I(S_0) = \big\{ \psi(S) : S \in \mathcal{M},\ F_w(\cdot\,; S) = F_w(\cdot\,; S_0) \big\}.$$

The feature is *partially identified* when $\Psi_I(S_0)$ contains more than one point and is a proper subset of the values that ψ can take in $\mathcal{M}$.

Identification is a property of the model and of the population distribution of the observables. It comes logically before estimation, which concerns finite samples. If two structures produce

the same distribution of data, no sample of any size can tell them apart. Athey and Haile (2002, pp. 2108–2109) draw three lessons that apply throughout the book. First, whether a model is identified is a question distinct from the choice of approximation used for estimation. Second, when a model is nonparametrically identified, a parametric specification can serve as a parsimonious approximation instead of a maintained hypothesis. Third, a failure of identification need not preclude testing. They show, for instance, that private values can be tested against common values in auctions even when neither model is identified (Chapter 15).

Moment conditions and local identification. Much of the book defines the parameter through moment conditions. Let $g(w;\theta)$ be an $L \times 1$ vector of functions, and suppose the true value solves

$$m(\theta_0) \equiv \mathbb{E}[g(w_i;\theta_0)] = 0. \tag{A.1}$$

The parameter is identified by (A.1) if θ_0 is the only zero of $m(\cdot)$ in Θ. It is *locally identified* if θ_0 is the only zero in some neighborhood of θ_0. Local identification has a simple sufficient condition.

Proposition A.2 (Local identification from a rank condition)**.** *Suppose $m(\theta_0) = 0$, m is differentiable at θ_0, and the $L \times K$ Jacobian $G = \frac{\partial m(\theta_0)}{\partial \theta^\top}$ has full column rank K. Then there is a neighborhood $\mathcal{N}$ of θ_0 such that $m(\theta) \neq 0$ for every $\theta \in \mathcal{N}$ with $\theta \neq \theta_0$.*

Proof. Let c^2 be the smallest eigenvalue of $G^\top G$. It is positive because G has full column rank. For any $h \in \mathbb{R}^K$,

$$\|Gh\|^2 = h^\top G^\top G h \geq c^2 \|h\|^2.$$

Differentiability at θ_0 gives $m(\theta) = G(\theta - \theta_0) + r(\theta)$ with $\frac{\|r(\theta)\|}{\|\theta - \theta_0\|} \to 0$ as $\theta \to \theta_0$. Choose a ball $\mathcal{N}$ around θ_0 on which $\|r(\theta)\| \leq \frac{c}{2}\|\theta - \theta_0\|$. For $\theta \in \mathcal{N}$ with $\theta \neq \theta_0$,

$$\|m(\theta)\| \geq \|G(\theta - \theta_0)\| - \|r(\theta)\| \geq c\|\theta - \theta_0\| - \frac{c}{2}\|\theta - \theta_0\| > 0. \qquad \square$$

Rothenberg (1971) gives the likelihood version of this result. When θ_0 is a regular point of the information matrix, θ_0 is locally identified if and only if the information matrix is nonsingular. In linear models, $m(\theta) = \mathbb{E}[z_i y_i] - \mathbb{E}[z_i x_i^\top]\theta$ has a constant Jacobian, so the rank condition delivers global identification. Nonlinear models need a global argument as well, such as the invertibility of market shares in the demand chapters (Section 7.2.3 and Chapter 8). A rank failure means that some direction in the parameter space leaves the moments unchanged to first order. The conduct parameter of Section A.1.2 gives an example.

Normalizations. Some parameters are unidentified because the model is invariant to a transformation of the structure. A *normalization* resolves the invariance by picking one structure from each class of observationally equivalent structures. In discrete choice, adding a constant to every utility, or multiplying every utility by a positive number, leaves choices unchanged (Proposition 6.4). The level of utility is therefore fixed by setting the outside good's mean utility to zero, and its scale by fixing the variance of the idiosyncratic shock.

The vertical model gives a sharper example. Consumer i obtains utility $u_{ij} = \delta_j - v_i p_j$ from product j, with quality $\delta_j = x_{jt}\beta + \xi_{jt}$. The price sensitivity v_i is exponential with rate λ, so $\mathbb{E}[v_i] = \frac{1}{\lambda}$. Fix $c > 0$ and multiply every utility by c:

$$c\,u_{ij} = c\,\delta_j - (c\,v_i)\,p_j.$$

Choices do not change. The rescaled sensitivity satisfies $\mathbb{P}(c\,v_i \leq v) = \mathbb{P}\big(v_i \leq \frac{v}{c}\big) = 1 - e^{-\frac{\lambda}{c}v}$, so it is exponential with rate $\frac{\lambda}{c}$. The structures (β, ξ, λ) and $(c\beta, c\xi, \frac{\lambda}{c})$ therefore imply the same

market shares for every $c > 0$. Only the products $\lambda\beta$ and $\lambda\xi$ are identified. The normalization $\lambda = 1$ measures quality in units of willingness to pay (Section 6.5.4 and Appendix C).

Identification needs restrictions. A model that admits every structure explains every data set, and then no feature is identified. The conduct parameter of Chapter 3 shows this starkly. Write the pricing relation with conduct free for every observation:

$$P_{it} = mc_{it} + \theta_{it} \frac{Q_{it}}{\left| \frac{\partial Q_{it}}{\partial P_{it}} \right|}. \tag{A.2}$$

Here θ_{it} is the conduct parameter. Take any observed (P_{it}, Q_{it}), any demand slope and any marginal cost function $mc_{it} = c(Q_{it}; \gamma)$. Setting

$$\theta_{it} = \frac{(P_{it} - mc_{it}) \left| \frac{\partial Q_{it}}{\partial P_{it}} \right|}{Q_{it}}$$

reproduces the data exactly, without an error term. Every cost function is then observationally equivalent to every other one. The model acquires content only after we restrict θ_{it}. It can be constant across observations, confined to $[0, 1]$, fixed at the value implied by a game, or orthogonal to instruments (Section 3.1.2). Confinement to $[0, 1]$ yields bounds on marginal cost instead of a point, which is a case of partial identification (Section 3.6.3).

Remark A.3 (Restrictions without functional forms). Restrictions need not be parametric. Consider a monopolist with an increasing cost function that pays a specific tax. Revealed preference alone implies that output does not rise when the tax rises from t to t', and that $p'q' - pq \leq t(q' - q)$ (Ashenfelter and Sullivan, 1987). The inequality holds for every demand and cost function, so a violation rejects monopoly without any functional form (Section 3.3.2).

A.1.2 Simultaneous equations

The oldest identification problem in economics is the estimation of a demand curve from market data (Working, 1927). Observed prices and quantities are equilibrium outcomes. Each one lies on both the demand curve and the supply curve, so a scatter of equilibria need not trace either curve.

Assumption A.4 (Linear supply and demand)**.** In each market t,

$$\text{demand: } q_t = a_d - b\, p_t + u_t^d, \qquad \text{supply: } q_t = a_s + c\, p_t + u_t^s, \tag{A.3}$$

with $b + c > 0$. The shocks (u_t^d, u_t^s) are independent and identically distributed across markets, with mean zero, variances σ_d^2 and σ_s^2, and $\mathrm{Cov}(u_t^d, u_t^s) = 0$.

The slopes have the usual signs when $b > 0$ and $c > 0$. Equating demand and supply gives the *reduced form*, which expresses each endogenous variable in terms of the exogenous shocks:

$$a_d - b\, p_t + u_t^d = a_s + c\, p_t + u_t^s,$$

$$p_t = \frac{a_d - a_s}{b + c} + \frac{u_t^d - u_t^s}{b + c}, \tag{A.4}$$

$$q_t = a_d - b\, p_t + u_t^d = \frac{c\, a_d + b\, a_s}{b + c} + \frac{c\, u_t^d + b\, u_t^s}{b + c}. \tag{A.5}$$

The last line substitutes (A.4) into demand and collects terms over the common denominator. Both shocks move the price, so the price is correlated with each structural error.

Proposition A.5 (OLS under simultaneity)**.** *Under Assumption A.4, the slope of the OLS regression of q_t on a constant and p_t converges in probability to*

$$\operatorname{plim} \hat{\beta}_{OLS} = \frac{c\,\sigma_d^2 - b\,\sigma_s^2}{\sigma_d^2 + \sigma_s^2} = \frac{\sigma_d^2}{\sigma_d^2 + \sigma_s^2}\,c + \frac{\sigma_s^2}{\sigma_d^2 + \sigma_s^2}\,(-b). \tag{A.6}$$

Proof. The OLS slope is the sample covariance of (q_t, p_t) divided by the sample variance of p_t. By the law of large numbers and the continuous mapping theorem it converges to $\frac{\operatorname{Cov}(q_t,p_t)}{\operatorname{Var}(p_t)}$. From (A.4) and the zero covariance of the shocks,

$$\operatorname{Var}(p_t) = \frac{\sigma_d^2 + \sigma_s^2}{(b+c)^2}.$$

The supply equation gives $\operatorname{Cov}(q_t, p_t) = c\operatorname{Var}(p_t) + \operatorname{Cov}(u_t^s, p_t)$, and (A.4) gives $\operatorname{Cov}(u_t^s, p_t) = -\frac{\sigma_s^2}{b+c}$. Therefore

$$\operatorname{Cov}(q_t, p_t) = \frac{c(\sigma_d^2 + \sigma_s^2)}{(b+c)^2} - \frac{(b+c)\,\sigma_s^2}{(b+c)^2} = \frac{c\,\sigma_d^2 - b\,\sigma_s^2}{(b+c)^2}.$$

Dividing by $\operatorname{Var}(p_t)$ gives (A.6). □

The OLS slope is a weighted average of the supply slope c and the demand slope $-b$. The weights are the shares of demand and supply shocks in the variance of price. Demand shocks move the equilibrium along the supply curve, and supply shocks move it along the demand curve. When demand shocks dominate, OLS recovers something close to the supply slope. The estimate can have either sign, and it equals the demand slope only when $\sigma_d^2 = 0$.

Corollary A.6 (Excluded shifters)**.** *Add an observed cost shifter w_t to supply, $q_t = a_s + c\,p_t + \delta w_t + u_t^s$, with $\delta \neq 0$, $\operatorname{Var}(w_t) > 0$, and w_t uncorrelated with u_t^d and u_t^s. Then $\frac{\operatorname{Cov}(w_t,q_t)}{\operatorname{Cov}(w_t,p_t)} = -b$. Symmetrically, an observed demand shifter excluded from supply identifies c.*

Proof. The reduced form for price becomes $p_t = \frac{a_d - a_s - \delta w_t + u_t^d - u_t^s}{b+c}$, so $\operatorname{Cov}(w_t, p_t) = -\frac{\delta \operatorname{Var}(w_t)}{b+c} \neq 0$. Demand gives $\operatorname{Cov}(w_t, q_t) = -b\operatorname{Cov}(w_t, p_t) + \operatorname{Cov}(w_t, u_t^d) = -b\operatorname{Cov}(w_t, p_t)$. Divide the second covariance by the first. □

The ratio in Corollary A.6 is the instrumental variables estimand of Section A.3. A shifter of one curve that is excluded from the other curve moves the equilibrium along the curve we want to estimate. Figure A.1 shows both results in simulated data. Demand and supply follow (A.3) with $a_d = 10$, $b = 1$, $a_s = 2$ and $c = 1$. Supply also contains a cost shifter $w_t \sim N(0,1)$ with $\delta = 1$. The shocks have standard deviations $\sigma_d = 0.6$ and $\sigma_s = 0.5$, so the composite supply shock $\delta w_t + u_t^s$ has variance 1.25. Proposition A.5 then predicts an OLS slope of $\frac{0.36-1.25}{0.36+1.25} = -0.553$, roughly half the demand slope of -1. Over 2,000 samples of 200 markets, the OLS slope averages -0.554 with a standard deviation of 0.059. The instrumental variables estimator that uses w_t averages -1.007 with a standard deviation of 0.086.

Order and rank conditions. Corollary A.6 extends to any linear system. Let y_t be a $G \times 1$ vector of endogenous variables and x_t an $M \times 1$ vector of exogenous variables with $\mathbb{E}[x_t x_t^\top]$ nonsingular. The structural system is $By_t + \Gamma x_t = u_t$, with B nonsingular and $\mathbb{E}[x_t u_t^\top] = 0$. Its reduced form is

$$y_t = \Pi x_t + v_t, \qquad \Pi = -B^{-1}\Gamma, \qquad v_t = B^{-1}u_t. \tag{A.7}$$

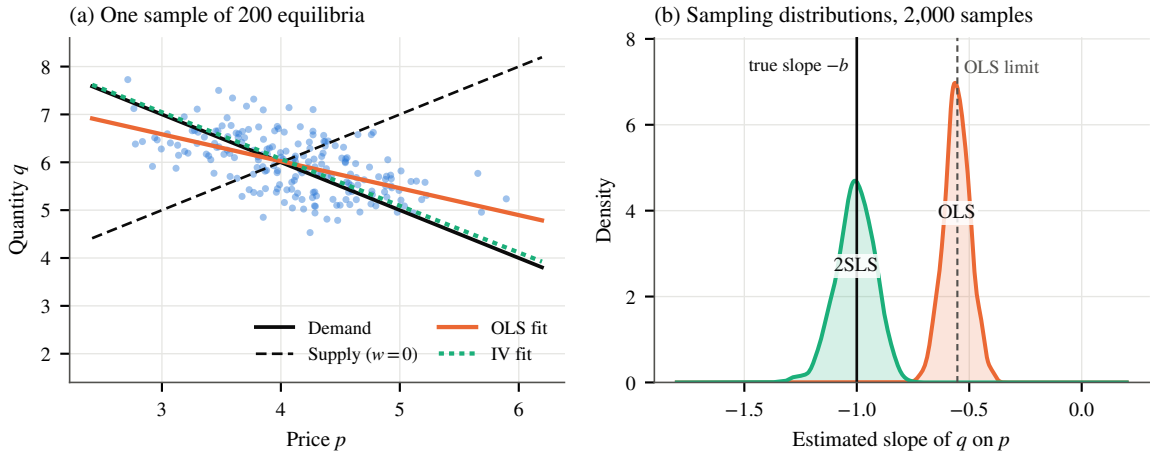

Figure A.1: Simultaneity bias and instrumental variables in a simulated market. Demand is $q_t = 10 - p_t + u_t^d$ and supply is $q_t = 2 + p_t + w_t + u_t^s$, with $w_t \sim N(0,1)$, $u_t^d \sim N(0, 0.36)$ and $u_t^s \sim N(0, 0.25)$, all independent. (a) One sample of 200 equilibria with the true demand curve and the supply curve at $w_t = 0$. The OLS fit has slope -0.563, and the IV fit with instrument w_t has slope -0.977. (b) Kernel densities of the OLS and two-stage least squares (2SLS, Section A.3.2) slopes over 2,000 samples of 200 markets. The solid line marks the demand slope -1 and the dashed line the OLS limit -0.553 from Proposition A.5. The mean first-stage F statistic (Section A.3.5) is 331. Seed 20261022, script `sim_iv.py`.

The reduced-form coefficients are identified, $\Pi = \mathbb{E}[y_t x_t^\top]\mathbb{E}[x_t x_t^\top]^{-1}$, because v_t is uncorrelated with x_t. Consider one structural equation, normalized on its first endogenous variable:

$$y_{1t} = Y_{1t}^\top \beta + X_{1t}^\top \gamma + u_{1t}. \tag{A.8}$$

It includes G_1 further endogenous variables Y_{1t} and M_1 exogenous variables X_{1t}. The remaining $M_2 = M - M_1$ exogenous variables X_{2t} are excluded. Partition the reduced form conformably,

$$y_{1t} = \pi_{11}^\top X_{1t} + \pi_{12}^\top X_{2t} + v_{1t}, \qquad Y_{1t} = \Pi_{21} X_{1t} + \Pi_{22} X_{2t} + V_{1t},$$

where Π_{22} is $G_1 \times M_2$. Substitute both into (A.8). The resulting identity holds for all values of the exogenous variables, and the reduced-form errors are uncorrelated with them. Hence the coefficients on X_{1t} and X_{2t} must match:

$$\pi_{11} = \Pi_{21}^\top \beta + \gamma, \qquad \pi_{12} = \Pi_{22}^\top \beta. \tag{A.9}$$

Proposition A.7 (Rank and order conditions)**.** *The coefficients (β, γ) of (A.8) are identified if and only if* $\operatorname{rank}(\Pi_{22}) = G_1$. *A necessary condition is $M_2 \geq G_1$, so the equation must exclude at least as many exogenous variables as it includes endogenous variables on its right-hand side.*

Proof. The second block of (A.9) is a system of M_2 linear equations in the G_1 unknowns β. If $\Pi_{22}^\top$ has full column rank G_1, the solution is unique:

$$\beta = (\Pi_{22}\Pi_{22}^\top)^{-1}\Pi_{22}\,\pi_{12}, \qquad \gamma = \pi_{11} - \Pi_{21}^\top \beta.$$

If the rank is below G_1, pick $h \neq 0$ with $\Pi_{22}^\top h = 0$. The pair $(\beta + h, \gamma - \Pi_{21}^\top h)$ also satisfies (A.9). The error it implies is

$$\begin{aligned} y_{1t} - Y_{1t}^\top(\beta + h) - X_{1t}^\top(\gamma - \Pi_{21}^\top h) &= u_{1t} - h^\top\left(\Pi_{21} X_{1t} + \Pi_{22} X_{2t} + V_{1t}\right) + h^\top \Pi_{21} X_{1t} \\ &= u_{1t} - h^\top V_{1t}, \end{aligned}$$

which is uncorrelated with x_t. The two coefficient vectors fit the same observables and satisfy the same exogeneity restrictions, so the data cannot distinguish them. The order condition follows from $\operatorname{rank}(\Pi_{22}) \le M_2$. □

In the market of Corollary A.6, demand includes one endogenous regressor (price) and excludes one exogenous variable (w_t). The relevant reduced-form coefficient is $\Pi_{22} = -\frac{\delta}{b+c}$, which is nonzero when $\delta \neq 0$, so demand is exactly identified. Supply excludes nothing, $M_2 = 0 < 1$, and its slope remains unidentified until we observe a demand shifter.

The link to conduct. The same algebra explains why conduct is hard to identify (Section 3.5). In the linear model of Equation (3.35), the supply relation is $P_t = b_0 + \lambda Q_t + b_2 W_t + u_t^s$ with composite slope $\lambda = b_1 - \frac{\theta}{a_1}$, where θ is conduct. An excluded demand shifter identifies λ by Proposition A.7. The slope of marginal cost b_1 and conduct θ enter only through λ. The Jacobian of the map from (b_1, θ) to the identified coefficients therefore has rank one, and the two are not separately identified (Proposition 3.26). A demand rotator, a variable that changes the slope of demand, makes the markup term move independently of quantity and restores identification (Bresnahan, 1982; Lau, 1982). Section 3.5.2 develops the argument.

A.1.3 Potential outcomes and selection

Many questions in the book ask what an intervention does: a merger, a tax, entry by a rival. The *potential outcomes* framework states such questions precisely. Let $d_i \in \{0, 1\}$ indicate treatment of unit i. The unit has two potential outcomes, $y_i(1)$ if treated and $y_i(0)$ if not, and we observe only $y_i = d_i\, y_i(1) + (1 - d_i)\, y_i(0)$. The *average treatment effect* is $\text{ATE} = \mathbb{E}[y_i(1) - y_i(0)]$, and the *average treatment effect on the treated* is $\text{ATT} = \mathbb{E}[y_i(1) - y_i(0) \mid d_i = 1]$.

Proposition A.8 (Selection bias)**.** *The difference in mean outcomes between treated and untreated units satisfies*

$$\mathbb{E}[y_i \mid d_i = 1] - \mathbb{E}[y_i \mid d_i = 0] = \text{ATT} + \big\{\mathbb{E}[y_i(0) \mid d_i = 1] - \mathbb{E}[y_i(0) \mid d_i = 0]\big\}. \tag{A.10}$$

Proof. Observed outcomes equal the relevant potential outcomes, so $\mathbb{E}[y_i \mid d_i = 1] = \mathbb{E}[y_i(1) \mid d_i = 1]$ and $\mathbb{E}[y_i \mid d_i = 0] = \mathbb{E}[y_i(0) \mid d_i = 0]$. Add and subtract $\mathbb{E}[y_i(0) \mid d_i = 1]$:

$$\mathbb{E}[y_i(1) \mid d_i = 1] - \mathbb{E}[y_i(0) \mid d_i = 1] + \mathbb{E}[y_i(0) \mid d_i = 1] - \mathbb{E}[y_i(0) \mid d_i = 0].$$

The first two terms form the ATT and the last two the bracket in (A.10). □

The bracket is the *selection bias*. It compares the untreated outcomes of two different groups, and it is nonzero whenever the treated would have fared differently even without treatment. Random assignment makes d_i independent of $(y_i(1), y_i(0))$. The selection term then vanishes, and the ATT equals the ATE.

Selection is the central problem of merger retrospectives. Merging firms differ from non-merging ones, and so do the rivals of merging firms. In hospital markets, non-merging hospitals whose rivals later merged had price growth of −2.9 percent in 1985–1988, against 4.2 percent for hospitals without merging rivals (Dafny, 2005, p. 16). A naive comparison would attribute part of this pre-existing gap to the mergers. Section A.3.1 shows how an instrument removes it.

The same decomposition applies to continuous treatments. In the cross-industry regressions of the structure-conduct-performance (SCP) paradigm, industry k has a potential Lerner index

$L_k(h)$ at each concentration level h, and we observe $L_k = L_k(HHI_k)$. Comparing industries at h and h',

$$\mathbb{E}[L_k \mid HHI_k = h] - \mathbb{E}[L_k \mid HHI_k = h'] = \mathbb{E}[L_k(h) - L_k(h') \mid HHI_k = h] + \big\{\mathbb{E}[L_k(h') \mid HHI_k = h] - \mathbb{E}[L_k(h') \mid HHI_k = h']\big\}.$$

The first term is a causal effect and the second a selection term, as in Equation (1.25). Concentration is an equilibrium outcome of the same demand and cost primitives that determine margins, so the selection term has no reason to vanish (Section 1.4.3).

Three empirical strategies on one industry. The airline studies of Chapter 9 show three ways to overcome selection, each with its own identifying assumption. Borenstein (1989) runs reduced-form fare regressions on a carrier's route and airport shares. His route-share effect is identified by an instrument, the carrier's share of endpoint enplanements. He excludes it on the ground that fares respond to actual competition only (Section A.3.4). Whinston and Collins (1992) run an event study of entry announcements. The value effect of entry on incumbents is identified by the timing of news under efficient stock markets (Section A.13). Berry et al. (2006) estimate a structural model of demand and pricing.[1] Markups are identified by the estimated demand system together with an equilibrium assumption on pricing. The three designs answer different questions, and their assumptions fail in different ways. A related distinction is between prospective analysis, which predicts the effect of a change before it happens, and retrospective analysis, which measures it afterwards (Chapter 11). Section A.12 develops the designs behind retrospectives.

Partial identification. When the assumptions needed for point identification are not credible, weaker assumptions often still bound the feature of interest. Haile and Tamer (2003) study English auctions in which bids need not equal values. They assume only that bidders never bid more than their values and never let an opponent win at a price they would have been willing to beat. These two inequalities bound the distribution of values from above and below. Aradillas-López et al. (2013, pp. 493–499) allow symmetric private values with nonnegative dependence when only the transaction price and the number of bidders are observed. The distribution of the highest value is then only partially identified. If values are independent of the number of bidders, variation in that number across auctions tightens the bounds on the seller's expected profit, the bidders' surplus and the optimal reserve price. Chapter 15 develops both results, and Section A.11.6 treats estimation and inference for bounds.

A.1.4 Monte Carlo experiments

A *Monte Carlo experiment* studies an estimator by applying it to data simulated from a known data-generating process. It proceeds in four steps.

(1) Specify the data-generating process completely: functional forms, the true parameter θ_0, the distributions of exogenous variables and errors, and the sample size n.

(2) Fix the seed of the random number generator, so that the experiment can be reproduced exactly.

(3) For $r = 1, \ldots, R$, draw a sample and compute the estimate $\hat{\theta}_r$, its standard error and any test decision $D_r \in \{0, 1\}$, which equals one if the test rejects.

[1] We read NBER Working Paper 5561 (1996), Berry et al. (1996), an earlier version of their chapter. Page and table numbers marked WP refer to it.

(4) Summarize the R replications.

For a scalar parameter the usual summaries are the bias $\bar{\theta} - \theta_0$ with $\bar{\theta} = \frac{1}{R}\sum_r \hat{\theta}_r$ and the standard deviation of $\hat{\theta}_r$ across replications. Others are the *root mean squared error* $\text{RMSE} = \left[\frac{1}{R}\sum_r (\hat{\theta}_r - \theta_0)^2\right]^{\frac{1}{2}}$, the coverage rate of nominal confidence intervals, and the rejection rate $\frac{1}{R}\sum_r D_r$ of a test. Adding and subtracting $\bar{\theta}$ inside the square gives

$$\frac{1}{R}\sum_{r=1}^{R}(\hat{\theta}_r - \theta_0)^2 = (\bar{\theta} - \theta_0)^2 + \frac{1}{R}\sum_{r=1}^{R}(\hat{\theta}_r - \bar{\theta})^2,$$

because the cross term $\frac{2}{R}(\bar{\theta} - \theta_0)\sum_r(\hat{\theta}_r - \bar{\theta})$ is zero. The squared RMSE is the squared bias plus the variance. Some estimators have no finite mean, such as just-identified two-stage least squares (Section A.3.5). For them the median and interquantile ranges are more informative than the mean and the RMSE.

Monte Carlo summaries are estimates with their own sampling error. Consider a test whose true rejection probability is α. The replications are independent, so $\sum_r D_r$ is binomial with R trials and success probability α. The estimated rejection rate $\hat{\alpha} = \frac{1}{R}\sum_r D_r$ therefore satisfies

$$\mathbb{E}[\hat{\alpha}] = \alpha, \qquad \text{Var}(\hat{\alpha}) = \frac{1}{R^2} R\,\alpha(1-\alpha) = \frac{\alpha(1-\alpha)}{R}, \qquad \text{se}(\hat{\alpha}) = \sqrt{\frac{\alpha(1-\alpha)}{R}}. \tag{A.11}$$

With $R = 10{,}000$ and $\alpha = 0.05$ the Monte Carlo standard error is 0.0022. A rejection rate of 0.058 then differs from 0.05 by more than three standard errors. In the same way, the Monte Carlo standard error of $\bar{\theta}$ is the standard deviation across replications divided by $\sqrt{R}$.

The book uses such experiments to study SCP regressions on simulated Cournot industries (Section 1.4.4) and estimators of random-coefficient demand on simulated markets (Chapter 8 and Appendix C). This appendix uses them throughout. They study instrumental variables (Figures A.1 and A.2), latent regimes (Figure A.5) and simulation estimators (Figure A.6). They also study clustered inference (Figure A.7), kernel estimators (Figures A.9 and A.10) and staggered difference in differences (Figure A.14). Every one of them reports its seed and the script that produced it.

A.2 Least squares, panel data and systems

Ordinary least squares is the workhorse of empirical work, and it reappears inside almost every estimator in the book. This section treats it as a projection, derives its large-sample behavior, lists the three classic sources of bias, and develops the panel and system extensions used in the chapters.

A.2.1 OLS as a projection

Let (y_i, x_i) be independent and identically distributed, with $\mathbb{E}[y_i^2]$ finite and $\mathbb{E}[x_i x_i^\top]$ finite and nonsingular. The *linear projection* of y_i on x_i has coefficient

$$\beta = \arg\min_b \ \mathbb{E}\left[(y_i - x_i^\top b)^2\right] = \mathbb{E}[x_i x_i^\top]^{-1}\mathbb{E}[x_i y_i]. \tag{A.12}$$

The second equality solves the first-order condition $\mathbb{E}[x_i(y_i - x_i^\top \beta)] = 0$. The *projection error* $e_i = y_i - x_i^\top \beta$ satisfies $\mathbb{E}[x_i e_i] = 0$ by construction. The projection exists whether or not any

economic model holds. A structural interpretation of β is an assumption: that the error of the economic model is uncorrelated with x_i, so the structural coefficient coincides with the projection coefficient.

In a sample of size n, stack the observations into y $(n \times 1)$ and X $(n \times K)$ with full column rank. The OLS estimator $\hat\beta = (X^\top X)^{-1} X^\top y$ solves the *normal equations* $X^\top (y - X\hat\beta) = 0$. Define the projection matrix $P_X = X(X^\top X)^{-1} X^\top$ and the *annihilator* $M_X = I_n - P_X$. Both are symmetric and idempotent, $M_X X = 0$, fitted values are $P_X y$ and residuals are $\hat e = M_X y$.

Theorem A.9 (Frisch-Waugh-Lovell)**.** *Partition $X = [X_1, X_2]$ and $\hat\beta = (\hat\beta_1^\top, \hat\beta_2^\top)^\top$ conformably, and let $M_{X_2} = I_n - X_2(X_2^\top X_2)^{-1} X_2^\top$. Then*

$$\hat\beta_1 = (X_1^\top M_{X_2} X_1)^{-1} X_1^\top M_{X_2} y = (\tilde X_1^\top \tilde X_1)^{-1} \tilde X_1^\top \tilde y, \qquad \tilde X_1 = M_{X_2} X_1,\ \tilde y = M_{X_2} y, \tag{A.13}$$

and the residuals of the regression of $\tilde y$ on $\tilde X_1$ equal the residuals of the full regression.

Proof. The normal equations of the full regression are

$$X_1^\top (y - X_1\hat\beta_1 - X_2\hat\beta_2) = 0, \qquad X_2^\top (y - X_1\hat\beta_1 - X_2\hat\beta_2) = 0.$$

The second block gives $\hat\beta_2 = (X_2^\top X_2)^{-1} X_2^\top (y - X_1\hat\beta_1)$. Substituting,

$$y - X_1\hat\beta_1 - X_2\hat\beta_2 = M_{X_2}(y - X_1\hat\beta_1).$$

The first block becomes $X_1^\top M_{X_2}(y - X_1\hat\beta_1) = 0$, so $\hat\beta_1 = (X_1^\top M_{X_2} X_1)^{-1} X_1^\top M_{X_2} y$. The inverse exists because X has full column rank. Since M_{X_2} is symmetric and idempotent, $X_1^\top M_{X_2} X_1 = \tilde X_1^\top \tilde X_1$ and $X_1^\top M_{X_2} y = \tilde X_1^\top \tilde y$. The full residual is $M_{X_2}(y - X_1\hat\beta_1) = \tilde y - \tilde X_1 \hat\beta_1$, which is the residual of the partialled regression. □

The theorem says that the coefficient on X_1 uses only the variation in X_1 that X_2 cannot explain. The theorem underlies fixed effects (Section A.2.4) and the control-function form of two-stage least squares (Section A.3.2). It also justifies partialling out exogenous regressors (Section A.3.5) and concentrating out linear parameters (Section A.5.7). The double-residual estimator of the partially linear model (Section A.11.4), the two-way fixed-effects regression (Section A.12.2) and event-study dummies (Section A.13.3) rest on it as well.

A.2.2 Large-sample theory

Assumption A.10 (Linear regression)**.**

(i) The observations (y_i, x_i) are independent and identically distributed.

(ii) $y_i = x_i^\top \beta + e_i$ with $\mathbb{E}[x_i e_i] = 0$.

(iii) $Q = \mathbb{E}[x_i x_i^\top]$ is finite and nonsingular.

(iv) $\mathbb{E}\|x_i\|^4 < \infty$ and $\mathbb{E}[e_i^4] < \infty$.

Part (iv) guarantees, by the Cauchy-Schwarz inequality, that $\Omega = \mathbb{E}[e_i^2 x_i x_i^\top]$ is finite.

Proposition A.11 (Consistency and asymptotic normality of OLS)**.** *Under Assumption A.10, $\hat\beta \xrightarrow{p} \beta$ and*

$$\sqrt{n}(\hat\beta - \beta) \xrightarrow{d} N\big(0,\ Q^{-1}\Omega Q^{-1}\big). \tag{A.14}$$

Proof. Substitute $y = X\beta + e$ into the estimator:

$$\hat{\beta} - \beta = \left(\frac{1}{n} X^\top X\right)^{-1} \frac{1}{n} X^\top e = \left(\frac{1}{n}\sum_{i=1}^{n} x_i x_i^\top\right)^{-1} \frac{1}{n}\sum_{i=1}^{n} x_i e_i.$$

By the weak law of large numbers, $\frac{1}{n}\sum_i x_i x_i^\top \xrightarrow{p} Q$ and $\frac{1}{n}\sum_i x_i e_i \xrightarrow{p} \mathbb{E}[x_i e_i] = 0$. Matrix inversion is continuous at the nonsingular Q, so the continuous mapping theorem gives $\hat{\beta} - \beta \xrightarrow{p} Q^{-1} \cdot 0 = 0$. For the distribution, multiply by $\sqrt{n}$:

$$\sqrt{n}(\hat{\beta} - \beta) = \left(\frac{1}{n}\sum_{i=1}^{n} x_i x_i^\top\right)^{-1} \frac{1}{\sqrt{n}}\sum_{i=1}^{n} x_i e_i.$$

The terms $x_i e_i$ are independent with mean zero and finite variance Ω, so the central limit theorem gives $\frac{1}{\sqrt{n}}\sum_i x_i e_i \xrightarrow{d} N(0, \Omega)$. By Slutsky's theorem the product converges to $Q^{-1}N(0,\Omega) = N(0, Q^{-1}\Omega Q^{-1})$. □

The variance in (A.14) is called a *sandwich* because Ω sits between two copies of Q^{-1}. Under *homoskedasticity*, $\mathbb{E}[e_i^2 \mid x_i] = \sigma^2$, the middle term becomes $\Omega = \sigma^2 Q$ and the variance collapses to $\sigma^2 Q^{-1}$. Its conventional estimator is $s^2(X^\top X)^{-1}$ with $s^2 = \frac{\hat{e}^\top \hat{e}}{n-K}$. Without homoskedasticity, White (1980) shows that

$$\hat{V}_{\text{HC0}} = (X^\top X)^{-1}\Big(\sum_{i=1}^{n} \hat{e}_i^2 x_i x_i^\top\Big)(X^\top X)^{-1} \tag{A.15}$$

consistently estimates the variance of $\hat{\beta}$, in the sense that $n\hat{V}_{\text{HC0}} \xrightarrow{p} Q^{-1}\Omega Q^{-1}$. Finite-sample versions adjust the squared residuals, which are too small on average. Let $h_{ii} = x_i^\top (X^\top X)^{-1} x_i$ be the *leverage* of observation i. Under homoskedasticity, $\hat{e} = M_X e$ implies

$$\mathbb{E}[\hat{e}_i^2 \mid X] = \sigma^2 (M_X)_{ii} = \sigma^2(1 - h_{ii}).$$

HC1 multiplies (A.15) by $\frac{n}{n-K}$. HC2 replaces $\hat{e}_i^2$ by $\frac{\hat{e}_i^2}{1-h_{ii}}$, which is unbiased under homoskedasticity. HC3 uses $\frac{\hat{e}_i^2}{(1-h_{ii})^2}$, which approximates the jackknife and is conservative in small samples (MacKinnon and White, 1985). In this book "robust" standard errors mean heteroskedasticity-robust standard errors. They still assume independence across observations. Clustered and serially correlated data need the estimators of Section A.8, which also covers heteroskedasticity and autocorrelation consistent (HAC) estimators.

A.2.3 Three sources of bias

OLS converges to the projection coefficient. It is biased for the structural coefficient whenever the structural error is correlated with the regressors. Three mechanisms produce that correlation.

Omitted variables. Suppose $y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + e_i$ with $\mathbb{E}[e_i] = 0$ and e_i uncorrelated with both regressors, but we regress y_i on a constant and x_{1i} only. The short slope converges to

$$\frac{\operatorname{Cov}(y_i, x_{1i})}{\operatorname{Var}(x_{1i})} = \frac{\beta_1 \operatorname{Var}(x_{1i}) + \beta_2 \operatorname{Cov}(x_{2i}, x_{1i}) + \operatorname{Cov}(e_i, x_{1i})}{\operatorname{Var}(x_{1i})} = \beta_1 + \beta_2 \frac{\operatorname{Cov}(x_{1i}, x_{2i})}{\operatorname{Var}(x_{1i})}. \tag{A.16}$$

The bias is the effect of the omitted variable times the slope of its projection on the included one. With vector regressors the bias is $\mathbb{E}[x_1 x_1^\top]^{-1}\mathbb{E}[x_1 x_2^\top]\beta_2$. In the firm-level regressions that pit industry concentration against firm market share, omitting the share loads its effect onto concentration whenever the two are correlated (Section 1.5.1).

Measurement error. Suppose $y_i = \beta_0 + \beta x_i^* + e_i$, but we observe $x_i = x_i^* + m_i$. The *classical* measurement error m_i has mean zero and variance σ_m^2 and is uncorrelated with x_i^* and e_i. The OLS slope of y_i on x_i converges to

$$\frac{\operatorname{Cov}(\beta_0 + \beta x_i^* + e_i,\; x_i^* + m_i)}{\operatorname{Var}(x_i^* + m_i)} = \frac{\beta \operatorname{Var}(x_i^*)}{\operatorname{Var}(x_i^*) + \sigma_m^2} \equiv \beta\lambda. \tag{A.17}$$

The *reliability ratio* $\lambda \in (0, 1]$ is the share of the variance of the measured regressor that is signal, so the slope is biased toward zero. Panel data with fixed effects can make this *attenuation* much worse (Griliches and Hausman, 1986).

Proposition A.12 (Attenuation with fixed effects)**.** *Let $y_{it} = \alpha_i + \beta x_{it}^* + e_{it}$ for $i = 1, \dots, n$ and $t = 1, \dots, T$, with T fixed, units independent, and $\mathbb{E}[e_{it} \mid x_{i1}^*, \dots, x_{iT}^*, \alpha_i] = 0$. We observe $x_{it} = x_{it}^* + m_{it}$, where m_{it} is independent across i and t, has mean zero and variance σ_m^2, and is independent of $\{x_{is}^*\}$, $\{e_{is}\}$ and α_i. Define the within variance $\operatorname{Var}_W(z) = \mathbb{E}\big[\frac{1}{T}\sum_t (z_{it} - \bar z_i)^2\big]$ with $\bar z_i = \frac{1}{T}\sum_t z_{it}$, and suppose $\operatorname{Var}_W(x^*) > 0$. As $n \to \infty$ the within estimator converges to*

$$\beta\lambda_W, \qquad \lambda_W = \frac{\operatorname{Var}_W(x^*)}{\operatorname{Var}_W(x^*) + \frac{T-1}{T}\sigma_m^2}. \tag{A.18}$$

Proof. Write $\ddot z_{it} = z_{it} - \bar z_i$. The within transformation removes α_i, so $\ddot y_{it} = \beta \ddot x_{it}^* + \ddot e_{it}$, and the measured regressor is $\ddot x_{it} = \ddot x_{it}^* + \ddot m_{it}$. The within estimator is $\frac{\sum_i \sum_t \ddot x_{it} \ddot y_{it}}{\sum_i \sum_t \ddot x_{it}^2}$. Divide numerator and denominator by nT and apply the law of large numbers across units. The numerator converges to $\beta \operatorname{Var}_W(x^*)$. The cross terms vanish because m is independent of x^* and e, and because strict exogeneity makes $\mathbb{E}[\ddot x_{it}^* \ddot e_{it}] = 0$. The denominator converges to $\operatorname{Var}_W(x^*) + \mathbb{E}\big[\frac{1}{T}\sum_t \ddot m_{it}^2\big]$. For each t,

$$\mathbb{E}[\ddot m_{it}^2] = \operatorname{Var}(m_{it}) - 2\operatorname{Cov}(m_{it}, \bar m_i) + \operatorname{Var}(\bar m_i) = \sigma_m^2 - \frac{2\sigma_m^2}{T} + \frac{\sigma_m^2}{T} = \frac{T-1}{T}\,\sigma_m^2.$$

The ratio of the two limits is (A.18). □

Compare λ_W with the reliability ratio $\lambda = \frac{\operatorname{Var}(x^*)}{\operatorname{Var}(x^*) + \sigma_m^2}$ of a pooled regression, which is valid if α_i is unrelated to the regressor. Inverting both ratios shows that $\lambda_W < \lambda$ if and only if

$$\frac{\operatorname{Var}_W(x^*)}{\operatorname{Var}(x^*)} < \frac{T-1}{T}.$$

The left side is the share of the signal's variance that occurs within units. The right side is the same share for independent noise. A persistent signal, whose variance is mostly between units, satisfies the inequality easily. For example, if $x_{it}^* = a_i + \xi_{it}$ with independent ξ_{it} of variance σ_ξ^2 and $\operatorname{Var}(a_i) = \sigma_a^2$, then $\operatorname{Var}_W(x^*) = \frac{T-1}{T}\sigma_\xi^2$ and $\lambda_W = \frac{\sigma_\xi^2}{\sigma_\xi^2 + \sigma_m^2}$. This falls short of λ whenever $\sigma_a^2 > 0$. The result is the formal content of the critique that panel regressions of margins on concentration with industry effects (Salinger, 1990) can worsen attenuation (Proposition 1.26).

Simultaneity. Proposition A.5 is the third mechanism. When the regressor is an equilibrium outcome, the error of each equation moves it. Invalid instruments can bring the same bias back. With national demand shocks, prices of the same brand in other cities are correlated with local demand errors. An instrumental variables estimator built on them then "is like doing ordinary least squares on a supply and demand system" (Bresnahan, 1997, p. 242). Section A.3.1 gives the general formula, and Section 10.6.3 works out the cereal case.

The structure-conduct-performance regression as a projection. These mechanisms combine in the cross-industry regression of margins on concentration. Its OLS slope converges to $\frac{\operatorname{Cov}(L_k, HHI_k)}{\operatorname{Var}(HHI_k)}$, a projection coefficient. Suppose every industry is a symmetric Cournot industry, so $L_k = \frac{HHI_k}{\varepsilon_k}$. If the elasticity ε_k is independent of HHI_k, then $\operatorname{Cov}(L_k, HHI_k) = \mathbb{E}[\frac{1}{\varepsilon_k}]\operatorname{Var}(HHI_k)$, and the slope converges to $\mathbb{E}[\frac{1}{\varepsilon_k}]$. Once elasticities, entry costs and conduct vary with concentration, the slope mixes comparative statics with respect to several primitives and has no structural meaning (Proposition 1.24).

A.2.4 Panel data

A *panel* observes units $i = 1, \dots, n$ over periods $t = 1, \dots, T$. The basic model is

$$y_{it} = x_{it}^\top \beta + \alpha_i + e_{it}, \tag{A.19}$$

where the unit effect α_i may be correlated with the regressors in any way. The key assumption is *strict exogeneity*, $\mathbb{E}[e_{it} \mid x_{i1}, \dots, x_{iT}, \alpha_i] = 0$: shocks in any period are unrelated to the regressors in every period.

Fixed effects. Stack the data unit by unit and write $D = I_n \otimes \iota_T$ for the $nT \times n$ matrix of unit dummies, where ι_T is a $T \times 1$ vector of ones. The *fixed-effects*, or *within*, estimator is OLS of y on X and D. By Theorem A.9 it equals OLS after premultiplying by

$$M_D = I_{nT} - D(D^\top D)^{-1} D^\top = I_n \otimes \left(I_T - \frac{1}{T} \iota_T \iota_T^\top \right),$$

which subtracts each unit's time mean. Hence $\hat{\beta}_W = \left(\sum_i \sum_t \ddot{x}_{it} \ddot{x}_{it}^\top \right)^{-1} \sum_i \sum_t \ddot{x}_{it} \ddot{y}_{it}$ with $\ddot{z}_{it} = z_{it} - \bar{z}_i$. It is consistent as $n \to \infty$ with T fixed under strict exogeneity. Regressors that do not vary over time are swept out, and the error variance is estimated with $nT - n - K$ degrees of freedom.

First differences. Differencing (A.19) also removes α_i: $\Delta y_{it} = \Delta x_{it}^\top \beta + \Delta e_{it}$ for $t \geq 2$. OLS on the differences is consistent when $\mathbb{E}[\Delta x_{it} \Delta e_{it}] = 0$. With $T = 2$ the two estimators coincide. The within deviations are $\ddot{z}_{i1} = -\frac{1}{2}\Delta z_{i2}$ and $\ddot{z}_{i2} = \frac{1}{2}\Delta z_{i2}$, so

$$\hat{\beta}_W = \left(\sum_i 2 \cdot \frac{1}{4} \Delta x_{i2} \Delta x_{i2}^\top \right)^{-1} \sum_i 2 \cdot \frac{1}{4} \Delta x_{i2} \Delta y_{i2} = \left(\sum_i \Delta x_{i2} \Delta x_{i2}^\top \right)^{-1} \sum_i \Delta x_{i2} \Delta y_{i2},$$

which is the first-difference estimator. With $T > 2$ they differ, and their relative efficiency depends on the serial correlation of e_{it}.

Random effects. If in addition $\mathbb{E}[\alpha_i \mid x_{i1}, \dots, x_{iT}] = 0$, the unit effect becomes part of a composite error $\alpha_i + e_{it}$. With $\operatorname{Var}(\alpha_i) = \sigma_\alpha^2$ and homoskedastic, serially uncorrelated e_{it}, the covariance

matrix of unit i's errors is $\Omega_i = \sigma_e^2 I_T + \sigma_\alpha^2 \iota_T \iota_T^\top$. Write $\bar{P} = \frac{1}{T}\iota_T \iota_T^\top$ and $\bar{Q} = I_T - \bar{P}$. These are orthogonal idempotent matrices, and

$$\Omega_i = \sigma_e^2 \bar{Q} + (\sigma_e^2 + T\sigma_\alpha^2)\bar{P}, \qquad \sigma_e\, \Omega_i^{-\frac{1}{2}} = \bar{Q} + \phi \bar{P} = I_T - (1-\phi)\bar{P}, \qquad \phi = \frac{\sigma_e}{\sqrt{\sigma_e^2 + T\sigma_\alpha^2}}.$$

Generalized least squares is therefore OLS of $y_{it} - \vartheta \bar{y}_i$ on $x_{it} - \vartheta \bar{x}_i$ with $\vartheta = 1 - \phi$. The *random-effects* estimator replaces σ_e^2 and σ_α^2 by estimates. It quasi-demeans: $\vartheta = 0$ gives pooled OLS, and $\vartheta \to 1$ as $\frac{T\sigma_\alpha^2}{\sigma_e^2} \to \infty$, so random effects approaches fixed effects in long panels with large unit variance. It is efficient when its assumptions hold and inconsistent when α_i is correlated with the regressors. Section A.3.6 tests between the two. Fuller and Battese (1974) extend the approach to crossed unit and time effects, $\alpha_i + \tau_t + e_{it}$.

Two-way fixed effects. Adding period effects gives $y_{it} = x_{it}^\top \beta + \alpha_i + \tau_t + e_{it}$. In a balanced panel, Theorem A.9 shows that the slope is OLS on the doubly demeaned data $\ddot{z}_{it} = z_{it} - \bar{z}_{i\cdot} - \bar{z}_{\cdot t} + \bar{z}_{\cdot\cdot}$, the deviations from unit, period and grand means. The variation that identifies β differs across these estimators. Pooled OLS uses all variation, including permanent differences across units. Fixed effects uses changes within units over time. Two-way fixed effects uses changes within units relative to the average change in the same period, so it is a difference-in-differences design with a continuous treatment (Section A.12.2).

Application: tax pass-through in cigarettes. Sumner (1981) estimates the pass-through of state cigarette excise taxes into retail prices. His equation (4) is $P_{it} = X_{it}\eta + \theta R_{it} + U_{it}$, with i indexing states, t years and R_{it} the tax per pack. Sumner's θ is the pass-through rate, which is neither conduct nor a generic parameter. In the notation of Equation (3.8) it is

$$p_{sy} = \mu_s + \tau_y + \rho\, t_{sy} + e_{sy}, \tag{A.20}$$

with state effects μ_s, year effects τ_y and pass-through rate ρ. The data are annual average prices and taxes for 1954–1978 in 47 states and the District of Columbia. Alaska, Hawaii and New Hampshire are excluded, which leaves 1,200 observations (pp. 1016–1017). Sumner's Table 1 reports three estimators of ρ, each with its standard error. Two-way fixed effects by OLS gives 1.074 (0.013). Pooled OLS with the national consumer price index in place of the year dummies and without state dummies gives 1.029 (0.011). A variance-components estimator with random state and year effects (Fuller and Battese, 1974) and the price index gives 1.069 (0.013). The R^2 is about 0.99 with the dummies and 0.95 without them.

The comparison shows what each estimator uses. The pooled regression compares price levels across states with permanently different taxes. Sumner notes that the three states with a large stake in tobacco growing and cigarette manufacturing, North Carolina, Virginia and Kentucky, all have low taxes (fn. 8). State dummies absorb such stable state characteristics (pp. 1015–1016), and the fixed-effects estimate rests on changes in taxes within states over time. The random-effects estimate lies close to the fixed-effects one. This is what quasi-demeaning predicts when $T = 25$ and the state variance component is large relative to the idiosyncratic variance. The reported standard errors treat the 1,200 observations as independent. Section A.8.5 recomputes them on a reconstructed panel, allowing for serial correlation within states (Table A.8), and Section A.12.2 reads the regression as a difference in differences with a continuous treatment. Section 3.2 discusses the economics of the test.

A.2.5 Systems of equations

Many models in the book consist of several equations estimated together. Examples are the share equations of a demand system, the residual demand curves of several firms, and the returns of several firms around one event.

Seemingly unrelated regressions. Let $y_g = X_g\beta_g + e_g$ for equations $g = 1, \dots, G$, each with n observations. Stack the equations as $y = X\beta + e$, with $y = (y_1^\top, \dots, y_G^\top)^\top$ and $X = \operatorname{diag}(X_1, \dots, X_G)$ block diagonal. Let $e_t = (e_{1t}, \dots, e_{Gt})^\top$ collect the errors of observation t, and assume $\mathbb{E}[e_t e_t^\top] = \Sigma$ with independence across t. Then $\operatorname{Var}(e) = \Sigma \otimes I_n$. Generalized least squares gives the *seemingly unrelated regressions* (SUR) estimator of Zellner (1962),

$$\hat\beta_{SUR} = \left[X^\top(\Sigma^{-1} \otimes I_n)X\right]^{-1} X^\top(\Sigma^{-1} \otimes I_n)\, y. \tag{A.21}$$

Feasible SUR replaces Σ by $\hat\Sigma_{gh} = \frac{1}{n}\hat e_g^\top \hat e_h$ from equation-by-equation OLS residuals. Iterating between $\hat\Sigma$ and $\hat\beta$ until convergence gives the Gaussian maximum likelihood estimator.

Proposition A.13 (When SUR equals OLS)**.** *If $X_g = X_0$ for every equation, or if Σ is diagonal, then* (A.21) *equals equation-by-equation OLS.*

Proof. Use $(A \otimes B)(C \otimes D) = AC \otimes BD$ and $(A \otimes B)^{-1} = A^{-1} \otimes B^{-1}$. With identical regressors, $X = I_G \otimes X_0$. Then

$$X^\top(\Sigma^{-1} \otimes I_n)X = (I_G \otimes X_0^\top)(\Sigma^{-1} \otimes I_n)(I_G \otimes X_0) = \Sigma^{-1} \otimes X_0^\top X_0,$$
$$X^\top(\Sigma^{-1} \otimes I_n)\, y = (\Sigma^{-1} \otimes X_0^\top)\, y.$$

The inverse of the first matrix is $\Sigma \otimes (X_0^\top X_0)^{-1}$, so

$$\hat\beta_{SUR} = \left[\Sigma \otimes (X_0^\top X_0)^{-1}\right](\Sigma^{-1} \otimes X_0^\top)\, y = \left[I_G \otimes (X_0^\top X_0)^{-1} X_0^\top\right] y,$$

which stacks the OLS regressions of each y_g on X_0. If $\Sigma = \operatorname{diag}(\sigma_1^2, \dots, \sigma_G^2)$, both $X^\top(\Sigma^{-1} \otimes I_n)X$ and $X^\top(\Sigma^{-1} \otimes I_n)y$ are block diagonal with blocks $\sigma_g^{-2} X_g^\top X_g$ and $\sigma_g^{-2} X_g^\top y_g$. The weights cancel equation by equation, leaving $(X_g^\top X_g)^{-1} X_g^\top y_g$. □

SUR gains precision only when the errors are correlated across equations and the regressors differ. It becomes indispensable when coefficients are restricted across equations. The linear approximate almost ideal demand system is a leading case of identical regressors. Every share equation contains the same log prices and the same log total expenditure deflated by the Stone index. Without cross-equation restrictions, OLS equation by equation therefore coincides with SUR (Section 5.6.4).

Adding up and cross-equation restrictions. Budget shares sum to one, so the errors of a complete share system sum to zero for every observation, and Σ is singular. We drop one equation and recover its coefficients from the adding-up restrictions. The maximum likelihood (iterated SUR) estimates do not depend on which equation is dropped (Barten, 1969). Symmetry and homogeneity restrictions take the linear form $R\beta = r$. Restricted GLS minimizes $(y - Xb)^\top W (y - Xb)$ subject to $Rb = r$, with $W = \Sigma^{-1} \otimes I_n$. The Lagrangian first-order condition $-2X^\top W(y - Xb) + 2R^\top \ell = 0$ gives $b = \hat\beta - VR^\top \ell$ with $V = (X^\top W X)^{-1}$. Imposing $Rb = r$ determines the multiplier ℓ:

$$\tilde\beta = \hat\beta - VR^\top \left(RVR^\top\right)^{-1} \left(R\hat\beta - r\right). \tag{A.22}$$

Which restrictions can be tested. Deaton and Muellbauer (1980b, Section 3.3, pp. 67–70) use the Rotterdam model to sort the restrictions of demand theory by how they can be tested. For goods $g = 1, \dots, G$ and periods t, the model is

$$\bar{w}_{gt}\,\Delta \ln q_{gt} = b_g\,\Delta \ln \bar{x}_t + \sum_{h=1}^{G} c_{gh}\,\Delta \ln p_{ht} + e_{gt}, \qquad \Delta \ln \bar{x}_t = \sum_{h=1}^{G} \bar{w}_{ht}\,\Delta \ln q_{ht} \tag{A.23}$$

(their eqs. 3.3 and 3.4). Here $\bar{w}_{gt}$ is the budget share used in the discrete approximation to the differentials. It is chosen so that the identity for $\Delta \ln \bar{x}_t$ holds in the data (p. 69). The variable $\Delta \ln \bar{x}_t$ is the change in real total expenditure, and b_g is the marginal budget share. The coefficient $c_{gh} = \frac{p_g p_h s_{gh}}{x}$ is a compensated price effect, where s_{gh} is the Slutsky term and x is total expenditure (their eqs. 3.5 and 3.6). The coefficients are treated as constants. Adding up requires $\sum_g b_g = 1$ and $\sum_g c_{gh} = 0$ for every h (their eq. 3.7). Homogeneity requires $\sum_h c_{gh} = 0$ for every g, and symmetry requires $c_{gh} = c_{hg}$ (eqs. 3.8 and 3.9). The three restrictions differ in how they can be tested.

Proposition A.14 (Adding up holds by construction)**.** *Let $y_g = X_0\beta_g + e_g$ for $g = 1, \dots, G$, with common regressors X_0 of full column rank. Suppose the data satisfy $\sum_g y_g = X_0 a$ for a known vector a. Then the OLS estimates satisfy $\sum_g \hat{\beta}_g = a$, and for every observation the OLS residuals sum to zero across equations.*

Proof. OLS is linear in the dependent variable, so

$$\sum_{g=1}^{G} \hat{\beta}_g = (X_0^\top X_0)^{-1} X_0^\top \sum_{g=1}^{G} y_g = (X_0^\top X_0)^{-1} X_0^\top X_0\, a = a.$$

The residuals then sum to $\sum_g y_g - X_0 \sum_g \hat{\beta}_g = X_0 a - X_0 a = 0$. □

In (A.23) every equation has the same regressors, and the left-hand sides sum to $\Delta \ln \bar{x}_t$, the first regressor. The proposition applies with a the first unit vector. OLS therefore gives $\sum_g \hat{b}_g = 1$ and $\sum_g \hat{c}_{gh} = 0$ whatever the data. Adding up cannot be tested, and it places no restriction on the explanatory power of the equations (p. 69). Homogeneity involves the coefficients of one equation only. It can be imposed and tested equation by equation, with a t or F test of $\sum_h c_{gh} = 0$. Symmetry links pairs of equations, so it needs the system, estimated by (A.22) with one equation dropped. The restrictions are also nested. Under adding up, symmetry gives $\sum_h c_{gh} = \sum_h c_{hg} = 0$ for every g, so symmetry implies homogeneity. Tests of symmetry therefore come after tests of homogeneity, and Section A.2.6 reports their outcome. Negativity, the requirement that the matrix $C = (c_{gh})$ be negative semidefinite, is an inequality restriction and needs other tools.

Section 5.6 applies these tools to the almost ideal demand system. Hausman (1997) combines SUR with instruments to estimate brand demand for cereal, a form of three-stage least squares (Sections A.3.8 and 10.5.5). In event studies with several firms and a common event date, SUR accounts for the contemporaneous correlation of returns in tests across firms (Binder, 1985, pp. 172–173). Whinston and Collins (1992) use it in this way (Sections A.13 and 9.6).

A.2.6 Testing linear restrictions

Consider q linear restrictions $H_0\colon R\beta = r$, with R a $q \times K$ matrix of rank q. Let $\hat{V}$ estimate the variance of $\hat{\beta}$, for example $\frac{1}{n}$ times a consistent estimator of the asymptotic variance in (A.14).

The *Wald statistic* is

$$\mathcal{W} = (R\hat{\beta} - r)^\top \left[R\hat{V}R^\top\right]^{-1}(R\hat{\beta} - r) \xrightarrow{d} \chi^2_q \quad \text{under } H_0. \tag{A.24}$$

The limit follows in two steps. Under H_0, $\sqrt{n}(R\hat{\beta} - r) = R\sqrt{n}(\hat{\beta} - \beta) \xrightarrow{d} N(0, RVR^\top)$ by Proposition A.11. If $\zeta \sim N(0, \Sigma_\zeta)$ is q-dimensional with Σ_ζ nonsingular, then $\Sigma_\zeta^{-\frac{1}{2}}\zeta \sim N(0, I_q)$, so $\zeta^\top\Sigma_\zeta^{-1}\zeta$ is a sum of q squared independent standard normals. Slutsky's theorem handles the estimated variance. With homoskedastic normal errors and the conventional variance estimator, $\frac{\mathcal{W}}{q}$ equals

$$F = \frac{\frac{1}{q}(\mathrm{SSR}_r - \mathrm{SSR}_u)}{\frac{1}{n-K}\mathrm{SSR}_u} \sim F(q, n-K),$$

where SSR_r and SSR_u are the restricted and unrestricted sums of squared residuals. The *Chow test* of equal coefficients in two groups is the special case in which the unrestricted model estimates each group separately (Chow, 1960b).

Four applications illustrate the range of uses.

- Genesove and Mullin (1998) test whether the price coefficient and intercept of sugar demand are equal across seasons.[2] With Newey-West standard errors, the $\chi^2_{(2)}$ statistics are 6.90, 28.18, 29.17 and 25.96 for quadratic, linear, log-linear and exponential demand (WP Table 6, p. 29). All exceed the 5 percent cutoff of 5.99, so demand rotates between seasons (Table 3.9). A pooled specification with a time trend tests instead that the high-season shifts in intercept and slope are both zero. Its statistics are 4.91, 22.73, 23.40 and 20.77 (WP Table 5, p. 28). The quadratic form does not reject there, so for that form the conclusion depends on the specification.

- The revenue test of Panzar and Rosse (1987) restricts a single linear combination, the sum $\hat{\psi} = \sum_k \hat{\beta}_k$ of factor-price elasticities of revenue. With $R = \iota^\top$, the statistic is $t = \frac{\hat{\psi} - \psi_0}{\sqrt{\iota^\top \hat{V} \iota}}$. Long-run competition implies $\psi = 1$, a two-sided test. Monopoly implies $\psi \leq 0$, and we reject it at 5 percent when $\frac{\hat{\psi}}{\mathrm{se}} > 1.645$ (Section 3.3.3).

- Borenstein (1989, pp. 353–354) rejects a common constant across airlines but fails to reject common slopes, so his fare equations pool the slopes and keep carrier effects. A Chow test does not reject equal route-share effects across the 20th, 50th and 80th fare percentiles, while it rejects a common coefficient on flight frequency (p. 358 and fn. 41). The three percentile regressions use the same routes, so a test across them must account for the covariance of their estimates, as a stacked or SUR regression does.

- Tests of demand theory apply the same logic to systems. Barten (1969) estimated the Rotterdam model (A.23) for 16 groups of Dutch consumption by maximum likelihood, with intercepts for gradual changes in tastes. Imposing homogeneity caused "a very large drop in the value of the maximized likelihood, much larger than could conceivably have arisen by chance" (Deaton and Muellbauer, 1980b, pp. 69–70). Symmetry was rejected as well, but Deaton (1972) gives technical grounds for doubting that test. Deaton (1974) found the same pattern for nine groups of British data from 1900 to 1970. Homogeneity was rejected, while symmetry as an additional restriction was not particularly damaging

[2] We read the working-paper version of Genesove and Mullin (1998). Equation, table and page numbers marked WP refer to it. Printed page numbers are those on the pages of that version.

(Deaton and Muellbauer, 1980b, p. 70). The likelihood ratio statistic used in these studies is asymptotically equivalent to $\mathcal{W}$ under H_0 (Theorem A.41). Each rejection is joint, of the theory and of a functional form. Deaton and Muellbauer stress that the Rotterdam, double-log and translog systems all reject, at least on aggregate data (pp. 72–74).

A.3 Instrumental variables

Instrumental variables (IV) are the book's main tool for endogenous regressors: prices in demand equations, quantities in supply relations, market shares in fare equations and mergers in price regressions. This section develops the linear model and two-stage least squares, then the special problems of nonlinear models and weak instruments. It closes with specification tests, heterogeneous effects and system estimation.

A.3.1 The IV model

Assumption A.15 (Linear instrumental variables)**.** The observations (y_i, x_i, z_i) are independent and identically distributed, with x_i of dimension K and z_i of dimension $L \geq K$, and

$$y_i = x_i^\top \beta + e_i. \tag{A.25}$$

(i) The instruments are exogenous, $\mathbb{E}[z_i e_i] = 0$.

(ii) The instruments are relevant, $\operatorname{rank} \mathbb{E}[z_i x_i^\top] = K$.

(iii) $\mathbb{E}[z_i z_i^\top]$ is finite and nonsingular, and $\mathbb{E}\|z_i\|^4$, $\mathbb{E}\|x_i\|^4$ and $\mathbb{E}[e_i^4]$ are finite.

Exogenous regressors, such as the constant, appear in both x_i and z_i. They serve as their own instruments and are called *included instruments*. The other elements of z_i are the *excluded instruments*. Exogeneity of an excluded instrument combines two claims. The instrument is unrelated to the unobserved determinants of the outcome, and it affects the outcome only through x_i, which is the *exclusion restriction*. Relevance requires the excluded instruments to predict every endogenous regressor beyond what the included instruments predict. In the just-identified case $L = K$, exogeneity gives $\beta = \mathbb{E}[z_i x_i^\top]^{-1}\mathbb{E}[z_i y_i]$, and the IV estimator is its sample analogue $\hat{\beta}_{IV} = (Z^\top X)^{-1} Z^\top y$.

Indirect least squares. Let $y_i = \beta_0 + \beta_1 x_i + e_i$ with one instrument z_i and a constant. Exogeneity gives $\operatorname{Cov}(z_i, y_i) = \beta_1 \operatorname{Cov}(z_i, x_i) + \operatorname{Cov}(z_i, e_i) = \beta_1 \operatorname{Cov}(z_i, x_i)$, so

$$\beta_1 = \frac{\operatorname{Cov}(z_i, y_i)}{\operatorname{Cov}(z_i, x_i)} = \frac{\frac{\operatorname{Cov}(z_i, y_i)}{\operatorname{Var}(z_i)}}{\frac{\operatorname{Cov}(z_i, x_i)}{\operatorname{Var}(z_i)}} = \frac{\rho_1}{\pi_1}. \tag{A.26}$$

Here π_1 is the slope of the *first stage*, the regression of x_i on z_i. The slope of the *reduced form*, the regression of y_i on z_i, is ρ_1. The IV estimand is the reduced-form effect of the instrument divided by its first-stage effect. The identity also holds exactly in the sample, because each estimator is a ratio of sample covariances. Estimating β_1 this way is called *indirect least squares*. With exogenous controls, Theorem A.9 shows that the identity holds after the controls are partialled out of y_i, x_i and z_i.

The Wald estimator. If z_i is binary with $p = \mathbb{P}(z_i = 1)$, then

$$\begin{aligned}\operatorname{Cov}(z_i, y_i) &= \mathbb{E}[z_i y_i] - \mathbb{E}[z_i]\mathbb{E}[y_i] \\ &= p\,\mathbb{E}[y_i \mid z_i = 1] - p\big(p\,\mathbb{E}[y_i \mid z_i = 1] + (1-p)\,\mathbb{E}[y_i \mid z_i = 0]\big) \\ &= p(1-p)\big(\mathbb{E}[y_i \mid z_i = 1] - \mathbb{E}[y_i \mid z_i = 0]\big).\end{aligned}$$

The same algebra applies to x_i, and (A.26) becomes the *Wald estimator*

$$\beta_1 = \frac{\mathbb{E}[y_i \mid z_i = 1] - \mathbb{E}[y_i \mid z_i = 0]}{\mathbb{E}[x_i \mid z_i = 1] - \mathbb{E}[x_i \mid z_i = 0]}. \tag{A.27}$$

Invalid instruments. If the instrument is correlated with the error, the same algebra gives

$$\operatorname{plim} \hat{\beta}_{1,IV} - \beta_1 = \frac{\operatorname{Cov}(z_i, e_i)}{\operatorname{Cov}(z_i, x_i)} = \frac{\operatorname{Corr}(z_i, e_i)}{\operatorname{Corr}(z_i, x_i)} \cdot \frac{\sigma_e}{\sigma_x}. \tag{A.28}$$

The OLS bias is $\frac{\operatorname{Cov}(x_i, e_i)}{\operatorname{Var}(x_i)} = \operatorname{Corr}(x_i, e_i)\frac{\sigma_e}{\sigma_x}$, so the ratio of the two biases is

$$\frac{\operatorname{plim} \hat{\beta}_{1,IV} - \beta_1}{\operatorname{plim} \hat{\beta}_{1,OLS} - \beta_1} = \frac{\operatorname{Corr}(z_i, e_i)}{\operatorname{Corr}(x_i, e_i)\,\operatorname{Corr}(z_i, x_i)}.$$

A weak instrument puts a small $\operatorname{Corr}(z_i, x_i)$ in the denominator. It magnifies even a slight correlation with the error, and IV can then be more biased than OLS. Weak and slightly invalid instruments are a dangerous mix. Bresnahan's critique of prices in other cities as instruments is an example. National demand shocks make $\operatorname{Cov}(z_i, e_i)$ positive, and the larger their share of price variation, the closer the IV bias comes to the OLS bias (Section 10.6.3). With a valid and strong instrument, by contrast, 2SLS is centered on the truth, as panel (b) of Figure A.1 shows.

Application: rival mergers and hospital prices. Dafny (2009) estimates the effect of hospital mergers on prices.[3] A comparison of merging with non-merging hospitals suffers from selection, because hospitals that merge differ in unobserved ways from those that do not. Following Eckbo (1983), she studies the *rivals* of merging hospitals instead. If prices are strategic complements, rivals raise their prices after a merger as well. Exposure to a rival's merger is still selected, because markets with mergers differ from markets without them, so she instruments for it.

The data combine 97 independent mergers between 1989 and 1996, in which two hospitals consolidated into a single licensed entity (Dranove and Lindrooth, 2003), with Medicare cost reports for 1985–2000 (pp. 12–15). The price of a hospital is its inpatient revenue per case-mix-adjusted non-Medicare discharge. The estimation sample contains 877 non-merging hospitals with at least two rivals within 7 miles. The treatment R_i is the number of rival mergers within 7 miles between 1989 and 1996, with mean 0.156 (Table 1). The outcome is price growth over the merger wave, $\Delta \ln p_i = \ln p_{i,1997} - \ln p_{i,1988}$, with mean 0.010. The instrument C_i is the number of *co-located* rival pairs, meaning pairs of rivals within 0.3 miles and at most five blocks of each other in 1988. The estimating equations are

$$R_i = \pi_0 + \pi_1 C_i + w_i^\top \pi_2 + v_i \qquad \text{(first stage)}, \tag{A.29}$$

$$\Delta \ln p_i = \rho_0 + \rho_1 C_i + w_i^\top \rho_2 + \varepsilon_i \qquad \text{(reduced form)}, \tag{A.30}$$

$$\Delta \ln p_i = \beta_0 + \beta_1 R_i + w_i^\top \beta_2 + e_i \qquad \text{(structural equation)}. \tag{A.31}$$

[3] Numbers and page references follow the NBER working-paper version, revised in October 2007 (Dafny, 2005). Table numbers refer to that version.

The controls w_i include hospital characteristics: ownership, teaching status, Medicaid share, debt-to-asset ratio, occupancy and bed-size categories. They also include market characteristics, namely population categories, the penetration of health maintenance organizations and log income per capita, with or without state fixed effects.

Relevance has an economic rationale. Co-located hospitals can save more by closing duplicate departments, and they gain more market power from merging, because location is a primary source of differentiation in inpatient care (p. 3). In the data, co-located hospitals merge at a rate of 11.0 percent, against 3.7 percent for other hospitals (p. 18). Exclusion requires that rival co-location affect price growth only through rival mergers. Dafny names the main threat. Before 1988, new hospitals might have entered next to existing ones in areas where prices were expected to rise. She argues that this is unlikely, because there has been very little entry into acute care since the Hill-Burton Act of 1946 (fn. 27).

Table A.2 reproduces the main results. One more co-located rival pair raises the number of rival mergers by 0.119, large relative to the mean of 0.156, with a t-statistic of about 6.6. It raises price growth by 0.045, against a mean of 0.010. Because the model is exactly identified, the IV estimate is the ratio (A.26). The rounded coefficients give $\frac{0.045}{0.119} = 0.378$, and the unrounded ones give the reported 0.376 (fn. 29). The implied price increase is $e^{0.376} - 1 = 46$ percent, or 35 percent with state fixed effects (fn. 30). OLS finds no effect, with an estimate of 0.016 and a standard error of 0.026. The sign of the OLS bias matches the pre-period evidence of Section A.1.3. Hospitals later exposed to rival mergers had lower price growth before the merger wave, so treating rival mergers as exogenous understates their effect.

Table A.2: Rival mergers and hospital price growth: first stage, reduced form, IV and OLS

	Without state effects	With state effects
A. First stage (OLS)		
Own merger on own co-location (N = 4,487)	0.066	0.062
	(0.016)	(0.016)
Rival mergers on co-located rival pairs (N = 877)	0.119	0.112
	(0.018)	(0.019)
B. Reduced form: log price growth on co-located rival pairs (OLS)		
1985–1988, before the merger wave (N = 877)	−0.016	−0.013
	(0.010)	(0.011)
1988–1997, merger period (N = 877)	0.045	0.034
	(0.014)	(0.015)

IV, instrument: co-located rival pairs	0.376	0.301
	(0.132)	(0.147)
OLS	0.016	−0.003
	(0.026)	(0.027)

Notes: Standard errors in parentheses. Every regression controls for the hospital and market characteristics listed in the text. The own-merger regression is a linear probability model on all 4,487 hospitals. The other rows use non-merging hospitals with at least two rivals within 7 miles. Price is inpatient revenue per case-mix-adjusted non-Medicare discharge, and price changes are censored at the 5th and 95th percentiles. Source: Dafny (2005), Table 2 (panel A), Table 3 (panel B) and Table 4 (panel C).

Several checks support the design. Rival co-location predicts price growth neither before nor after the merger wave (panel B), so co-located markets were not on steeper price paths. The

IV estimate barely moves when all controls are dropped, at 0.352 (0.132) (Appendix Table 1). It more than doubles when the market radius shrinks to 5 miles, at 0.962 (0.377), and it vanishes at 10 miles, at 0.051 (0.054) (Table 5). Effects that fade with distance are what a local market-power mechanism predicts. Two further checks appear below. An overidentification test with two distance bands does not reject (Section A.3.6). Using fitted values from a nonlinear first stage as the instrument gives a smaller but significant estimate (Section A.3.3). The estimate is local to the mergers that the instrument moves, which are mergers of co-located hospitals with especially large gains in market power (p. 26 and Section A.3.7). Section 11.6.9 develops the economics.

A.3.2 Two-stage least squares

With more instruments than regressors, $L > K$, the sample moment conditions $\frac{1}{n}Z^\top(y - Xb) = 0$ have no exact solution. *Two-stage least squares* (2SLS) uses the linear combinations of the instruments that best predict the regressors. Let $P_Z = Z(Z^\top Z)^{-1}Z^\top$ and $\hat{X} = P_Z X$. The estimator is

$$\hat{\beta}_{2SLS} = (X^\top P_Z X)^{-1} X^\top P_Z y. \tag{A.32}$$

Three routes lead to (A.32).

(a) The first route regresses each column of X on Z and then regresses y on the fitted values $\hat{X}$. Because P_Z is symmetric and idempotent, $(\hat{X}^\top \hat{X})^{-1}\hat{X}^\top y = (X^\top P_Z X)^{-1} X^\top P_Z y$. Exogenous regressors are among the instruments, so their fitted values equal themselves.

(b) The second route uses $\hat{X}$ as instruments in the just-identified IV formula: $(\hat{X}^\top X)^{-1}\hat{X}^\top y = (X^\top P_Z X)^{-1} X^\top P_Z y$.

(c) The third route minimizes the quadratic form $(y - Xb)^\top Z(Z^\top Z)^{-1}Z^\top(y - Xb)$ in the moment conditions. Its first-order condition $-2X^\top Z(Z^\top Z)^{-1}Z^\top(y - Xb) = 0$ gives (A.32). This is the generalized method of moments with weighting matrix $(Z^\top Z)^{-1}$ (Equation (A.52) in Section A.5.2).

When $L = K$, $Z^\top X$ is square and invertible, and

$$\begin{aligned}(X^\top Z(Z^\top Z)^{-1}Z^\top X)^{-1} X^\top Z(Z^\top Z)^{-1}Z^\top y &= (Z^\top X)^{-1}(Z^\top Z)(X^\top Z)^{-1} X^\top Z(Z^\top Z)^{-1}Z^\top y \\ &= (Z^\top X)^{-1} Z^\top y,\end{aligned}$$

so 2SLS reduces to IV. In particular, a just-identified estimate does not depend on which linear combination of the instruments is used.

Proposition A.16 (Asymptotics of 2SLS)**.** *Under Assumption A.15, let* $Q_{zx} = \mathbb{E}[z_i x_i^\top]$, $Q_{zz} = \mathbb{E}[z_i z_i^\top]$, $\Omega = \mathbb{E}[e_i^2 z_i z_i^\top]$ *and* $H = Q_{zx}^\top Q_{zz}^{-1} Q_{zx}$. *Then* $\hat{\beta}_{2SLS} \xrightarrow{p} \beta$ *and*

$$\sqrt{n}(\hat{\beta}_{2SLS} - \beta) \xrightarrow{d} N\big(0,\ H^{-1} Q_{zx}^\top Q_{zz}^{-1}\, \Omega\, Q_{zz}^{-1} Q_{zx} H^{-1}\big). \tag{A.33}$$

Under conditional homoskedasticity, $\mathbb{E}[e_i^2 \mid z_i] = \sigma^2$, *the variance reduces to* $\sigma^2 H^{-1}$.

Proof. Substituting $y = X\beta + e$ into (A.32),

$$\hat{\beta}_{2SLS} - \beta = \left[\frac{X^\top Z}{n}\left(\frac{Z^\top Z}{n}\right)^{-1}\frac{Z^\top X}{n}\right]^{-1}\frac{X^\top Z}{n}\left(\frac{Z^\top Z}{n}\right)^{-1}\frac{Z^\top e}{n}.$$

By the law of large numbers, $\frac{Z^\top X}{n} \xrightarrow{p} Q_{zx}$, $\frac{Z^\top Z}{n} \xrightarrow{p} Q_{zz}$ and $\frac{Z^\top e}{n} \xrightarrow{p} \mathbb{E}[z_i e_i] = 0$. Relevance makes H nonsingular, because Q_{zx} has rank K and Q_{zz}^{-1} is positive definite. The continuous mapping theorem gives consistency. Multiplying by $\sqrt{n}$ replaces $\frac{Z^\top e}{n}$ by $\frac{1}{\sqrt{n}} \sum_i z_i e_i$, which converges in distribution to $N(0, \Omega)$ by the central limit theorem. Slutsky's theorem gives (A.33). Under homoskedasticity $\Omega = \sigma^2 Q_{zz}$, and the sandwich collapses to $\sigma^2 H^{-1} H H^{-1} = \sigma^2 H^{-1}$. □

The variance is estimated by replacing population moments with sample moments and e_i with the 2SLS residual $\hat{e}_i = y_i - x_i^\top \hat{\beta}_{2SLS}$. The homoskedastic estimator is $\hat{\sigma}^2 (X^\top P_Z X)^{-1}$ with $\hat{\sigma}^2 = \frac{1}{n} \sum_i \hat{e}_i^2$. The heteroskedasticity-robust estimator is

$$(X^\top P_Z X)^{-1} X^\top Z (Z^\top Z)^{-1} \Big(\sum_{i=1}^n \hat{e}_i^2 z_i z_i^\top \Big) (Z^\top Z)^{-1} Z^\top X (X^\top P_Z X)^{-1}.$$

Clustered versions replace the middle sum by sums over clusters (Section A.8.2).

Why a manual second stage reports wrong standard errors. Running the second stage by hand gives the right point estimate and the wrong standard errors. The software computes residuals from the regressors it sees, $\tilde{e} = y - \hat{X}\hat{\beta}$. Write $\hat{V} = X - \hat{X} = M_Z X$ for the first-stage residuals. Then

$$\tilde{e} = y - X\hat{\beta} + (X - \hat{X})\hat{\beta} = \hat{e} + \hat{V}\hat{\beta},$$

where $\hat{e} = y - X\hat{\beta}$ is the correct residual. Let v_i be the error of the population projection of x_i on z_i. Then

$$\frac{1}{n} \tilde{e}^\top \tilde{e} \xrightarrow{p} \mathbb{E}\big[(e_i + v_i^\top \beta)^2\big] = \sigma^2 + 2\beta^\top \mathbb{E}[v_i e_i] + \beta^\top \mathbb{E}[v_i v_i^\top] \beta.$$

The manual second stage estimates the variance of the reduced-form error $e_i + v_i^\top \beta$, which can be larger or smaller than σ^2. The correct variance estimator computes residuals with the original regressors X.

Proposition A.17 (Control-function form of 2SLS)**.** *Partition $X = [X_1, X_2]$, where the exogenous columns X_1 are among the instruments and the columns X_2 are endogenous. Let $\hat{V}_2 = M_Z X_2$ be the first-stage residuals of the endogenous regressors. In the OLS regression of y on X and $\hat{V}_2$, the coefficient on X equals $\hat{\beta}_{2SLS}$.*

Proof. By Theorem A.9 the coefficient on X is $(X^\top M_{\hat{V}} X)^{-1} X^\top M_{\hat{V}} y$, where $M_{\hat{V}}$ is the annihilator of $\hat{V}_2$. Decompose $X = \hat{X} + M_Z X$. Since $M_Z X_1 = 0$, the matrix $M_Z X = [0, \hat{V}_2]$ lies in the column space of $\hat{V}_2$, so $M_{\hat{V}} M_Z X = 0$. Moreover $\hat{V}_2^\top \hat{X} = X_2^\top M_Z P_Z X = 0$, so $M_{\hat{V}} \hat{X} = \hat{X}$. Together these give $M_{\hat{V}} X = \hat{X}$. Substituting,

$$(X^\top M_{\hat{V}} X)^{-1} X^\top M_{\hat{V}} y = (\hat{X}^\top \hat{X})^{-1} \hat{X}^\top y = \hat{\beta}_{2SLS}.$$ □

The residual $\hat{V}_2$ acts as a *control function*. It absorbs the part of the regressor that is correlated with the error, and the remaining variation in X is the instrumented variation. A test that its coefficient is zero is the regression form of the Hausman test (Section A.3.6). The OLS standard errors for β in this regression are invalid in general, because $\hat{V}_2$ is an estimated regressor (Section A.5.6).

Example: logit demand. Berry's inversion turns logit demand into a linear equation, $\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$ (Berry, 1994). Firms observe ξ_{jt} when they set prices, so $\mathrm{Cov}(p_{jt}, \xi_{jt}) > 0$ and OLS biases the price coefficient $-\alpha$ toward zero. 2SLS with excluded cost shifters or rival characteristics applies (A.32), with y the stacked log share ratios and $X = (x, p)$ (Section 7.3.4).

A.3.3 Endogeneity in nonlinear models

Two-stage least squares relies on linearity. Replacing an endogenous regressor by its first-stage fitted value inside a nonlinear function is called the *forbidden regression*, and it is inconsistent in general.

Proposition A.18 (The forbidden regression)**.** *Let $y_i = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + e_i$ with $\mathbb{E}[e_i \mid z_i] = 0$. Let $\mu(z_i) = \mathbb{E}[x_i \mid z_i]$, $v_i = x_i - \mu(z_i)$ and $\sigma^2(z_i) = \mathbb{E}[v_i^2 \mid z_i]$, and assume the relevant moments are finite. The population regression of y_i on $(1, \mu(z_i), \mu(z_i)^2)$ has coefficients*

$$(\beta_0 + \beta_2 c_0,\ \beta_1 + \beta_2 c_1,\ \beta_2 + \beta_2 c_2), \tag{A.34}$$

where (c_0, c_1, c_2) are the coefficients of the linear projection of $\sigma^2(z_i)$ on $(1, \mu(z_i), \mu(z_i)^2)$. The slopes are correct only if $c_1 = c_2 = 0$, for example when $\sigma^2(z_i)$ is constant.

Proof. Write $\mu_i = \mu(z_i)$ and substitute $x_i = \mu_i + v_i$:

$$y_i = \beta_0 + \beta_1 \mu_i + \beta_2 \mu_i^2 + u_i, \qquad u_i = \beta_1 v_i + 2\beta_2 \mu_i v_i + \beta_2 v_i^2 + e_i.$$

Conditional on z_i, $\mathbb{E}[v_i \mid z_i] = 0$, $\mathbb{E}[v_i^2 \mid z_i] = \sigma^2(z_i)$ and $\mathbb{E}[e_i \mid z_i] = 0$. Hence $\mathbb{E}[u_i \mid z_i] = \beta_2 \sigma^2(z_i)$. Write $u_i = \beta_2 \sigma^2(z_i) + \tilde{u}_i$ with $\mathbb{E}[\tilde{u}_i \mid z_i] = 0$. The term $\tilde{u}_i$ is uncorrelated with every function of z_i, including $(1, \mu_i, \mu_i^2)$, so it does not affect the projection. The term $\beta_2 \sigma^2(z_i)$ adds $\beta_2(c_0, c_1, c_2)$ to the coefficients. □

The root of the problem is that $\mathbb{E}[q(x_i) \mid z_i] \neq q(\mathbb{E}[x_i \mid z_i])$ for a nonlinear function q. Here $\mathbb{E}[x_i^2 \mid z_i] = \mu(z_i)^2 + \sigma^2(z_i)$, and the gap $\sigma^2(z_i)$ is generally correlated with the fitted values. Simulated data show the size of the problem. Let $z_i \sim N(0,1)$, $x_i = z_i + v_i$ and $y_i = 1 + x_i + 0.5x_i^2 + e_i$, where $v_i = s(z_i)\eta_i$ and $e_i = 0.8\eta_i + 0.6\epsilon_i$ with independent standard normal η_i and ϵ_i. The common component η_i makes x_i endogenous. With heteroskedastic first-stage errors, $s(z)^2 = 0.25 + z^2$, we have $\sigma^2(z_i) = 0.25 + \mu_i^2$ and $(c_0, c_1, c_2) = (0.25, 0, 1)$. Proposition A.18 predicts coefficients $(1.125, 1, 1)$, which double the curvature. In one sample of 10^6 observations the forbidden regression gives $(1.123, 0.996, 1.001)$, while 2SLS with instruments $(1, z_i, z_i^2)$ for $(1, x_i, x_i^2)$ gives $(1.000, 1.000, 0.500)$. With homoskedastic errors, $s(z)^2 = 1.25$, only the intercept is affected. The forbidden regression gives $(1.622, 0.999, 0.501)$, against a predicted intercept of $1 + 0.5 \times 1.25 = 1.625$.

Four valid approaches handle endogeneity in nonlinear models.

(i) The first approach uses nonlinear functions of the instruments as instruments. If $\mathbb{E}[e_i \mid z_i] = 0$, then $\mathbb{E}[h(z_i)e_i] = 0$ for every function h. Squares, interactions and fitted values from any first-stage model, linear or not, are valid instruments. They lose validity only when they replace the regressor itself. Borenstein (1989, p. 353) instruments the route Herfindahl index, which contains the square of the endogenous route share, with

$$IRUTHERF = \widehat{RUTSHARE}^2 + \frac{RUTHERF - RUTSHARE^2}{(1 - RUTSHARE)^2}\left(1 - \widehat{RUTSHARE}\right)^2. \tag{A.35}$$

The first term squares the first-stage fitted share. The second rescales the Herfindahl index of the traffic that the carrier does not carry, so that it is unchanged when the fitted share replaces the actual one. The variable is valid if the share instrument is valid and if the carrier's price does not affect how the rest of the traffic is divided among its rivals. It enters only as an excluded instrument in the first stage for the Herfindahl index. Dafny (2005, Appendix Table 1) similarly uses fitted values from a negative binomial first stage as the instrument for rival mergers, which gives 0.222 (0.099).

(ii) The second approach is nonlinear instrumental variables. When the model is nonlinear in parameters, write it as a residual function $\rho(w_i;\theta)$ with $\mathbb{E}[\rho(w_i;\theta_0) \mid z_i] = 0$. Nonlinear two-stage least squares (Amemiya, 1974) minimizes $\rho(\theta)^\top P_Z \rho(\theta)$, where $\rho(\theta)$ stacks the residuals. The sugar pricing equation of Genesove and Mullin (1998) is an example. Its residual multiplies the conduct parameter by the price and by the demand intercept, so it is nonlinear in the parameters (Equation (A.49) in Section A.5.1, and Equation (3.62)). Their quadratic demand, $\ln M_t = b_s + 2\ln(\alpha_s - P_t) + e_t$, is nonlinear in the choke price α_s (Section 3.7.4). Hausman (1997, p. 231) estimates a CES demand system for cereal brands by nonlinear 2SLS and reports $\hat{\rho} = 0.580$ with an asymptotic standard error of 0.00001. Precision of that order is rare in demand estimation and deserves scrutiny before use (Section 10.5.9). Section A.5 develops the general theory.

(iii) The third approach uses a *control function*. Suppose the first stage is $x_i = h(z_i) + v_i$ with v_i independent of z_i, and $\mathbb{E}[e_i \mid z_i, v_i] = \kappa(v_i)$ for some function κ. Then $\mathbb{E}[y_i \mid x_i, z_i] = q(x_i;\beta) + \kappa(v_i)$, and adding an estimate of $\kappa(\hat{v}_i)$ to the model restores consistency (Rivers and Vuong, 1988; Petrin and Train, 2010). In the linear model this reproduces 2SLS (Proposition A.17) and needs no assumption beyond exogeneity. In nonlinear models it needs more: a correctly specified first stage with an additive error independent of the instruments, and a form for κ. In the homoskedastic quadratic design above, adding $\hat{v}_i$ linearly recovers $(1.000, 1.000, 0.500)$ with a control-function coefficient of 0.716, equal to the true $\frac{0.8}{\sqrt{1.25}}$.

(iv) The fourth approach, the one most used in industrial organization, inverts the model so that the structural error enters linearly. The logit inversion (Berry, 1994) and the random-coefficient contraction recover the unobserved quality $\xi_{jt}(\theta)$ from market shares, and linear or nonlinear IV then applies to $\mathbb{E}[z_{jt}\xi_{jt}(\theta_0)] = 0$ (Section 7.2 and Chapter 8).

A related caution concerns plug-in procedures. Chaudhuri et al. (2006, WP p. 20) regress prices on the instruments and plug the predicted prices into a constrained least-squares estimation of their demand system.[4] This coincides with 2SLS when predicted prices enter the estimating equations linearly. Prices may also enter nonlinearly, for example through a price index that deflates expenditure. The procedure is then a version of the forbidden regression, and its consistency needs a separate argument (Section 5.9.5).

A.3.4 Where instruments come from in IO

Instruments in industrial organization come from economic models of how prices and quantities are determined. A good instrument shifts the endogenous variable for a reason that the outcome equation excludes. Table A.3 lists the families used in this book. Three general points organize it.

First, the number of excluded instruments must be at least the number of endogenous regressors (Proposition A.7). A product-space demand system with J prices in every equation needs at least J instruments that move prices independently of one another. Market-wide cost shifters, which move all prices together, cannot do this (Chapter 5). Second, the classic cost-shifter strategy is often weak in practice, because input prices typically vary little within a market. Exceptions arise when products are made in different locations, or when cost

[4] We read NBER Working Paper 10159 (December 2003), the working-paper version of Chaudhuri et al. (2006). Page and footnote numbers marked WP refer to it, and its printed page numbers equal its PDF page numbers minus two.

factors interact with exogenous characteristics that vary across products (Ackerberg et al., 2007, Section 1.4.3).[5] Third, oligopoly pricing supplies instruments that competitive models do not. Markups depend on the characteristics of rival products and on who owns them, so these variables shift prices even though they are excluded from utility (Bresnahan, 1987; Berry et al., 1995).

Table A.3: Families of instruments in industrial organization

Family	Why it moves the endogenous variable	Examples in the book	Main threat
Cost shifters excluded from demand	Shift marginal cost and move the equilibrium along demand	Cuban raw-sugar imports (Section 3.7.4), brewery distance times a diesel price index (Section 11.8.7), the milk price in simulated yogurt markets (Appendix C)	Little variation across products in a market, or input prices that respond to demand
Firm-specific cost shifters	Shift one firm's supply and trace out its residual demand	Capacity, average plant size and Colorado wages in brewing (Section 3.4)	Capacity chosen in anticipation of demand, and short samples
Demand shifters and rotators	Move the equilibrium along the supply relation, and rotations separate conduct from cost	Seasons in sugar demand (Section 3.7.4), demand rotators (Section 3.5.2)	Shifters that also move cost or conduct, and conduct that varies with demand (Section A.3.7)
Characteristics of other products	Markups fall in crowded parts of characteristic space and rise when nearby products share an owner	Sums of rival and own-firm characteristics, differentiation instruments (Section 8.6.4)	Characteristics chosen with knowledge of ξ, inefficiency relative to optimal instruments (Section A.5.5), weakness with many products
Prices of the same product in other markets	Common cost shocks move the product's price in every market	Prices in other cities for cereal (Sections 8.13.7 and 10.5.5)	National demand shocks such as advertising campaigns (Section 10.6.3)
Market structure and institutions	Entry, product counts, ownership and regulation shift markups or group prices	Number of SKUs and regulated SKU prices (Section 5.9.5), rival co-location (Table A.2), a post-merger indicator for ABI and MillerCoors products (Section 11.8.7), endpoint enplanement share (Section 9.5.5), products per nest (Section 7.5.4)	Entry and product choice that respond to demand, and new products that shift demand directly

Notes: SKU denotes a stock-keeping unit. The sources for the first three rows are Genesove and Mullin (1998), Miller and Weinberg (2017, p. 1775), Baker and Bresnahan (1988) and Bresnahan (1982). The sources for the other rows are Berry et al. (1995), Gandhi and Houde (2019), Hausman (1997), Nevo (2001), Bresnahan (1997), Chaudhuri et al. (2006), Dafny (2009) and Borenstein (1989), with Miller and Weinberg (2017) again for the post-merger indicator.

The instruments in each row rest on a specific economic argument. Cost shifters are valid because consumers do not care about the cost of inputs. In Genesove and Mullin (1998),

[5] We read the draft of June 14, 2006 of Ackerberg et al. (2007). Section numbers refer to that draft and may differ from the published chapter.

Cuban imports of raw sugar shift the cost of refining, and Cuban supply varied with harvests, weather and war (Section 3.7.4). Firm-specific cost shifters identify a single firm's residual demand, because rivals' costs do not move it except through the firm's own output. Baker and Bresnahan (1988) use capacity, which brewers change infrequently and in large increments. Characteristics of rival products are valid under the assumption that characteristics are set before, and independently of, the unobserved quality ξ. That assumption fails if firms design products knowing ξ, and predetermination alone does not deliver it. Prices in other markets rely on independence of demand shocks across markets after unit effects are removed, the panel logic of Hausman and Taylor (1981). National demand shocks break it. Market-structure instruments rely on institutional features that move prices for reasons unrelated to current demand. Borenstein's endpoint enplanement share is excluded on the argument that fares respond to actual entry and not to potential entry (p. 352).

Arguing for exclusion. Exclusion cannot be tested in a just-identified model, so it rests on economic arguments supported by indirect evidence. Three kinds of evidence recur. The first is timing. An instrument fixed before the shocks of the outcome equation, such as co-location measured in 1988 or capacity installed years earlier, cannot respond to those shocks. It may still be correlated with persistent unobservables. The second is falsification. The instrument should not predict outcomes in periods when the mechanism cannot operate, as rival co-location fails to predict hospital price growth before and after the merger wave (Table A.2). The third is overidentification. With more instruments than endogenous regressors, the overidentification test checks whether different instruments imply the same parameter (Section A.3.6). It cannot detect a bias that all instruments share.

A.3.5 Weak instruments

An instrument is *weak* when it explains little of the endogenous regressor. Relevance in Assumption A.15 may hold, yet the normal approximation of Proposition A.16 is poor in samples of realistic size. Weak instruments bias 2SLS toward OLS, make its distribution far from normal and distort conventional tests.

The concentration parameter. Consider one endogenous regressor and L excluded instruments, after any exogenous regressors have been partialled out with Theorem A.9:

$$y = x\beta + e, \qquad x = Z\pi + v, \tag{A.36}$$

where Z is $n \times L$ and treated as fixed. The rows of (e, v) are independent, with mean zero, variances σ_e^2 and σ_v^2, and covariance σ_{ev}. The strength of the instruments is measured by the *concentration parameter*

$$\mu^2 = \frac{\pi^\top Z^\top Z \pi}{\sigma_v^2}, \tag{A.37}$$

the signal in the first stage relative to its noise. The first-stage F statistic for $H_0\colon \pi = 0$ is $F = \frac{\frac{1}{L} x^\top P_Z x}{\frac{1}{n-L} x^\top M_Z x}$. Two facts give its expectation. First, $\operatorname{tr}(P_Z) = \operatorname{tr}\big((Z^\top Z)^{-1} Z^\top Z\big) = L$, so $\mathbb{E}[v^\top P_Z v] = \sigma_v^2 \operatorname{tr}(P_Z) = L\sigma_v^2$ and $\mathbb{E}[x^\top P_Z x] = \pi^\top Z^\top Z \pi + L\sigma_v^2$. Second, $M_Z Z = 0$, so $\mathbb{E}[x^\top M_Z x] = (n - L)\sigma_v^2$. The ratio of expectations is

$$\mathbb{E}[F] \approx \frac{\pi^\top Z^\top Z \pi + L\sigma_v^2}{L\sigma_v^2} = 1 + \frac{\mu^2}{L}. \tag{A.38}$$

The first-stage F is thus an estimate of $1 + \frac{\mu^2}{L}$, and irrelevant instruments give F near one.

Proposition A.19 (Bias of 2SLS with weak instruments)**.** *In model* (A.36)*, approximate the expectation of the ratio* $\hat{\beta}_{2SLS} - \beta = \frac{x^\top P_Z e}{x^\top P_Z x}$ *by the ratio of expectations. Then*

$$\mathbb{E}[\hat{\beta}_{2SLS}] - \beta \approx \frac{\sigma_{ev}}{\sigma_v^2} \cdot \frac{L}{\mu^2 + L} \approx \frac{\sigma_{ev}}{\sigma_v^2} \cdot \frac{1}{\mathbb{E}[F]}. \tag{A.39}$$

Proof. With one regressor, (A.32) gives $\hat{\beta}_{2SLS} - \beta = \frac{x^\top P_Z e}{x^\top P_Z x}$. The numerator is $x^\top P_Z e = \pi^\top Z^\top e + v^\top P_Z e$. The first term has mean zero. The second has mean $\mathbb{E}[v^\top P_Z e] = \operatorname{tr}\big(P_Z \mathbb{E}[e v^\top]\big) = \sigma_{ev} \operatorname{tr}(P_Z) = L\sigma_{ev}$. The denominator has mean $\pi^\top Z^\top Z \pi + L\sigma_v^2$, as shown above. The ratio is

$$\frac{L\sigma_{ev}}{\pi^\top Z^\top Z \pi + L\sigma_v^2} = \frac{\sigma_{ev}}{\sigma_v^2} \cdot \frac{L}{\mu^2 + L},$$

and $\frac{L}{\mu^2+L} = \frac{1}{1+\frac{\mu^2}{L}} \approx \frac{1}{\mathbb{E}[F]}$ by (A.38). □

With irrelevant instruments, $\mu^2 = 0$, the approximate bias equals $\frac{\sigma_{ev}}{\sigma_v^2}$, which is also the bias of OLS when $\pi = 0$. 2SLS then centers on the OLS limit. More generally, the bias of 2SLS relative to that of OLS is roughly $\frac{1}{\mathbb{E}[F]}$. A first-stage F of 10 corresponds to a relative bias of about 10 percent, which is the origin of a popular rule of thumb.

Remark A.20 (Accuracy of the approximation). The ratio of expectations ignores the correlation between numerator and denominator. A second-order expansion gives the bias $\frac{\sigma_{ev}}{\sigma_v^2} \cdot \frac{L-2}{\mu^2}$ (Nagar, 1959), which is more accurate when μ^2 is large relative to L. Finite-sample moments of 2SLS exist only up to order $L - 1$ (Kinal, 1980). A just-identified 2SLS estimator therefore has no mean, and with $L = 2$ it has a mean but no variance. In the design of Figure A.2 ($L = 3$ and $\frac{\sigma_{ev}}{\sigma_v^2} = 0.5$), the simulated mean bias is 0.352, 0.054 and 0.004 for $\mu^2 = 1$, 10 and 100. The ratio of expectations gives 0.375, 0.115 and 0.015, and the second-order formula gives 0.5, 0.05 and 0.005. The first approximation works when instruments are nearly irrelevant and the second when they are moderately strong.

Consequences. Figure A.2 shows three consequences in a simulated design. It uses (A.36) with $\beta = 0$, $n = 500$, three fixed standard normal instruments, unit error variances and 10,000 replications per design. Panel (a) shows that with $\mu^2 = 1$ the distribution of 2SLS is wide and centered near the OLS limit. It concentrates around the truth only as μ^2 grows. Panel (b) shows the size of the nominal 5 percent Wald (t) test of $\beta = 0$. With strong endogeneity, $\rho = \operatorname{Corr}(e_i, v_i) = 0.95$, the test rejects a true null 77 percent of the time when $\frac{\mu^2}{L} = 0.1$, 43 percent when $\frac{\mu^2}{L} = 1$ and 11 percent when $\frac{\mu^2}{L} = 10$. Even at $\frac{\mu^2}{L} = 100$ the rejection rate is 6.2 percent, more than five Monte Carlo standard errors above 5 percent. With $\rho = 0.5$ the distortion is milder and peaks near 10 percent. The simulated mean first-stage F tracks $1 + \frac{\mu^2}{L}$ closely, for instance 2.02 at $\frac{\mu^2}{L} = 1$ and 10.98 at $\frac{\mu^2}{L} = 10$.

Diagnostics. The standard diagnostic is the first-stage F statistic for the excluded instruments. Staiger and Stock (1997) suggest treating $F < 10$ as a sign of weak instruments, which by Proposition A.19 corresponds to a relative bias of roughly 10 percent. Stock and Yogo (2005) tabulate cutoffs for the Cragg-Donald version of the statistic under homoskedasticity, for chosen tolerances on the relative bias of 2SLS or on the size of Wald tests. With heteroskedastic, serially correlated or clustered errors, the homoskedastic F is invalid. Practitioners then report the

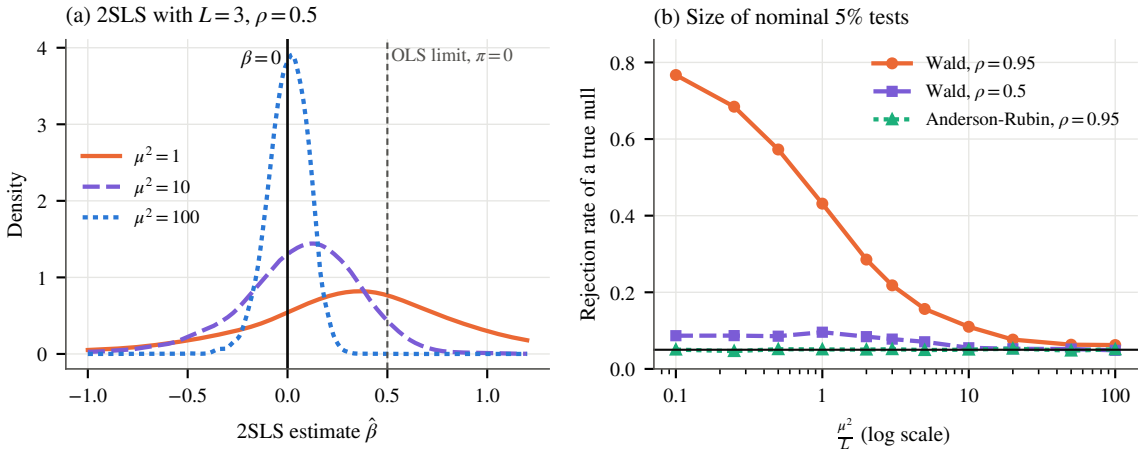

Figure A.2: Weak instruments in a simulated design. The model is $y = x\beta + e$, $x = Z\pi + v$ with $\beta = 0$, $n = 500$, three fixed standard normal instruments, and (e_i, v_i) bivariate normal with unit variances and correlation ρ. The vector π is scaled to hit each concentration parameter μ^2 exactly. (a) Kernel densities of 2SLS over 10,000 replications for $\mu^2 \in \{1, 10, 100\}$ with $\rho = 0.5$. The dashed line marks $\rho = 0.5$, the OLS limit with irrelevant instruments. (b) Rejection rates of nominal 5 percent tests of the true null $\beta = 0$, plotted against $\frac{\mu^2}{L}$ on a log scale. The Wald test uses homoskedastic 2SLS standard errors with $\rho = 0.95$ and $\rho = 0.5$, and the Anderson-Rubin test uses $\rho = 0.95$. The horizontal line is the nominal size. The Monte Carlo standard error of a rejection rate of 0.05 is 0.0022. Seed 20261022, script `sim_iv.py`.

robust Wald statistic of Kleibergen and Paap (2006), divided by L, and compare it informally with the Stock-Yogo values. Montiel Olea and Pflueger (2013) derive an *effective* F statistic with valid cutoffs for one endogenous regressor. With several endogenous regressors, every first-stage F can be large while the instruments still fail to separate the regressors from one another. The conditional F statistics of Sanderson and Windmeijer (2016) address this case. They are needed in the nested logit regression, where both price and the log within-nest share are endogenous (Section 7.5.4). Table A.4 summarizes the rules.

The first-stage R^2 is not a weak-instrument diagnostic, because it includes the explanatory power of the exogenous regressors. Chaudhuri et al. (2006, WP fn. 23) report first-stage R^2 between 0.57 and 0.95 for their product-group prices, and 0.17 for domestic ciprofloxacin. Their instrument list includes region-by-product dummies (WP p. 20), which can explain much of the variation in price levels on their own. What matters is the contribution of the excluded instruments, measured by the partial R^2 or the partial F statistic after the exogenous regressors are partialled out. An overall F can also hide weak subsets. In the simulated markets of Appendix C, the cluster-robust first-stage F for seven excluded instruments is 92.5, but six of them are jointly weak with $F = 2.32$. Nearly all the strength comes from one cost shifter.

Inference that is robust to weak instruments. The *Anderson-Rubin test* (Anderson and Rubin, 1949) remains valid however weak the instruments are. To test $H_0\colon \beta = \beta_0$, form $\tilde{y} = y - x\beta_0$, which equals e under the null. Regress $\tilde{y}$ on Z and test that all coefficients are zero:

$$AR(\beta_0) = \frac{\frac{1}{L}\tilde{y}^\top P_Z \tilde{y}}{\frac{1}{n-L}\tilde{y}^\top M_Z \tilde{y}}. \tag{A.40}$$

Suppose the errors are normal, homoskedastic and independent of Z. Under H_0, $\frac{1}{\sigma_e^2} e^\top P_Z e \sim \chi^2_L$

Table A.4: Weak-instrument diagnostics and conventional thresholds

Diagnostic	Setting	Threshold	Source
First-stage F on excluded instruments	One endogenous regressor, homoskedastic errors	$F > 10$ as a rule of thumb	Staiger and Stock (1997)
Cragg-Donald F with tabulated cutoffs	Homoskedastic errors, one or more endogenous regressors	With one endogenous regressor, 9.08 for relative bias of at most 10 percent when $L = 3$, and 16.38 ($L = 1$) or 22.30 ($L = 3$) for a nominal 5 percent Wald test with true size of at most 10 percent	Stock and Yogo (2005, Tables 5.1–5.2)
Kleibergen-Paap Wald F	Heteroskedastic or clustered errors	No formal cutoffs, compared informally with the Stock-Yogo values	Kleibergen and Paap (2006)
Effective F	One endogenous regressor with heteroskedastic, serially correlated or clustered errors	23.1 as a conservative rule for a 2SLS Nagar bias of at most 10 percent of a worst-case benchmark, at the 5 percent level	Montiel Olea and Pflueger (2013, p. 358)
Conditional F	Several endogenous regressors	With $K = 2$, each statistic compared with the Stock-Yogo values for one endogenous regressor and $L - 1$ instruments	Sanderson and Windmeijer (2016, Section 4)
tF adjustment	Just identified, one endogenous regressor	$F > 104.7$ for the usual cutoff of 1.96 to give a true 5 percent test	Lee et al. (2022)

Notes: L is the number of excluded instruments and K the number of endogenous regressors. The cutoffs depend on the number of instruments and on the chosen tolerance, and the cited sources give full tables.

and $\frac{1}{\sigma_e^2} e^\top M_Z e \sim \chi^2_{n-L}$, because P_Z and M_Z are idempotent with ranks L and $n-L$. The two quadratic forms are independent because $P_Z M_Z = 0$. Hence $AR(\beta_0) \sim F(L, n-L)$ exactly, whatever the value of π. With K_1 exogenous regressors partialled out, the denominator degrees of freedom become $n - L - K_1$. Without normality, $L \cdot AR(\beta_0)$ is asymptotically χ^2_L, and heteroskedasticity- or cluster-robust versions use a robust Wald test of the coefficients on Z.

A confidence set collects the values β_0 that the test does not reject. The Anderson-Rubin set can be a bounded interval, the union of two rays, the whole real line, or even empty. An unbounded set is the right answer when the data carry little information about β. In panel (b) of Figure A.2, the Anderson-Rubin test rejects between 4.7 and 5.3 percent of the time at every instrument strength. Its weakness is power when $L > K$, because it tests $\beta = \beta_0$ jointly with the overidentifying restrictions. The conditional likelihood ratio test of Moreira (2003) is more powerful, and it coincides with the Anderson-Rubin test in the just-identified case. Andrews et al. (2019) survey these methods.

Many instruments. Adding instruments that carry little information raises L without raising μ^2, and by Proposition A.19 it pushes 2SLS toward OLS. In the limit with as many instruments as observations, $P_Z = I_n$ and 2SLS equals OLS. Limited-information maximum likelihood (LIML) is approximately median-unbiased and much less sensitive to the number of instruments. The jackknife IV estimator removes the own-observation term that causes the bias (Angrist et al., 1999). In demand estimation, Armstrong (2016) shows that the characteristics of rival products can be weak instruments in markets with many products. Markups then converge to limits that hardly depend on rivals' characteristics (Section 8.6.4).

A.3.6 Specification tests

Overidentification. When $L > K$, the instruments imply more moment conditions than parameters, and we can test whether they are mutually consistent. Under homoskedasticity, the *Sargan statistic* is n times the R^2 of the regression of the 2SLS residuals on all instruments. It converges to χ^2_{L-K} under the null that every instrument is exogenous (Sargan, 1958). Hansen's J statistic is the robust version (Theorem A.34). Dafny (2005, pp. 23–24) splits her instrument into the number of rival pairs less than 0.2 miles apart and the number between 0.2 and 0.3 miles apart. The Sargan statistic is 0.36 with a p-value of 0.55, so the two bands imply similar effects. The test has limits. It is identically zero in a just-identified model. It has no power against a bias that all instruments share. Both of Dafny's bands measure distances between the same hospitals, so they would fail together if co-location itself were correlated with unobserved price growth.

The Hausman principle. A second family of tests compares two estimators. One is efficient under the null hypothesis, and the other is consistent under both the null and the alternative.

Lemma A.21 (Hausman)**.** *Let $\hat\beta_E$ and $\hat\beta_C$ be estimators of β such that, under H_0, $\sqrt{n}\big((\hat\beta_E - \beta)^\top, (\hat\beta_C - \beta)^\top\big)^\top$ converges to a normal vector with variances V_E and V_C and cross-covariance $C = \operatorname{Acov}(\hat\beta_E, \hat\beta_C)$. Here* Avar *and* Acov *denote the asymptotic variance and covariance of $\sqrt{n}$ times the centered estimators. If $\hat\beta_E$ is asymptotically efficient under H_0, then $C = V_E$. Equivalently, $\hat\beta_E$ is asymptotically uncorrelated with $\hat\beta_C - \hat\beta_E$, and*

$$\operatorname{Avar}(\hat\beta_C - \hat\beta_E) = V_C - V_E. \tag{A.41}$$

Proof. Write $D = \hat\beta_C - \hat\beta_E$, which converges to zero under H_0. Its asymptotic covariance with $\hat\beta_E$ is $C - V_E$. For fixed vectors a and b and a scalar λ, the estimator $a^\top \hat\beta_E + \lambda b^\top D$ is consistent

for $a^\top \beta$. Its asymptotic variance is

$$f(\lambda) = a^\top V_E a + 2\lambda\, a^\top (C - V_E) b + \lambda^2\, b^\top \operatorname{Avar}(D)\, b.$$

Efficiency of $\hat{\beta}_E$ requires $f(\lambda) \geq f(0)$ for every λ, so the derivative at zero, $2a^\top(C - V_E)b$, must vanish. This holds for all a and b, so $C = V_E$. Then $\operatorname{Avar}(D) = V_C - C - C^\top + V_E = V_C - V_E$. □

The *Hausman statistic* is

$$\mathcal{H} = (\hat{\beta}_C - \hat{\beta}_E)^\top \left[\hat{V}_C - \hat{V}_E\right]^- (\hat{\beta}_C - \hat{\beta}_E) \xrightarrow{d} \chi^2_q, \tag{A.42}$$

where $\hat{V}_C$ and $\hat{V}_E$ estimate the finite-sample variances, the superscript denotes a generalized inverse, and q is the rank of $V_C - V_E$ (Hausman, 1978). When OLS is compared with 2SLS, q equals the number of endogenous regressors tested. Two practical problems arise. The estimated difference $\hat{V}_C - \hat{V}_E$ need not be positive semidefinite in finite samples, and OLS is efficient only under homoskedasticity. The regression form avoids both. Add the first-stage residuals of the suspect regressors to the OLS regression, as in Proposition A.17, and test that their coefficients are jointly zero with a robust Wald test. Under homoskedasticity this test is asymptotically equivalent to (A.42).

The principle appears throughout the book.

- Borenstein (1989) rejects exogeneity of the route share and the route Herfindahl index, and so reports 2SLS. A Hausman test does not reject exogeneity of the load factor "at any reasonable significance level", so he treats it as exogenous (pp. 352 and 356–357). The cost of instrumenting shows in his Table 2. For the 80th percentile fare, the route-share coefficient is 0.1259 (0.0349) by OLS and 0.2238 (0.0784) by 2SLS. The route Herfindahl coefficient moves from −0.0120 (0.0425) to −0.1787 (0.0901). The 2SLS standard errors are more than twice the OLS ones.
- Dafny (2005, p. 21) reports that Hausman tests easily reject equality of the IV and OLS estimates in Table A.2.
- Hausman (1997) notes that weekly supermarket prices may be predetermined with respect to demand shocks, in which case OLS is consistent and efficient. A Hausman test of OLS against IV can decide (Section 10.5.5).
- In panel data, random effects is efficient under its assumptions and fixed effects is consistent whether or not the unit effects are correlated with the regressors. Their difference tests $\mathbb{E}[\alpha_i \mid x_{i1}, \ldots, x_{iT}] = 0$ (Section A.2.4).
- The test of independence of irrelevant alternatives of Hausman and McFadden (1984) compares logit estimates from the full choice set with estimates from a restricted set. The restricted estimates are consistent under both hypotheses and inefficient under the null (Equation (10.89)).

A.3.7 What IV estimates when effects differ

So far the effect of x_i has been the same for every unit. When effects differ, IV estimates a weighted average of them, and the weights depend on the instrument.

Theorem A.22 (Local average treatment effect)**.** *Let z_i and d_i be binary. Each unit has potential treatments $d_i(1)$ and $d_i(0)$, one for each value of the instrument, and potential outcomes $y_i(d, z)$. Assume the following.*

(i) The instrument is independent of the potential outcomes and treatments $\{y_i(d,z), d_i(z) : d, z \in \{0,1\}\}$.

(ii) The instrument is excluded from the outcome, $y_i(d,1) = y_i(d,0) \equiv y_i(d)$ *for* $d = 0, 1$.

(iii) The instrument is relevant, $\mathbb{E}[d_i(1) - d_i(0)] \neq 0$.

(iv) Treatment is monotone in the instrument, $d_i(1) \geq d_i(0)$ *for every* i.

Then the Wald estimand (A.27) *equals* $\mathbb{E}[y_i(1) - y_i(0) \mid d_i(1) > d_i(0)]$*, the average effect for* compliers*, the units whose treatment the instrument changes (Imbens and Angrist, 1994).*

Proof. By exclusion, the observed outcome is $y_i = y_i(0) + d_i(z_i)\big(y_i(1) - y_i(0)\big)$. By independence,

$$\mathbb{E}[y_i \mid z_i = 1] - \mathbb{E}[y_i \mid z_i = 0] = \mathbb{E}\big[\big(d_i(1) - d_i(0)\big)\big(y_i(1) - y_i(0)\big)\big].$$

Monotonicity makes $d_i(1) - d_i(0)$ equal to one for compliers and zero for everyone else, so the right side equals $\mathbb{P}(\text{complier})\,\mathbb{E}[y_i(1) - y_i(0) \mid \text{complier}]$. Independence also gives $\mathbb{E}[d_i \mid z_i = 1] - \mathbb{E}[d_i \mid z_i = 0] = \mathbb{E}[d_i(1) - d_i(0)] = \mathbb{P}(\text{complier})$, which is nonzero by relevance. The ratio is the complier average effect. □

The population splits into *always-takers* ($d_i(1) = d_i(0) = 1$), *never-takers* ($d_i(1) = d_i(0) = 0$), compliers, and *defiers* ($d_i(1) < d_i(0)$), whom monotonicity rules out. Different instruments move different compliers, so two valid instruments can identify different averages, and an overidentification test can then reject even though both instruments are exogenous. With a continuous endogenous variable, Angrist et al. (2000) show that the linear IV estimand in a supply and demand system is a weighted average of the derivatives of the structural function. The weights are largest at prices where the instrument shifts the equilibrium most. Dafny's estimate is local in this sense, since the instrument moves only mergers of co-located hospitals.

An IO analogue. Corts (1999) makes the same point about conduct. Write the supply relation as $P_t - c_t = \theta_t m_t$, with conduct θ_t and $m_t = Q_t \left|\frac{\partial Q_t}{\partial P_t}\right|^{-1}$. Suppose marginal cost is known and a demand shifter Z_t serves as the instrument for m_t in an equation with a constant conduct parameter. The IV estimand is

$$\frac{\operatorname{Cov}(Z_t, P_t - c_t)}{\operatorname{Cov}(Z_t, m_t)} = \frac{\operatorname{Cov}(Z_t, \theta_t m_t)}{\operatorname{Cov}(Z_t, m_t)},$$

which for small demand movements is $\frac{\mathrm{d}(\theta m)}{\mathrm{d}m} = \theta + m\frac{\mathrm{d}\theta}{\mathrm{d}m}$. The estimator recovers the marginal response of the markup to demand, which can differ sharply from the average level of conduct. If $\theta_t = a - b\, m_t$, the estimand is $a - 2b\bar{m}$, while average conduct is $a - b\bar{m}$ (Section 3.6.2).

A.3.8 System IV: three-stage least squares

When several equations each contain endogenous regressors, they can be estimated jointly. Stack G equations $y_g = X_g\beta_g + e_g$ with a common $n \times L$ instrument matrix Z, block-diagonal X, and error vector $e_t = (e_{1t}, \dots, e_{Gt})^\top$ with $\mathbb{E}[e_t e_t^\top \mid z_t] = \Sigma$. The moment conditions are $\mathbb{E}[e_t \otimes z_t] = 0$, and under conditional homoskedasticity their covariance matrix is $\mathbb{E}[(e_t \otimes z_t)(e_t \otimes z_t)^\top] = \Sigma \otimes \mathbb{E}[z_t z_t^\top]$. Efficient GMM (Section A.5.3) weights the sample moments $(I_G \otimes Z^\top)(y - X\beta)$ by the inverse of this matrix, estimated by $\hat{\Sigma}^{-1} \otimes (Z^\top Z)^{-1}$. Since $(I_G \otimes Z)(\hat{\Sigma}^{-1} \otimes (Z^\top Z)^{-1})(I_G \otimes Z^\top) = \hat{\Sigma}^{-1} \otimes P_Z$, the first-order condition gives the *three-stage least squares* (3SLS) estimator of Zellner and Theil (1962),

$$\hat{\beta}_{3SLS} = \left[X^\top(\hat{\Sigma}^{-1} \otimes P_Z)X\right]^{-1} X^\top(\hat{\Sigma}^{-1} \otimes P_Z)\, y. \tag{A.43}$$

The three stages are the first-stage regressions, 2SLS for each equation to estimate $\hat{\Sigma}_{gh} = \frac{1}{n}\hat{e}_g^\top \hat{e}_h$, and the system estimator (A.43). By the logic of Proposition A.13, 3SLS equals equation-by-equation 2SLS when Σ is diagonal or every equation is exactly identified. Its gains come from correlated errors and from restrictions across equations. Its cost is that misspecification of any one equation contaminates the estimates of all of them. The estimated Σ also adds noise in small samples.

Application: residual demand in brewing. Baker and Bresnahan (1988) estimate the inverse residual demand curves of Anheuser-Busch, Pabst and Coors jointly by 3SLS. Each equation regresses the firm's log price on its log quantity, demand shifters and cost variables. The coefficient on own quantity, η_j^R, is the inverse elasticity of residual demand. Own quantity is instrumented by firm-specific cost shifters: capacity for every firm, average plant size for Anheuser-Busch and Pabst, and the Colorado manufacturing wage for Coors, which brewed only in Golden. The joint estimation exploits the correlation of errors across the three equations. It also imposes a cross-equation restriction, under which industry cost variables enter every equation through one common marginal cost index (their eq. 12). The data are annual for 1962–1982, so each equation has only 21 observations (Table 3).

The estimates of η_j^R are −0.745 (0.054) for Coors, −0.058 (0.031) for Pabst and −0.312 (0.064) for Anheuser-Busch before 1975. An interaction with the post-1975 period, when light beer was introduced, is 0.282 (0.040), so Anheuser-Busch's inverse elasticity falls to −0.030 after 1975 (Table 3). Single-equation 2SLS gives similar elasticities "with little noticeable efficiency loss" (fn. 20). Treating quantity as exogenous gives −0.738, −0.053 and −0.312 (fn. 26), so simultaneity bias is small in these data. With 21 observations per equation, several regressors and an estimated three-by-three covariance matrix, the asymptotic standard errors should be read with caution. Section 3.4 interprets the results.

The estimators of this section all have closed forms. Many structural models in industrial organization do not. Their parameters enter nonlinearly, their errors enter through an equilibrium, or their likelihood involves an integral. Section A.4 therefore turns to estimators defined by optimizing a criterion, which include 2SLS and 3SLS as special cases, and Section A.5.6 returns to the joint estimation of demand and supply.

A.4 Extremum estimators

Almost every estimator in this book maximizes or minimizes a criterion function. Least squares minimizes a sum of squared residuals. Maximum likelihood maximizes a log-likelihood. The BLP estimator minimizes a quadratic form in sample moments. Simulated versions replace an intractable integral inside the criterion by an average over random draws. It pays to prove consistency and asymptotic normality once, for the whole class, and then to read off each special case. This section does that, following Newey and McFadden (1994). As in the rest of the appendix, θ is a generic parameter vector, here of dimension K, and the data $w_1, \ldots, w_n$ are independent and identically distributed unless stated otherwise. The convergence notation is the one set out in the introduction to this appendix.

Definition A.23 (Extremum estimator)**.** Let $\Theta \subset \mathbb{R}^K$ be a parameter space and $Q_n(\theta)$ a criterion function that depends on the data. An *extremum estimator* is any $\hat{\theta} \in \Theta$ with

$$Q_n(\hat{\theta}) \geq \sup_{\theta \in \Theta} Q_n(\theta) - o_p(1). \tag{A.44}$$

The *limit criterion* is a nonrandom function $Q_0(\theta)$ to which $Q_n(\theta)$ converges in probability.

The $o_p(1)$ slack in (A.44) allows for numerical optimization that stops close to, but not exactly at, the supremum. This slack is enough for consistency. Asymptotic normality needs a tighter optimization tolerance, condition (v) of Theorem A.27. The leading examples are the following.

1. *Nonlinear least squares* sets $Q_n(\theta) = -\frac{1}{n}\sum_{i=1}^n \{y_i - m(x_i;\theta)\}^2$, with limit $Q_0(\theta) = -\mathbb{E}[\{y_i - m(x_i;\theta)\}^2]$. Ordinary least squares is the case $m(x;\theta) = x^\top\theta$.
2. *Maximum likelihood* sets $Q_n(\theta) = \frac{1}{n}\sum_{i=1}^n \ln f(y_i \mid x_i;\theta)$, with limit $Q_0(\theta) = \mathbb{E}[\ln f(y_i \mid x_i;\theta)]$ (Section A.6).
3. The *generalized method of moments* sets $Q_n(\theta) = -\bar{g}_n(\theta)^\top W_n \bar{g}_n(\theta)$, with limit $Q_0(\theta) = -\mathbb{E}[g(w_i;\theta)]^\top W \mathbb{E}[g(w_i;\theta)]$ (Section A.5). Here $\bar{g}_n(\theta) = \frac{1}{n}\sum_i g(w_i;\theta)$, and W_n is a weighting matrix.
4. *Simulated estimators* use the same criteria with an expectation inside g or f replaced by a simulation average (Section A.7).

The first two are *M-estimators*, because Q_n is a sample average of a function of one observation. GMM is a *minimum distance* estimator, because Q_n is a quadratic form in sample averages. The general theorems below cover both.

A.4.1 Consistency

Consistency rests on two ideas. The limit criterion must have a unique maximum at the true value. The sample criterion must be close to the limit criterion everywhere on the parameter space, not only at each point separately.

Theorem A.24 (Consistency of extremum estimators)**.** *Suppose that (i) $Q_0(\theta)$ is uniquely maximized at θ_0 (identification), (ii) Θ is compact, (iii) $Q_0(\theta)$ is continuous, and (iv) $\sup_{\theta\in\Theta}|Q_n(\theta) - Q_0(\theta)| \xrightarrow{p} 0$ (uniform convergence). Then any extremum estimator satisfies $\hat{\theta} \xrightarrow{p} \theta_0$.*

Proof. Fix $\epsilon > 0$. Three events occur w.p.a.1. By (A.44), $Q_n(\hat{\theta}) > Q_n(\theta_0) - \frac{\epsilon}{3}$. By uniform convergence, $Q_0(\hat{\theta}) > Q_n(\hat{\theta}) - \frac{\epsilon}{3}$, since $\hat{\theta} \in \Theta$. Again by uniform convergence, $Q_n(\theta_0) > Q_0(\theta_0) - \frac{\epsilon}{3}$. Chaining the three inequalities gives, w.p.a.1,

$$Q_0(\hat{\theta}) > Q_n(\hat{\theta}) - \frac{\epsilon}{3} > Q_n(\theta_0) - \frac{2\epsilon}{3} > Q_0(\theta_0) - \epsilon. \tag{A.45}$$

Now let $\mathcal{N}$ be any open set that contains θ_0. The set $\Theta \cap \mathcal{N}^c$ is closed and bounded, hence compact. Since Q_0 is continuous, it attains its supremum on this set at some θ^*. Identification gives $Q_0(\theta^*) < Q_0(\theta_0)$. Choose $\epsilon = Q_0(\theta_0) - Q_0(\theta^*) > 0$. Then (A.45) says that, w.p.a.1,

$$Q_0(\hat{\theta}) > Q_0(\theta^*) = \sup_{\theta\in\Theta\cap\mathcal{N}^c} Q_0(\theta).$$

So $\hat{\theta} \notin \Theta \cap \mathcal{N}^c$, that is, $\hat{\theta} \in \mathcal{N}$, w.p.a.1. Because $\mathcal{N}$ was arbitrary, $\hat{\theta} \xrightarrow{p} \theta_0$. □

Figure A.3 draws the argument. Uniform convergence traps Q_n in a band of half-width ϵ around Q_0. The maximizer of Q_n must then achieve a value of Q_0 within 2ϵ of the maximum, and identification confines such points to a neighborhood of θ_0 that shrinks with ϵ.

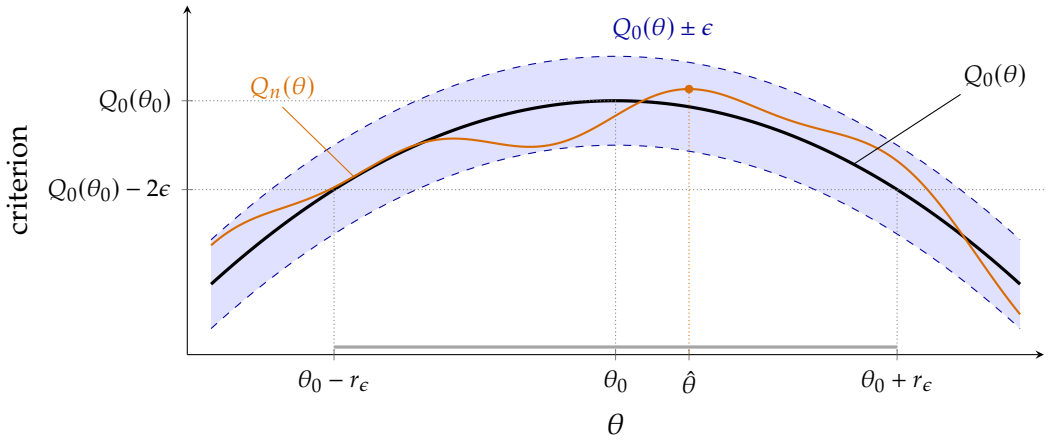

Figure A.3: The consistency argument for extremum estimators. The thick curve is the limit criterion Q_0, maximized only at θ_0. Uniform convergence places the sample criterion Q_n inside the shaded band $Q_0 \pm \epsilon$. The maximizer $\hat{\theta}$ of Q_n then satisfies $Q_0(\hat{\theta}) > Q_0(\theta_0) - 2\epsilon$, so it lies in the interval $[\theta_0 - r_\epsilon, \theta_0 + r_\epsilon]$ marked on the horizontal axis. The curves are illustrative: $Q_0(\theta) = 2 - \frac{1}{2}(\theta - 2)^2$ and $\epsilon = 0.35$.

Pointwise convergence of $Q_n(\theta)$ to $Q_0(\theta)$ at each θ is not enough. Take $\Theta = [0, 2]$ and

$$Q_n(\theta) = -\theta^2 + 2 \max\left\{0,\ 1 - n\left|\theta - 1 - \frac{1}{n}\right|\right\}.$$

At each fixed θ the spike eventually moves away, so $Q_n(\theta) \to Q_0(\theta) = -\theta^2$, which is maximized at 0. Yet $Q_n(1 + \frac{1}{n}) = 2 - (1 + \frac{1}{n})^2$ is close to 1, above $Q_n(0) = 0$. The maximizer converges to 1, not to 0. Uniform convergence fails because $\sup_\theta |Q_n - Q_0| = 2$ for every n.

Uniform convergence is usually verified with a uniform law of large numbers. The next lemma is the version we use most often. It is Newey and McFadden (1994, Lemma 2.4).

Lemma A.25 (Uniform law of large numbers)**.** *Let w_i be i.i.d., Θ compact, and $a(w, \theta)$ continuous in θ at each $\theta \in \Theta$ with probability one. If $\mathbb{E}[\sup_{\theta \in \Theta} \|a(w_i, \theta)\|] < \infty$, then $\mathbb{E}[a(w_i, \theta)]$ is continuous and*

$$\sup_{\theta \in \Theta} \left\| \frac{1}{n} \sum_{i=1}^{n} a(w_i, \theta) - \mathbb{E}[a(w_i, \theta)] \right\| \xrightarrow{p} 0.$$

The integrable envelope $\sup_\theta \|a(w, \theta)\|$ is the *dominance condition*. Continuity and compactness let us cover Θ by finitely many small balls. On each ball the function moves little, and the ordinary law of large numbers applies at the finitely many centers. For maximum likelihood we apply the lemma to $a = \ln f$. For GMM we apply it to $a = g$ and then use the continuity of the quadratic form.

Compactness is a nuisance in practice, since few applied parameter spaces are bounded. For concave criteria it can be dropped. This matters for the logit and multinomial logit likelihoods, which are globally concave (Proposition A.42).

Theorem A.26 (Consistency with a concave criterion)**.** *Suppose that θ_0 is an interior point of a convex set Θ, $Q_n(\theta)$ is concave on Θ for each n, $Q_n(\theta) \xrightarrow{p} Q_0(\theta)$ for each $\theta \in \Theta$, and Q_0 is uniquely maximized at θ_0. Then $\hat{\theta}$ exists w.p.a.1 and $\hat{\theta} \xrightarrow{p} \theta_0$.*

The proof (Newey and McFadden, 1994, Theorem 2.7) uses a fact from convex analysis. Pointwise convergence of concave functions implies uniform convergence on compact subsets of the interior. Apply Theorem A.24 on a small closed ball around θ_0. Concavity then rules out a maximizer outside the ball. A concave function that is higher at the center of a ball than everywhere on its boundary is also higher at the center than anywhere outside the ball.

Identification, condition (i), is the substantive assumption. It says that the model and the data distribution single out θ_0. Section A.1 discusses what it requires in IO models. Conditions (ii) to (iv) are regularity conditions that hold in most smooth applications.

A.4.2 Asymptotic normality

Once $\hat{\theta}$ is consistent, a Taylor expansion of the first-order condition around θ_0 delivers its limit distribution.

Theorem A.27 (Asymptotic normality of extremum estimators)**.** *Suppose the following conditions hold.*

(i) $\hat{\theta} \xrightarrow{p} \theta_0$, *and* θ_0 *is in the interior of* Θ.

(ii) $Q_n(\theta)$ *is twice continuously differentiable on a neighborhood* $\mathcal{N}$ *of* θ_0.

(iii) $\sqrt{n}\,\nabla_\theta Q_n(\theta_0) \xrightarrow{d} N(0, \Sigma)$.

(iv) There is a matrix function $H(\theta)$, *continuous at* θ_0, *with* $\sup_{\theta\in\mathcal{N}}\|\nabla_{\theta\theta} Q_n(\theta) - H(\theta)\| \xrightarrow{p} 0$ *and* $H = H(\theta_0)$ *nonsingular.*

(v) $\sqrt{n}\,\nabla_\theta Q_n(\hat{\theta}) \xrightarrow{p} 0$. *An exact interior maximizer satisfies this with* $\nabla_\theta Q_n(\hat{\theta}) = 0$.

Then

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N\big(0,\ H^{-1}\Sigma H^{-1}\big). \tag{A.46}$$

Proof. Because $\hat{\theta} \xrightarrow{p} \theta_0$ and θ_0 is interior, $\hat{\theta}$ lies in $\mathcal{N}$ and in the interior of Θ w.p.a.1. Write $r_n = \nabla_\theta Q_n(\hat{\theta})$ for the gradient at the estimate. By (v), $\sqrt{n}\,r_n \xrightarrow{p} 0$. Apply the mean value theorem to each element of the gradient. For row k there is a point $\bar{\theta}^{(k)}$ on the segment between $\hat{\theta}$ and θ_0 with

$$r_{n,k} = \frac{\partial Q_n(\theta_0)}{\partial \theta_k} + \frac{\partial^2 Q_n(\bar{\theta}^{(k)})}{\partial \theta_k \partial \theta^\top}(\hat{\theta} - \theta_0).$$

Stack the rows into the matrix $\bar{H}_n$, whose row k is the k-th row of the Hessian evaluated at $\bar{\theta}^{(k)}$. Then

$$r_n = \nabla_\theta Q_n(\theta_0) + \bar{H}_n(\hat{\theta} - \theta_0).$$

Each $\bar{\theta}^{(k)}$ converges in probability to θ_0. By (iv) and the continuity of H at θ_0,

$$\|\bar{H}_n - H\| \le \sup_{\theta\in\mathcal{N}}\|\nabla_{\theta\theta} Q_n(\theta) - H(\theta)\| + \max_k \|H(\bar{\theta}^{(k)}) - H\| \xrightarrow{p} 0.$$

So $\bar{H}_n$ is invertible w.p.a.1, and

$$\sqrt{n}(\hat{\theta} - \theta_0) = -\bar{H}_n^{-1}\sqrt{n}\,\nabla_\theta Q_n(\theta_0) + \bar{H}_n^{-1}\sqrt{n}\,r_n.$$

The second term converges in probability to zero by (v). By (iii), Slutsky's theorem and the continuous mapping theorem, the right side converges in distribution to $-H^{-1}Z$ with $Z \sim N(0, \Sigma)$. Its variance is $H^{-1}\Sigma H^{-1}$, because H is symmetric. □

Condition (v) cannot be dropped. Take Y_i i.i.d. $N(0,1)$, $\theta_0 = 0$, $Q_n(\theta) = -\frac{1}{2}(\theta - \bar{Y})^2$, and an optimizer that stops at $\hat{\theta} = \bar{Y} + n^{-\frac{1}{4}}$. The criterion shortfall is $\frac{1}{2}n^{-\frac{1}{2}} = o(1)$, so $\hat{\theta}$ is a consistent extremum estimator and (i)–(iv) hold. Yet $\sqrt{n}\,\hat{\theta} = \sqrt{n}\,\bar{Y} + n^{\frac{1}{4}}$ diverges. An optimization error that vanishes more slowly than the sampling error swamps it. Under local quadratic curvature, a criterion shortfall of order $o_p(n^{-1})$ is enough for (v).

The variance in (A.46) is a *sandwich*. The outer pieces measure the curvature of the criterion, the inner piece the noise in its slope at the truth. A consistent estimator replaces H by $\nabla_{\theta\theta} Q_n(\hat{\theta})$ and Σ by an estimate of the variance of $\sqrt{n}\,\nabla_\theta Q_n(\theta_0)$. For an M-estimator with $Q_n = \frac{1}{n}\sum_i q(w_i;\theta)$, that estimate is $\frac{1}{n}\sum_i \nabla_\theta q(w_i;\hat{\theta}) \nabla_\theta q(w_i;\hat{\theta})^\top$. With dependent data it becomes a clustered or HAC estimate (Sections A.8.2 and A.8.3).

The theorem fails in three situations that occur in IO. If θ_0 lies on the boundary of Θ, the first-order condition need not hold. A variance component or a regime probability equal to zero is the usual case (Section A.6.7). If Q_n is not differentiable, the expansion must be replaced by an argument based on stochastic equicontinuity. Simulated frequency estimators and some auction estimators are examples (Pakes and Pollard, 1989). If H is singular, the rank condition for local identification fails. The parameter θ_0 may still be identified through higher-order terms, but the normal approximation breaks down and the rate of convergence changes.

A.4.3 Profile objectives

Many IO estimators split the parameters into a block that is easy to optimize given the rest and a block that is hard. Optimizing out the easy block first leaves a *profile* (or *concentrated*) criterion in the hard block alone.

Proposition A.28 (Profile criteria)**.** *Partition $\theta = (\theta_1, \theta_2)$ with $\Theta = \Theta_1 \times \Theta_2$. Suppose that for each θ_2 the maximizer $\hat{\theta}_1(\theta_2) = \arg\max_{\theta_1 \in \Theta_1} Q_n(\theta_1, \theta_2)$ exists and is unique. Define the profile criterion $\tilde{Q}_n(\theta_2) = Q_n(\hat{\theta}_1(\theta_2), \theta_2)$.*

(a) $(\hat{\theta}_1, \hat{\theta}_2)$ maximizes Q_n jointly if and only if $\hat{\theta}_2$ maximizes $\tilde{Q}_n$ and $\hat{\theta}_1 = \hat{\theta}_1(\hat{\theta}_2)$.

(b) Suppose Q_n is twice continuously differentiable and that, on a neighborhood of θ_2, $\hat{\theta}_1(\cdot)$ is continuous with values in the interior of Θ_1. If the Hessian block $H_{11} = \nabla_{\theta_1\theta_1} Q_n$ is nonsingular at $(\hat{\theta}_1(\theta_2), \theta_2)$, then

$$\nabla_{\theta_2} \tilde{Q}_n(\theta_2) = \nabla_{\theta_2} Q_n\big(\hat{\theta}_1(\theta_2), \theta_2\big), \qquad \nabla_{\theta_2\theta_2} \tilde{Q}_n(\theta_2) = H_{22} - H_{21} H_{11}^{-1} H_{12}, \tag{A.47}$$

where the blocks of the Hessian of Q_n are evaluated at $(\hat{\theta}_1(\theta_2), \theta_2)$.

Proof. (a) For any (θ_1, θ_2),

$$Q_n(\theta_1, \theta_2) \le Q_n(\hat{\theta}_1(\theta_2), \theta_2) = \tilde{Q}_n(\theta_2).$$

Hence $\sup_\theta Q_n(\theta) = \sup_{\theta_2} \tilde{Q}_n(\theta_2)$. If $\hat{\theta}_2$ maximizes $\tilde{Q}_n$, then $(\hat{\theta}_1(\hat{\theta}_2), \hat{\theta}_2)$ attains this common supremum. Conversely, if $(\hat{\theta}_1, \hat{\theta}_2)$ maximizes Q_n, then $\tilde{Q}_n(\hat{\theta}_2) \ge Q_n(\hat{\theta}_1, \hat{\theta}_2) = \sup_{\theta_2} \tilde{Q}_n$, and uniqueness of the inner maximizer gives $\hat{\theta}_1 = \hat{\theta}_1(\hat{\theta}_2)$.

(b) Because the inner maximizer is interior, the inner first-order condition $\nabla_{\theta_1} Q_n(\hat{\theta}_1(\theta_2), \theta_2) = 0$ holds on the neighborhood. The implicit function theorem gives a locally unique C^1 solution of this condition. By continuity $\hat{\theta}_1(\cdot)$ coincides with it, and differentiating the condition gives

$$H_{11} \frac{\partial \hat{\theta}_1}{\partial \theta_2^\top} + H_{12} = 0 \quad \Longrightarrow \quad \frac{\partial \hat{\theta}_1}{\partial \theta_2^\top} = -H_{11}^{-1} H_{12}.$$

By the chain rule,

$$\nabla_{\theta_2}\tilde{Q}_n = \left(\frac{\partial\hat{\theta}_1}{\partial\theta_2^\top}\right)^\top \nabla_{\theta_1}Q_n + \nabla_{\theta_2}Q_n = \nabla_{\theta_2}Q_n,$$

because the first term vanishes by the inner first-order condition. This is the envelope theorem. Differentiating once more,

$$\nabla_{\theta_2\theta_2}\tilde{Q}_n = H_{21}\frac{\partial\hat{\theta}_1}{\partial\theta_2^\top} + H_{22} = H_{22} - H_{21}H_{11}^{-1}H_{12}. \qquad \square$$

Part (a) is what makes nested estimation legitimate. Part (b) says how to get standard errors. By the partitioned inverse formula, $(H_{22} - H_{21}H_{11}^{-1}H_{12})^{-1}$ is the $(2,2)$ block of H^{-1}. For maximum likelihood, where the asymptotic variance is $(-H)^{-1}$, the inverse Hessian of the profile log-likelihood therefore gives the correct variance for $\hat{\theta}_2$. It already accounts for the estimation of θ_1. For GMM the full sandwich is needed, and Section A.5.7 gives the formula.

Three applications recur in this book. In the normal linear regression, the variance σ^2 can be profiled out. The log-likelihood at $\hat{\sigma}^2(\beta) = \frac{1}{n}\sum_i (y_i - x_i^\top\beta)^2$ is $-\frac{n}{2}\ln\hat{\sigma}^2(\beta)$ plus a constant. This is the form behind the Cox statistic of Proposition 6.52. In the BLP estimator, the linear demand parameters have a closed form given the nonlinear ones (Proposition 8.20). In supply-side estimation with many fixed effects, the effects and the linear cost parameters can be concentrated out by least squares. Miller and Weinberg (2017, p. 1780) do this when they estimate the internalization and cost parameters of the beer industry after the MillerCoors joint venture (Chapter 11).

Profiling does not cure an *incidental parameters* problem. Suppose $y_{it} = \mu_i + e_{it}$ with $e_{it} \sim N(0,\sigma^2)$, $i = 1,\dots,N$ and $t = 1,\dots,T$, with T fixed and $N \to \infty$. Profiling out each μ_i gives $\hat{\mu}_i = \bar{y}_i$ and

$$\hat{\sigma}^2 = \frac{1}{NT}\sum_{i=1}^{N}\sum_{t=1}^{T}(y_{it} - \bar{y}_i)^2 \xrightarrow{p} \frac{T-1}{T}\sigma^2.$$

The estimator is inconsistent (Neyman and Scott, 1948). The number of profiled parameters grows with the sample, so the fixed-dimension assumptions of Theorem A.24 fail. In linear models the bias has a known form, but in nonlinear models with many fixed effects it contaminates every parameter.

A.4.4 Numerical practice

The theorems describe the global maximizer. A computer returns a point where an algorithm stopped. The gap between the two is a frequent source of error in structural IO, and good practice narrows it.

Gradient methods iterate $\theta^{(m+1)} = \theta^{(m)} - \lambda_m A_m^{-1}\nabla_\theta Q_n(\theta^{(m)})$, where $\lambda_m > 0$ is a step length and A_m approximates the Hessian. Newton's method uses the Hessian itself and converges quadratically near a maximum with a negative definite Hessian. Quasi-Newton methods such as BFGS build A_m from successive gradients. For maximum likelihood, the method of Berndt et al. (1974) (BHHH) replaces the Hessian by minus the outer product of the scores. That matrix is negative semidefinite by construction. By the information equality of Section A.6.2, it is consistent for the Hessian at the truth. Derivative-free methods such as Nelder and Mead's simplex need only function values. They are slow but robust to kinks.

We recommend the following checks.

1. Scale the parameters so that a unit change in each moves the criterion by similar amounts. Poor scaling makes gradient methods take tiny steps along flat directions.
2. Use analytic gradients when possible. Finite differences lose about half the digits of the criterion.
3. Start the optimizer from many points. If different starts end at different values, report the best and investigate the others. Porter (1983a, p. 309) reports that his switching model converged to the same estimates from several disparate starting points. Knittel and Metaxoglou (2014) show that BLP estimates can depend on the optimizer and the starting values (Chapter 8).
4. At the reported optimum, check that the gradient is close to zero and that the Hessian is negative definite. A singular Hessian signals that the rank condition for local identification fails.
5. Hold simulation draws fixed across evaluations. Redrawing them makes the criterion change between calls, and the optimizer never settles (Section A.7).
6. When the criterion contains an inner fixed point, such as the BLP contraction, solve the inner problem to a tight tolerance. Inner-loop error makes the outer criterion noisy and can produce false convergence (Dubé et al., 2012).

Some criteria are not smooth at all. In the vertical model the ordering of products by quality depends on the quality coefficients. When two products swap places, the predicted prices and quantities jump, and so does the likelihood (Section 6.6.5). Gradient methods then behave erratically, and derivative-free search or a grid over the offending parameters is safer. Frequency simulators produce step functions for the same reason, which is why smooth simulators are preferred (Section A.7).

A.5 Generalized method of moments

The generalized method of moments (GMM) of Hansen (1982) is the workhorse estimator of structural IO. It needs only a set of population moment conditions implied by the model, and no full likelihood. Demand estimation with instruments, supply relations with unobserved cost shocks, and their joint estimation all fit this mold.

A.5.1 Moment conditions

Definition A.29 (Moment conditions)**.** Let $g(w;\theta)$ be an $L \times 1$ vector of functions of the data w and the $K \times 1$ parameter θ, with $L \geq K$. The model implies the *moment conditions*

$$\mathbb{E}[g(w_i;\theta_0)] = 0. \tag{A.48}$$

The parameter is *globally identified* by (A.48) if $\mathbb{E}[g(w_i;\theta)] \neq 0$ for every $\theta \neq \theta_0$ in Θ. It is *locally identified* if the $L \times K$ Jacobian $G = \mathbb{E}\big[\frac{\partial g(w_i;\theta_0)}{\partial \theta^\top}\big]$ has rank K.

The *order condition* $L \geq K$ is necessary for the rank condition. When g is linear in θ the rank condition gives global identification. When g is nonlinear it gives only local identification (Proposition A.2), and global identification must be argued separately. The applications in this book use the following moment functions.

1. *Least squares* uses $g(w_i;\beta) = x_i(y_i - x_i^\top\beta)$, with $L = K$.
2. *Linear instrumental variables* use $g(w_i;\beta) = z_i(y_i - x_i^\top\beta)$, with z_i an $L\times 1$ vector of instruments (Section A.3).
3. *Nonlinear instrumental variables*. In the sugar study of Genesove and Mullin (1998), demand is $Q = \beta(\alpha - P)^\gamma$ and marginal cost is $c_0 + kP^{raw}$. The pricing rule with conduct parameter θ is $P = \frac{\alpha\theta + c_0\gamma}{\gamma+\theta} + \frac{\gamma}{\gamma+\theta}kP^{raw}$. With (α,γ) set at their demand estimates, the moment function for $\psi = (\theta, c_0, k)$ is
$$g(w_t;\psi) = z_t\left\{(\gamma+\theta)P_t - \alpha\theta - c_0\gamma - \gamma k P_t^{raw}\right\}. \tag{A.49}$$
Here z_t contains the log of Cuban raw-sugar imports, a high-season dummy and a constant (Genesove and Mullin, WP eq. 13). The raw price is instrumented because shocks to the pricing rule move it. Here θ is the conduct parameter of Section 3.7.6. Letting conduct differ in price-war periods replaces θ by $\theta_0 + (\theta_1 - \theta_0)WAR_t$ and adds the war dummy to z_t, which keeps the system just identified (Section 3.7.7).
4. *Demand moments in differentiated products*. With the logit inversion, the structural error is $\xi_{jt}(\theta) = \ln s_{jt} - \ln s_{0t} - x_{jt}\beta + \alpha p_{jt}$ (Chapter 7). With random coefficients, $\xi_{jt}(\theta) = \delta_{jt}(s_t;\theta_2) - x_{jt}\beta + \alpha p_{jt}$, where $\delta_{jt}(s_t;\theta_2)$ inverts the share system (Chapter 8). Either way $g = z_{jt}\xi_{jt}(\theta)$.
5. *Supply moments*. Under Bertrand-Nash pricing, marginal cost is price minus the markup implied by demand, $mc_{jt}(\theta) = p_{jt} + [(\Omega_t \odot \Delta_t^\top)^{-1}s_t]_j$. In this item Ω_t is the ownership matrix of market t, and Δ_t has (j,k) element $\frac{\partial s_{jt}}{\partial p_{kt}}$ (Chapter 4). If $mc_{jt} = w_{jt}\gamma + \omega_{jt}$, the cost moment is $g = z^s_{jt}\{mc_{jt}(\theta) - w_{jt}\gamma\}$.
6. *Conditional moment restrictions*. Many models state $\mathbb{E}[\rho(w_i;\theta_0)\mid z_i] = 0$ for a residual vector ρ. Any matrix of functions $A(z_i)$ then gives unconditional moments $\mathbb{E}[A(z_i)\rho(w_i;\theta_0)] = 0$. Which functions to use is the optimal instruments problem of Section A.5.5.
7. *Simulated moments*, where an expectation inside g is replaced by a simulation average (Section A.7).

A.5.2 The estimator and its asymptotic distribution

Definition A.30 (GMM estimator)**.** Let $\bar g_n(\theta) = \frac{1}{n}\sum_{i=1}^n g(w_i;\theta)$ and let W_n be a symmetric positive semidefinite $L\times L$ matrix with $W_n \xrightarrow{p} W$. The *GMM estimator* is
$$\hat\theta = \arg\min_{\theta\in\Theta}\ \bar g_n(\theta)^\top W_n\,\bar g_n(\theta). \tag{A.50}$$

Consistency follows from Theorem A.24 with $Q_n(\theta) = -\bar g_n(\theta)^\top W_n \bar g_n(\theta)$ and $Q_0(\theta) = -\mathbb{E}[g(\theta)]^\top W\mathbb{E}[g(\theta)]$, writing $\mathbb{E}[g(\theta)]$ for $\mathbb{E}[g(w_i;\theta)]$. The limit is maximized, with value zero, at every θ where $W\mathbb{E}[g(\theta)] = 0$. Identification therefore requires $W\mathbb{E}[g(\theta)] \neq 0$ for $\theta \neq \theta_0$, which holds when W is positive definite and the moments identify θ_0. Uniform convergence follows from Lemma A.25 applied to g, if g is continuous in θ and $\mathbb{E}[\sup_\theta\|g(w_i;\theta)\|] < \infty$. Indeed, adding and subtracting terms,
$$|Q_n(\theta) - Q_0(\theta)| \le \|\bar g_n - \mathbb{E}g\|^2\|W_n\| + 2\|\mathbb{E}g\|\,\|W_n\|\,\|\bar g_n - \mathbb{E}g\| + \|\mathbb{E}g\|^2\|W_n - W\|,$$
and each term converges to zero uniformly on the compact Θ.

Theorem A.31 (Asymptotic normality of GMM)**.** *Suppose the following conditions hold.*

(i) $\hat{\theta} \xrightarrow{p} \theta_0$*, with* θ_0 *interior.*

(ii) $g(w;\theta)$ *is continuously differentiable in* θ *on a neighborhood* $\mathcal{N}$ *of* θ_0*.*

(iii) $\sqrt{n}\,\bar{g}_n(\theta_0) \xrightarrow{d} N(0,S)$*.*

(iv) $G_n(\theta) = \frac{\partial \bar{g}_n(\theta)}{\partial \theta^\top}$ *satisfies* $\sup_{\theta\in\mathcal{N}}\|G_n(\theta) - G(\theta)\| \xrightarrow{p} 0$ *for a function* $G(\theta)$ *continuous at* θ_0*.*

(v) $W_n \xrightarrow{p} W$*, and* $G^\top W G$ *is nonsingular, where* $G = G(\theta_0)$*.*

Then

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V), \qquad V = (G^\top W G)^{-1} G^\top W S W G (G^\top W G)^{-1}. \tag{A.51}$$

Proof. W.p.a.1 the estimator is interior and satisfies the first-order condition of (A.50),

$$G_n(\hat{\theta})^\top W_n\, \bar{g}_n(\hat{\theta}) = 0.$$

A mean value expansion of each element of $\bar{g}_n(\hat{\theta})$ around θ_0 gives

$$\bar{g}_n(\hat{\theta}) = \bar{g}_n(\theta_0) + \bar{G}_n(\hat{\theta} - \theta_0),$$

where row ℓ of $\bar{G}_n$ is row ℓ of G_n evaluated at a point between $\hat{\theta}$ and θ_0. Substitute into the first-order condition:

$$G_n(\hat{\theta})^\top W_n \bar{g}_n(\theta_0) + G_n(\hat{\theta})^\top W_n \bar{G}_n(\hat{\theta} - \theta_0) = 0.$$

By (i), (iv) and (v), $G_n(\hat{\theta})^\top W_n \bar{G}_n \xrightarrow{p} G^\top W G$, which is nonsingular. Solve and multiply by $\sqrt{n}$:

$$\sqrt{n}(\hat{\theta} - \theta_0) = -\big[G_n(\hat{\theta})^\top W_n \bar{G}_n\big]^{-1} G_n(\hat{\theta})^\top W_n \sqrt{n}\,\bar{g}_n(\theta_0).$$

By (iii) and Slutsky's theorem the right side converges in distribution to $-(G^\top W G)^{-1} G^\top W Z$ with $Z \sim N(0,S)$, whose variance is V. □

With i.i.d. data, $S = \mathbb{E}[g(w_i;\theta_0)g(w_i;\theta_0)^\top]$, estimated by $\hat{S} = \frac{1}{n}\sum_i g(w_i;\hat{\theta})g(w_i;\hat{\theta})^\top$. The Jacobian is estimated by $\hat{G} = G_n(\hat{\theta})$. The plug-in $\hat{V}$ replaces each population matrix by its estimate.

Linear instrumental variables. Stack the data as y $(n\times 1)$, X $(n\times K)$ and Z $(n\times L)$. Then $\bar{g}_n(\beta) = \frac{1}{n}Z^\top(y - X\beta)$, and the criterion is $\frac{1}{n^2}(y - X\beta)^\top Z W_n Z^\top (y - X\beta)$. The first-order condition is

$$-\frac{2}{n^2} X^\top Z W_n Z^\top (y - X\beta) = 0,$$

so

$$\hat{\beta} = \big(X^\top Z W_n Z^\top X\big)^{-1} X^\top Z W_n Z^\top y. \tag{A.52}$$

With $W_n = (\frac{1}{n}Z^\top Z)^{-1}$ this is two-stage least squares, (A.32), the third route of Section A.3.2. Here $G = -\mathbb{E}[z_i x_i^\top]$, so (A.51) becomes the IV sandwich of Proposition A.16. When $L = K$, the algebra of Section A.3.2 shows that (A.52) collapses to $(Z^\top X)^{-1}Z^\top y$ whatever W_n is. The general lesson is that a just-identified GMM estimator sets $\bar{g}_n(\hat{\theta}) = 0$, so the weighting matrix plays no role.

A.5.3 Efficient weighting

The weighting matrix matters only when $L > K$. It decides how to trade off moments that cannot all be set to zero in the sample. The best choice weights each moment by the inverse of its noise.

Proposition A.32 (Efficient weighting matrix)**.** *Under the assumptions of Theorem A.31 with S positive definite, the asymptotic variance $V(W)$ in (A.51) satisfies $V(W) - (G^\top S^{-1} G)^{-1} \geq 0$ for every admissible W. The lower bound is attained at $W = S^{-1}$, where $V = (G^\top S^{-1} G)^{-1}$.*

Proof. Define the $K \times L$ matrix

$$A = (G^\top W G)^{-1} G^\top W - (G^\top S^{-1} G)^{-1} G^\top S^{-1}.$$

Since S is positive definite, $ASA^\top \geq 0$. Expand the product term by term:

$$\begin{aligned} ASA^\top = {} & (G^\top W G)^{-1} G^\top W S W G (G^\top W G)^{-1} - (G^\top W G)^{-1} G^\top W G (G^\top S^{-1} G)^{-1} \\ & - (G^\top S^{-1} G)^{-1} G^\top W G (G^\top W G)^{-1} + (G^\top S^{-1} G)^{-1} G^\top S^{-1} G (G^\top S^{-1} G)^{-1}. \end{aligned}$$

The first term is $V(W)$. After cancellation, each of the last three matrix products equals $(G^\top S^{-1} G)^{-1}$, and they enter with signs minus, minus and plus. So $ASA^\top = V(W) - (G^\top S^{-1} G)^{-1}$, which is positive semidefinite. Setting $W = S^{-1}$ in (A.51) gives

$$V(S^{-1}) = (G^\top S^{-1} G)^{-1} G^\top S^{-1} S S^{-1} G (G^\top S^{-1} G)^{-1} = (G^\top S^{-1} G)^{-1}. \qquad \square$$

The efficient weight depends on S, which depends on θ_0. Three feasible versions are in use.

1. *Two-step GMM*. Estimate $\tilde{\theta}$ with a fixed weight, such as $(\frac{1}{n} Z^\top Z)^{-1}$. Form

$$\hat{S} = \frac{1}{n} \sum_{i=1}^{n} g(w_i; \tilde{\theta}) g(w_i; \tilde{\theta})^\top$$

   and re-estimate with $W_n = \hat{S}^{-1}$.

2. *Iterated GMM*. Repeat the second step, updating $\hat{S}$ each time, until the estimates stop changing.

3. *Continuously updated GMM* (CUE) of Hansen et al. (1996). Minimize $\bar{g}_n(\theta)^\top \hat{S}(\theta)^{-1} \bar{g}_n(\theta)$, where $\hat{S}(\theta)$ is evaluated at the same θ.

All three have the efficient limit distribution. They differ in finite samples. The two-step estimator can be biased when the estimated weight is correlated with the sample moments, a problem that grows with the number of moments (Altonji and Segal, 1996). CUE is invariant to linear transformations of the moments and behaves better with weak instruments (Hansen et al., 1996; Stock and Wright, 2000), but its criterion can be flat and multimodal.

Proposition A.33 (Efficient GMM and 2SLS)**.** *In the linear model $y_i = x_i^\top \beta + e_i$ with $\mathbb{E}[z_i e_i] = 0$ and conditional homoskedasticity $\mathbb{E}[e_i^2 \mid z_i] = \sigma^2$, efficient GMM is 2SLS, and its asymptotic variance is $\sigma^2 \big(\mathbb{E}[x_i z_i^\top] \mathbb{E}[z_i z_i^\top]^{-1} \mathbb{E}[z_i x_i^\top]\big)^{-1}$.*

Proof. By the law of iterated expectations,

$$S = \mathbb{E}[e_i^2 z_i z_i^\top] = \mathbb{E}\big[\mathbb{E}[e_i^2 \mid z_i] z_i z_i^\top\big] = \sigma^2 \mathbb{E}[z_i z_i^\top].$$

So the efficient weight is proportional to $\mathbb{E}[z_i z_i^\top]^{-1}$, estimated by a multiple of $(\frac{1}{n} Z^\top Z)^{-1}$. A scalar multiple of W_n does not change (A.52), which then equals 2SLS. Substituting $G = -\mathbb{E}[z_i x_i^\top]$ and S into $(G^\top S^{-1} G)^{-1}$ gives the stated variance. $\square$

Under heteroskedasticity, two-step GMM with $\hat{S} = \frac{1}{n}\sum_i \hat{e}_i^2 z_i z_i^\top$ is more efficient than 2SLS. The estimate of S must match the dependence in the data, and this is where most of the practical work lies.

- With independent observations, $\hat{S} = \frac{1}{n}\sum_i g_i g_i^\top$, with $g_i = g(w_i; \tilde{\theta})$.
- With clusters $c = 1, \dots, C$ whose moments are correlated within but not across clusters, sum the moments within each cluster first, $\hat{S} = \frac{1}{n}\sum_c \left(\sum_{i \in c} g_i\right)\left(\sum_{i \in c} g_i\right)^\top$. In demand estimation the natural cluster is the market, or the product when the same product appears in several years (Chapter 8). Miller and Weinberg (2017, p. 1775) cluster by region in the optimal weighting matrix of their demand estimator.
- With serial correlation, use a heteroskedasticity and autocorrelation consistent (HAC) estimator (Section A.8.3). Genesove and Mullin compute Newey-West standard errors with four lags for their quarterly sugar data (WP, printed p. 36).

A.5.4 Testing

With more moments than parameters, the sample cannot set every moment to zero. How far the minimized criterion stays from zero is evidence on the validity of the moments.

Theorem A.34 (Hansen's J test)**.** *Suppose the assumptions of Theorem A.31 hold, S is positive definite, $\hat{S} \xrightarrow{p} S$, and $\hat{\theta}$ is efficient GMM with $W_n = \hat{S}^{-1}$. If all L moment conditions hold, then*

$$J_n = n\, \bar{g}_n(\hat{\theta})^\top \hat{S}^{-1} \bar{g}_n(\hat{\theta}) \xrightarrow{d} \chi^2_{L-K}. \tag{A.53}$$

Proof. From the proof of Theorem A.31 with $W = S^{-1}$,

$$\sqrt{n}(\hat{\theta} - \theta_0) = -(G^\top S^{-1} G)^{-1} G^\top S^{-1} \sqrt{n}\, \bar{g}_n(\theta_0) + o_p(1).$$

Substitute this into the mean value expansion $\sqrt{n}\,\bar{g}_n(\hat{\theta}) = \sqrt{n}\,\bar{g}_n(\theta_0) + \bar{G}_n \sqrt{n}(\hat{\theta} - \theta_0)$:

$$\sqrt{n}\,\bar{g}_n(\hat{\theta}) = \left[I_L - G(G^\top S^{-1} G)^{-1} G^\top S^{-1}\right] \sqrt{n}\,\bar{g}_n(\theta_0) + o_p(1).$$

Let C be a symmetric matrix with $C^2 = S^{-1}$, and write $\xi_n = C\sqrt{n}\,\bar{g}_n(\theta_0)$. Then $\xi_n \xrightarrow{d} N(0, CSC) = N(0, I_L)$. Premultiplying by C and using $C^{-1}C = I_L$,

$$C\sqrt{n}\,\bar{g}_n(\hat{\theta}) = \left[I_L - CG(G^\top C^2 G)^{-1} G^\top C\right] \xi_n + o_p(1) = M \xi_n + o_p(1).$$

The matrix M is the residual-maker for the columns of CG. It is symmetric and idempotent, with trace $L - \operatorname{tr}[(G^\top C^2 G)^{-1} G^\top C^2 G] = L - K$. Since $\hat{S}^{-1} \xrightarrow{p} C^2$,

$$J_n = \left(C\sqrt{n}\,\bar{g}_n(\hat{\theta})\right)^\top \left(C\sqrt{n}\,\bar{g}_n(\hat{\theta})\right) + o_p(1) = \xi_n^\top M \xi_n + o_p(1).$$

A quadratic form of a standard normal vector in a symmetric idempotent matrix of rank $L - K$ is χ^2_{L-K}. □

In the linear homoskedastic model the J statistic reduces to Sargan (1958)'s statistic. With $\hat{S} = \hat{\sigma}^2 \frac{1}{n} Z^\top Z$ and $\bar{g}_n = \frac{1}{n} Z^\top \hat{e}$, where $\hat{e}$ is the 2SLS residual,

$$J_n = n \frac{\hat{e}^\top Z (Z^\top Z)^{-1} Z^\top \hat{e}}{\hat{e}^\top \hat{e}} = n R^2,$$

the sample size times the R^2 from regressing $\hat{e}$ on Z. When Z and X both contain a constant, the 2SLS residuals sum to zero and the centered and uncentered R^2 coincide.

The J test has power only against violations that cannot be absorbed by moving θ. If every instrument is invalid in a way that a different parameter value could rationalize, J stays small. In a just-identified model $J_n \equiv 0$. A J test that does not reject is therefore weak evidence for the instruments, and a rejection does not say which moment fails. When a subset of instruments is suspect, the *difference-in-J* or C statistic helps. It compares J_n from all L moments with J_n from the $L_1 \geq K$ maintained moments, computed with the corresponding block of the same $\hat{S}$. Under the null that the $L - L_1$ suspect moments hold, the difference converges to $\chi^2_{L-L_1}$.

Two applications illustrate the statistic. In the simulated yogurt markets of Section C.6, logit demand is estimated with the price of milk and six competition instruments for one endogenous price. Two-step GMM gives $J = 8.82$ with six degrees of freedom ($p = 0.18$), so the overidentifying restrictions are not rejected. Miller and Weinberg (2017) report J statistics of 13.94, 13.75, 13.91 and 14.15 for their four random coefficients nested logit specifications of beer demand (Table IV, p. 1777). That table, which Table 11.31 reproduces, does not report the degrees of freedom. The text gives eight for the first two specifications and seven for the other two, and it states that the models cannot be rejected at the 5 percent level (p. 1776). Our computation gives p-values of 0.083, 0.089, 0.053 and 0.049. The last statistic, 14.15, lies just above 14.07, the 95 percent quantile of χ^2_7. The test therefore narrowly rejects the fourth specification at the 5 percent level, contrary to the paper's statement.

Hypotheses about θ can be tested in three ways, which parallel the likelihood trinity of Section A.6.4. Let $H_0 : a(\theta_0) = 0$ impose r restrictions, with $A = \frac{\partial a(\theta_0)}{\partial \theta^\top}$ of rank r, and let $\tilde{\theta}$ be the efficient GMM estimator under the restrictions.

- The *Wald* statistic $n\, a(\hat{\theta})^\top [\hat{A}\hat{V}\hat{A}^\top]^{-1} a(\hat{\theta})$ uses only the unrestricted estimate. By the delta method (Theorem A.59) it converges to χ^2_r.
- The *distance* statistic $D_n = n[\bar{g}_n(\tilde{\theta})^\top \hat{S}^{-1} \bar{g}_n(\tilde{\theta}) - \bar{g}_n(\hat{\theta})^\top \hat{S}^{-1} \bar{g}_n(\hat{\theta})]$ is the GMM analogue of the likelihood ratio. It must use the efficient weight and the same $\hat{S}$ in both terms. Repeating the proof of Theorem A.34, both criteria are quadratic forms in the same ξ_n, with idempotent matrices of ranks $L - K + r$ and $L - K$. The column space removed under the restrictions is contained in that removed without them, so the difference of the two matrices is idempotent of rank r, and $D_n \xrightarrow{d} \chi^2_r$.
- The *Lagrange multiplier* statistic uses only $\tilde{\theta}$. It is $n\, \bar{g}_n(\tilde{\theta})^\top \hat{S}^{-1} \tilde{G} (\tilde{G}^\top \hat{S}^{-1} \tilde{G})^{-1} \tilde{G}^\top \hat{S}^{-1} \bar{g}_n(\tilde{\theta})$ with $\tilde{G} = G_n(\tilde{\theta})$, and also converges to χ^2_r.

Under the null and local alternatives the three statistics are asymptotically equivalent.

A.5.5 Optimal instruments

A conditional moment restriction $\mathbb{E}[\rho(w_i; \theta_0) \mid z_i] = 0$ implies infinitely many unconditional moments. The question is which functions of z_i to use. The answer, due to Chamberlain (1987), gives a lower bound on the variance of every GMM estimator built from the restriction and says how to reach it.

Let ρ be $p \times 1$. Define the conditional Jacobian and conditional variance

$$D(z) = \mathbb{E}\left[\frac{\partial \rho(w_i; \theta_0)}{\partial \theta^\top} \,\middle|\, z_i = z \right] \quad (p \times K), \qquad \Omega(z) = \mathbb{E}\big[\rho(w_i; \theta_0) \rho(w_i; \theta_0)^\top \mid z_i = z \big] \quad (p \times p).$$

For a $K \times p$ matrix of functions $A(z)$, let $\hat{\theta}_A$ solve the just-identified equations

$$\frac{1}{n}\sum_{i=1}^{n} A(z_i)\rho(w_i;\hat{\theta}_A) = 0.$$

Proposition A.35 (Optimal instruments)**.** *Suppose $\Omega(z)$ is positive definite and $\Gamma_A = \mathbb{E}[A(z_i)D(z_i)]$ is nonsingular. Then $\sqrt{n}(\hat{\theta}_A - \theta_0) \xrightarrow{d} N(0, V_A)$ with*

$$V_A = \Gamma_A^{-1}\mathbb{E}\big[A(z_i)\Omega(z_i)A(z_i)^\top\big]\Gamma_A^{-1\top}.$$

The choice $A^*(z) = D(z)^\top\Omega(z)^{-1}$ gives $V^* = \big(\mathbb{E}[D(z_i)^\top\Omega(z_i)^{-1}D(z_i)]\big)^{-1}$, and $V_A - V^* \geq 0$ for every admissible A.

Proof. The moment function is $g = A(z)\rho$. By iterated expectations its Jacobian is $G = \mathbb{E}[A(z_i)\frac{\partial\rho}{\partial\theta^\top}] = \mathbb{E}[A(z_i)D(z_i)] = \Gamma_A$, and its variance is $S = \mathbb{E}[A\rho\rho^\top A^\top] = \mathbb{E}[A\Omega A^\top]$. With $L = K$, (A.51) reduces to $G^{-1}SG^{-1\top}$, which is V_A. For the bound, write $m_A = A(z_i)\rho_i$ and $m^* = A^*(z_i)\rho_i$. By iterated expectations,

$$\mathbb{E}[m_A m^{*\top}] = \mathbb{E}\big[A(z_i)\,\mathbb{E}[\rho_i\rho_i^\top \mid z_i]\,\Omega(z_i)^{-1}D(z_i)\big] = \mathbb{E}[A(z_i)D(z_i)] = \Gamma_A,$$

and in the same way $\mathbb{E}[m^*m^{*\top}] = \mathbb{E}[D^\top\Omega^{-1}D] = V^{*-1}$. Let $u = \Gamma_A^{-1}m_A - V^*m^*$. Then

$$\begin{aligned}0 \leq \mathbb{E}[uu^\top] &= \Gamma_A^{-1}\mathbb{E}[m_A m_A^\top]\Gamma_A^{-1\top} - \Gamma_A^{-1}\mathbb{E}[m_A m^{*\top}]V^* - V^*\mathbb{E}[m^*m_A^\top]\Gamma_A^{-1\top} + V^*\mathbb{E}[m^*m^{*\top}]V^* \\ &= V_A - V^* - V^* + V^* = V_A - V^*.\end{aligned}$$

Setting $A = A^*$ gives $\Gamma_{A^*} = V^{*-1}$ and $V_{A^*} = V^*$. □

An overidentified GMM estimator that uses a finite vector of instruments $a(z_i)$ is asymptotically an A-estimator, with $A(z) = G^\top W a(z)$, so it cannot beat V^*. The optimal instruments reproduce familiar estimators in simple cases. In the linear model with $\rho = y - x^\top\beta$ and homoskedastic errors, $D(z) = -\mathbb{E}[x \mid z]$ and $\Omega = \sigma^2$, so the optimal instrument is the conditional mean of the regressors. When that mean is linear in z, 2SLS is efficient. Under heteroskedasticity the optimal instrument is $\frac{\mathbb{E}[x|z]}{\sigma^2(z)}$, which weights observations by the inverse of their error variance.

The sugar moment (A.49) shows what the formula says in a nonlinear model. With $\rho_t = (\gamma + \theta)P_t - \alpha\theta - c_0\gamma - \gamma k P_t^{raw}$ and $\psi = (\theta, c_0, k)$,

$$D(z_t) = \mathbb{E}\left[\frac{\partial\rho_t}{\partial\psi^\top}\,\middle|\,z_t\right] = \big(\mathbb{E}[P_t \mid z_t] - \alpha,\ -\gamma,\ -\gamma\,\mathbb{E}[P_t^{raw} \mid z_t]\big).$$

The efficient instruments are the predicted refined and raw prices given the exogenous variables, scaled by the inverse conditional variance. A linear first stage in z_t approximates them.

Feasible optimal instruments replace D and Ω by estimates. A first consistent estimate of θ, followed by nonparametric or series regressions of $\frac{\partial\rho}{\partial\theta^\top}$ and $\rho\rho^\top$ on z, gives an estimator with the efficient limit distribution (Newey, 1990). In the BLP model $\rho = (\xi_{jt}, \omega_{jt})$, and $D(z) = \mathbb{E}[\frac{\partial\xi_{jt}}{\partial\theta^\top} \mid z]$ depends on the equilibrium prices, which depend on the unobservables. Berry et al. (1999) approximate it by evaluating the derivatives at prices predicted with the unobservables set to zero. Reynaert and Verboven (2014) show large efficiency gains from such approximations relative to sums of rival characteristics (Chapter 8).

A.5.6 Two-step estimators and generated regressors

Structural IO is full of sequential estimation. Demand is estimated first, and its estimates are plugged into a supply relation, a markup formula or a welfare calculation. The second step treats the first-step estimate as if it were known, and its conventional standard errors are wrong. The fix is to view both steps as one GMM estimator (Newey, 1984; Murphy and Topel, 1985).

Let the first step estimate γ by solving $\frac{1}{n}\sum_i m(w_i;\hat\gamma)=0$, with as many equations as elements of γ. Let the second step estimate θ by solving $\frac{1}{n}\sum_i g(w_i;\hat\theta,\hat\gamma)=0$, also just identified. An overidentified second step fits the same mold, with g replaced by $G_\theta^\top W g$. Define the population Jacobians and covariances

$$M_\gamma=\mathbb{E}\left[\frac{\partial m}{\partial \gamma^\top}\right],\quad G_\gamma=\mathbb{E}\left[\frac{\partial g}{\partial \gamma^\top}\right],\quad G_\theta=\mathbb{E}\left[\frac{\partial g}{\partial \theta^\top}\right],\quad \begin{pmatrix}S_{mm}&S_{mg}\\S_{gm}&S_{gg}\end{pmatrix}=\operatorname{Var}\begin{pmatrix}m(w_i;\gamma_0)\\g(w_i;\theta_0,\gamma_0)\end{pmatrix},$$

all evaluated at (θ_0,γ_0).

Proposition A.36 (Variance of a two-step estimator)**.** *Under the conditions of Theorem A.31 for the stacked moments $(m^\top,g^\top)^\top$, with M_γ and G_θ nonsingular, $\sqrt{n}(\hat\theta-\theta_0)\xrightarrow{d}N(0,V_\theta)$ with*

$$V_\theta=G_\theta^{-1}\Big[S_{gg}-G_\gamma M_\gamma^{-1}S_{mg}-S_{gm}M_\gamma^{-1\top}G_\gamma^\top+G_\gamma M_\gamma^{-1}S_{mm}M_\gamma^{-1\top}G_\gamma^\top\Big]G_\theta^{-1\top}. \tag{A.54}$$

Proof. The two steps solve the stacked just-identified system $\frac{1}{n}\sum_i\psi(w_i;\gamma,\theta)=0$ with $\psi=(m^\top,g^\top)^\top$. Its Jacobian with respect to (γ,θ) is block lower triangular, because m does not depend on θ:

$$\Gamma=\begin{pmatrix}M_\gamma&0\\G_\gamma&G_\theta\end{pmatrix},\qquad \Gamma^{-1}=\begin{pmatrix}M_\gamma^{-1}&0\\-G_\theta^{-1}G_\gamma M_\gamma^{-1}&G_\theta^{-1}\end{pmatrix}.$$

One checks the inverse by multiplying the two matrices. By Theorem A.31 with $L=K$, the joint variance is $\Gamma^{-1}\operatorname{Var}(\psi)\Gamma^{-1\top}$. The rows of Γ^{-1} that belong to θ are $G_\theta^{-1}[-G_\gamma M_\gamma^{-1},\ I]$. Hence

$$V_\theta=G_\theta^{-1}\big[-G_\gamma M_\gamma^{-1},\ I\big]\begin{pmatrix}S_{mm}&S_{mg}\\S_{gm}&S_{gg}\end{pmatrix}\begin{pmatrix}-M_\gamma^{-1\top}G_\gamma^\top\\I\end{pmatrix}G_\theta^{-1\top}.$$

Multiplying out the middle product gives the four terms in (A.54). □

The formula has a transparent reading. Expanding the second-step equations,

$$\sqrt{n}(\hat\theta-\theta_0)\approx -G_\theta^{-1}\Big[\sqrt{n}\,\bar g_n(\theta_0,\gamma_0)+G_\gamma\sqrt{n}(\hat\gamma-\gamma_0)\Big],\qquad \sqrt{n}(\hat\gamma-\gamma_0)\approx -M_\gamma^{-1}\sqrt{n}\,\bar m_n(\gamma_0).$$

The naive variance $G_\theta^{-1}S_{gg}G_\theta^{-1\top}$ keeps only the first term. The correction depends on G_γ, the sensitivity of the second-step moments to the first-step parameters. Two special cases matter.

- If $G_\gamma=0$, no correction is needed. The second step is then insensitive to small errors in $\hat\gamma$.
- If the two steps use independent errors, $S_{gm}=0$, and with $V_\gamma=M_\gamma^{-1}S_{mm}M_\gamma^{-1\top}$,

$$V_\theta=G_\theta^{-1}S_{gg}G_\theta^{-1\top}+G_\theta^{-1}G_\gamma V_\gamma G_\gamma^\top G_\theta^{-1\top}. \tag{A.55}$$

The correction is then a positive semidefinite addition, and naive standard errors are too small. With correlated errors the correction can go either way.

The sugar pricing equation. Genesove and Mullin (1998) estimate the pricing moment (A.49) with (α, γ) fixed at the demand estimates. Their variance for (θ, c_0, k) is $W_2 + V$ (WP, printed p. 36). Here W_2 is the Newey-West variance that treats demand as known. The term V combines W_1, the Newey-West variance of the demand parameters, with D and C, the derivatives of the pricing moments with respect to (θ, c_0, k) and to the demand parameters. They assume no correlation between the demand and pricing errors. In our notation $G_\theta = D$, $G_\gamma = C$, $V_\gamma = W_1$ and $S_{gm} = 0$. Equation (A.55) then reads $V_\theta = W_2 + D^{-1}CW_1C^\top D^{-1\top}$, which is their formula up to the orientation in which the derivative matrices are written. The pricing system is just identified in both of their cases. With k unknown there are three instruments for three parameters, and with $k = 1.075$ imposed there are two for two.

The same paper shows how much the correction can matter for a simple statistic. The direct measure of conduct is the mean of the elasticity-adjusted Lerner index $L_{\eta t} = \eta(\hat{\gamma})\frac{P_t - c_t}{P_t}$, in which the demand elasticity η is estimated. Genesove and Mullin add the moment $\frac{1}{n}\sum_t L_{\eta t} - \bar{L}_\eta = 0$ to the moments of their demand IV estimates and compute GMM standard errors for $\bar{L}_\eta$ (WP fn. 45). Table A.5 shows that accounting for the estimated elasticity more than doubles the standard error for all four demand curves.

Table A.5: Standard errors of the mean adjusted Lerner index with and without the correction for estimated demand

Demand curve	Mean $\bar{L}_\eta$	s.e. treating η as known	s.e. accounting for estimated η	Ratio
Quadratic	.099	.010	.024	2.4
Linear	.107	.012	.028	2.3
Log-linear	.095	.008	.021	2.6
Exponential	.097	.009	.022	2.4

Notes: Genesove and Mullin, working-paper Table 8, columns (1), (3) and (4). The unadjusted Lerner index has mean .054 and standard error .0046. The ratio column is our computation. The corrected standard errors stack the moment for $\bar{L}_\eta$ with the demand moments (WP fn. 45).

Rotations and generated regressors. In the two-step rotation estimator of Section 3.5.2, the second step regresses price on the generated regressor $\hat{Q}_t^* = -\frac{Q_t}{\hat{a}_1 + \hat{a}_3 Z_t}$ with coefficient θ (Equation (3.38)). The second-step moment is $g_t = h_t^s(P_t - b_0 - b_1 Q_t - \theta \hat{Q}_t^*(a) - b_2 W_t)$. Its derivative with respect to (a_1, a_3) is

$$\frac{\partial g_t}{\partial (a_1, a_3)} = -\theta \, h_t^s \, \frac{Q_t}{(a_1 + a_3 Z_t)^2} \, (1, \; Z_t).$$

So G_γ is proportional to θ. Under the null of competitive pricing, $\theta_0 = 0$, the correction vanishes, and the naive t test of $\theta = 0$ is asymptotically valid. Away from the null, and for confidence intervals, the correction is needed. Joint GMM estimation of both equations (Equation (3.39)) delivers correct standard errors automatically and is more efficient.

Generated regressands. In the logit supply problem of Section C.6, implied marginal cost $p_{jt} - \frac{1}{\hat{\alpha}(1 - S_{ft})}$ is regressed on cost shifters. The dependent variable depends on $\hat{\alpha}$, and $G_\gamma = \mathbb{E}[z_{jt}^s \frac{1}{\alpha^2(1 - S_{ft})}] \neq 0$. Because every markup is close to $\frac{1}{\alpha}$ when shares are small, the error in $\hat{\alpha}$ loads almost entirely on the intercept. Its standard error rises from 0.016 to 0.065 with the stacked formula. A market bootstrap that re-estimates α in each replication gives 0.072. The slope standard errors barely change (Table C.24). The bootstrap is the practical fix when the steps are many (Section A.9.4).

Supply estimated given demand. Miller and Weinberg (2017, p. 1780) estimate the post-merger internalization parameter κ and the marginal cost parameters from a supply moment $\mathbb{E}[z\,\eta^*(\theta^S;\hat{\theta}^D)] = 0$, taking the demand estimates $\hat{\theta}^D$ as given. They report standard errors clustered by region with a correction for the first-stage demand estimates, for which they cite Wooldridge (2010). This is Proposition A.36 with clustered S (Chapter 11).

Joint estimation is the clean alternative to every two-step procedure. Stacking (m, g) and estimating (γ, θ) by efficient GMM gives correct standard errors. It also uses cross-equation correlation for efficiency when the blocks overidentify the parameters. In the sugar application it means stacking the demand moments with (A.49) and estimating the demand parameters, θ, c_0 and k together. The airline hub model of Chapter 9 and the BLP model with a supply side (Chapter 8) stack demand and cost moments in the same way. Joint estimation changes the first-block estimates only when the second block has more moments than new parameters. If the supply block has exactly as many moments as cost parameters, the joint estimate of the demand parameters equals GMM on the demand moments alone with weight $W_{dd} - W_{ds}W_{ss}^{-1}W_{sd}$. With the efficient weight this is efficient GMM on the demand moments (Proposition C.26). The cross-equation correlation then improves only the supply-side estimates.

A.5.7 Computation

Nonlinear GMM criteria are minimized numerically, and the advice of Section A.4.4 applies. Two structural features make the search much easier in IO models.

Proposition A.37 (Concentrating out linear parameters)**.** *Partition $\theta = (\theta_1, \theta_2)$ and suppose the sample moments are linear in θ_1, $\bar{g}_n(\theta) = a_n(\theta_2) - B_n(\theta_2)\theta_1$, with $B_n(\theta_2)^\top W_n B_n(\theta_2)$ nonsingular. For each θ_2 the minimizer over θ_1 is*

$$\hat{\theta}_1(\theta_2) = \left(B_n^\top W_n B_n\right)^{-1} B_n^\top W_n a_n, \tag{A.56}$$

and $\hat{\theta}_2$ minimizes the profile criterion $a_n^\top \left[W_n - W_n B_n (B_n^\top W_n B_n)^{-1} B_n^\top W_n\right] a_n$, with a_n and B_n evaluated at θ_2.

Proof. For fixed θ_2 the criterion $(a_n - B_n\theta_1)^\top W_n (a_n - B_n\theta_1)$ is a convex quadratic in θ_1. Its gradient $-2B_n^\top W_n(a_n - B_n\theta_1)$ vanishes at (A.56). Substituting back, $a_n - B_n\hat{\theta}_1(\theta_2) = [I - B_n(B_n^\top W_n B_n)^{-1}B_n^\top W_n]a_n$, and the quadratic form in this vector simplifies to the stated profile criterion. Proposition A.28(a) completes the argument. □

In the BLP model, $a_n(\theta_2) = \frac{1}{n}Z^\top\delta(\theta_2)$ and $B_n = \frac{1}{n}Z^\top X$, which does not depend on θ_2. The outer search runs over the few nonlinear parameters only (Proposition 8.20). Because $\hat{\theta}_1(\theta_2)$ is optimal for each θ_2, the envelope result (A.47) gives the gradient of the profile criterion,

$$\frac{\partial}{\partial\theta_2^\top}\left[\bar{g}_n^\top W_n \bar{g}_n\right] = 2\bar{g}_n^\top W_n \frac{1}{n} Z^\top \frac{\partial\delta(\theta_2)}{\partial\theta_2^\top}, \qquad \frac{\partial\delta}{\partial\theta_2^\top} = -\left(\frac{\partial s}{\partial\delta^\top}\right)^{-1}\frac{\partial s}{\partial\theta_2^\top}.$$

The second expression applies the implicit function theorem (Appendix B) to the share equations $s(\delta, \theta_2) = s^{obs}$, market by market. Standard errors must still come from the full sandwich (A.51) for (θ_1, θ_2). The profile criterion serves the search only, and its Hessian does not give the GMM variance.

Ackerberg et al. (2007) describe the BLP estimator as three steps: simulate shares for given nonlinear parameters, invert them with the contraction to recover δ, and interact the implied

ξ with instruments. They stress that the criterion is random for three reasons. The product characteristics are a draw, the observed shares are computed from a finite sample of consumers, and the predicted shares are simulated. Asymptotic theory then lets the number of products, the consumer sample and the number of simulation draws grow together (Berry et al., 2004b). Sampling and simulation error enter through $\ln s_{jt}$, and their effect grows as shares shrink (Section A.7, Chapter 8).

The nested fixed point is not the only formulation. Mathematical programming with equilibrium constraints (MPEC) treats δ as a vector of parameters and minimizes the GMM criterion over (θ, δ) subject to $s(\delta, \theta_2) = s^{obs}$ (Su and Judd, 2012; Dubé et al., 2012). The two formulations have the same solution. MPEC avoids the inner loop and its tolerance, at the cost of a large but sparse constrained problem.

A.6 Maximum likelihood

Maximum likelihood (ML) is the efficient estimator when the model specifies the full distribution of the data. IO uses it for discrete choices by individual consumers, for bids in auctions, for entry decisions, and for models with latent regimes such as cartel price wars. This section develops the theory and then works through these likelihoods.

A.6.1 Likelihood and identification

Let y_i be the outcome and x_i the conditioning variables, with conditional density (or probability mass function) $f(y \mid x; \theta)$ indexed by $\theta \in \Theta$. Write the log-likelihood contribution and the average log-likelihood as

$$\ell_i(\theta) = \ln f(y_i \mid x_i; \theta), \qquad \mathcal{L}_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \ell_i(\theta).$$

The ML estimator maximizes $\mathcal{L}_n$. Conditioning on x_i loses nothing when the marginal distribution of x_i does not depend on θ. The limit criterion is $Q_0(\theta) = \mathbb{E}_0[\ln f(y_i \mid x_i; \theta)]$, where $\mathbb{E}_0$ is the expectation under the true distribution. The next lemma shows that the truth maximizes it.

Lemma A.38 (Information inequality)**.** *Suppose $f(y \mid x; \theta_0)$ is the true conditional density and $\mathbb{E}_0|\ln f(y_i \mid x_i; \theta)| < \infty$ for all θ. Then $\mathbb{E}_0[\ln f(y_i \mid x_i; \theta)] \le \mathbb{E}_0[\ln f(y_i \mid x_i; \theta_0)]$, with equality only if $f(\cdot \mid x_i; \theta) = f(\cdot \mid x_i; \theta_0)$ with probability one.*

Proof. Fix x and write $f_\theta = f(\cdot \mid x; \theta)$. The logarithm is strictly concave, so Jensen's inequality gives

$$\mathbb{E}_0\left[\ln \frac{f_\theta(y)}{f_{\theta_0}(y)} \,\middle|\, x\right] \le \ln \mathbb{E}_0\left[\frac{f_\theta(y)}{f_{\theta_0}(y)} \,\middle|\, x\right] = \ln \int_{f_{\theta_0}>0} f_\theta(y)\,\mathrm{d}y \le \ln 1 = 0.$$

The first inequality is strict unless the ratio $\frac{f_\theta}{f_{\theta_0}}$ is constant on the support of f_{θ_0}. Both densities integrate to one, so the constant must be one. Taking expectations over x proves the claim. □

The gap $Q_0(\theta_0) - Q_0(\theta)$ is the expected *Kullback-Leibler divergence* of f_θ from f_{θ_0}. The lemma turns condition (i) of Theorem A.24 into a primitive condition. The parameter is identified when different values of θ imply different conditional distributions. Add compactness, continuity of $\ln f$ in θ, and the dominance condition $\mathbb{E}_0[\sup_\theta |\ln f(y_i \mid x_i; \theta)|] < \infty$, and Lemma A.25 and Theorem A.24 give consistency (Newey and McFadden, 1994, Theorem 2.5).

A.6.2 Score, information and asymptotic normality

The *score* is $s_i(\theta) = \nabla_\theta \ell_i(\theta)$, and the *information matrix* is $\mathcal{I}(\theta_0) = \mathbb{E}[s_i(\theta_0) s_i(\theta_0)^\top]$. Write $H(\theta) = \mathbb{E}[\nabla_{\theta\theta} \ell_i(\theta)]$ for the expected Hessian.

Lemma A.39 (Information equality)**.** *Suppose the support of $f(\cdot \mid x; \theta)$ does not depend on θ, f is twice differentiable in θ, and differentiation under the integral sign is permitted. Then*

$$\mathbb{E}[s_i(\theta_0) \mid x_i] = 0 \qquad \text{and} \qquad \mathbb{E}[s_i(\theta_0) s_i(\theta_0)^\top \mid x_i] = -\mathbb{E}[\nabla_{\theta\theta} \ell_i(\theta_0) \mid x_i].$$

Proof. For every θ, $\int f(y \mid x; \theta)\, \mathrm{d}y = 1$. Differentiate with respect to θ and use $\nabla_\theta f = f \, \nabla_\theta \ln f$:

$$0 = \int \nabla_\theta f(y \mid x; \theta)\, \mathrm{d}y = \int \nabla_\theta \ln f(y \mid x; \theta)\, f(y \mid x; \theta)\, \mathrm{d}y.$$

At $\theta = \theta_0$ the right side is $\mathbb{E}[s_i(\theta_0) \mid x_i = x]$. Differentiate the middle identity once more with respect to $\theta^\top$, using the product rule:

$$0 = \int \left[\nabla_{\theta\theta} \ln f \; f + \nabla_\theta \ln f \, \left(\nabla_\theta \ln f\right)^\top f \right] \mathrm{d}y.$$

At θ_0 this reads $\mathbb{E}[\nabla_{\theta\theta} \ell_i \mid x] + \mathbb{E}[s_i s_i^\top \mid x] = 0$. □

Theorem A.40 (Asymptotic normality of ML)**.** *Under the conditions of Theorem A.27 for $Q_n = \mathcal{L}_n$ and of Lemma A.39, with $\mathcal{I} = \mathcal{I}(\theta_0)$ nonsingular,*

$$\sqrt{n}(\hat\theta - \theta_0) \xrightarrow{d} N\left(0, \mathcal{I}^{-1}\right).$$

Proof. The scores are i.i.d. with mean zero and variance $\mathcal{I}$, so the central limit theorem gives $\sqrt{n}\, \nabla_\theta \mathcal{L}_n(\theta_0) = \frac{1}{\sqrt{n}} \sum_i s_i(\theta_0) \xrightarrow{d} N(0, \mathcal{I})$. Thus $\Sigma = \mathcal{I}$ in Theorem A.27. The Hessian limit is $H = H(\theta_0) = -\mathcal{I}$ by Lemma A.39. The sandwich collapses: $H^{-1} \Sigma H^{-1} = \mathcal{I}^{-1} \mathcal{I} \mathcal{I}^{-1} = \mathcal{I}^{-1}$. □

The variance $\mathcal{I}^{-1}$ is the smallest possible. The *Cramér-Rao bound* states that any unbiased estimator T of θ based on n observations has $\operatorname{Var}(T) \geq (n\mathcal{I})^{-1}$. The proof is short. Differentiating $\mathbb{E}_\theta[T] = \theta$ gives $\operatorname{Cov}(T, S_n) = I$, where $S_n = \sum_i s_i(\theta)$ has variance $n\mathcal{I}$. The covariance matrix of (T, S_n) is positive semidefinite, so $\operatorname{Var}(T) - \operatorname{Cov}(T, S_n) \operatorname{Var}(S_n)^{-1} \operatorname{Cov}(S_n, T) = \operatorname{Var}(T) - (n\mathcal{I})^{-1} \geq 0$. Among regular estimators the same bound holds asymptotically, and ML attains it.

ML is also a GMM estimator, with the score as the moment function and $L = K$. The score is the optimal moment in the sense of Proposition A.35. Any other set of moments implied by the model gives a variance at least as large. This is why simulated or method-of-moments estimators are less efficient than ML when the likelihood is available and correct.

Three consistent estimators of the asymptotic variance $\mathcal{I}^{-1}$ are in use. The *Hessian* estimator inverts minus the average Hessian, $-\frac{1}{n} \sum_i \nabla_{\theta\theta} \ell_i(\hat\theta)$. The *outer product of gradients* (OPG) estimator inverts $\frac{1}{n} \sum_i s_i(\hat\theta) s_i(\hat\theta)^\top$. Both inverted matrices estimate $\mathcal{I}$. The *sandwich* estimator combines them as $\hat H^{-1} \hat\Sigma \hat H^{-1}$, with $\hat H$ the average Hessian and $\hat\Sigma$ the OPG. All three are consistent for $\mathcal{I}^{-1}$ when the model is correct. Only the sandwich remains valid when it is not, as the next subsection shows. A large gap between the Hessian and the OPG estimates is itself evidence of misspecification, which is the idea behind White's information matrix test (White, 1982).

A.6.3 Quasi-maximum likelihood

When the assumed density is wrong, the ML estimator still converges. Its limit is the *pseudo-true value*

$$\theta^* = \arg\max_{\theta \in \Theta} \mathbb{E}_0[\ln f(y_i \mid x_i; \theta)],$$

the member of the parametric family closest to the truth in Kullback-Leibler divergence (White, 1982). We then call $\hat{\theta}$ a *quasi-maximum likelihood* (QML) estimator. Theorem A.27 still applies with θ_0 replaced by θ^*, and the asymptotic variance is the sandwich $H^{-1}\Sigma H^{-1}$ with $\Sigma = \mathbb{E}_0[s_i s_i^\top]$ evaluated at θ^*. The information equality fails, so $\Sigma \neq -H$ in general.

QML is useful when θ^* equals a parameter of interest even though the density is wrong. The leading case is a correctly specified conditional mean. Suppose $\mathbb{E}[y_i \mid x_i] = m(x_i; \beta_0)$, but the errors are neither normal nor homoskedastic. The Gaussian quasi-log-likelihood is

$$\ell_i(\beta, \sigma^2) = -\frac{1}{2}\ln(2\pi\sigma^2) - \frac{\{y_i - m(x_i;\beta)\}^2}{2\sigma^2},$$

with score for β equal to $\frac{1}{\sigma^2}\nabla_\beta m(x_i;\beta)\{y_i - m(x_i;\beta)\}$. At β_0 its expectation is zero by iterated expectations, because $\mathbb{E}[y_i - m(x_i;\beta_0) \mid x_i] = 0$. So $\beta^* = \beta_0$ under identification, and the Gaussian QML estimator is nonlinear least squares with heteroskedasticity-robust standard errors. The same holds for any density in the linear exponential family, such as the Poisson, when the mean is correctly specified (Gourieroux et al., 1984).

In applied work the lesson is to report sandwich standard errors whenever the likelihood is a convenient approximation. Ellison (1994, p. 40) computes robust standard errors from numerical derivatives for all his switching models.

A.6.4 The trinity of tests

Let $H_0 : a(\theta_0) = 0$ impose r restrictions, with $A(\theta) = \frac{\partial a(\theta)}{\partial \theta^\top}$ of full row rank. Let $\hat{\theta}$ be the unrestricted and $\tilde{\theta}$ the restricted ML estimator, and let $\bar{s}_n(\theta) = \frac{1}{n}\sum_i s_i(\theta)$ be the average score. The three classical statistics are

$$\mathcal{W} = n\, a(\hat{\theta})^\top \big[A(\hat{\theta})\hat{\mathcal{I}}^{-1}A(\hat{\theta})^\top\big]^{-1} a(\hat{\theta}), \tag{A.57}$$

$$\mathcal{LR} = 2n\big[\mathcal{L}_n(\hat{\theta}) - \mathcal{L}_n(\tilde{\theta})\big], \tag{A.58}$$

$$\mathcal{LM} = n\, \bar{s}_n(\tilde{\theta})^\top \tilde{\mathcal{I}}^{-1} \bar{s}_n(\tilde{\theta}), \tag{A.59}$$

where $\hat{\mathcal{I}}$ and $\tilde{\mathcal{I}}$ estimate the information matrix at $\hat{\theta}$ and $\tilde{\theta}$. The Wald statistic (A.57) is the nonlinear version of the linear Wald statistic (A.24), with the delta method (Theorem A.59) supplying the variance of $a(\hat{\theta})$.

Theorem A.41 (The trinity)**.** *Under the conditions of Theorem A.40 and H_0, each of $\mathcal{W}$, $\mathcal{LR}$ and $\mathcal{LM}$ converges in distribution to χ^2_r, and the differences between any two of them are $o_p(1)$.*

Proof for a simple null. Take $H_0 : \theta_0 = \theta^\circ$, so $r = K$ and $\tilde{\theta} = \theta^\circ$. The general case follows the same steps after a reparametrization that separates restricted and free directions (Engle, 1984).

Wald. Here $\mathcal{W} = n(\hat{\theta} - \theta^\circ)^\top \hat{\mathcal{I}}(\hat{\theta} - \theta^\circ)$. Since $\sqrt{n}(\hat{\theta} - \theta^\circ) \xrightarrow{d} N(0, \mathcal{I}^{-1})$ and $\hat{\mathcal{I}} \xrightarrow{p} \mathcal{I}$, the statistic converges to χ^2_K.

Likelihood ratio. Expand $\mathcal{L}_n(\theta^\circ)$ to second order around $\hat{\theta}$, where the gradient is zero:

$$\mathcal{L}_n(\theta^\circ) = \mathcal{L}_n(\hat{\theta}) + \frac{1}{2}(\theta^\circ - \hat{\theta})^\top \nabla_{\theta\theta}\mathcal{L}_n(\bar{\theta})(\theta^\circ - \hat{\theta}),$$

with $\bar{\theta}$ between the two points. Since $\nabla_{\theta\theta}\mathcal{L}_n(\bar{\theta}) \xrightarrow{p} -\mathcal{I}$,

$$\mathcal{LR} = n(\hat{\theta} - \theta^\circ)^\top \mathcal{I}(\hat{\theta} - \theta^\circ) + o_p(1) = \mathcal{W} + o_p(1).$$

Lagrange multiplier. The central limit theorem gives $\sqrt{n}\,\bar{s}_n(\theta^\circ) \xrightarrow{d} N(0, \mathcal{I})$, so $\mathcal{LM} \xrightarrow{d} \chi^2_K$ directly. The expansion of the first-order condition in the proof of Theorem A.27 gives $\sqrt{n}\,\bar{s}_n(\theta^\circ) = \mathcal{I}\sqrt{n}(\hat{\theta} - \theta^\circ) + o_p(1)$. Substituting, $\mathcal{LM} = n(\hat{\theta} - \theta^\circ)^\top \mathcal{I}(\hat{\theta} - \theta^\circ) + o_p(1) = \mathcal{W} + o_p(1)$. □

Figure A.4 shows the geometry for one parameter. The likelihood ratio measures the vertical drop in the log-likelihood from its peak to the null value. The Wald test measures the horizontal distance between $\hat{\theta}$ and the null value, scaled by the curvature. The LM test measures the slope at the null value, scaled by the curvature. For a quadratic log-likelihood the three coincide. Otherwise they differ in finite samples.

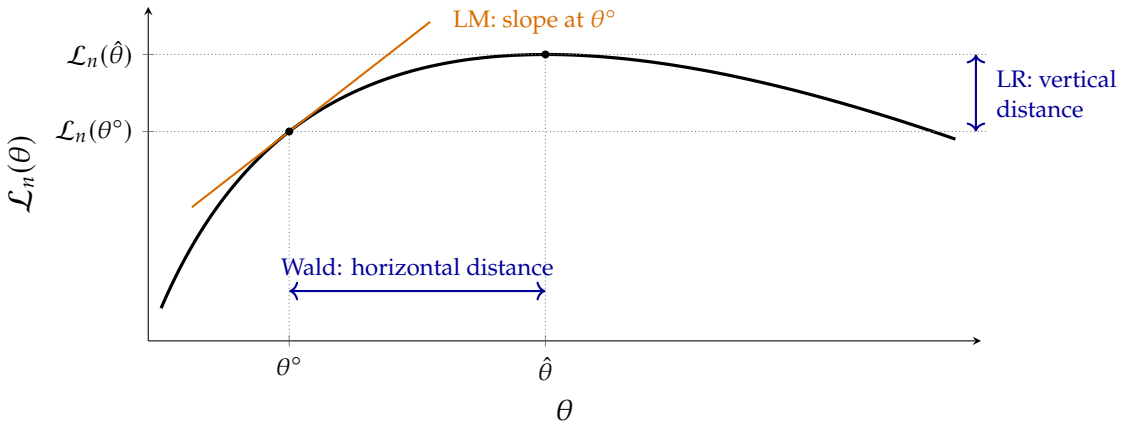

Figure A.4: Geometry of the Wald, likelihood ratio and Lagrange multiplier tests of $H_0 : \theta = \theta^\circ$ for one parameter. The curve is an illustrative log-likelihood, $\mathcal{L}_n(\theta) = 4\ln\theta - 2\theta$, maximized at $\hat{\theta} = 2$, with $\theta^\circ = 1$. The straight segment is the tangent at θ°, whose slope is the score.

The tests differ in what they require. Wald needs only the unrestricted estimate, LM only the restricted one, and LR both. LM is convenient when the restricted model is easy and the unrestricted one hard, for instance when testing whether a random coefficient has zero variance starting from logit estimates. Wald is not invariant to how the restriction is written. Suppose $\hat{\theta} = 2$ with standard error 0.5. Writing H_0 as $\theta = 1$ gives $\mathcal{W} = (\frac{2-1}{0.5})^2 = 4$. Writing it as $\ln\theta = 0$ gives, by the delta method, $\mathcal{W} = (\frac{\ln 2}{0.25})^2 = 7.7$. Writing it as $\frac{1}{\theta} = 1$ gives $\mathcal{W} = (\frac{0.5}{0.125})^2 = 16$. The likelihood ratio is the same for all three, because it depends only on the values of the likelihood. In the normal linear regression the three satisfy $\mathcal{W} \geq \mathcal{LR} \geq \mathcal{LM}$ in every sample (Berndt and Savin, 1977).

A likelihood ratio test from the book illustrates the mechanics. Porter and Zona (1993) estimate a ranked logit model of bids, described in Section A.6.5, three times: on all bid ranks,

on the lowest bids only, and on the higher ranks only.[6] If the same coefficients govern both parts, the restricted log-likelihood is the all-ranks value and the unrestricted one is the sum of the two separate values. For competitive firms the log-likelihoods are -291.4, -89.85 and -199.4 (WP Table 5), so

$$\mathcal{LR} = 2\big[(-89.85) + (-199.4) - (-291.4)\big] = 4.3,$$

with six degrees of freedom and a p-value of 0.64 (our computation). For cartel members the values are -73.97, -44.58 and -24.92 (WP Table 6), so $\mathcal{LR} = 8.94$ with four degrees of freedom and a p-value of 0.063. Porter and Zona reject the null of no phantom bidding for the cartel at about the 10 percent level, and they do not reject it for the competitive firms (Chapter 13).

Table A.6 collects the tests used in this book.

A.6.5 Likelihoods for discrete outcomes

Binary choice. Let a latent index $y_i^* = x_i^\top \beta + \varepsilon_i$ determine the outcome $y_i = \mathbf{1}\{y_i^* > 0\}$, with ε_i independent of x_i and symmetric with distribution function F. Then $\mathbb{P}(y_i = 1 \mid x_i) = F(x_i^\top \beta)$, and

$$\mathcal{L}_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} \Big[y_i \ln F(x_i^\top \beta) + (1 - y_i) \ln\{1 - F(x_i^\top \beta)\} \Big].$$

The *logit* takes $F = \Lambda$ with $\Lambda(v) = \frac{e^v}{1+e^v}$, and the *probit* takes $F = \Phi$, the standard normal distribution function. Only $\frac{\beta}{\sigma_\varepsilon}$ is identified, so the scale of ε is normalized (Section A.1.1). For the logit, $\Lambda'(v) = \Lambda(v)\{1 - \Lambda(v)\}$, so the score and the Hessian are

$$\nabla_\beta \mathcal{L}_n = \frac{1}{n} \sum_i \{y_i - \Lambda(x_i^\top \beta)\} x_i, \qquad \nabla_{\beta\beta} \mathcal{L}_n = -\frac{1}{n} \sum_i \Lambda(x_i^\top \beta)\{1 - \Lambda(x_i^\top \beta)\} x_i x_i^\top. \tag{A.60}$$

Proposition A.42 (Concavity of the logit likelihood)**.** *If $\sum_i x_i x_i^\top$ is positive definite, the binary logit log-likelihood is strictly concave in β. Hence it has at most one maximizer, and any solution of the first-order condition is the ML estimator.*

Proof. Each weight $\Lambda(1 - \Lambda)$ in (A.60) lies in $(0, \tfrac{1}{4}]$. For any $c \neq 0$,

$$c^\top \nabla_{\beta\beta} \mathcal{L}_n \, c = -\frac{1}{n} \sum_i \Lambda_i (1 - \Lambda_i)(x_i^\top c)^2 < 0,$$

because $x_i^\top c \neq 0$ for some i when $\sum_i x_i x_i^\top$ is positive definite. A strictly concave function has at most one maximizer, and a stationary point of a concave function is a global maximizer. □

A maximizer can fail to exist. If some linear combination of the regressors separates the ones from the zeros perfectly, the likelihood rises without bound along that direction. The probit log-likelihood is also concave, because Φ and $1 - \Phi$ are log-concave. Theorem A.26 then gives consistency without compactness.

[6] We read NBER Working Paper 4013 (March 1992), the working-paper version of Porter and Zona (1993). Table numbers refer to that version.

Table A.6: Specification and hypothesis tests used in this book

Test	Statistic	Null distribution	Estimates needed	Example in the book
Wald	$n\, a(\hat{\theta})^\top [\hat{A}\hat{V}\hat{A}^\top]^{-1} a(\hat{\theta})$	χ^2_r	unrestricted	equal sugar demand coefficients across seasons (Chapter 3)
Likelihood ratio	$2n[\mathcal{L}_n(\hat{\theta}) - \mathcal{L}_n(\tilde{\theta})]$	χ^2_r	both	stability of ranked-logit coefficients across bid ranks (Chapter 13)
Lagrange multiplier	$n\, \bar{s}_n(\tilde{\theta})^\top \tilde{\mathcal{I}}^{-1} \bar{s}_n(\tilde{\theta})$	χ^2_r	restricted	zero variance of a random coefficient from logit estimates (Chapter 8)
Hansen J	$n\, \bar{g}_n(\hat{\theta})^\top \hat{S}^{-1} \bar{g}_n(\hat{\theta})$	χ^2_{L-K}	efficient GMM	overidentifying restrictions in logit and RC logit demand (Appendix C)
Hausman	$(\hat{\beta}_C - \hat{\beta}_E)^\top [\hat{V}_C - \hat{V}_E]^- (\hat{\beta}_C - \hat{\beta}_E)$	χ^2, d.f. = rank of $V_C - V_E$	efficient and robust	exogeneity of route share and concentration (Chapter 9)
Anderson-Rubin	F test of Z in a regression of $y - X\beta^\circ$ on Z	$F(L, n-L-K_1)$ under normality	none	weak-instrument robust confidence sets (Section A.3.5)
First-stage F	F test of excluded instruments in the first stage	noncentral F	first stage	instrument strength in demand estimation (Section A.3.5)
Cox	centered $\mathcal{LR}$ between non-nested models, standardized	$N(0,1)$	both models	collusion against Bertrand pricing in 1955 autos (Chapter 6)
Vuong	$\frac{\sqrt{n}\,\overline{LR}}{\hat{\omega}}$	$N(0,1)$	both models	choosing between non-nested demand or conduct models
Conditional Kolmogorov	$\max_j \sqrt{n}\,\lvert H_n(Z_j) - F_n(Z_j, \hat{\theta})\rvert$	parametric bootstrap	parametric model	Gamma-Weibull bid distributions in timber auctions (Chapter 15)

Notes: r is the number of restrictions, L the number of moments and K the number of parameters. Subscripts C and E denote an estimator consistent under both hypotheses and one efficient under the null. The superscript $-$ denotes a generalized inverse. In the Anderson-Rubin row, L counts the excluded instruments and K_1 the exogenous regressors partialled out. $\overline{LR}$ is the average pointwise log-likelihood ratio and $\hat{\omega}$ its standard deviation (Section A.6.8). H_n and F_n are defined in Section A.6.9.

Multinomial and conditional logit. Let consumer i choose one of $J+1$ alternatives with utilities $u_{ij} = x_{ij}^\top \beta + \epsilon_{ij}$ and ϵ_{ij} i.i.d. type-I extreme value. With $d_{ij} = 1$ if i chooses j, the conditional logit of McFadden (1974) has

$$P_{ij}(\beta) = \frac{e^{x_{ij}^\top \beta}}{\sum_{k=0}^{J} e^{x_{ik}^\top \beta}}, \qquad \mathcal{L}_n(\beta) = \frac{1}{n}\sum_i \sum_j d_{ij} \ln P_{ij}(\beta).$$

Using $\frac{\partial \ln P_{ij}}{\partial \beta} = x_{ij} - \bar{x}_i$ with $\bar{x}_i = \sum_k P_{ik} x_{ik}$,

$$\nabla_\beta \mathcal{L}_n = \frac{1}{n}\sum_i \sum_j d_{ij}(x_{ij} - \bar{x}_i), \qquad \nabla_{\beta\beta} \mathcal{L}_n = -\frac{1}{n}\sum_i \sum_j P_{ij}(x_{ij} - \bar{x}_i)(x_{ij} - \bar{x}_i)^\top.$$

The Hessian is minus a weighted covariance matrix, so the log-likelihood is concave. With consumer-level data in many markets, product-market constants δ_{jt} can be estimated by ML along with the taste-heterogeneity parameters. They absorb the unobserved quality ξ_{jt}. The mean price coefficient is then recovered in a second step, $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, which still needs instruments (Chapters 7 and 8). This is a two-step estimator in the sense of Section A.5.6.

Binomial entry. Athey et al. (2011) model the entry of loggers into Forest Service timber auctions. Each of $N_{L,t}$ potential loggers enters sale t independently with probability $p_L(X_t, N_t) = \Lambda(X_t \alpha_X + N_t \alpha_N)$, where X_t are sale characteristics and N_t the numbers of potential entrants. The number of entrants is then $n_{L,t} \sim \text{Binomial}(N_{L,t}, p_L(X_t, N_t))$, and

$$\ln L(\alpha) = \sum_t \Big[n_{L,t} \ln p_L(X_t, N_t) + (N_{L,t} - n_{L,t}) \ln\{1 - p_L(X_t, N_t)\} \Big] + \text{const.}$$

This is a grouped logit. The score is $\sum_t \{n_{L,t} - N_{L,t} p_L(X_t, N_t)\}(X_t, N_t)^\top$ and the log-likelihood is concave. They estimate it on $N = 339$ Northern and $N = 382$ California observations. The coefficient on the number of active loggers is -0.041 (0.006) in the North and -0.050 (0.007) in California (Table IV). More potential entrants lower each one's entry probability, as a mixed-strategy entry equilibrium predicts (Chapter 15).

Rank-ordered logit. Sometimes we observe a full ranking of alternatives, such as the order of all bids in a procurement auction. Let $U_j = V_j + \epsilon_j$ with ϵ_j i.i.d. type-I extreme value, $j = 1, \dots, J$.

Proposition A.43 (Rank-ordered logit)**.** *The probability of the ranking $U_{r_1} > U_{r_2} > \cdots > U_{r_J}$ is*

$$\mathbb{P}(U_{r_1} > U_{r_2} > \cdots > U_{r_J}) = \prod_{m=1}^{J} \frac{e^{V_{r_m}}}{\sum_{k=m}^{J} e^{V_{r_k}}}. \tag{A.61}$$

Proof. The type-I extreme value distribution function is $\mathbb{P}(\epsilon \le a) = \exp(-e^{-a})$. Hence $E_j = e^{-\epsilon_j}$ is exponential with rate one, since $\mathbb{P}(e^{-\epsilon_j} > t) = \mathbb{P}(\epsilon_j < -\ln t) = e^{-t}$. Define $T_j = e^{-U_j} = e^{-V_j} E_j$, which is exponential with rate $\lambda_j = e^{V_j}$. The map $u \mapsto e^{-u}$ is decreasing, so the ranking of the U's from highest to lowest is the ranking of the T's from smallest to largest. For independent exponentials, $\mathbb{P}(T_{r_1} = \min_k T_k) = \frac{\lambda_{r_1}}{\sum_k \lambda_k}$. By the memoryless property, given that T_{r_1} is the minimum, the excesses $T_k - T_{r_1}$ for $k \neq r_1$ are again independent exponentials with rates λ_k, independent of T_{r_1}. The ordering of the remaining T's equals the ordering of these excesses, so the argument repeats on the remaining set. Multiplying the stage probabilities gives (A.61), with $\lambda_{r_m} = e^{V_{r_m}}$. $\square$

The ranking likelihood "explodes" into a sequence of logit choices from shrinking choice sets (Beggs et al., 1981). Each auction contributes one product (A.61), and the sample likelihood is the product over auctions. Standard multinomial logit software estimates it.

Porter and Zona (1993) apply the model to bids for highway paving contracts on Long Island, 1979–1985. They approximate the equilibrium bid function by $\log b_{it} = \alpha_t + X_{it}\beta + \epsilon_{it}$, with an auction effect α_t and an auction-specific error variance σ_t^2. They deflate the data by the estimated σ_t. The probability that firm i submits the lowest bid is then a multinomial logit in the deflated cost shifters Z_{it}, in which the auction effect cancels:

$$\mathbb{P}(b_{it} < b_{jt} \ \forall j \neq i) = \frac{e^{\beta Z_{it}}}{\sum_j e^{\beta Z_{jt}}}.$$

The low bid is the "most preferred" alternative, so with r_m the firm whose bid is ranked m-th lowest among n_t bids, (A.61) gives the likelihood $L(\beta) = \prod_t \prod_{i=1}^{n_t} \frac{e^{\beta Z_{r_i t}}}{\sum_{j=i}^{n_t} e^{\beta Z_{r_j t}}}$. The model follows from the bid equation if minus the bid error is type-I extreme value (WP pp. 24–25). The product splits into the factor for the lowest bid ($i = 1$) and the factors for the higher ranks ($i \geq 2$). Under the model both parts identify the same β. Phantom bids by cartel members, placed above the designated winner's bid, need not reflect costs. The likelihood ratio test of equal coefficients computed above therefore detects them, with the competitive firms as a check on the specification (Hausman and Ruud, 1987).

A.6.6 Latent variables

Many IO models contain variables that the firms observe and the econometrician does not: an auction-level shock common to all bidders, or the regime of a cartel. The likelihood of the data integrates the latent variable out,

$$f(y \mid x; \theta) = \int f(y \mid x, u; \theta)\, \mathrm{d}F(u \mid x; \theta).$$

Three cases arise in this book: an integral with a closed form, a finite mixture, and a hidden Markov chain.

Closed-form heterogeneity: Gamma-Weibull bids

Athey et al. (2011) find that sealed bids in the same timber auction are highly correlated given observed sale characteristics. Following Krasnokutskaya (2011), they let an auction characteristic u, known to the bidders but not to the econometrician, shift all bids. Conditional on (X, u, N, n), the bid of a bidder of type $k \in \{L, M\}$ (logger or mill) is Weibull (journal p. 237, eq. 8):

$$G_k(b \mid X, u, N, n) = 1 - \exp\left\{-u\left(\frac{b}{\lambda_k(X, N, n)}\right)^{\rho_k(n)}\right\}. \tag{A.62}$$

The scale satisfies $\ln \lambda_k = X\beta_X + N\beta_N + n\beta_{n,k} + \beta_{0,k}$ and the shape satisfies $\ln \rho_k = n\gamma_{n,k} + \gamma_{0,k}$. The heterogeneity u is Gamma with mean one and variance σ_u^2, independent of (X, N, n). Athey, Levin and Seira (ALS) denote this variance by θ. Bids are independent given u. A large u lowers every bid in the auction by the common factor $u^{-\frac{1}{\rho_k}}$, since (A.62) says that $u^{\frac{1}{\rho_k}} b$ is Weibull with parameters (λ_k, ρ_k) whatever u is.

Proposition A.44 (Closed-form auction likelihood)**.** *Let auction t have the set of participants $\mathcal{N}_t$, with $|\mathcal{N}_t| = n$ bids b_i, and write $z_i = (\frac{b_i}{\lambda_{k(i)}})^{\rho_{k(i)}}$. The joint density of the bids is*

$$\ell_t = \prod_{i \in \mathcal{N}_t} \left[\frac{\rho_{k(i)}}{\lambda_{k(i)}} \left(\frac{b_i}{\lambda_{k(i)}} \right)^{\rho_{k(i)}-1} \right] \frac{\Gamma\left(n + \frac{1}{\sigma_u^2}\right)}{\Gamma\left(\frac{1}{\sigma_u^2}\right) \left(\sigma_u^2\right)^{\frac{1}{\sigma_u^2}} \left(\sum_{i \in \mathcal{N}_t} z_i + \frac{1}{\sigma_u^2} \right)^{n + \frac{1}{\sigma_u^2}}}. \tag{A.63}$$

Proof. Differentiating (A.62), the density of one bid given u is

$$g_k(b \mid u) = u \, \frac{\rho_k}{\lambda_k} \left(\frac{b}{\lambda_k} \right)^{\rho_k - 1} e^{-uz}, \qquad z = \left(\frac{b}{\lambda_k} \right)^{\rho_k}.$$

Given u the bids are independent, so their joint density is

$$u^n \prod_{i \in \mathcal{N}_t} \left[\frac{\rho_{k(i)}}{\lambda_{k(i)}} \left(\frac{b_i}{\lambda_{k(i)}} \right)^{\rho_{k(i)}-1} \right] \exp\Big(- u \sum_{i \in \mathcal{N}_t} z_i \Big).$$

A Gamma variable with mean one and variance σ_u^2 has shape $a = \frac{1}{\sigma_u^2}$, scale σ_u^2, and density $\frac{u^{a-1} e^{-\frac{u}{\sigma_u^2}}}{\Gamma(a)(\sigma_u^2)^a}$. Integrating u out leaves

$$\frac{1}{\Gamma(a)(\sigma_u^2)^a} \int_0^\infty u^{n+a-1} \exp\left\{ -u \left(\sum_i z_i + \frac{1}{\sigma_u^2} \right) \right\} \mathrm{d}u = \frac{\Gamma(n+a)}{\Gamma(a)(\sigma_u^2)^a \left(\sum_i z_i + \frac{1}{\sigma_u^2} \right)^{n+a}},$$

by the Gamma integral $\int_0^\infty u^{c-1} e^{-du} \, \mathrm{d}u = \frac{\Gamma(c)}{d^c}$. Multiplying by the product term gives (A.63). □

The Gamma mixing distribution is conjugate to the exponential kernel in (A.62), which is why the integral has a closed form. ALS write their likelihood in an online appendix (journal p. 238). The expression above is our derivation from their specification. They estimate it on sales with at least two bidders (Table IV notes). The estimates of $\ln \sigma_u^2$ are -0.502 (0.120) in the Northern sales and -0.416 (0.124) in California (Table IV). These imply $\sigma_u^2 = 0.61$ and 0.66, with delta-method standard errors of 0.07 and 0.08 (our computation). Auction heterogeneity is substantial. The fitted model reproduces the moments of normalized bids. In the North the data show a mean of 2.16, a standard deviation of 1.18, a between-auction standard deviation of 0.94 and a within-auction standard deviation of 0.75. The model predicts 2.12, 1.21, 0.97 and 0.70 (journal p. 238). When no conjugate pair exists, the integral is computed by quadrature or simulation (Section A.7).

Finite mixtures and switching regressions: the JEC cartel

Porter (1983a) studies the Joint Executive Committee (JEC), a legal railroad cartel that set rates for grain shipped east from Chicago. The data are weekly from 1880 to 1886, 328 observations. The cartel alternated between collusive periods and price wars, and the econometrician does not know with certainty which weeks were which. Let Q_t be the tonnage shipped, p_t the grain rate and L_t a dummy for the Great Lakes being open to navigation. Let S_t collect dummies for entry and acquisitions and I_t indicate the collusive regime. The model is (journal pp. 304–305)

$$\log Q_t = \alpha_0 + \alpha_1 \log p_t + \alpha_2 L_t + U_{1t}, \tag{A.64}$$

$$\log p_t = \beta_0 + \beta_1 \log Q_t + \beta_2 S_t + \beta_3 I_t + U_{2t}. \tag{A.65}$$

The errors $U_t = (U_{1t}, U_{2t})^\top$ are i.i.d. $N(0, \Sigma)$. Twelve four-week seasonal dummies enter both equations and are suppressed here. The regime shifts only the intercept of the supply relation. Porter derives (A.65) from firm first-order conditions $p_t(1 + \frac{\theta_t}{\alpha_1}) = MC_i(q_{it})$. If price wars are Bertrand and collusive periods have constant conduct θ, then $\beta_3 = -\ln(1 + \frac{\theta}{\alpha_1})$.

Write the system as $B y_t = \Gamma X_t + \Delta I_t + U_t$ with $y_t = (\log Q_t, \log p_t)^\top$, $X_t = (1, L_t, S_t^\top)^\top$ and

$$B = \begin{pmatrix} 1 & -\alpha_1 \\ -\beta_1 & 1 \end{pmatrix}, \qquad \Delta = \begin{pmatrix} 0 \\ \beta_3 \end{pmatrix}, \qquad \Gamma = \begin{pmatrix} \alpha_0 & \alpha_2 & 0 \\ \beta_0 & 0 & \beta_2^\top \end{pmatrix}.$$

Given I_t, the change of variables from U_t to y_t has Jacobian $|\det B| = |1 - \alpha_1\beta_1|$, so

$$h(y_t \mid I_t) = (2\pi)^{-1} |\Sigma|^{-\frac{1}{2}} |\det B| \exp\left\{ -\frac{1}{2} (B y_t - \Gamma X_t - \Delta I_t)^\top \Sigma^{-1} (B y_t - \Gamma X_t - \Delta I_t) \right\}. \tag{A.66}$$

If the regimes are known, 2SLS or ML with I_t as data is straightforward. Porter instead treats I_t as an i.i.d. Bernoulli variable with $\mathbb{P}(I_t = 1) = \lambda$. The density of y_t is then a two-component mixture, and the likelihood is (journal p. 306, eq. 5)

$$L(\Omega, \lambda) = \prod_{t=1}^{T} \left[\lambda h(y_t \mid 1) + (1 - \lambda) h(y_t \mid 0) \right], \tag{A.67}$$

with $\Omega = (B, \Gamma, \Delta, \Sigma)$.

Mixture likelihoods are awkward to maximize directly, because the log of a sum does not separate. The *expectation-maximization* (EM) algorithm of Dempster et al. (1977) exploits the fact that the likelihood would be easy if the regimes were observed. The complete-data log-likelihood is

$$\ln L^c(\Omega, \lambda) = \sum_t \Big[I_t \{ \ln \lambda + \ln h(y_t \mid 1) \} + (1 - I_t) \{ \ln(1 - \lambda) + \ln h(y_t \mid 0) \} \Big].$$

Starting from $(\Omega^{(m)}, \lambda^{(m)})$, iterate two steps.

1. *E step.* Compute the posterior probability of collusion in each week by Bayes' rule,

$$w_t^{(m)} = \mathbb{P}(I_t = 1 \mid y_t; \Omega^{(m)}, \lambda^{(m)}) = \frac{\lambda^{(m)} h(y_t \mid 1; \Omega^{(m)})}{\lambda^{(m)} h(y_t \mid 1; \Omega^{(m)}) + (1 - \lambda^{(m)}) h(y_t \mid 0; \Omega^{(m)})}. \tag{A.68}$$

2. *M step.* Maximize the expected complete-data log-likelihood, which replaces I_t by $w_t^{(m)}$ in $\ln L^c$. This gives $\lambda^{(m+1)} = \frac{1}{T} \sum_t w_t^{(m)}$ and

$$\Omega^{(m+1)} = \arg\max_{\Omega} \sum_t \Big[w_t^{(m)} \ln h(y_t \mid 1; \Omega) + (1 - w_t^{(m)}) \ln h(y_t \mid 0; \Omega) \Big],$$

   a weighted full-information ML problem.

Porter adapts the version of this algorithm proposed by Kiefer (1980) for switching regressions. He stops when the correlation between successive w_t series exceeds .999 (journal p. 306).

A detail of the M step deserves care. The weighted objective is not the known-regime likelihood with w_t substituted for I_t. Write $e_t = B y_t - \Gamma X_t$. The expected complete-data

log-likelihood weights the quadratic forms of the two regimes by w_t and $1-w_t$, and completing the square gives

$$w_t(e_t-\Delta)^\top\Sigma^{-1}(e_t-\Delta)+(1-w_t)e_t^\top\Sigma^{-1}e_t=(e_t-w_t\Delta)^\top\Sigma^{-1}(e_t-w_t\Delta)+w_t(1-w_t)\Delta^\top\Sigma^{-1}\Delta.$$

The plug-in shortcut drops the last term, which matters when posterior probabilities are far from zero and one. In the simulated example below, the shortcut converges to $\hat\beta_3=0.618$, with a mixture log-likelihood 5.7 points below the maximum attained by exact EM.

Proposition A.45 (EM never lowers the likelihood)**.** *Let* $\vartheta=(\Omega,\lambda)$ *and let* $\vartheta^{(m+1)}$ *maximize* $Q(\vartheta\mid\vartheta^{(m)})=\mathbb{E}[\ln L^c(\vartheta)\mid y;\vartheta^{(m)}]$*. Then* $\ln L(\vartheta^{(m+1)})\geq\ln L(\vartheta^{(m)})$*.*

Proof. Let $k(I\mid y;\vartheta)$ be the conditional probability of the regime sequence I given the data. By the definition of conditional probability, $\ln L(\vartheta)=\ln L^c(\vartheta)-\ln k(I\mid y;\vartheta)$ for every I. Take the expectation over I under $k(\cdot\mid y;\vartheta^{(m)})$. The left side does not depend on I, so

$$\ln L(\vartheta)=Q(\vartheta\mid\vartheta^{(m)})-\mathcal{H}(\vartheta\mid\vartheta^{(m)}),\qquad \mathcal{H}(\vartheta\mid\vartheta^{(m)})=\mathbb{E}[\ln k(I\mid y;\vartheta)\mid y;\vartheta^{(m)}].$$

By Lemma A.38 applied to the conditional distribution of I, $\mathcal{H}(\vartheta\mid\vartheta^{(m)})\leq\mathcal{H}(\vartheta^{(m)}\mid\vartheta^{(m)})$ for every ϑ. The M step gives $Q(\vartheta^{(m+1)}\mid\vartheta^{(m)})\geq Q(\vartheta^{(m)}\mid\vartheta^{(m)})$. Hence

$$\begin{aligned}\ln L(\vartheta^{(m+1)})-\ln L(\vartheta^{(m)})&=\big[Q(\vartheta^{(m+1)}\mid\vartheta^{(m)})-Q(\vartheta^{(m)}\mid\vartheta^{(m)})\big]\\&\quad-\big[\mathcal{H}(\vartheta^{(m+1)}\mid\vartheta^{(m)})-\mathcal{H}(\vartheta^{(m)}\mid\vartheta^{(m)})\big]\geq 0.\end{aligned}$$

□

The proof also shows that the gradient of $\mathcal{H}(\cdot\mid\vartheta^{(m)})$ is zero at $\vartheta^{(m)}$. So a fixed point of EM is a stationary point of the observed likelihood. It need not be the global maximum. Convergence is linear, and slow when the regimes carry much missing information. EM does not deliver standard errors. They come from the observed information of the mixture likelihood (A.67) at the EM solution (Louis, 1982).

After estimation each week is classified as collusive if $\hat w_t>.5$. The rule minimizes the expected number of misclassified weeks (Lee and Porter, 1984). The expected number of errors of a classification $\hat I_t$ is $\sum_t[\hat I_t(1-\hat w_t)+(1-\hat I_t)\hat w_t]$, and each term is minimized by choosing $\hat I_t=1$ exactly when $\hat w_t>1-\hat w_t$.

Porter compares 2SLS with a regime series reported in the trade press (the PO series) and ML with the estimated series (PN). The demand estimates are almost identical, with price elasticities of $-.742$ (.121) and $-.800$ (.091). The regime coefficient $\hat\beta_3$ rises from .382 (.059) under 2SLS to .545 (.032) under ML. It is larger and has about half the standard error. The R^2 of the supply relation rises from .320 to .863 (Table 3). The implied conduct parameter is

$$\hat\theta=\hat\alpha_1\big(e^{-\hat\beta_3}-1\big)=-0.800\times\big(e^{-0.545}-1\big)=0.336,$$

which Porter calls roughly consistent with Cournot behavior in collusive periods (journal p. 309). At sample means, collusive weeks have prices about 66 percent higher, quantities about 33 percent lower and revenues about 11 percent higher than price-war weeks (Table 4, p. 310). The full table and its interpretation are in Chapter 13.

Figure A.5 applies the algorithm to simulated data with the same structure. Demand and supply parameters are set near Porter's ML estimates, and the regime follows a Markov chain with the transition probabilities that Ellison (1994) estimates. The simulated sample has six price wars covering 65 of 328 weeks. Exact EM from a median split of the supply residuals converges in 25 iterations to $\hat\beta_3=0.563$ (0.030), against the true 0.545. The correlation between

successive w_t series first exceeds .999 at iteration 10. The rule $\hat{w}_t > .5$ misclassifies 11 weeks. The log-likelihood rises at every iteration, as Proposition A.45 requires. A random starting classification shows the other side of the proposition. It carries no information about the regimes, so the first M step sets $\hat{\beta}_3$ close to zero. With equal regime densities every posterior equals λ, and the algorithm stays at this degenerate fixed point, 37.3 log points below the maximum (Figure A.5, panel a).

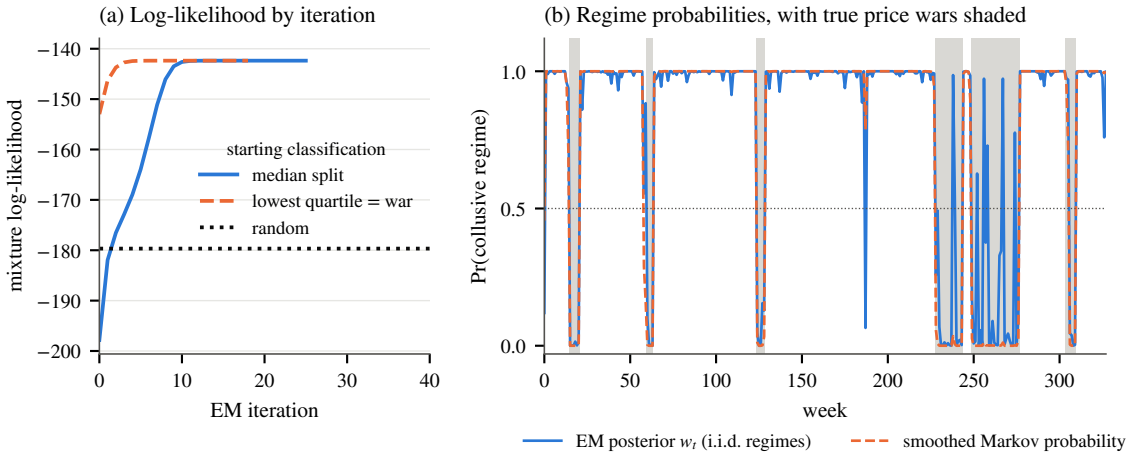

Figure A.5: EM and Markov-switching estimation of a simulated two-regime supply relation. The design is (A.64) and (A.65) with $T = 328$, $(\alpha_0, \alpha_1, \alpha_2) = (9.09, -0.80, -0.43)$, $(\beta_0, \beta_1, \beta_2, \beta_3) = (-2.70, 0.09, -0.20, 0.545)$, one entry dummy, independent errors with standard deviations 0.40 and 0.16, and a Markov regime with $\mathbb{P}(I_{t+1} = 1 \mid I_t = 1) = 0.975$ and $\mathbb{P}(I_{t+1} = 1 \mid I_t = 0) = 0.067$. (a) Mixture log-likelihood by EM iteration from three starting classifications. (b) Posterior probabilities of collusion from the i.i.d. mixture (EM) and smoothed probabilities from the Markov-switching model estimated by the Hamilton filter. Hidden Markov models: Ellison's re-estimation

Porter's i.i.d. regimes ignore the persistence of price wars. Ellison (1994) re-estimates the JEC model with two changes (journal p. 40). First, the demand error follows an AR(1) process, $U_{1t} = \rho U_{1,t-1} + V_{1t}$ with $|\rho| < 1$, where ρ now denotes an autoregressive coefficient. Second, the regime follows a Markov chain whose transition probabilities are logits,

$$\mathbb{P}(I_{t+1} = 1 \mid I_t, Z_t) = \frac{e^{\gamma^\top W_t}}{1 + e^{\gamma^\top W_t}}, \tag{A.69}$$

where Z_t is the set of predetermined variables at t and W_t contains functions of I_t and of Z_t. With W_t equal to a separate constant for each value of I_t, the chain is a first-order Markov process. Adding market-share or demand variables to W_t tests what triggers price wars. Ellison maximizes the joint likelihood of the structural equations and of the path of transitions.

The likelihood of a hidden Markov model is computed by the filter of Hamilton (1989). Let $\mathcal{F}_t$ be the data up to week t, and let $h_k(y_t) = f(y_t \mid I_t = k, \mathcal{F}_{t-1})$ be the density of week t's data in regime k. In Ellison's model, h_k is (A.66) with U_{1t} replaced by $V_{1t} = U_{1t} - \rho U_{1,t-1}$. Write $p_{k,t} = \mathbb{P}(I_{t+1} = 1 \mid I_t = k, Z_t)$, the predicted probability $\xi_{t|t-1} = \mathbb{P}(I_t = 1 \mid \mathcal{F}_{t-1})$, and the filtered probability $\xi_{t|t} = \mathbb{P}(I_t = 1 \mid \mathcal{F}_t)$.

Proposition A.46 (Hamilton filter)**.** *Suppose y_t depends on the regime history only through I_t, given $\mathcal{F}_{t-1}$, and the regime follows* (A.69)*. Then for $t = 1, \dots, T$,*

$$f(y_t \mid \mathcal{F}_{t-1}) = \xi_{t|t-1} h_1(y_t) + (1 - \xi_{t|t-1}) h_0(y_t), \tag{A.70}$$

$$\xi_{t|t} = \frac{\xi_{t|t-1} h_1(y_t)}{f(y_t \mid \mathcal{F}_{t-1})}, \tag{A.71}$$

$$\xi_{t+1|t} = p_{1,t}\, \xi_{t|t} + p_{0,t}\, (1 - \xi_{t|t}), \tag{A.72}$$

and the log-likelihood is $\ln L = \sum_{t=1}^{T} \ln f(y_t \mid \mathcal{F}_{t-1})$.

Proof. Equation (A.70) is the law of total probability over the two values of I_t given $\mathcal{F}_{t-1}$. Equation (A.71) is Bayes' rule, $\mathbb{P}(I_t = 1 \mid y_t, \mathcal{F}_{t-1}) = \frac{\mathbb{P}(I_t = 1 \mid \mathcal{F}_{t-1}) f(y_t \mid I_t = 1, \mathcal{F}_{t-1})}{f(y_t \mid \mathcal{F}_{t-1})}$. Equation (A.72) again applies the law of total probability, now over I_t given $\mathcal{F}_t$, using that the transition depends on $\mathcal{F}_t$ only through (I_t, Z_t). Finally, the joint density of $(y_1, \dots, y_T)$ factors into one-step predictive densities, $f(y_1, \dots, y_T) = \prod_t f(y_t \mid \mathcal{F}_{t-1})$. □

The recursion needs a starting value $\xi_{1|0}$, usually the stationary probability $\frac{p_0}{1 - p_1 + p_0}$ when the transition probabilities are constant. Probabilities that use the whole sample come from a backward pass (Kim, 1994):

$$\mathbb{P}(I_t = 1 \mid \mathcal{F}_T) = \xi_{t|t} \left[p_{1,t} \frac{\mathbb{P}(I_{t+1} = 1 \mid \mathcal{F}_T)}{\xi_{t+1|t}} + (1 - p_{1,t}) \frac{\mathbb{P}(I_{t+1} = 0 \mid \mathcal{F}_T)}{1 - \xi_{t+1|t}} \right].$$

In the simulated data of Figure A.5, the Markov-switching model estimated by maximizing this likelihood gives $\mathbb{P}(I_{t+1} = 1 \mid I_t = 1) = 0.975$ and $\mathbb{P}(I_{t+1} = 1 \mid I_t = 0) = 0.099$, against the true 0.975 and 0.067. The smoothed probabilities misclassify 5 weeks, against 11 for the i.i.d. mixture. Using the persistence of regimes sharpens the classification of short-lived deviations.

Ellison's estimates (Table 2) give regime constants of 3.675 (.474) after a collusive week and −2.641 (.404) after a price war week. A collusive week is followed by another with probability $\frac{e^{3.675}}{1 + e^{3.675}} = .975$. A price war week is followed by collusion with probability only $\frac{e^{-2.641}}{1 + e^{-2.641}} = .067$, so wars persist with probability .933 per week. The implied mean durations are about 40 weeks for collusive spells and 15 weeks for wars, and the stationary share of collusive weeks is .73 (our computation). Dependence also moves the structural estimates. Allowing AR(1) demand errors, with $\hat{\rho} = .832$ (.085), raises the estimated demand elasticity from .84 to 1.80 (journal p. 42). Porter's approximation to the degree of collusion, $\hat{\alpha}_1(e^{-\hat{\beta}_3} - 1)$, rises from .40 to .85. The estimated elasticity is imprecise, with a standard error of 1.29. The log-likelihood rises from 37.2 to 181.0. If both values are computed on the same 328 weeks, the implied likelihood ratio statistic for $\rho = 0$ is 287.6 (our computation).

Ellison then adds candidate triggers to W_t in the transition from collusion to war (Table 3). An unusually high market share for one firm (BIGSHARE1) enters with coefficient −.77 (.49), and the unanticipated demand shock V_{1t} with −4.15 (2.64). Both have the predicted sign and are significant at about the 6 percent level in one-tailed tests. With only six price wars in the sample, these tests have little power. Chapter 13 discusses what they imply for the theories of Green and Porter (1984) and Rotemberg and Saloner (1986). The econometric point is that joint ML of the regimes, the transitions and the structural equations uses the timing of every war. A two-step procedure that first classifies weeks and then regresses the classification on triggers may lose power through misclassification at the onset of wars (journal p. 39).

A.6.7 Non-regular problems

The standard theory assumes that the support of the data does not depend on θ, that θ_0 is interior, and that the likelihood is smooth. Each assumption fails in some IO application, and each failure changes the asymptotics.

Proposition A.47 (Parameter-dependent support)**.** *Let $X_1, \ldots, X_n$ be i.i.d. uniform on $[0, \theta_0]$. The ML estimator is $\hat{\theta} = \max_i X_i$, and*

$$\frac{n(\theta_0 - \hat{\theta})}{\theta_0} \xrightarrow{d} \text{Exponential}(1).$$

Proof. The likelihood is $\theta^{-n}\mathbf{1}\{\theta \geq \max_i X_i\}$, which is zero below the sample maximum and decreasing above it. So $\hat{\theta} = \max_i X_i$. For $0 \leq t \leq n$,

$$\mathbb{P}\left(\frac{n(\theta_0 - \hat{\theta})}{\theta_0} > t\right) = \mathbb{P}\left(\max_i X_i < \theta_0\left(1 - \frac{t}{n}\right)\right) = \left(1 - \frac{t}{n}\right)^n \to e^{-t}. \qquad \square$$

The estimator converges at rate n, faster than $\sqrt{n}$, and its limit is not normal. It is biased downward, with $\mathbb{E}[\hat{\theta}] = \frac{n}{n+1}\theta_0$. The information equality fails because the support moves with θ. The derivative of $\ln f = -\ln\theta$ is $-\frac{1}{\theta}$, whose mean is not zero. The same structure arises in first-price auctions, where the upper end of the bid support depends on the parameters of the value distribution. Donald and Paarsch (1996) develop estimators and tests for this case based on extreme order statistics (Chapter 15). Proposition A.67 shows that the nonparametric bootstrap fails here.

Proposition A.48 (A parameter on the boundary)**.** *Let θ be scalar with $\Theta = [0, \infty)$ and $\theta_0 = 0$. Suppose the log-likelihood extends smoothly to a neighborhood of zero, where the unconstrained maximizer $\hat{\theta}_u$ satisfies $\sqrt{n}\,\hat{\theta}_u \xrightarrow{d} N(0, \mathcal{I}^{-1})$. Then the likelihood ratio statistic for $H_0 : \theta = 0$ converges in distribution to an equal mixture of a point mass at zero and a χ^2_1.*

Proof. A second-order expansion around zero, with $\bar{s}_n(0) = \mathcal{I}\hat{\theta}_u + o_p(n^{-\frac{1}{2}})$, gives uniformly in θ of order $n^{-\frac{1}{2}}$,

$$2n\left[\mathcal{L}_n(\theta) - \mathcal{L}_n(0)\right] = n\mathcal{I}\left(2\theta\hat{\theta}_u - \theta^2\right) + o_p(1).$$

Maximize over $\theta \geq 0$. If $\hat{\theta}_u > 0$ the maximum is at $\theta = \hat{\theta}_u$, with value $n\mathcal{I}\hat{\theta}_u^2$. If $\hat{\theta}_u \leq 0$ the maximum is at $\theta = 0$, with value zero. So $\mathcal{LR} = (\max\{0, Z_n\})^2 + o_p(1)$ with $Z_n = \sqrt{n\mathcal{I}}\,\hat{\theta}_u \xrightarrow{d} N(0, 1)$. Half the time $Z_n \leq 0$ and the statistic is zero. Otherwise it is the square of a standard normal. $\square$

The 5 percent cutoff of this mixture is the 90th percentile of χ^2_1, 2.71, not the usual 3.84 (Chernoff, 1954; Self and Liang, 1987; Andrews, 2001). Zero variances of random coefficients and zero regime probabilities are boundary nulls of this kind. Testing the number of regimes is harder still. In Porter's model (A.67) the null of a single regime can be written in two ways. If $\lambda = 0$, then λ lies on the boundary and β_3 is not identified, because it multiplies a regime that never occurs. The case $\lambda = 1$ is symmetric. Then $I_t = 1$ in every week, so β_3 cannot be separated from the intercept β_0. If $\beta_3 = 0$, the two mixture components coincide, and λ is not identified. In both cases a parameter is identified only under the alternative. The likelihood ratio then has no χ^2 limit (Davies, 1977), and Hansen (1992) develops bounds for Markov-switching models.

Porter's own test shows the problem at work. He maximizes the likelihood once with switching and once subject to $\Delta = 0$, which in (A.65) means $\beta_3 = 0$. Let $\bar{L}_1$ and $\bar{L}_0$ be the two maximized average log-likelihoods. He reports $2T(\bar{L}_1 - \bar{L}_0) = 554.1$, refers it to a χ^2_1 distribution, and rejects "the hypothesis that no switch occurred" (journal p. 312). Under $\Delta = 0$ the mixture density $\lambda h(y_t \mid 1) + (1-\lambda)h(y_t \mid 0)$ equals $h(y_t \mid 0)$ for every λ. The restricted likelihood is therefore flat in λ, and the unrestricted fit chooses λ and β_3 together. The statistic is the largest of a family of likelihood ratios indexed by λ. Its null distribution is stochastically larger than χ^2_1, and the χ^2_1 reference is invalid. The size of the statistic still settles the question in practice. The 0.1 percent cutoff of χ^2_1 is 10.83, and 554.1 is about fifty times larger, so the rejection very likely survives any valid correction. Porter also notes that $\hat{\beta}_3$ is significantly positive (journal p. 311). A t test of $\beta_3 = 0$ faces the same difficulty, because it is computed at an estimate $\hat{\lambda}$ that has no limit under the null.

A discontinuous likelihood is the third failure. Bresnahan (1987) solves the vertical model for equilibrium prices and quantities, adds independent normal errors to observed prices and quantities, and maximizes the resulting likelihood (Section 6.6.5). The likelihood jumps when two products swap positions in the quality ordering. The derivative-based expansion of Theorem A.27 is unavailable at the jumps. Estimation then relies on derivative-free search, and asymptotic theory requires the true parameter to lie away from the discontinuities.

A.6.8 Non-nested tests

Two models are *non-nested* when neither is a special case of the other. Collusion and Bertrand pricing with the same demand system are an example (Section 6.6.6). The likelihood ratio does not have a χ^2 distribution in this case, and its sign alone is uninformative. Two approaches are standard.

Let model F have density $f(y \mid x; \theta)$ and model G density $g(y \mid x; \gamma)$, with ML estimates $\hat{\theta}$ and $\hat{\gamma}$. Write the pointwise log-likelihood ratio as $d_i = \ln f(y_i \mid x_i; \hat{\theta}) - \ln g(y_i \mid x_i; \hat{\gamma})$ and $LR_n = \sum_i d_i$.

The test of Cox (1961, 1962) takes F as the null. If F is true with parameter θ, the estimator $\hat{\gamma}$ converges to a pseudo-true value $\gamma(\theta)$, and $\frac{1}{n} LR_n$ converges to $\mathbb{E}_\theta[\ln f(y \mid x; \theta) - \ln g(y \mid x; \gamma(\theta))]$. Cox's statistic centers LR_n by a consistent estimate of this expectation, computed under F at $\hat{\theta}$, and divides by an estimate of its standard deviation. Under F it is asymptotically standard normal. A large negative value says that G fits better than F would lead us to expect. The roles are then reversed. There are four possible outcomes: reject neither, reject one of the two, or reject both. Rejecting both is informative, because it says that neither model is adequate. Proposition 6.52 gives the statistic for nonlinear regressions with normal errors, and Table 6.4 reports Bresnahan's tests of conduct in the 1955 automobile market.

The test of Vuong (1989) treats the models symmetrically. It asks which model is closer to the truth in Kullback-Leibler divergence.

Proposition A.49 (Vuong's model selection test)**.** *Let θ^* and γ^* be the pseudo-true values of the two models. Suppose $\mathbb{P}\{f(y \mid x; \theta^*) \neq g(y \mid x; \gamma^*)\} > 0$, so that the models are strictly non-nested, and let $\hat{\omega}^2 = \frac{1}{n}\sum_i (d_i - \bar{d})^2$ with $\bar{d} = \frac{1}{n} LR_n$. Under $H_0 : \mathbb{E}[\ln f(y \mid x; \theta^*) - \ln g(y \mid x; \gamma^*)] = 0$ and standard regularity conditions,*

$$T_V = \frac{\sqrt{n}\,\bar{d}}{\hat{\omega}} \xrightarrow{d} N(0,1).$$

Proof sketch. Let $\bar{d}^* = \frac{1}{n}\sum_i [\ln f(y_i \mid x_i; \theta^*) - \ln g(y_i \mid x_i; \gamma^*)]$. Expand $\bar{d}$ around the pseudo-true values. The first-order term in θ is $\bar{s}^f_n(\theta^*)^\top(\hat{\theta} - \theta^*)$, where $\bar{s}^f_n$ is the average score of model

F. Its expectation at θ^* is zero because θ^* maximizes $\mathbb{E} \ln f$. So $\bar{s}_n^f(\theta^*) = O_p(n^{-\frac{1}{2}})$, and with $\hat{\theta} - \theta^* = O_p(n^{-\frac{1}{2}})$ the product is $O_p(n^{-1})$. The same holds for γ. Hence $\sqrt{n}\,\bar{d} = \sqrt{n}\,\bar{d}^* + o_p(1)$. Under H_0, $\bar{d}^*$ is an average of i.i.d. terms with mean zero and variance $\omega^2 > 0$, the latter by strict non-nestedness. The central limit theorem and $\hat{\omega} \xrightarrow{p} \omega$ finish the argument. □

A large positive T_V favors F, a large negative one favors G, and a value near zero says the data cannot tell the models apart. If the models overlap, so that $\omega^2 = 0$, the statistic has a different limit, and Vuong gives a separate procedure. Rivers and Vuong (2002) extend the test to general estimation criteria, including GMM, which makes it usable for comparing conduct models estimated from moment conditions.

A.6.9 Testing a parametric distribution

Parametric models of bids or values are convenient, but their shape restrictions drive the results. A specification test for the whole conditional distribution is then valuable. The Kolmogorov-Smirnov statistic $\sup_y \sqrt{n}|F_n(y) - F(y;\hat{\theta})|$ compares the empirical and fitted distribution functions. With estimated parameters its null distribution depends on the model, so tables computed for a known F are wrong, and the cutoff must be simulated.

Andrews (1997) extends the idea to a conditional distribution. Let $Z_i = (Y_i, X_i)$, with Y_i the endogenous outcomes and X_i the exogenous covariates, and let the model specify $F(y \mid x;\theta)$. Define the empirical distribution function of Z and a semiparametric estimate of it that uses the model for Y given X and the empirical distribution of X:

$$H_n(y,x) = \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}\{Y_i \le y, X_i \le x\}, \qquad F_n(y,x;\theta) = \frac{1}{n}\sum_{i=1}^{n} F(y \mid X_i;\theta)\mathbf{1}\{X_i \le x\}.$$

The *conditional Kolmogorov* statistic is $CK_n = \max_{j \le n} \sqrt{n}\,|H_n(Z_j) - F_n(Z_j;\hat{\theta})|$. Its null distribution is obtained by a parametric bootstrap.

1. Estimate $\hat{\theta}$ and compute CK_n.
2. For $b = 1, \dots, B$, draw $Y_i^* \sim F(\cdot \mid X_i;\hat{\theta})$ for each i, holding the covariates fixed. Re-estimate $\hat{\theta}^*$ on the simulated sample and compute CK_n^*.
3. Reject at level a if CK_n exceeds the $(1-a)$ quantile of $CK_n^{*1}, \dots, CK_n^{*B}$.

Re-estimating θ in each replication accounts for the fact that the fitted model is closer to the data than the true model would be.

Athey et al. (2011, journal p. 241) apply the test to their Gamma-Weibull model. The exogenous covariates are the sale characteristics (X, N) and the endogenous variables are the bids. They cannot reject the parametric specification even at the 20 percent level, in both the Northern and the California sales. Together with the close fit of the bid moments reported above, this supports using the fitted bid distributions to recover values and entry costs (Chapter 15).

A.7 Simulation-based estimation

The GMM and likelihood theory of Sections A.5 and A.6 assumes that we can evaluate the moment function or the density at any trial parameter. Many structural models in industrial

organization imply moments or likelihoods that are integrals with no closed form. The market share of a product in a random coefficients model integrates individual logit probabilities over the distribution of tastes (Chapter 8). The expected winning bid in a first-price auction is the expected second-highest value, an integral over the joint distribution of all bidders' values (Laffont et al., 1995). The expected profit of an entrant integrates over values, rivals and bids (Athey et al., 2011). A counterfactual auction outcome is an expectation over simulated auctions (Asker, 2010). This section shows how such integrals are replaced by averages over random draws and what the replacement does to the properties of the estimator. The answer depends on how the simulated integral enters the objective. When it enters linearly, as in a moment condition, simulation adds variance but no bias. When it enters through a nonlinear function, such as a logarithm, it adds bias that vanishes only as the number of draws grows.

Throughout the section θ is a generic parameter vector, n is the number of observations and n_s is the number of simulation draws per observation (the notation of Chapter 8). Several papers write S for n_s, and we translate their formulas.

A.7.1 Monte Carlo integration

Let ν be a random vector with known distribution F, which may depend on θ only through a known transformation of standardized draws. The target is an expectation

$$\phi(\theta) = \mathbb{E}_\nu\big[q(\nu;\theta)\big] = \int q(\nu;\theta)\,\mathrm{d}F(\nu), \tag{A.73}$$

for a function q that we can evaluate at any (ν,θ). The *Monte Carlo simulator* of $\phi(\theta)$ averages q over n_s independent draws $\nu_1,\dots,\nu_{n_s}$ from F:

$$\tilde{\phi}(\theta) = \frac{1}{n_s}\sum_{r=1}^{n_s} q(\nu_r;\theta). \tag{A.74}$$

Proposition A.50 (Monte Carlo integration)**.** *Suppose $\sigma_q^2(\theta) = \mathrm{Var}_\nu(q(\nu;\theta))$ is finite. Then*

(i) $\mathbb{E}[\tilde{\phi}(\theta)] = \phi(\theta)$*, so the simulator is unbiased.*

(ii) $\mathrm{Var}(\tilde{\phi}(\theta)) = \frac{\sigma_q^2(\theta)}{n_s}$.

(iii) $\sqrt{n_s}\,(\tilde{\phi}(\theta) - \phi(\theta)) \xrightarrow{d} N(0,\sigma_q^2(\theta))$ *as* $n_s \to \infty$.

The simulation error is $O_p(n_s^{-\frac{1}{2}})$ whatever the dimension of ν.

Proof. The draws are independent and identically distributed, so each term of (A.74) has mean $\phi(\theta)$ and variance $\sigma_q^2(\theta)$. Linearity of expectation gives (i). Independence gives

$$\mathrm{Var}\big(\tilde{\phi}(\theta)\big) = \frac{1}{n_s^2}\sum_{r=1}^{n_s}\mathrm{Var}\big(q(\nu_r;\theta)\big) = \frac{n_s\,\sigma_q^2(\theta)}{n_s^2} = \frac{\sigma_q^2(\theta)}{n_s}.$$

Part (iii) is the Lindeberg-Lévy central limit theorem. The dimension of ν enters only through σ_q^2, which proves the last claim. □

The last statement explains why simulation dominates deterministic rules in high dimensions. A product quadrature rule with m nodes per dimension needs m^d function evaluations in

d dimensions, while the accuracy of (A.74) depends on n_s alone. Quadrature and quasi-Monte Carlo sequences can be far more accurate in one to three dimensions, and Section 8.3.5 compares them for market shares.

Uses in the book. Four kinds of integrals recur. First, the random coefficients share $s_{jt} = \int s_{ijt}\,\mathrm{d}F(\nu_i)$ is simulated by averaging individual logit probabilities over draws of tastes (Section 8.3). Second, Laffont et al. (1995) simulate the expected winning bid of a first-price auction (Section A.7.4). Third, Athey et al. (2011, p. 245) compute the expected profit of a logger or a mill in a sealed-bid timber sale by simulation. They simulate 5,000 auctions for each plausible number of entering loggers and mills, up to 8 mills and 25 loggers. Fourth, Asker (2010) computes damages and efficiency losses from 100,000 auctions simulated from estimated value distributions (Section 13.8).

Smooth and frequency simulators. When q is an indicator, for example the indicator that a simulated consumer chooses product j, the simulator (A.74) is a *frequency simulator*. It is a step function of θ and can equal zero. When part of the integral has a closed form, we can integrate it analytically and simulate only the rest. In logit models the extreme value shocks are integrated exactly, and q becomes a choice probability. The result is a *smooth simulator*. It is differentiable in θ, strictly positive, and has smaller variance because conditioning removes the variance of the integrated part (Lemma 8.12).

Common random numbers. An estimator that uses simulated integrals evaluates them at many trial values of θ. The draws must be taken once, before estimation, and held fixed across all evaluations. With fresh draws at each evaluation the objective function becomes a different random function every time it is computed. It is then discontinuous in θ, and a numerical optimizer never converges. With fixed draws the simulated objective is a deterministic and smooth function of θ, so the draws can be treated as part of the data. The asymptotic theory below takes this view. The practical rule "take the draws only once" is therefore part of the definition of the estimator.

Importance sampling. Draws from F can be wasteful when q is large only on a small region of the support. *Importance sampling* draws from another density g and reweights. Let f be the density of ν and write

$$\phi = \int q(\nu)\, f(\nu)\,\mathrm{d}\nu = \int q(\nu)\,\frac{f(\nu)}{g(\nu)}\, g(\nu)\,\mathrm{d}\nu = \mathbb{E}_g\!\left[q(\nu)\,\frac{f(\nu)}{g(\nu)}\right].$$

The ratio $w(\nu) = \frac{f(\nu)}{g(\nu)}$ is the *importance weight*, and the importance sampling simulator is

$$\tilde{\phi}_g = \frac{1}{n_s}\sum_{r=1}^{n_s} q(\nu_r)\, w(\nu_r), \qquad \nu_r \overset{\text{i.i.d.}}{\sim} g. \tag{A.75}$$

Lemma A.51 (Importance sampling)**.** *Suppose $g(\nu) > 0$ wherever $q(\nu)f(\nu) \neq 0$. Then*

(i) $\mathbb{E}_g[\tilde{\phi}_g] = \phi$.

(ii) $\mathrm{Var}_g(\tilde{\phi}_g) = \frac{1}{n_s}\left[\int \frac{q(\nu)^2 f(\nu)^2}{g(\nu)}\,\mathrm{d}\nu - \phi^2\right]$.

(iii) The variance is minimized by $g^*(\nu) = \frac{|q(\nu)|f(\nu)}{\int |q(u)|f(u)\,\mathrm{d}u}$. If $q \geq 0$, the minimum variance is zero.

Proof. Part (i) is the change of measure displayed above. For (ii), each term has second moment

$$\mathbb{E}_g\left[q(\nu)^2 w(\nu)^2\right] = \int q(\nu)^2 \frac{f(\nu)^2}{g(\nu)^2}\, g(\nu)\, \mathrm{d}\nu = \int \frac{q(\nu)^2 f(\nu)^2}{g(\nu)}\, \mathrm{d}\nu,$$

and its mean is ϕ. Subtracting ϕ^2 and dividing by n_s gives (ii). For (iii), only the integral in (ii) depends on g. The Cauchy-Schwarz inequality gives

$$\left(\int |q| f \, \mathrm{d}\nu\right)^2 = \left(\int \frac{|q| f}{\sqrt{g}} \sqrt{g}\, \mathrm{d}\nu\right)^2 \le \int \frac{q^2 f^2}{g}\, \mathrm{d}\nu \cdot \int g \, \mathrm{d}\nu = \int \frac{q^2 f^2}{g}\, \mathrm{d}\nu,$$

with equality when $\frac{|q| f}{\sqrt{g}}$ is proportional to $\sqrt{g}$, that is, when $g \propto |q| f$. If $q \ge 0$, the bound equals ϕ^2 and the variance in (ii) is zero. □

The optimal density g^* is infeasible because its normalizing constant is ϕ itself. The lemma still guides practice. A good importance density is close to proportional to $|q| f$, and its tails must not be thinner than those of $|q| f$. If they are, the integral in (ii) diverges and a few draws with huge weights dominate the average. Importance sampling has a second advantage in estimation. If θ enters only through the weight $\frac{f(\nu;\theta)}{g(\nu)}$ and the draws come from a fixed g, then the simulator is as smooth in θ as f.

Three applications in the book use it. Laffont et al. (1995, pp. 960–961, 969) draw values from a log-normal importance density centered at a preliminary estimate, and θ appears only in the density ratio (Section A.7.4). Gentzkow (2007, p. 732, n. 31) draws each consumer's random effects from their distribution conditional on the observed choices, computed at a preliminary estimate. That density is the posterior of ν given the data, the analogue of $g^* \propto q f$ for a likelihood contribution. Berry et al. (1995, Section 6.3) over-sample households likely to buy a new car, since most households buy none in a given year (Section 8.3.4).

Remark A.52 (Sampling error versus simulation error). Simulation error comes from the econometrician's draws and can be made small by raising n_s. Sampling error in the data cannot. If an observed market share is the fraction of M sampled consumers who buy a product, its sampling standard deviation is about $\sqrt{\frac{s(1-s)}{M}}$. In airline ticket samples with fewer than ten sampled passengers per product, this error is large and is not removed by any number of simulation draws (Section 9.7.5). Section 8.5.7 shows how Berry et al. (1995) separate the two sources in the asymptotic variance.

A.7.2 The method of simulated moments

The *method of simulated moments* (MSM) of McFadden (1989) and Pakes and Pollard (1989) replaces an intractable conditional mean in a moment condition by an unbiased simulator. We state the leading case, a conditional mean restriction. The data $w_i = (y_i, x_i)$ are independent across i, and

$$\mathbb{E}[y_i \mid x_i] = m(x_i; \theta_0), \qquad m(x;\theta) = \int q(x, \nu; \theta)\, \mathrm{d}F(\nu). \tag{A.76}$$

For example, y_i may be a vector of choice indicators and q the vector of logit probabilities given tastes ν. Let $z_i = z(x_i)$ be an $L \times \dim(y)$ matrix of instruments, functions of x_i. For each observation we draw $\nu_{i1}, \ldots, \nu_{in_s}$ from F, independently across i and of the data, and form

$$\tilde{m}_i(\theta) = \frac{1}{n_s} \sum_{r=1}^{n_s} q(x_i, \nu_{ir}; \theta), \qquad \tilde{g}_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} z_i \big(y_i - \tilde{m}_i(\theta)\big). \tag{A.77}$$

The MSM estimator minimizes $\tilde{g}_n(\theta)^\top W_n \tilde{g}_n(\theta)$. Write $e_i = y_i - m(x_i;\theta_0)$ for the structural error and $\eta_i = \tilde{m}_i(\theta_0) - m(x_i;\theta_0)$ for the simulation error. Define

$$\Sigma_y(x) = \operatorname{Var}(y \mid x), \qquad V(x) = \operatorname{Var}_\nu\big(q(x,\nu;\theta_0)\big), \qquad G = -\mathbb{E}\Big[z_i \frac{\partial m(x_i;\theta_0)}{\partial \theta^\top}\Big].$$

Proposition A.53 (Method of simulated moments)**.** *Assume the conditions of Theorem A.31 for the GMM estimator with exact moments, with q continuously differentiable in θ and dominated by an integrable function. Let n_s be fixed and $W_n \xrightarrow{p} W$.*

(i) The MSM estimator is consistent as $n \to \infty$.

(ii) $\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N\big(0, (G^\top W G)^{-1} G^\top W \big[S + \frac{1}{n_s} S_{sim}\big] W G (G^\top W G)^{-1}\big)$, where $S = \mathbb{E}[z_i \Sigma_y(x_i) z_i^\top]$ and $S_{sim} = \mathbb{E}[z_i V(x_i) z_i^\top]$.

(iii) If $V(x) \le \Sigma_y(x)$ for all x in the positive semidefinite order, the asymptotic variance is at most $(1 + \frac{1}{n_s})$ times that of GMM with exact moments and the same W. The bound holds with equality for a frequency simulator of choice indicators.

Proof. For (i), the summands of $\tilde{g}_n(\theta)$ are independent across i because the draws are. The simulator is unbiased and the draws are independent of y_i, so $\mathbb{E}[\tilde{m}_i(\theta) \mid x_i, y_i] = m(x_i;\theta)$. Hence

$$\mathbb{E}\big[z_i(y_i - \tilde{m}_i(\theta))\big] = \mathbb{E}\big[z_i(y_i - m(x_i;\theta))\big] = \mathbb{E}\big[z_i\big(m(x_i;\theta_0) - m(x_i;\theta)\big)\big].$$

The population moment of the simulated estimator is the population moment of exact GMM. It is zero only at θ_0 by the identification condition. A uniform law of large numbers applies under the dominance condition, and Theorem A.24 gives consistency.

For (ii), evaluate the simulated moment at θ_0:

$$\tilde{g}_n(\theta_0) = \frac{1}{n}\sum_{i=1}^n z_i\big[(y_i - m(x_i;\theta_0)) - (\tilde{m}_i(\theta_0) - m(x_i;\theta_0))\big] = \frac{1}{n}\sum_{i=1}^n z_i(e_i - \eta_i).$$

The summands are independent with mean zero. Conditional on (x_i, y_i), η_i has mean zero and variance $\frac{1}{n_s} V(x_i)$ by Proposition A.50. The cross term vanishes:

$$\mathbb{E}\big[z_i e_i \eta_i^\top z_i^\top\big] = \mathbb{E}\big[z_i e_i\, \mathbb{E}[\eta_i \mid x_i, y_i]^\top z_i^\top\big] = 0.$$

Hence

$$\operatorname{Var}\big(z_i(e_i - \eta_i)\big) = \mathbb{E}[z_i e_i e_i^\top z_i^\top] + \mathbb{E}[z_i \eta_i \eta_i^\top z_i^\top] = S + \frac{1}{n_s} S_{\text{sim}},$$

and the central limit theorem gives $\sqrt{n}\,\tilde{g}_n(\theta_0) \xrightarrow{d} N(0, S + \frac{1}{n_s} S_{\text{sim}})$. The simulated Jacobian $\frac{\partial \tilde{g}_n}{\partial \theta^\top}$ converges uniformly to G by the same unbiasedness argument applied to $\frac{\partial q}{\partial \theta}$. The mean value expansion in the proof of Theorem A.31 then applies unchanged.

For (iii), write

$$S + \frac{1}{n_s} S_{\text{sim}} = \Big(1 + \frac{1}{n_s}\Big) S - \frac{1}{n_s}\mathbb{E}\big[z_i(\Sigma_y(x_i) - V(x_i)) z_i^\top\big].$$

The last expectation is positive semidefinite when $\Sigma_y \ge V$. Pre- and post-multiplying by $(G^\top W G)^{-1} G^\top W$ and its transpose preserves the order. For a frequency simulator of a choice indicator, q is itself an indicator with $\operatorname{Var}_\nu(q \mid x) = \Sigma_y(x)$, so $V = \Sigma_y$. □

The condition $V \le \Sigma_y$ holds for the smooth logit simulator. The smooth simulator is the conditional expectation of the frequency simulator given the taste draw, so its variance is smaller by the law of total variance (Lemma 8.12). The factor $(1 + \frac{1}{n_s})$ is therefore an upper bound on the price of simulation. With 10 draws per observation it is a 10 percent increase in variance, about 5 percent in standard errors.

Two departures from the setting of the proposition are common in industrial organization. First, in market-level demand estimation the draws are shared by all products in a market, and the number of markets or products drives the asymptotics. The simulation error then adds a separate term to the variance of the moments, V_3 in Berry et al. (1995). Their correction raised the reported standard errors by about 5 to 20 percent, and one standard error doubled (p. 859, see Section 8.5.7). Second, the simulated integral often enters nonlinearly. The BLP inversion uses the logarithm of simulated shares, and $\mathbb{E}[\ln \tilde{s}] < \ln s$ by Jensen's inequality. The bias is of order $\frac{1}{n_s}$ and does not average out across markets (Proposition 8.13). Consistency then requires n_s to grow with the sample, exactly as for simulated maximum likelihood below.

MSM has two practical costs. Efficient MSM requires the optimal instruments of Section A.5.5, which depend on the unknown parameters and are computed from a preliminary estimate. When that estimate is poor, efficiency can be poor as well (Gourieroux and Monfort, 1996, pp. 43–44). In addition, moments for discrete outcomes require the simulated probability of every possible outcome, which is expensive when the outcome space is large. Both points led Gentzkow (2007, p. 732) to prefer simulated maximum likelihood.

A.7.3 Simulated maximum likelihood

Let the density of y_i given x_i be a mixture over unobserved heterogeneity,

$$f(y_i \mid x_i; \theta) = \int f(y_i \mid x_i, \nu; \theta)\, \mathrm{d}F(\nu).$$

Simulated maximum likelihood (SML), introduced by Lerman and Manski (1981), maximizes $\sum_i \ln \tilde{f}_i(\theta)$ with

$$\tilde{f}_i(\theta) = \frac{1}{n_s} \sum_{r=1}^{n_s} f_{ir}(\theta), \qquad f_{ir}(\theta) = f(y_i \mid x_i, \nu_{ir}; \theta). \tag{A.78}$$

The simulator $\tilde{f}_i$ is unbiased for $f_i = f(y_i \mid x_i; \theta)$, but it enters through the logarithm.

Proposition A.54 (Bias of simulated maximum likelihood)**.** *Let $v_i(\theta) = \mathrm{Var}_\nu(f(y_i \mid x_i, \nu; \theta))$, so that $\mathrm{Var}(\tilde{f}_i \mid x_i, y_i) = \frac{v_i}{n_s}$. Suppose $f(y_i \mid x_i, \nu; \theta)$ is bounded below by a positive constant.*

(i) $\mathbb{E}\big[\ln \tilde{f}_i \mid x_i, y_i\big] = \ln f_i - \frac{1}{2}\frac{v_i}{n_s f_i^2} + O(n_s^{-\frac{3}{2}})$.

(ii) For fixed n_s, the SML estimator converges in probability to the maximizer θ_{n_s} of $\mathbb{E}[\ln \tilde{f}_i(\theta)]$. With $D(\theta) = \mathbb{E}\big[\frac{v_i(\theta)}{2 f_i(\theta)^2}\big]$ and H the expected Hessian of the log-likelihood at θ_0, $\theta_{n_s} - \theta_0 = \frac{1}{n_s} H^{-1} \nabla D(\theta_0) + o(\frac{1}{n_s})$. SML is inconsistent for fixed n_s.

(iii) If $n_s \to \infty$ and $\frac{\sqrt{n}}{n_s} \to 0$, then $\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, \mathcal{I}^{-1})$, the limit of exact maximum likelihood.

Proof. For (i), expand $\ln \tilde{f}_i$ around f_i to third order with the Lagrange remainder:

$$\ln \tilde{f}_i = \ln f_i + \frac{\tilde{f}_i - f_i}{f_i} - \frac{(\tilde{f}_i - f_i)^2}{2 f_i^2} + \frac{(\tilde{f}_i - f_i)^3}{3 \bar{f}_i^3},$$

where $\bar{f}_i$ lies between $\tilde{f}_i$ and f_i and is bounded below by assumption. The linear term has conditional mean zero. The quadratic term has conditional mean $-\frac{v_i}{2n_s f_i^2}$. The expected absolute cube of the deviation of an average of n_s bounded independent terms from its mean is $O(n_s^{-\frac{3}{2}})$, which bounds the remainder. The argument is the one in the proof of Proposition 8.13.

For (ii), the simulated log-likelihood is an average of independent terms whose expectation is, by (i), $\mathbb{E}[\ln f_i(\theta)] - \frac{1}{n_s} D(\theta) + O(n_s^{-\frac{3}{2}})$. The extremum estimator converges to the maximizer of this limit (Theorem A.24). The first-order condition at θ_{n_s} reads $\nabla Q(\theta_{n_s}) - \frac{1}{n_s}\nabla D(\theta_{n_s}) = 0$, with $Q(\theta) = \mathbb{E}[\ln f_i(\theta)]$. A first-order expansion of ∇Q around θ_0, where $\nabla Q(\theta_0) = 0$, gives

$$H(\theta_{n_s} - \theta_0) = \frac{1}{n_s}\nabla D(\theta_0) + o\Big(\frac{1}{n_s}\Big), \qquad \theta_{n_s} - \theta_0 = \frac{1}{n_s} H^{-1}\nabla D(\theta_0) + o\Big(\frac{1}{n_s}\Big).$$

The gradient $\nabla D(\theta_0)$ is not zero in general, so $\theta_{n_s} \neq \theta_0$.

For (iii) we sketch the argument of Lee (1992) and Gourieroux and Monfort (1996). Decompose

$$\sqrt{n}(\hat{\theta} - \theta_0) = \sqrt{n}(\hat{\theta} - \theta_{n_s}) + \sqrt{n}(\theta_{n_s} - \theta_0).$$

By (ii) the second term is of order $\frac{\sqrt{n}}{n_s}$, which vanishes by assumption. The first term behaves like the maximum likelihood estimator, plus a simulation variance of order $\frac{1}{n_s}$ that also vanishes. □

The proposition contrasts with Proposition A.53. MSM is consistent with a single draw per observation. SML is inconsistent for fixed n_s by (ii), and under standard uniform regularity it is consistent when $n_s \to \infty$ with n. Growth faster than $\sqrt{n}$ is the stronger condition of (iii). It removes the simulation bias at the $\sqrt{n}$ scale, so that SML attains the exact maximum likelihood limit. SML is nonetheless popular because it requires no instruments, is efficient in the limit, and needs only the probability of the observed outcome.

Bias correction. Part (i) suggests removing the leading bias term. The sample variance of the n_s terms in (A.78), divided by n_s, is unbiased for $\mathrm{Var}(\tilde{f}_i)$:

$$\hat{V}_i = \frac{1}{n_s(n_s - 1)} \sum_{r=1}^{n_s} \big(f_{ir} - \tilde{f}_i\big)^2, \qquad \mathbb{E}\big[\hat{V}_i \mid x_i, y_i\big] = \frac{v_i}{n_s}.$$

The *bias-corrected* SML estimator maximizes $\sum_i \big[\ln \tilde{f}_i + \frac{\hat{V}_i}{2\tilde{f}_i^2}\big]$ (Gourieroux and Monfort, 1996, p. 45). Because $\hat{V}_i = O_p(\frac{1}{n_s})$ and $\tilde{f}_i = f_i + O_p(n_s^{-\frac{1}{2}})$, the expectation of the correction equals $\frac{v_i}{2n_s f_i^2}$ up to $O(n_s^{-\frac{3}{2}})$. The correction therefore removes the term of order $\frac{1}{n_s}$, and the remaining bias is of smaller order.

Evidence from a simulation. Figure A.6 compares the estimators in a design where the integral is one-dimensional, so that exact maximum likelihood can be computed by quadrature. Each of $N = 1{,}000$ individuals makes $T = 5$ binary choices with utility $b_0 + \beta_i x_{it} + \epsilon_{it}$, logistic ϵ_{it}, and a random coefficient $\beta_i \sim N(b_1, \sigma^2)$ that is constant across the individual's choices. The true values are $b_0 = -0.5$ and $b_1 = \sigma = 1$. The likelihood of individual i integrates the product of five logit probabilities over β_i, as in the partial panel of Gentzkow (2007). The MSM estimator uses three moments per individual. They match the choice frequency, its covariance with x_{it}, and the frequency of repeated choices across pairs of occasions weighted by $x_{it}x_{is}$. The last moment identifies σ, because a common β_i makes choices persistent.

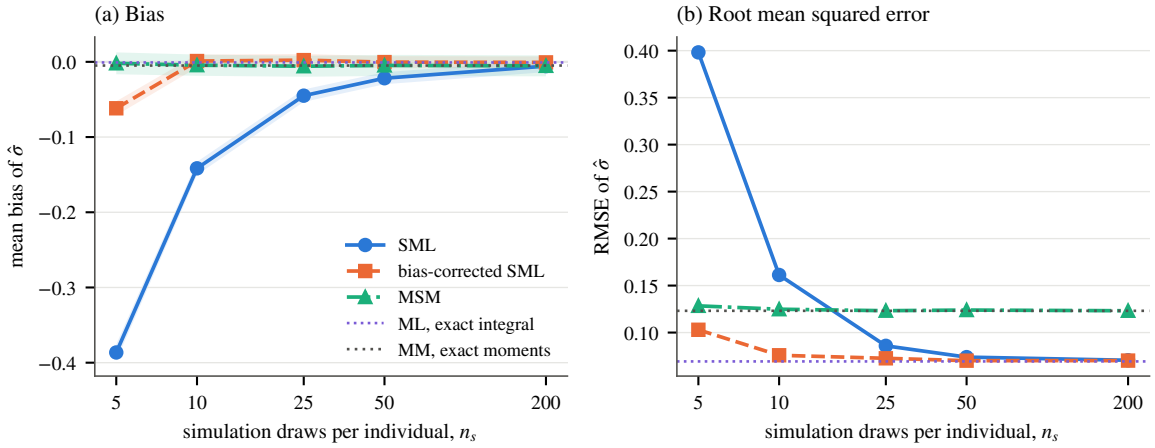

Figure A.6: Simulation estimators of the standard deviation σ of a random coefficient. Panel (a) shows the mean bias of $\hat{\sigma}$ and panel (b) its root mean squared error, against the number of draws per individual. The design is a panel binary logit with $N = 1{,}000$ individuals, $T = 5$ choices each, $x_{it} \sim N(0.5, 1)$, $b_0 = -0.5$, $b_1 = 1$, $\sigma = 1$. SML uses (A.78), bias-corrected SML adds $\frac{\hat{V}_i}{2\tilde{f}_i^2}$, and MSM solves three simulated moment equations. The horizontal lines are maximum likelihood and the exact-moment estimator computed with 40-point Gauss-Hermite quadrature. Shaded bands are ±1.96 Monte Carlo standard errors. 300 replications, seed 20261022.

The results match the theory. With $n_s = 5$ draws, SML underestimates $\sigma = 1$ by 0.386 on average, and the bias falls to 0.142, 0.045, 0.022 and 0.006 at 10, 25, 50 and 200 draws. From 25 draws on, n_s times the bias is roughly constant, as the $\frac{1}{n_s}$ rate predicts. The bias pulls $\hat{\sigma}$ down because a smaller σ makes the individual likelihood terms less variable across draws, which raises $\mathbb{E}[\ln \tilde{f}_i]$ in part (i) of the proposition. The bias spills over to the mean coefficient b_1, which is too small by 0.161 at five draws. The corrected estimator cuts the bias in $\hat{\sigma}$ to 0.062 at five draws and to less than 0.003 from ten draws on. MSM is consistent at every fixed n_s, as Proposition A.53 predicts, and its Monte Carlo bias is small at every n_s in the table. Its standard deviation at five draws is 0.129, against 0.123 with exact moments. The ratio of 1.04 is below the bound $\sqrt{1 + \frac{1}{5}} = 1.10$ because the logit simulator is smooth. MSM's root mean squared error of about 0.12 exceeds that of maximum likelihood (0.069) at every n_s. Three just-identifying moments use the information in the data less efficiently than the likelihood. SML overtakes MSM between 10 and 25 draws, and the corrected version does so already at five.

A worked case: Gentzkow (2007). Gentzkow (2007) estimates a demand system for print and online newspapers in Washington, DC, from survey reports of reading over the last day and the last five weekdays (Section 10.10). The likelihood of a respondent's report integrates a product of daily logit probabilities over a three-dimensional normal vector of random effects (his eq. 6). He uses SML with 300 draws per consumer and the first-order bias correction of Gourieroux and Monfort (1996, p. 45). His footnote 32 derives the correction by the expansion in Proposition A.54(i) (p. 732). The draws come from the importance density of Lemma A.51. For each consumer he computes the probability of the observed report once, at a preliminary estimate and with 200 draws. He then draws the random effects from their distribution conditional on the report, by acceptance and rejection, and reweights (p. 732, n. 31 and eqs. 13–14). Standard errors use the robust formula of McFadden and Train (2000). Standard

errors of welfare statistics come from 100 draws from the estimated asymptotic distribution of the parameters (p. 733), a method we discuss in Section A.7.6. He chose SML over MSM for the reasons given above. In preliminary tests the two gave similar parameters, and MSM took 10 to 20 times longer to compute (p. 732). The sample has 16,179 respondents (Table 5), large enough that the correction for $n_s = 300$ matters little, as in Figure A.6. Section 10.10.7 gives the full estimator.

A.7.4 Simulated nonlinear least squares

Laffont et al. (1995) faced an integral inside a regression function. In a first-price or descending auction with independent private values, the equilibrium bid function has no closed form for most value distributions. The support of the winning bid also depends on the parameters. Maximum likelihood is then both non-regular and computationally heavy, since the bid function must be inverted for every observation and every trial parameter (p. 958, see Proposition A.47). They proposed a least-squares estimator based on a simulated conditional mean that is consistent for a fixed number of draws.

The naive estimator and its limit. Index auctions by $l = 1, \dots, n$ (their L), and let b_l^w be the winning bid, with $b_l^w = p_l^o$ when the object is unsold and p_l^o the reserve price. Let x_l collect the reserve price and the auction characteristics, and let $m_l(\theta) = \mathbb{E}[b_l^w \mid x_l]$. Nonlinear least squares would minimize $\frac{1}{n}\sum_l (b_l^w - m_l(\theta))^2$. Suppose $\bar{X}_l(\theta) = \frac{1}{n_s}\sum_{s=1}^{n_s} X_{sl}(\theta)$ is an unbiased simulator of $m_l(\theta)$, with draws independent of b_l^w given x_l. The naive estimator minimizes (their eq. 8)

$$Q_n^{\text{naive}}(\theta) = \frac{1}{n}\sum_{l=1}^{n}\big(b_l^w - \bar{X}_l(\theta)\big)^2. \tag{A.79}$$

To find its limit, write $b_l^w - \bar{X}_l(\theta) = (b_l^w - m_l(\theta_0)) + (m_l(\theta_0) - m_l(\theta)) + (m_l(\theta) - \bar{X}_l(\theta))$. Given x_l, the first and third terms have mean zero and are independent of each other, and the second is fixed. All cross products therefore have conditional mean zero, and

$$\mathbb{E}\big[(b_l^w - \bar{X}_l(\theta))^2 \mid x_l\big] = \sigma_0^2(x_l) + \big(m_l(\theta_0) - m_l(\theta)\big)^2 + \frac{1}{n_s}\,\omega_l(\theta), \tag{A.80}$$

where $\sigma_0^2(x_l) = \mathrm{Var}(b_l^w \mid x_l)$ and $\omega_l(\theta) = \mathrm{Var}(X_{sl}(\theta) \mid x_l)$. The first term does not depend on θ, and the second is minimized at θ_0. The third term is the average simulator variance, $A_L(\theta)$ in their eq. (9). It depends on θ, so the naive estimator converges to a value that trades fit for a smaller simulator variance. It is inconsistent for any fixed n_s.

The corrected estimator. The sample variance of the draws, divided by n_s, is unbiased for $\frac{1}{n_s}\omega_l(\theta)$. Subtracting it gives the simulated nonlinear least squares (SNLLS) objective (their eqs. 10–11):

$$Q_n^*(\theta) = \frac{1}{n}\sum_{l=1}^{n}\Big[\big(b_l^w - \bar{X}_l(\theta)\big)^2 - \frac{1}{n_s(n_s-1)}\sum_{s=1}^{n_s}\big(X_{sl}(\theta) - \bar{X}_l(\theta)\big)^2\Big]. \tag{A.81}$$

By (A.80), each bracket has conditional mean $\sigma_0^2(x_l) + (m_l(\theta_0) - m_l(\theta))^2$, the limit of exact nonlinear least squares. The estimator is consistent for any fixed n_s as $n \to \infty$ (their Proposition 1), and $Q_n^*(\hat{\theta})$ consistently estimates the mean squared error of the model.

Its asymptotic variance shows the price of simulation (their Proposition 2). Let $\mu_l = \frac{\partial m_l(\theta_0)}{\partial \theta}$, let $Y_{sl}(\theta) = \frac{\partial X_{sl}(\theta)}{\partial \theta}$, and let ω_l, Ω_l and C_l be the conditional variances of $X_{sl}(\theta_0)$ and $Y_{sl}(\theta_0)$ and

their covariance. Then $\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, \mathcal{H}^{-1}\mathcal{J}\mathcal{H}^{-1})$ with $\mathcal{H} = \mathbb{E}[\mu_l \mu_l^\top]$ and

$$\mathcal{J} = \mathbb{E}\Big[\sigma_0^2(x_l)\mu_l\mu_l^\top + \frac{1}{n_s}\big(\sigma_0^2(x_l)\Omega_l + \omega_l\mu_l\mu_l^\top\big) + \frac{1}{n_s(n_s-1)}\big(\omega_l\Omega_l + C_l C_l^\top\big)\Big]. \tag{A.82}$$

The first term alone gives the variance of exact nonlinear least squares. The excess is of order $\frac{1}{n_s}$ and disappears as $n_s \to \infty$. Their Proposition 3 gives a heteroskedasticity-robust estimator of $\mathcal{H}^{-1}\mathcal{J}\mathcal{H}^{-1}$ that is also consistent for fixed n_s.

The simulator: revenue equivalence. The construction of X_{sl} uses auction theory. Let N bidders (their I) have independent values from $F_l(\cdot;\theta)$ with density f_l, and let $v_{(N)}$ and $v_{(N-1)}$ be the highest and second-highest values. For a value $v \geq p^o$, the first-price equilibrium bid equals the expected payment of the winner in a second-price auction (their Lemma, eq. 12):

$$e(v) = \mathbb{E}\big[\max(v_{(N-1)}, p^o) \mid v_{(N)} = v\big].$$

The winning bid is $e(v_{(N)})$ when the object sells, and the convention $b^w = p^o$ covers the unsold case. Taking expectations over $v_{(N)}$ with the law of iterated expectations gives (their eq. 14)

$$m_l(\theta) = \mathbb{E}\big[\max(v_{(N-1)l}, p_l^o)\big] = \int\cdots\int \max\big(u_{(N-1)}, p_l^o\big)\prod_{i=1}^{N} f_l(u_i;\theta)\,\mathrm{d}u_1\cdots\mathrm{d}u_N.$$

This is the revenue equivalence theorem at work: the expected winning bid equals the expected second-highest value, truncated at the reserve price (Chapter 14). The integrand needs no bid function. With importance densities g_l and draws $u_{1l}^s, \ldots, u_{Nl}^s$ from g_l, the simulator is (their eq. 17)

$$X_{sl}(\theta) = \max\big(u_{(N-1)l}^s, p_l^o\big)\prod_{i=1}^{N}\frac{f_l(u_{il}^s;\theta)}{g_l(u_{il}^s)}.$$

The parameter appears only in the density ratio outside the maximum, so Q_n^* is twice continuously differentiable when f_l is. Simulating with draws from $F_l(\cdot;\theta)$ would instead put θ inside the maximum. With draws $F_l^{-1}(U_{il}^s;\theta)$ from fixed uniforms U_{il}^s, the maximum is continuous in θ but kinked where the reserve starts to bind. A frequency simulator built from indicators of simulated events would be a step function of θ. Neither would make Q_n^* twice continuously differentiable.

The application. The data are 81 descending auctions of greenhouse eggplants in Marmande, France, in the summer of 1990, each selling a single case (p. 967). Values are log-normal, with the mean of log values linear in six auction characteristics and the standard deviation fixed at 0.05 from retail price dispersion (pp. 968–969). The estimates use 20 draws per auction, and 30 draws gave analogous results (p. 969, n. 19). The number of bidders is treated as an unknown integer. The criterion is minimized over N from 11, the number of regular buyers, to 23, and the minimum is at $N = 18$ (p. 970). This suggests that one large buyer acts for about eight retailers. The fit gives an R^2 of 0.895 (p. 971). Chapter 15 discusses the estimates.

A.7.5 Indirect inference

Indirect inference (Gourieroux et al., 1993; Smith, 1993) fits a simple auxiliary model to the real data and to data simulated from the structural model. It chooses θ so that the two fits agree. Let $\hat{\beta}$ be an auxiliary estimator, such as OLS coefficients or the parameters of a reduced-form

logit, computed on the data. For a trial θ, simulate H data sets of the same size from the structural model with fixed draws, compute $\tilde{\beta}_h(\theta)$ on each, and average them into $\bar{\beta}(\theta)$. The estimator is

$$\hat{\theta} = \arg\min_{\theta} \big(\hat{\beta} - \bar{\beta}(\theta)\big)^{\top} W \big(\hat{\beta} - \bar{\beta}(\theta)\big).$$

The probability limit of $\tilde{\beta}_h(\theta)$ is the *binding function* $b(\theta)$, and identification requires b to be one to one near θ_0. The auxiliary model need not be correctly specified. If $\sqrt{n}(\hat{\beta} - b(\theta_0))$ has asymptotic variance Λ, the H independent simulated estimates have the same variance each, so the average has variance $\frac{\Lambda}{H}$. The estimator therefore behaves like a minimum-distance estimator with variance inflated by the factor $(1 + \frac{1}{H})$, the analogue of Proposition A.53. MSM is the special case in which the auxiliary statistics are sample moments.

A.7.6 Inference on functions of estimated parameters

Many reported quantities are nonlinear functions $a(\theta)$ that are themselves computed by simulation: median margins, welfare changes, predicted auction outcomes. The delta method of Section A.9.1 needs the derivative of a, which may be costly or unstable. Krinsky and Robb (1986) proposed a simulation alternative.

Remark A.55 (Drawing from the estimated asymptotic distribution). Given $\hat{\theta}$ and an estimate $\hat{V}$ of its variance:

(1) Draw $\theta^{(1)}, \ldots, \theta^{(R)}$ independently from $N(\hat{\theta}, \hat{V})$.

(2) Compute $a(\theta^{(r)})$ for each draw, solving any equilibrium or simulation problem that a requires.

(3) Report the standard deviation of the $a(\theta^{(r)})$, or their 2.5 and 97.5 percentiles as a 95 percent interval.

The method is common in the book's applications. Nevo (2001, Table VIII, note) computes 95 percent intervals for median margins from 1,500 draws (Section 8.13). Gentzkow (2007, p. 733) uses 100 draws for welfare statistics. Athey et al. (2011, p. 248) call their version a parametric bootstrap. They resample from the asymptotic distribution of the bid and entry parameters and recompute the expected auction outcomes for each draw.

The method rests on the same approximation as the delta method, the normality of $\hat{\theta}$. It retains the nonlinearity of a, which helps when a is far from linear over the likely range of θ. It does not correct a poor normal approximation for $\hat{\theta}$ itself, and it does not resample the data. Section A.9.4 compares it with bootstraps that re-estimate the model.

A.8 Standard errors under dependence

The variance formulas of Sections A.2 and A.5 assume independent observations. Industrial organization data rarely satisfy that assumption. Prices of the same product are observed in many cities, products in the same market share demand shocks, and a state's prices are observed every year. This section derives the cost of ignoring such dependence and the estimators that allow for it.

A.8.1 One formula for all robust variances

Consider the linear model $y = X\beta + e$ with n observations and K regressors, and the OLS estimator $\hat{\beta} = (X^\top X)^{-1} X^\top y$. Its sampling error is $\hat{\beta} - \beta = (X^\top X)^{-1} \sum_i x_i e_i$, so conditional on X

$$\operatorname{Var}(\hat{\beta} \mid X) = (X^\top X)^{-1} \Omega_n (X^\top X)^{-1}, \qquad \Omega_n = \sum_{i=1}^{n} \sum_{j=1}^{n} x_i x_j^\top \mathbb{E}[e_i e_j \mid X]. \tag{A.83}$$

Every robust variance estimator replaces the "meat" Ω_n by

$$\hat{\Omega}_n = \sum_{i=1}^{n} \sum_{j=1}^{n} k_{ij}\, x_i x_j^\top \hat{e}_i \hat{e}_j, \tag{A.84}$$

for weights $k_{ij} \in [0, 1]$ that state which pairs of observations may be correlated. The estimators differ only in k_{ij}:

- Heteroskedasticity-robust estimators (HC, White, 1980) set $k_{ij} = \mathbf{1}\{i = j\}$.
- Cluster-robust estimators set $k_{ij} = \mathbf{1}\{c(i) = c(j)\}$, with $c(i)$ the cluster of observation i.
- The Newey-West estimator for a time series sets $k_{ij} = \max\{0, 1 - \frac{|t_i - t_j|}{m+1}\}$ for a lag length m.
- Two-way clustering sets $k_{ij} = \mathbf{1}\{g(i) = g(j) \text{ or } h(i) = h(j)\}$ for two grouping variables.
- Spatial HAC estimators (Conley, 1999) let k_{ij} decline in the economic distance between i and j.

Plugging $\hat{e}_i \hat{e}_j$ for $e_i e_j$ is useless for a single pair, but the sum over many pairs averages out the noise. Each estimator is consistent when the pairs it drops are uncorrelated and the pairs it keeps are few relative to the sample. Section A.2.2 covered the HC case, including the finite-sample versions HC1 to HC3. HC estimators suffice when observations are independent. The rest of this section treats the other cases.

A.8.2 Clustered data

Let the observations fall into C clusters, $c = 1, \ldots, C$, with n_c observations in cluster c. Errors are independent across clusters and may be correlated within. We first measure the cost of ignoring the correlation.

Proposition A.56 (Moulton factor)**.** *Let $y_{ic} = \alpha + \beta x_{ic} + e_{ic}$ with C clusters of equal size $\bar{n}$. Conditional on the regressor, let the errors be homoskedastic with variance σ^2, uncorrelated across clusters and equicorrelated within clusters with correlation ρ_e. Let $\tilde{x}_{ic} = x_{ic} - \bar{x}$ and define the intra-cluster correlation of the regressor as*

$$\rho_x = \frac{\sum_c \sum_{i \neq j} \tilde{x}_{ic} \tilde{x}_{jc}}{(\bar{n} - 1) \sum_c \sum_i \tilde{x}_{ic}^2}.$$

Then

$$\operatorname{Var}(\hat{\beta} \mid x) = \frac{\sigma^2}{\sum_c \sum_i \tilde{x}_{ic}^2} \left[1 + (\bar{n} - 1)\rho_x \rho_e\right]. \tag{A.85}$$

The first factor is the conventional OLS variance. If the regressor is constant within clusters, $\rho_x = 1$ and the factor is $1 + (\bar{n} - 1)\rho_e$.

Proof. By the Frisch-Waugh-Lovell theorem, $\hat\beta - \beta = \frac{\sum_c \sum_i \tilde x_{ic} e_{ic}}{\sum_c \sum_i \tilde x_{ic}^2}$. Write $D = \sum_c \sum_i \tilde x_{ic}^2$. The numerator has variance

$$\begin{aligned}\operatorname{Var}\Big(\sum_c \sum_i \tilde x_{ic} e_{ic}\Big) &= \sum_c \Big[\sum_i \tilde x_{ic}^2 \sigma^2 + \sum_{i \neq j} \tilde x_{ic}\tilde x_{jc}\rho_e \sigma^2\Big] \\ &= \sigma^2 D + \rho_e \sigma^2 (\bar n - 1)\rho_x D \\ &= \sigma^2 D\left[1 + (\bar n - 1)\rho_x \rho_e\right].\end{aligned}$$

The first line uses independence across clusters and the equicorrelation within. The second substitutes the definition of ρ_x. Dividing by D^2 gives (A.85). If x is constant within clusters, every cross product $\tilde x_{ic}\tilde x_{jc}$ equals $\tilde x_{ic}^2$, so the numerator of ρ_x is $(\bar n - 1)D$. □

The factor can be large even when ρ_e is modest. With 20 observations per cluster and $\rho_x = \rho_e = 0.5$, it equals $1 + 19 \times 0.25 = 5.75$, so the true standard error is $\sqrt{5.75} = 2.40$ times the conventional one. A nominal 5 percent t-test that uses the conventional standard error then rejects a true null with probability about $\mathbb{P}(|Z| > \frac{1.96}{2.40}) = 0.41$ in large samples. With unequal cluster sizes, Moulton (1986) shows that $\bar n - 1$ is replaced by $\frac{\operatorname{Var}(n_c)}{\bar n} + \bar n - 1$. Moulton (1990) documents the problem for regressions of individual outcomes on aggregate variables, where $\rho_x = 1$.

The cluster-robust variance. The cluster-robust estimator of Liang and Zeger (1986) sets $k_{ij} = \mathbf{1}\{c(i) = c(j)\}$ in (A.84). With X_c and $\hat e_c$ the rows of cluster c, and the finite-sample factor used by most software, it is

$$\hat V_{\text{CR1}} = \frac{C}{C-1}\,\frac{n-1}{n-K}\,(X^\top X)^{-1}\Big(\sum_{c=1}^{C} X_c^\top \hat e_c \hat e_c^\top X_c\Big)(X^\top X)^{-1}. \tag{A.86}$$

It allows any correlation and heteroskedasticity within clusters. Its consistency rests on the number of clusters. When cluster sizes are bounded and $C \to \infty$, the terms $X_c^\top e_c e_c^\top X_c$ are independent across clusters, and $\frac{1}{C}\sum_c X_c^\top e_c e_c^\top X_c$ converges to its mean by a law of large numbers. Replacing e_c by $\hat e_c$ changes the average by $o_p(1)$ because $\hat\beta$ is consistent. When each observation is its own cluster, $C = n$ and $\frac{C}{C-1}\frac{n-1}{n-K} = \frac{n}{n-K}$, so CR1 reduces to HC1. For 2SLS, replace X by $\hat X = P_Z X$ in the bread and $x_i \hat e_i$ by $\hat x_i \hat e_i$ in the meat, with residuals computed from X. For GMM, estimate the long-run covariance of the moments by $\hat S = \frac{1}{n}\sum_c \hat g_c \hat g_c^\top$ with $\hat g_c = \sum_{i \in c} g(w_i; \hat\theta)$. When fixed effects are nested within clusters, software differs on whether K counts them. We count every regressor, including the dummies, which gives slightly larger standard errors.

The level of clustering. The cluster should contain every pair of observations whose errors may be correlated, and clusters must be numerous. Bertrand et al. (2004) show the stakes for difference-in-differences regressions on state-year panels.[7] Placebo state laws, assigned at random, were "significant" at the 5 percent level in up to 45 percent of their simulations with conventional standard errors (WP p. 3). Outcomes and treatment indicators are both serially correlated within states. Clustering by state, the level at which treatment is assigned, restored approximately correct size with many states. The rejection rate was 6 percent in their panel of 51 states, and it rose to 8.5 percent with 10 states and 15 percent with 6 states (WP p. 18

[7] We read NBER Working Paper 8841 (2002), the working-paper version of Bertrand et al. (2004). Pages marked WP refer to it.

and Table 9). Abadie et al. (2023) add a design-based view. Clustering adjusts for clustered sampling or clustered assignment of the regressor of interest. Correlated outcomes alone do not call for it when assignment is at the individual level and the sample covers the population.

Two-way clustering. In a state-year panel, errors may be correlated within states over time and within years across states. Two-way clustering (Cameron et al., 2011) keeps every pair that shares a state or a year. The indicator of that event satisfies the inclusion-exclusion identity

$$\mathbf{1}\{g(i) = g(j) \text{ or } h(i) = h(j)\} = \mathbf{1}\{g(i) = g(j)\} + \mathbf{1}\{h(i) = h(j)\} - \mathbf{1}\{g(i) = g(j),\ h(i) = h(j)\}.$$

Substituting into (A.84) gives $\hat{V}_{2\text{way}} = \hat{V}_g + \hat{V}_h - \hat{V}_{g\cap h}$: cluster by the first dimension, cluster by the second, and subtract the estimate clustered by their intersection. In a panel with one observation per state-year, the intersection estimator is the HC estimator. The difference can fail to be positive semidefinite in small samples, and then negative eigenvalues are set to zero. Asymptotic justification requires the number of clusters in both dimensions to grow, so inference should use the smaller of the two counts.

Few clusters. With few clusters, CR1 standard errors are too small and t-statistics are far from normal. Two corrections are standard (Cameron and Miller, 2015). The first compares the t-statistic with the quantiles of the t distribution with $C - 1$ degrees of freedom. The second is the wild cluster bootstrap of Cameron et al. (2008).

Remark A.57 (Wild cluster bootstrap-t). To test $H_0 : \beta_k = \beta_k^0$ with CR1 standard errors:

(1) Compute $t = \frac{\hat{\beta}_k - \beta_k^0}{\widehat{\text{se}}_{\text{CR1}}(\hat{\beta}_k)}$ from the data.

(2) Estimate the model with the null imposed, and keep its coefficients $\tilde{\beta}$ and residuals $\tilde{e}_{ic}$.

(3) For $b = 1, \ldots, B$, draw one weight $w_c^{(b)} \in \{-1, 1\}$ per cluster, each value with probability $\frac{1}{2}$ (Rademacher weights), and form $y_{ic}^{(b)} = x_{ic}^\top \tilde{\beta} + w_c^{(b)} \tilde{e}_{ic}$.

(4) Regress $y^{(b)}$ on X, and compute $t^{(b)} = \frac{\hat{\beta}_k^{(b)} - \beta_k^0}{\widehat{\text{se}}_{\text{CR1}}(\hat{\beta}_k^{(b)})}$ with the same formula as in step (1).

(5) Report the p-value $\frac{1}{B}\sum_{b=1}^{B} \mathbf{1}\{|t^{(b)}| \geq |t|\}$.

Three features make the procedure work. Multiplying a whole cluster's residuals by one weight preserves any correlation pattern within the cluster. Imposing the null makes the bootstrap data satisfy the hypothesis being tested, which improves size. The statistic is studentized, which yields the asymptotic refinement of Section A.9.2. With Rademacher weights there are only 2^C distinct weight vectors, and with $C = 5$ the bootstrap p-value can take only a few values. Weight distributions with more support points enlarge this set. When very few clusters are treated, the residuals of treated clusters carry the treatment effect estimate and the wild bootstrap fails (MacKinnon and Webb, 2017). Methods that use the control clusters to estimate the error distribution are then needed (Conley and Taber, 2011).

Figure A.7 reports a simulation with the parameters of the Moulton example. The conventional test rejects the true null in 38 to 44 percent of replications for every number of clusters, close to the 41 percent predicted above. HC1 standard errors do no better, because the problem is correlation, which HC1 ignores. CR1 standard errors with normal quantiles reject 19 percent of the time with 5 clusters, 14 percent with 10 and 6 percent with 100. Using t_{C-1} quantiles lowers the rejection rate to 10 percent with 5 clusters and 8 to 10 percent with 10 to 20 clusters. The wild cluster bootstrap rejects between 4.3 and 6.9 percent of the time for every C. Each rate has a Monte Carlo standard error of about 0.007.

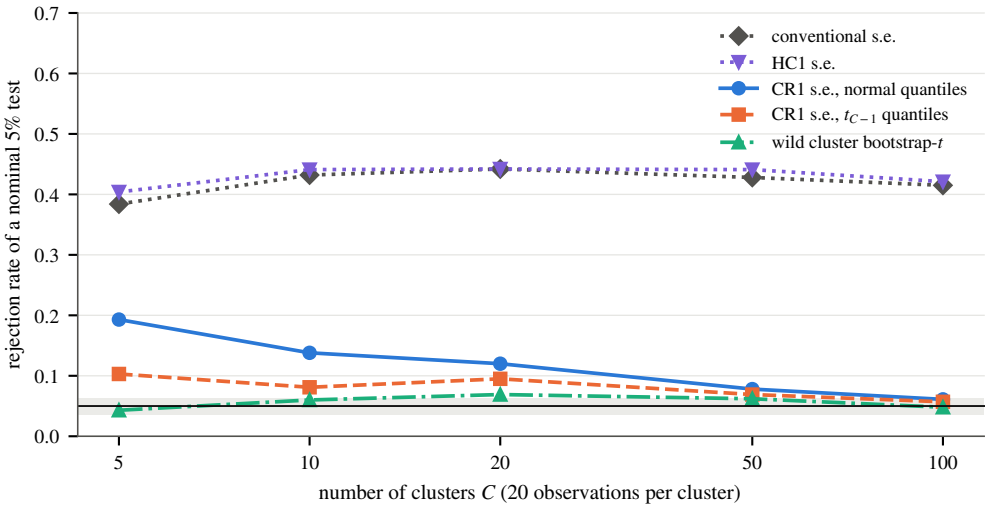

Figure A.7: Rejection rates of nominal 5 percent tests of a true null when errors and the regressor are both correlated within clusters. In the design, $y_{ic} = e_{ic}$ is regressed on a constant and x_{ic}. Both x_{ic} and e_{ic} are sums of independent normal cluster and idiosyncratic components, with intra-cluster correlations $\rho_x = \rho_e = 0.5$. There are 20 observations per cluster, 1,000 replications per C and 399 bootstrap draws, with seed 20261022. The gray band is the 95 percent Monte Carlo range around 0.05.

A.8.3 Serial correlation and HAC estimators

In a time series $t = 1, \dots, T$, let g_t be a mean-zero score or moment, for example $x_t e_t$. Write $\Gamma_j = \mathbb{E}[g_t g_{t-j}^\top]$ for its autocovariance at lag j, with $\Gamma_{-j} = \Gamma_j^\top$. Under covariance stationarity,

$$\operatorname{Var}\Big(\frac{1}{\sqrt{T}}\sum_{t=1}^{T} g_t\Big) = \frac{1}{T}\sum_{t=1}^{T}\sum_{s=1}^{T}\Gamma_{t-s} = \sum_{j=-(T-1)}^{T-1}\Big(1-\frac{|j|}{T}\Big)\Gamma_j \longrightarrow S = \sum_{j=-\infty}^{\infty}\Gamma_j,$$

where the middle step counts the $T - |j|$ pairs with $t - s = j$ and the limit holds when the autocovariances are absolutely summable. The matrix S is the *long-run variance*, and it replaces Ω_n in (A.83) and S in the GMM formulas.

Example A.58 (AR(1) regressor and error)**.** Let x_t and e_t be independent stationary AR(1) processes with autocorrelations ρ_x and ρ_e. Then $\Gamma_j = \mathbb{E}[x_t x_{t-j}]\mathbb{E}[e_t e_{t-j}] = \sigma_x^2\sigma_e^2(\rho_x\rho_e)^{|j|}$, and

$$S = \sigma_x^2\sigma_e^2\Big[1 + 2\sum_{j=1}^{\infty}(\rho_x\rho_e)^j\Big] = \sigma_x^2\sigma_e^2\,\frac{1+\rho_x\rho_e}{1-\rho_x\rho_e}.$$

The conventional variance uses only $\Gamma_0 = \sigma_x^2\sigma_e^2$, so it is too small by the factor $\frac{1+\rho_x\rho_e}{1-\rho_x\rho_e}$. With $\rho_x = 0.85$ and $\rho_e = 0.64$, the factor is 3.4 and the standard error ratio is 1.8. These are the within-state autocorrelations of the tax and of the residual in the cigarette panel of Section A.8.5.

The Newey-West estimator. A natural estimator truncates the sum at lag m and uses sample autocovariances $\hat\Gamma_j = \frac{1}{T}\sum_{t=j+1}^{T}\hat g_t\hat g_{t-j}^\top$. The unweighted truncated sum can fail to be positive semidefinite. Newey and West (1987) downweight the autocovariances linearly:

$$\hat S_{\mathrm{NW}} = \hat\Gamma_0 + \sum_{j=1}^{m}\Big(1-\frac{j}{m+1}\Big)\big(\hat\Gamma_j + \hat\Gamma_j^\top\big). \tag{A.87}$$

The Bartlett weights $1 - \frac{j}{m+1}$ guarantee a positive semidefinite estimate. To see why, form the block sums $\hat{B}_t = \sum_{k=0}^{m} \hat{g}_{t-k}$ and consider $\frac{1}{(m+1)T} \sum_t \hat{B}_t \hat{B}_t^\top$, an average of outer products and hence positive semidefinite. Expanding the product, $\hat{g}_{t-k}\hat{g}_{t-l}^\top$ appears for each pair (k, l), and the number of pairs with $k - l = j$ is $m + 1 - |j|$. The weight on lag j is therefore $\frac{m+1-|j|}{m+1} = 1 - \frac{|j|}{m+1}$, which reproduces (A.87) up to terms at the ends of the sample. Consistency requires $m \to \infty$ with $\frac{m}{T} \to 0$. A common rule of thumb is $m = \lfloor 4(\frac{T}{100})^{\frac{2}{9}} \rfloor$. In Newey and West (1994, p. 634) this formula is only a preliminary lag in an automatic procedure for the Bartlett kernel. The procedure uses it to estimate a constant $\hat{\gamma}$ and then sets $m = \lfloor \hat{\gamma} T^{\frac{1}{3}} \rfloor$ (p. 635). Genesove and Mullin (1998) report Newey-West standard errors with four lags for their quarterly sugar demand and pricing equations (Section 3.7).

Panels. In a panel with many units and a short time dimension, clustering by unit allows arbitrary serial correlation within units, and nothing more is needed if units are independent. When units share common shocks that time effects do not remove, Driscoll and Kraay (1998) average the scores across units within each period and apply (A.87) to the resulting time series. Their estimator allows any cross-sectional dependence, but it requires a long panel and allows only serial correlation that dies out within m periods. Conley (1999) extends the HAC idea to dependence that declines with spatial or economic distance.

A.8.4 Dependence structures in IO data

The book's applications show four recurring structures. The first is the same product observed in many markets in the same period, whose prices respond to common cost and demand shocks. Ashenfelter and Hosken (2010, WP p. 25) observe the prices of the same products in many geographic markets each period,[8] and therefore cluster on the time period, citing Moulton (1987). Their reference list contains only Moulton (1990) (WP p. 39), which makes the same point about aggregate regressors. The second is the same product or unit observed repeatedly over time. Ashenfelter et al. (2013, WP p. 14) cluster by SKU in their appliance price regressions. Berry et al. (1995, pp. 862–863) treat the sum of the moments of a car model over all its years as one observation, which allows any correlation across years for a given model. The third is common shocks to all products in a market. Berry et al. (1996, WP p. 17) assume independence across airline markets and a factor structure that correlates demand and cost errors within a market (Section 9.7.5). They also note that the average product has fewer than 10 sampled passengers, and they leave the correction of standard errors for this sampling error to future research (WP p. 17). The fourth is serial correlation that a structural model must represent explicitly. Ellison (1994) models an AR(1) demand error inside his Markov-switching likelihood, and doing so changes the point estimates as well as the standard errors (Chapter 13). Table A.7 collects the inference methods used in the book.

A.8.5 Worked application: Sumner's regression revisited

Sumner (1981) tests for competition in cigarettes by regressing the retail price per pack on the excise tax in a state-year panel (Sections A.2.4 and 3.2.2). His most complete specification is the two-way fixed effects regression (A.20) of Section A.2.4,

$$p_{sy} = \mu_s + \tau_y + \rho\, t_{sy} + e_{sy},$$

[8] We read NBER Working Paper 13859 (2008) of Ashenfelter and Hosken (2010) and NBER Working Paper 17476 (2011) of Ashenfelter et al. (2013). Pages marked WP refer to them.

Table A.7: Inference under dependence in the book's applications

Application	Data structure	Inference used	Source
Sumner (1981), re-estimated	State-year panel, 48 units, 25 years	Clusters by state, by year and both, Driscoll-Kraay, wild cluster bootstrap	Table A.8
Genesove and Mullin (1998)	Quarterly time series, 1890–1914	Newey-West, 4 lags, with the pricing equation corrected for estimated demand	Section 3.7
Ashenfelter and Hosken (2010)	Product by city by period	Clusters on the time period	WP p. 25
Ashenfelter et al. (2013)	SKU by month	Clusters by SKU	WP p. 14
Berry et al. (1995)	Car model by year	Moments summed over a model's years, simulation variance added	pp. 862–863 and Section 8.5.7
Berry et al. (1996)	Products in airline markets	Independence across markets and a factor structure within them, share sampling error not corrected	WP p. 17 and Section 9.7.5
Miller and Weinberg (2017)	Brand-size product by region by period	Clusters by region, two-step correction for estimated demand	pp. 1775, 1780 and Chapter 11
Chaudhuri et al. (2006)	Product by region by month	Bootstrap over months, 300 replications, all products and regions kept	WP p. 21
Nevo (2001)	Brand by city by quarter	1,500 draws from the asymptotic distribution for median margins	Table VIII
Asker (2010)	Auctions	Bootstrap over auctions, 5,000 iterations, 90 percent intervals	Tables 7–10
Gentzkow (2007)	Survey respondents	Robust SML standard errors, 100 parameter draws for welfare	p. 733
Athey et al. (2011)	Timber sales	Matching standard errors of Abadie and Imbens (2006), parametric bootstrap	pp. 230, 248

Notes: WP page numbers refer to working-paper versions of the papers.

with state effects μ_s, year effects τ_y and pass-through ρ. Competition with flat marginal cost implies $\rho = 1$. Sumner reports $\hat{\rho} = 1.074$ with a conventional standard error of 0.013 (Table 1), so the t-statistic for $\rho = 1$ is 5.7. Both the price and the tax are persistent within states, so the conventional standard error is suspect.

We re-estimate the regression on a panel reconstructed from *The Tax Burden on Tobacco* (1983, Table 13) and the CPI-U of the Bureau of Labor Statistics. It covers 47 states and the District of Columbia from 1954 to 1978, 1,200 state-years, the same coverage as Sumner's. Prices and taxes are nominal cents per pack, and the tax is the state tax plus the federal tax of 8 cents. The computations are in `figures/appA/src/sumner_inference.py`. Table A.8 reports three specifications and six variance estimators.

Table A.8: Cigarette tax pass-through: standard errors and tests of $\rho = 1$ under different dependence assumptions

	Sumner	Re-estimation							
Specification	(1981)	$\hat{\rho}$	Conv.	HC1	State	Year	Two-way	DK	Wild
(1) State, year effects, OLS	1.074 (0.013)	1.075	0.013	0.015	0.034	0.013	0.033	0.016	
p-value for $\rho = 1$			<0.001	<0.001	0.033	<0.001	0.034	<0.001	0.044
(2) CPI, OLS	1.029 (0.011)	1.029	0.011	0.013	0.030	0.023	0.035	0.027	
p-value for $\rho = 1$			0.007	0.030	0.340	0.207	0.416	0.299	0.358
(3) CPI, random effects	1.069 (0.013)	1.069	0.013	0.015	0.033	0.015	0.033	0.020	
p-value for $\rho = 1$			<0.001	<0.001	0.042	<0.001	0.046	0.002	

Notes: The dependent variable is the retail price in cents per pack and the regressor of interest the combined state and federal tax in cents per pack, 1,200 state-years. The first column reproduces Sumner's Table 1 (standard errors in parentheses). The other columns report our estimate of ρ and its standard error under six estimators. Conv.: conventional OLS or GLS. HC1: heteroskedasticity-robust. State and Year: CR1 clustered by state (48 clusters) or by year (25). Two-way: clustered by state and year (Cameron et al., 2011). DK: Driscoll and Kraay (1998) with Bartlett weights and 2 lags. p-values use normal quantiles for Conv. and HC1, t_{47} for State, t_{24} for Year, Two-way and DK. Wild: wild cluster bootstrap-t by state with the null imposed, Rademacher weights and 9,999 draws. Row (2) replaces the year effects by the national CPI and drops the state effects. Row (3) has the regressors of row (2) and is two-way random-effects GLS (Fuller and Battese, 1974), and its robust variants apply the formulas to the GLS-transformed regression. K counts all dummies in row (1).

Row (1). The re-estimation reproduces Sumner's estimate and conventional standard error. The HC1 standard error is 15 percent larger. Clustering by state raises the standard error to 0.034, 2.6 times the conventional value. The within-state first-order autocorrelation of the residuals is 0.64 and that of the within-transformed tax is 0.85. Example A.58 predicts a standard error ratio of about 1.8 for these values, and the ratio of the clustered to the HC1 standard error is 2.2. Clustering by year leaves the standard error at 0.013. The year effects absorb the common national shocks, so the residuals of different states in the same year are nearly uncorrelated. The two-way estimate, 0.033, is close to the state-clustered one for the same reason. The Driscoll-Kraay estimate, 0.016, allows any correlation across states but only two lags of serial correlation, and it misses the persistence that clustering by state captures. The rejection of $\rho = 1$ survives every estimator that allows correlation within states, with p-values from 0.033 to 0.044, but its margin is far thinner than a t-statistic of 5.7 suggests. The wild

cluster bootstrap p-value of 0.044 has a Monte Carlo standard error of 0.002.

Row (2). Without state effects, persistent differences in state price levels enter the error, and they are correlated over time within a state. The conventional standard error of 0.011 gives $p = 0.007$. Clustering by state, by year or by both, the Driscoll-Kraay estimator and the wild cluster bootstrap all give p above 0.2. The apparent rejection of competition in this specification is an artifact of the conventional standard error.

Row (3). The random-effects GLS estimate reproduces Sumner's 1.069. Its conventional standard error assumes that a constant state effect captures all within-state correlation. The residuals of the transformed regression remain serially correlated, and the state-clustered standard error is 0.033, with $p = 0.042$. Random effects therefore do not substitute for clustering when the error has more persistence than a permanent effect.

The lesson is general. In a panel with persistent regressors and errors, the conventional and heteroskedasticity-robust standard errors can overstate precision by a factor of two or more. The clustering level should follow the dependence that the fixed effects leave in the error. Here the fixed effects leave serial correlation within states, while the correlation across states within a year is negligible.

A.9 The delta method and the bootstrap

Empirical work rarely stops at the estimated parameters. A pass-through coefficient is turned into an elasticity, demand parameters into markups, and a demand system into the welfare effect of a counterfactual. This section develops the two general tools for the uncertainty of such quantities, the delta method and the bootstrap, and shows when each fails.

A.9.1 The delta method

Theorem A.59 (Delta method)**.** *Suppose $\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V)$ for $\theta_0 \in \mathbb{R}^K$. Let $a : \mathbb{R}^K \to \mathbb{R}^q$ be continuously differentiable in a neighborhood of θ_0, with Jacobian $A(\theta) = \frac{\partial a(\theta)}{\partial \theta^\top}$ $(q \times K)$ and $A = A(\theta_0)$. Then*

$$\sqrt{n}\big(a(\hat{\theta}) - a(\theta_0)\big) \xrightarrow{d} N(0, AVA^\top).$$

If $\hat{V} \xrightarrow{p} V$, then $A(\hat{\theta})\hat{V}A(\hat{\theta})^\top \xrightarrow{p} AVA^\top$.

Proof. Since $\sqrt{n}(\hat{\theta} - \theta_0)$ converges in distribution, $\hat{\theta} - \theta_0 = O_p(n^{-\frac{1}{2}})$ and $\hat{\theta} \xrightarrow{p} \theta_0$. For each component a_k, the mean value theorem gives a point $\bar{\theta}_k$ on the segment between $\hat{\theta}$ and θ_0 with

$$a_k(\hat{\theta}) - a_k(\theta_0) = \frac{\partial a_k(\bar{\theta}_k)}{\partial \theta^\top}(\hat{\theta} - \theta_0).$$

Stack these rows into a matrix $\bar{A}$. Each $\bar{\theta}_k \xrightarrow{p} \theta_0$, so $\bar{A} \xrightarrow{p} A$ by continuity of the derivatives. Then

$$\sqrt{n}\big(a(\hat{\theta}) - a(\theta_0)\big) = \bar{A}\,\sqrt{n}(\hat{\theta} - \theta_0),$$

and Slutsky's theorem gives convergence to $A\,N(0, V) = N(0, AVA^\top)$. The second claim follows from the continuous mapping theorem. □

In practice the delta-method standard error of a scalar $a(\hat{\theta})$ is $\sqrt{\nabla a(\hat{\theta})^\top \hat{V}_n \nabla a(\hat{\theta})}$, where $\hat{V}_n = \frac{\hat{V}}{n}$ is the estimated variance of $\hat{\theta}$. We now work through the cases that recur in the book.

Example A.60 (Elasticity implied by pass-through)**.** Under monopoly or constant conduct with constant-elasticity demand and flat marginal cost, pass-through is $\rho = \frac{\varepsilon}{\varepsilon-1}$, where ε is the elasticity the firms behave as if they face (Section 3.2.2). Inverting gives $\varepsilon = a(\rho) = \frac{\rho}{\rho-1}$ for $\rho > 1$. The derivative is

$$a'(\rho) = \frac{(\rho-1)-\rho}{(\rho-1)^2} = -\frac{1}{(\rho-1)^2}, \qquad \operatorname{se}(\hat{\varepsilon}) = \frac{\operatorname{se}(\hat{\rho})}{(\hat{\rho}-1)^2}.$$

Sumner's estimate $\hat{\rho} = 1.074$ with standard error 0.013 gives $\hat{\varepsilon} = \frac{1.074}{0.074} = 14.5$ and a delta-method standard error of $\frac{0.013}{0.074^2} = 2.37$.[9] Our re-estimate $\hat{\rho} = 1.0746$ gives $\hat{\varepsilon} = 14.4$, with a standard error of 2.38 based on the conventional standard error and 6.11 based on the state-clustered one. The standard error of $\hat{\varepsilon}$ is about 180 times that of $\hat{\rho}$, because the derivative is the inverse square of $\hat{\rho} - 1 = 0.075$.

Example A.61 (Marginal cost from an inverse-elasticity rule)**.** With an observed price p and an estimated elasticity, the Lerner rule $\frac{p-c}{p} = \frac{1}{\varepsilon}$ gives $\hat{c} = p(1 - \frac{1}{\hat{\varepsilon}})$ (Corollary 1.11). The derivative $\frac{\mathrm{d}c}{\mathrm{d}\varepsilon} = \frac{p}{\varepsilon^2}$ yields $\operatorname{se}(\hat{c}) = \frac{p}{\hat{\varepsilon}^2}\operatorname{se}(\hat{\varepsilon})$. Chaining with Example A.60, $c = p(1 - \frac{\rho-1}{\rho}) = \frac{p}{\rho}$, so $\operatorname{se}(\hat{c}) = \frac{p}{\hat{\rho}^2}\operatorname{se}(\hat{\rho})$. The cost implied by pass-through is precise even when the elasticity is not, because a markup of a few percent is small whatever its exact value.

Example A.62 (Willingness to pay as a ratio)**.** In a demand model with utility $x\beta - \alpha p$, the willingness to pay for characteristic k is $r = \frac{\beta_k}{\alpha}$. The gradient with respect to (β_k, α) is $(\frac{1}{\alpha}, -\frac{\beta_k}{\alpha^2})$, so

$$\widehat{\operatorname{Var}}(\hat{r}) = \frac{1}{\hat{\alpha}^2}\left[\hat{V}_{kk} - 2\hat{r}\hat{V}_{k\alpha} + \hat{r}^2\hat{V}_{\alpha\alpha}\right],$$

with $\hat{V}$ the estimated covariance of $(\hat{\beta}_k, \hat{\alpha})$. When $\hat{\alpha}$ is imprecise, the distribution of the ratio is far from normal. Fieller (1954) proposed an exact alternative under normality. The statistic $\hat{\beta}_k - r\hat{\alpha}$ has mean zero at the true ratio and variance $V_{kk} - 2rV_{k\alpha} + r^2V_{\alpha\alpha}$. The Fieller set collects the values r that a test does not reject:

$$\left\{r : (\hat{\beta}_k - r\hat{\alpha})^2 \le z^2\left(\hat{V}_{kk} - 2r\hat{V}_{k\alpha} + r^2\hat{V}_{\alpha\alpha}\right)\right\},$$

with z the normal quantile. The inequality is quadratic in r, with leading coefficient $\hat{\alpha}^2 - z^2\hat{V}_{\alpha\alpha}$. The set is a bounded interval if and only if this coefficient is positive, that is, if $\hat{\alpha}$ is significantly different from zero. Otherwise it is the whole line or the union of two half-lines, which correctly signals that the data cannot bound the ratio.

Example A.63 (Elasticities and markups from demand parameters)**.** In the logit model, the own-price elasticity is $\varepsilon_{jj} = -\alpha p_j(1 - s_j)$ and the single-product markup is $p_j - c_j = \frac{1}{\alpha(1-s_j)}$ (Chapter 7). Both depend on the estimates only through $\hat{\alpha}$, with derivatives $-p_j(1 - s_j)$ and $-\frac{1}{\alpha^2(1-s_j)}$. The relative standard error of the markup therefore equals that of $\hat{\alpha}$. In the AIDS model elasticities are functions of many parameters, and the full gradient and covariance matrix are needed (Chapter 5).

[9] Sumner's printed implied elasticities equal $\frac{1}{1-\hat{\rho}}$, for example −13.5 for the first row. They are one unit smaller in magnitude than $\frac{\hat{\rho}}{\hat{\rho}-1}$, because they treat $\hat{\rho} - 1$ as the markup over cost instead of using the Lerner condition (Section 3.2.2).

Example A.64 (Log points and percentages)**.** A coefficient β on the log scale implies a proportional effect $a(\beta) = e^{\beta} - 1$, with $\text{se}(\hat{a}) = e^{\hat{\beta}}\text{se}(\hat{\beta})$. Dafny (2009) estimates by instrumental variables that a rival merger raises hospital price growth by 0.376 log points, with standard error 0.132 (WP Table 4, see Section A.3.1). The implied increase is $e^{0.376} - 1 = 46$ percent, with delta-method standard error $e^{0.376} \times 0.132 = 0.19$. The symmetric 95 percent interval is $[8, 83]$ percent. Mapping the endpoints of the interval for β through $e^{\beta} - 1$ gives $[12, 89]$ percent, which respects the asymmetry of the transformation.

When the delta method fails. Three situations break the linear approximation. First, if $A = 0$ the first-order term vanishes. For scalar θ with $a'(\theta_0) = 0$ and $a''(\theta_0) \neq 0$, a second-order expansion gives $n(a(\hat{\theta}) - a(\theta_0)) \xrightarrow{d} \frac{1}{2}a''(\theta_0)V\chi^2_1$. For example, $n\hat{\theta}^2$ converges to $V\chi^2_1$ when $\theta_0 = 0$. Second, if a is not differentiable at θ_0, as with $|\theta|$, $\max\{\theta_1, \theta_2\}$ at $\theta_1 = \theta_2$, or bounds defined by extrema, the limit is not normal. Third, if a is differentiable but very nonlinear over the region where $\hat{\theta}$ is likely to fall, the normal approximation is poor in any finite sample. A denominator close to zero is the typical case.

Example A.60 is of the third kind. With the state-clustered standard error, the 95 percent delta-method interval for the elasticity is $14.4 \pm 2.012 \times 6.11 = [2.1, 26.7]$, using t_{47} quantiles. The lower end corresponds to $\rho = \frac{2.1}{1.1} = 1.9$, a value far outside the confidence interval for ρ, which is $[1.006, 1.143]$. A better interval maps the endpoints. Because $a(\rho) = \frac{\rho}{\rho - 1}$ is strictly decreasing on $(1, \infty)$,

$$\mathbb{P}\big(a(\rho_0) \in [a(\rho_U), a(\rho_L)]\big) = \mathbb{P}\big(\rho_0 \in [\rho_L, \rho_U]\big)$$

whenever $\rho_L > 1$. The mapped interval inherits the exact coverage of the interval for ρ. Here it is $[a(\rho_U), a(\rho_L)] = [\frac{1.1430}{0.1430}, \frac{1.006177}{0.006177}] = [8.0, 162.9]$, strongly asymmetric. We show ρ_L with more digits because the map is very steep near one. With the conventional standard error the two intervals are $[9.7, 19.1]$ and $[10.9, 21.5]$, much closer, because $\hat{\rho}$ is then many standard errors from one. If the interval for ρ contained one, the set of elasticities consistent with the data would be unbounded, and no symmetric interval could represent it. Figure A.8 shows these intervals together with a bootstrap distribution.

A.9.2 The bootstrap: principle and theory

The bootstrap of Efron (1979) estimates the sampling distribution of a statistic by recomputing it on samples drawn from an estimate of the population. Let the data $w_1, \ldots, w_n$ be independent draws from F, and let $T_n = \sqrt{n}(\hat{\theta} - \theta_0)$ have distribution $G_n(\cdot, F)$. The *plug-in principle* replaces the unknown F by the empirical distribution $\hat{F}_n$, which puts mass $\frac{1}{n}$ on each observation. The bootstrap estimate of $G_n(\cdot, F)$ is $G_n(\cdot, \hat{F}_n)$, the distribution of $\sqrt{n}(\hat{\theta}^* - \hat{\theta})$ when $\hat{\theta}^*$ is computed from a sample of size n drawn from $\hat{F}_n$. That distribution is computed by simulation.

Remark A.65 (Nonparametric bootstrap). For $b = 1, \ldots, B$:

(1) Draw n observations from $\{w_1, \ldots, w_n\}$ with replacement.

(2) Compute the estimator on this sample, $\hat{\theta}^*_b$, with exactly the procedure used on the data.

The bootstrap standard error is the standard deviation of $\hat{\theta}^*_1, \ldots, \hat{\theta}^*_B$. In regression, drawing whole observations (y_i, x_i) is the *pairs bootstrap*, which is robust to heteroskedasticity.

Proposition A.66 (Bootstrap consistency for the mean)**.** *Let $X_1, \dots, X_n$ be i.i.d. with variance $\sigma^2 > 0$ and $\mathbb{E}|X|^3 < \infty$. Let $\bar{X}^*$ be the mean of a bootstrap sample. Then*

$$\sup_x \left| \mathbb{P}^*\big(\sqrt{n}(\bar{X}^* - \bar{X}) \le x\big) - \mathbb{P}\big(\sqrt{n}(\bar{X} - \mu) \le x\big) \right| \xrightarrow{a.s.} 0,$$

where $\mathbb{P}^*$ is the probability over bootstrap draws given the data.

Proof. Given the data, $\bar{X}^*$ is the mean of n independent draws from $\hat{F}_n$, which has mean $\bar{X}$, variance $\hat{\sigma}^2 = \frac{1}{n}\sum_i (X_i - \bar{X})^2$ and third absolute central moment $\hat{\kappa}_3 = \frac{1}{n}\sum_i |X_i - \bar{X}|^3$. The Berry-Esseen inequality bounds the distance between the conditional distribution of $\sqrt{n}(\bar{X}^* - \bar{X})$ and $N(0, \hat{\sigma}^2)$:

$$\sup_x \left| \mathbb{P}^*\big(\sqrt{n}(\bar{X}^* - \bar{X}) \le x\big) - \Phi\Big(\frac{x}{\hat{\sigma}}\Big) \right| \le \frac{C_0\, \hat{\kappa}_3}{\hat{\sigma}^3 \sqrt{n}},$$

for a universal constant C_0. By the strong law of large numbers, $\hat{\sigma}^2 \to \sigma^2$ and $\hat{\kappa}_3$ converges to a finite limit almost surely, so the bound tends to zero. The same inequality applied to the original sample bounds the distance between the distribution of $\sqrt{n}(\bar{X} - \mu)$ and $\Phi(\frac{x}{\sigma})$ by a term of order $n^{-\frac{1}{2}}$. Finally, $\sup_x |\Phi(\frac{x}{\hat{\sigma}}) - \Phi(\frac{x}{\sigma})| \to 0$ because $\hat{\sigma} \to \sigma$. The triangle inequality combines the three bounds. □

The result extends to smooth functions of means, which include OLS, IV and GMM estimators, and to many other statistics (Bickel and Freedman, 1981; Hall, 1992). The common structure is that $\hat{\theta}$ is asymptotically a smooth function of averages, so the bootstrap reproduces the first-order normal approximation. Section A.9.5 shows what happens without that structure.

Confidence intervals. Let q^*_α be the α quantile of the bootstrap estimates $\hat{\theta}^*_b$. Four intervals with nominal coverage $1 - \alpha$ are standard.

(i) The *percentile* interval is $[q^*_{\frac{\alpha}{2}}, q^*_{1-\frac{\alpha}{2}}]$.

(ii) The *basic* interval uses the bootstrap distribution of $\hat{\theta}^* - \hat{\theta}$ as an estimate of that of $\hat{\theta} - \theta_0$. From $\mathbb{P}(q^*_{\frac{\alpha}{2}} - \hat{\theta} \le \hat{\theta} - \theta_0 \le q^*_{1-\frac{\alpha}{2}} - \hat{\theta}) \approx 1 - \alpha$, solving for θ_0 gives $[2\hat{\theta} - q^*_{1-\frac{\alpha}{2}},\ 2\hat{\theta} - q^*_{\frac{\alpha}{2}}]$.

(iii) The *percentile-t* interval bootstraps the studentized statistic $t^*_b = \frac{\hat{\theta}^*_b - \hat{\theta}}{\mathrm{se}^*_b}$, with se^*_b computed on bootstrap sample b by the same formula as on the data. With t^*_α its quantiles, the interval is $[\hat{\theta} - t^*_{1-\frac{\alpha}{2}}\mathrm{se},\ \hat{\theta} - t^*_{\frac{\alpha}{2}}\mathrm{se}]$.

(iv) The *bias-corrected and accelerated* (BCa) interval uses the percentile interval at adjusted levels $\alpha_j = \Phi\big(z_0 + \frac{z_0 + z_{\alpha_j}}{1 - \hat{a}(z_0 + z_{\alpha_j})}\big)$ for the two nominal levels. The bias correction is $z_0 = \Phi^{-1}(\frac{1}{B}\sum_b \mathbf{1}\{\hat{\theta}^*_b < \hat{\theta}\})$, and the acceleration $\hat{a} = \frac{\sum_i (\bar{\theta}_{(\cdot)} - \hat{\theta}_{(i)})^3}{6[\sum_i (\bar{\theta}_{(\cdot)} - \hat{\theta}_{(i)})^2]^{\frac{3}{2}}}$ comes from the leave-one-out estimates $\hat{\theta}_{(i)}$ and their mean $\bar{\theta}_{(\cdot)}$.

The percentile and BCa intervals are *transformation respecting*. If a is monotone, the interval for $a(\theta)$ is the image of the interval for θ. The basic and percentile-t intervals are not.

Asymptotic refinement. Under regularity conditions the distribution of a statistic admits an Edgeworth expansion. For a studentized statistic t_n,

$$\mathbb{P}(t_n \le x) = \Phi(x) + n^{-\frac{1}{2}} p(x)\phi(x) + O(n^{-1}),$$

where the polynomial p depends on the skewness of the data. The normal approximation therefore errs by order $n^{-\frac{1}{2}}$. The bootstrap distribution has the same expansion with p replaced by its sample analogue $\hat{p}$, and $\hat{p} - p = O_p(n^{-\frac{1}{2}})$. The bootstrap error is therefore $O_p(n^{-1})$. This *asymptotic refinement* requires an asymptotically *pivotal* statistic, whose limit distribution does not depend on unknown parameters (Hall, 1992; Horowitz, 2001). The unstudentized $\sqrt{n}(\hat{\theta} - \theta_0)$ has a limit that depends on V, and bootstrapping it gives no refinement. Percentile-t intervals and the wild cluster bootstrap-t of Remark A.57 bootstrap pivotal statistics for this reason.

Number of replications. The bootstrap distribution is itself simulated, with Monte Carlo error that falls with B. Standard errors need fewer replications than tail quantiles. Efron and Tibshirani (1993) suggest that 200 replications rarely need to be exceeded for standard errors, and Andrews and Buchinsky (2000) give a three-step rule that chooses B for a desired accuracy. Chaudhuri et al. (2006, WP p. 21) cite both and use 300 replications "to be safe." Asker (2010) uses 5,000 iterations for 90 percent intervals. For a bootstrap p-value $\hat{p}$, the Monte Carlo standard error is $\sqrt{\frac{\hat{p}(1-\hat{p})}{B}}$. Choosing B so that $(B+1)\alpha$ is an integer, as with $B = 9{,}999$, makes the bootstrap test exact in the ideal case of an exactly pivotal statistic.

A.9.3 Bootstraps for dependent data

Resampling individual observations destroys any dependence among them. The bootstrap must resample the units that are independent. The *cluster* or *block* bootstrap draws whole clusters with replacement and keeps all observations of each drawn cluster. It is the resampling counterpart of the cluster-robust variance and needs many clusters for the same reason. A cluster drawn twice enters as two distinct clusters, which matters when the model has cluster fixed effects.

Chaudhuri et al. (2006, WP p. 21) bootstrap their AIDS estimates for antibiotics in India. Their errors are likely correlated across regions within a month, for example through a national advertising campaign. They resample months with replacement and keep the same months for all products. Each drawn month brings all four regions and all seven products, which preserves the cross-regional and cross-product correlation without modelling it. The design treats months as independent, an assumption that serial correlation in demand shocks would violate. With 24 months, the number of independent units is also modest. Asker (2010, p. 743) computes confidence intervals for damages in a stamp-auction ring by resampling auctions. His intervals are visibly asymmetric. Mean naive damages are \$74.21 with a 90 percent interval of $[49.10, 152.74]$, and mean damages under his upper-bound assumption are \$36.99 with interval $[23.47, 81.88]$ (Table 7). A symmetric interval would misrepresent such skewed distributions.

For a single time series, the *moving-block bootstrap* (Künsch, 1989) resamples overlapping blocks of ℓ consecutive observations, with $\ell \to \infty$ and $\frac{\ell}{T} \to 0$. The *wild bootstrap* (Wu, 1986; Mammen, 1993) keeps the regressors fixed and multiplies each residual by an independent random weight with mean zero and variance one, which preserves heteroskedasticity. Its cluster version is Remark A.57.

The Sumner panel. We apply a pairs cluster bootstrap by state to row (1) of Table A.8, with $B = 9{,}999$. Each replication draws 48 states with replacement, treats repeated states as distinct, and re-estimates (A.20) with state and year effects. The bootstrap standard error of $\hat{\rho}$ is 0.033, close to the clustered 0.034 and to the jackknife value of 0.034 obtained by deleting one state at a time. Table A.9 compares intervals. For ρ, all methods give similar intervals that exclude one.

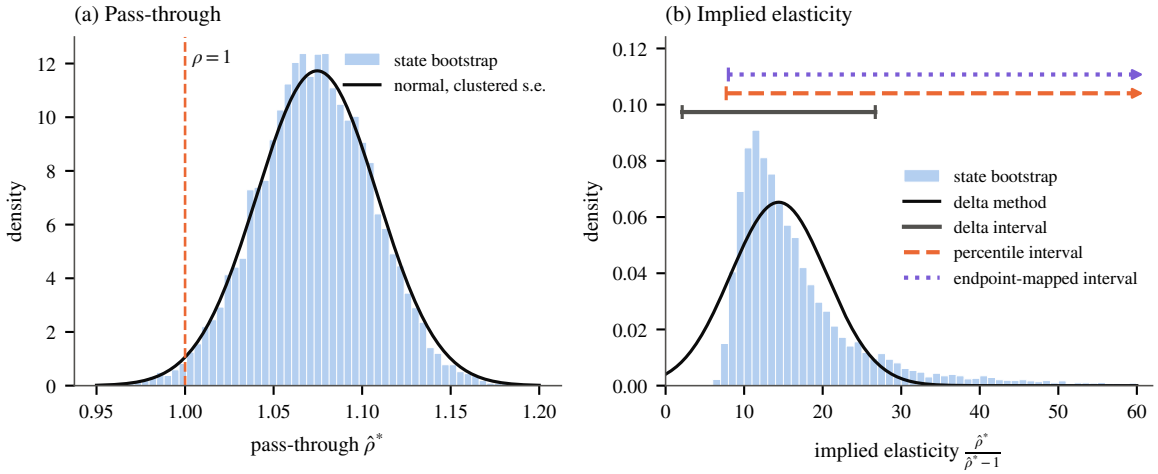

Figure A.8: State-cluster bootstrap of the cigarette tax pass-through regression with state and year effects. (a) 9,999 bootstrap estimates $\hat{\rho}^*$ and the normal density with the state-clustered standard error. (b) Implied elasticity $\frac{\hat{\rho}^*}{\hat{\rho}^*-1}$ and the delta-method normal density. The horizontal bars are 95 percent intervals: delta method [2.1, 26.7], bootstrap percentile [7.7, 68.9], and the mapped endpoints of the clustered interval for ρ, [8.0, 162.9]. Arrows mark intervals that extend beyond the plotted range. 4.4 percent of the bootstrap elasticities lie outside [0, 60] and are not plotted. Seed 20261022.

The bootstrap distribution in Figure A.8(a) is close to normal, and 1.3 percent of the bootstrap estimates are at or below one.

Table A.9: 95 percent intervals for pass-through and the implied elasticity

Method	ρ	$\varepsilon = \frac{\rho}{\rho-1}$
Clustered t_{47} interval, delta method for ε	[1.006, 1.143]	[2.1, 26.7]
Clustered t_{47} interval, endpoints mapped	[1.006, 1.143]	[8.0, 162.9]
Bootstrap percentile	[1.008, 1.137]	[7.7, 68.9]
Bootstrap percentile for ρ, endpoints mapped		[8.3, 126.8]
Bootstrap basic	[1.012, 1.141]	[−40.1, 21.1]
Bootstrap percentile-t	[1.012, 1.143]	
Bootstrap BCa, endpoints mapped for ε	[1.012, 1.142]	[8.0, 81.2]

Notes: Row (1) of Table A.8, $\hat{\rho} = 1.075$ and $\hat{\varepsilon} = 14.4$. Pairs cluster bootstrap by state with 9,999 replications. The percentile-t interval studentizes with the CR1 standard error in each replication. BCa uses the jackknife over states for the acceleration ($\hat{a} = 0.019$, $z_0 = 0.030$).

For the elasticity the methods disagree sharply. Because 1.3 percent of the $\hat{\rho}^*$ lie below one, the same share of bootstrap elasticities is negative and huge in magnitude. The percentile interval for ε is then not the image of the percentile interval for ρ. The map $\frac{\rho}{\rho-1}$ is monotone on each side of one, but not over the whole bootstrap support, so the transformation-respecting property fails. The basic interval reflects the long right tail to the left and includes negative elasticities, which makes no economic sense. The bootstrap standard deviation of the elasticity is 222, a meaningless number. The ratio has no finite moments whenever the distribution of its denominator has positive density at zero. Intervals for ε should be built from an interval for ρ and mapped through the monotone function, as in the second and last rows.

A.9.4 Multi-step estimators and counterfactuals

The bootstrap's main practical advantage is that it handles estimators built in several steps. The rule is simple: every step that uses the data must be repeated in every replication. Holding a first-step estimate fixed omits its sampling variance, the problem that the analytical correction of Proposition A.36 addresses. Two examples recur in the book.

The first is a generated regressand. Marginal costs implied by a logit pricing condition, $mc_{jt} = p_{jt} - \frac{1}{\hat{\alpha}(1-S_{ft})}$, depend on the demand estimate $\hat{\alpha}$. Regressing them on cost shifters with the usual standard errors treats $\hat{\alpha}$ as known. A market bootstrap that re-estimates α in each of 5,000 replications raises the standard error of the intercept from 0.016 to 0.072 in the simulated markets of Section C.6. The slopes barely change, because uncertainty about α moves all markups together.

The second is a counterfactual. Chaudhuri et al. (2006, WP p. 25) compute standard errors for counterfactual prices and welfare losses under patent enforcement by bootstrapping the original sample 300 times. For each sample they re-estimate the demand system and recompute the counterfactual equilibrium prices and welfare losses for each policy scenario. When a replication's counterfactual did not converge, they compute the standard errors from the replications that did (WP p. 25, n. 29). Dropping failed replications is common but not innocuous. If failures occur for particular parameter values, the retained replications are a selected sample of the bootstrap distribution.

Parametric bootstrap and parameter draws. Two cheaper procedures are often called a parametric bootstrap, and they differ. The first simulates new data sets from the fitted model $F(\cdot;\hat{\theta})$ and re-estimates on each. It is the natural way to compute the null distribution of a specification test whose statistic has no tractable limit. Athey et al. (2011, p. 241) use it for the conditional Kolmogorov test of Andrews (1997) and cannot reject their parametric bid model even at the 20 percent level. The second draws parameter vectors from the estimated asymptotic distribution $N(\hat{\theta}, \hat{V})$ and recomputes the statistic of interest without re-estimating (Remark A.55). Athey, Levin and Seira use this second procedure for the predicted outcomes of their Table V (p. 248), as do Nevo (2001) and Gentzkow (2007).

The validity conditions follow from what each procedure resamples. Parameter draws are valid when $\hat{\theta}$ is approximately normal and a is smooth. They are first-order equivalent to the delta method and cost one evaluation of a per draw. Re-estimating on resampled data also captures departures of $\hat{\theta}$ from normality, and it is the only one of the three that can deliver a refinement. It is also the most expensive. Gentzkow (2007, p. 733, n. 33) notes that bootstrapping would require estimating all parameters for each resample, which adds greatly to the computational cost.

A.9.5 When the bootstrap fails

Bootstrap consistency rests on the statistic being a smooth function of the empirical distribution. Without smoothness it can fail, and the canonical example is an extreme order statistic.

Proposition A.67 (The bootstrap of a sample maximum)**.** *Let $X_1, \dots, X_n$ be i.i.d. uniform on $[0, \theta]$ and $\hat{\theta} = \max_i X_i$. Then $\frac{n(\theta-\hat{\theta})}{\theta}$ converges in distribution to the standard exponential distribution, which is continuous (Proposition A.47). For the nonparametric bootstrap,*

$$\mathbb{P}^*\big(\hat{\theta}^* = \hat{\theta}\big) = 1 - \left(1 - \frac{1}{n}\right)^n \longrightarrow 1 - e^{-1} \approx 0.632.$$

The bootstrap distribution of $\frac{n(\hat{\theta}-\hat{\theta}^*)}{\hat{\theta}}$ *has an atom of mass about 0.632 at zero and does not converge to the exponential limit.*

Proof. The bootstrap maximum equals $\hat{\theta}$ if and only if the largest observation is drawn at least once. Each of the n independent draws misses it with probability $1-\frac{1}{n}$, so it is never drawn with probability $(1-\frac{1}{n})^n$. Taking logs, $n\ln(1-\frac{1}{n}) = n(-\frac{1}{n}-\frac{1}{2n^2}-\cdots) \to -1$, so $(1-\frac{1}{n})^n \to e^{-1}$. A limit distribution with an atom of mass $1-e^{-1}$ at zero cannot equal the continuous exponential distribution. □

The probability is already close to its limit in small samples: 0.651 for $n = 10$, 0.634 for $n = 100$ and 0.632 for $n = 1{,}000$. The intuition is that the bootstrap cannot draw values beyond the sample maximum, while the sampling distribution of $\hat{\theta}$ is driven by how far the maximum falls short of the true endpoint.

The same failure appears in other non-regular problems. Parameters on the boundary of the parameter space, such as a zero variance component, invalidate the bootstrap of the estimator (Andrews, 2000). Non-smooth functionals, such as bounds formed as the maximum or minimum of estimated functions, behave like the maximum above (Section A.11.6). With weak instruments the estimator is not asymptotically normal and the bootstrap does not fix it (Section A.3.5). Heavy tails and statistics without moments, like the elasticity ratio above, are a further case. Two remedies are general (Politis et al., 1999). *Subsampling* recomputes the statistic on subsamples of size b drawn without replacement, with $b \to \infty$ and $\frac{b}{n} \to 0$, and rescales by the known rate. The *m-out-of-n bootstrap* draws $m < n$ observations with replacement, with $\frac{m}{n} \to 0$. Both work under much weaker conditions because a small subsample behaves like a fresh sample from the population. The relevance for this book is direct. Auction models whose bid support depends on the parameters (Donald and Paarsch, 1996), estimators built on extreme order statistics, and partially identified models (Chapter 15) all fall outside the standard bootstrap's guarantees.

A.10 Nonparametric estimation of distributions and densities

The estimators of the previous sections are parametric, in the sense that a finite-dimensional θ indexes the model. Several of the book's estimators instead recover an unknown distribution without a parametric family. The structural auction literature is the main user. The value distribution of an ascending auction is recovered from the distribution of transaction prices. In a first-price auction it is recovered from the distribution and density of bids (Chapter 15). Bidding rings and procurement auctions with unobserved heterogeneity add a deconvolution step (Chapter 13), and hedonic demand models use nonparametric regression (Chapter 6). This section develops the estimators of distribution functions and densities on which these applications rest. Section A.11 turns to regression, deconvolution and bounds.

The notation is local to these two sections. A *kernel* $\mathcal{K}$ is a weighting function, $h > 0$ is a *bandwidth*, and $\mathcal{K}_h(u) = \frac{1}{h}\mathcal{K}(\frac{u}{h})$. The constants $\mu_2 = \int u^2\mathcal{K}(u)\,\mathrm{d}u$ and $\kappa_2 = \int \mathcal{K}(u)^2\,\mathrm{d}u$ are the second moment and the roughness of the kernel, and R counts the derivatives of the target function. In the auction applications we follow Guerre et al. (2000), hereafter GPV, and write L for the number of auctions. In these two sections L is therefore neither a Lerner index nor a number of instruments. Each auction has N bidders (GPV write I), bids are B_{il}, and the bid distribution and density are G and g.

A.10.1 The empirical distribution function

Let $X_1, \dots, X_n$ be independent draws from a distribution function F on $\mathbb{R}$. The *empirical distribution function* puts mass $\frac{1}{n}$ on each observation:

$$\hat{F}_n(x) = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}\{X_i \le x\}. \tag{A.88}$$

Proposition A.68 (Properties of the empirical distribution function)**.** *Let $X_1, \dots, X_n$ be i.i.d. with distribution function F.*

(i) For every x, $\mathbb{E}[\hat{F}_n(x)] = F(x)$ and $\operatorname{Var}(\hat{F}_n(x)) = \frac{F(x)(1-F(x))}{n}$.

(ii) For every x, $\sqrt{n}(\hat{F}_n(x) - F(x)) \xrightarrow{d} N(0, F(x)(1-F(x)))$.

(iii) (Glivenko-Cantelli) $\sup_x |\hat{F}_n(x) - F(x)| \to 0$ almost surely.

(iv) (Dvoretzky-Kiefer-Wolfowitz) For every $\epsilon > 0$, $\mathbb{P}\left(\sup_x |\hat{F}_n(x) - F(x)| > \epsilon\right) \le 2e^{-2n\epsilon^2}$.

Proof. For fixed x the indicators $\mathbf{1}\{X_i \le x\}$ are i.i.d. Bernoulli variables with success probability $F(x)$. Their mean is $F(x)$ and their variance is $F(x)(1-F(x))$. Averaging n of them divides the variance by n, which proves (i). Part (ii) is the Lindeberg-Lévy central limit theorem applied to the same Bernoulli average. Parts (iii) and (iv) are classical uniform results. The constant 2 in front of the exponential in (iv) is due to Massart (1990). □

Part (iv) yields a confidence band that holds for all x at once. Setting $2e^{-2n\epsilon^2} = \alpha$ gives $\epsilon_\alpha = \sqrt{\frac{\ln(\frac{2}{\alpha})}{2n}}$, and the band $\hat{F}_n(x) \pm \epsilon_\alpha$ contains the whole function F with probability at least $1-\alpha$. With $n = 200$ and $\alpha = 0.05$ the half-width is about 0.096. The band needs no smoothing and no estimate of a density, which makes the empirical distribution function the natural first step of every estimator in this section.

Order-statistic inversion. In a second-price or ascending auction with symmetric independent private values, the price equals the second-highest value (Chapter 14). Suppose we observe only prices w_l from L_N auctions with N bidders each. The price is $v_{(N-1:N)}$, and its distribution function is

$$F_w(v) = \mathbb{P}\left(v_{(N-1:N)} \le v\right) = \phi_N(F(v)), \qquad \phi_N(x) = Nx^{N-1}(1-x) + x^N. \tag{A.89}$$

The second-highest value lies below v exactly when at least $N-1$ of the N values do. The first term of ϕ_N is the probability that exactly $N-1$ values lie below v, and the second that all N do. The derivative is

$$\phi_N'(x) = N(N-1)x^{N-2}(1-x) - Nx^{N-1} + Nx^{N-1} = N(N-1)x^{N-2}(1-x),$$

which is positive on $(0,1)$. So ϕ_N is a strictly increasing bijection of $[0,1]$, and $F(v) = \phi_N^{-1}(F_w(v))$. More generally, the k-th lowest of N i.i.d. draws has distribution function

$$F_{(k:N)}(v) = \frac{N!}{(N-k)!\,(k-1)!} \int_0^{F(v)} t^{k-1}(1-t)^{N-k}\,\mathrm{d}t, \tag{A.90}$$

which is strictly increasing in $F(v)$ (Athey and Haile, 2002, eq. (5)). Any single order statistic with known N therefore identifies F, and (A.89) is the case $k = N-1$.

The plug-in estimator replaces F_w by the empirical distribution function of the prices, $\hat{F}(v) = \phi_N^{-1}(\hat{F}_w(v))$, computed by bisection at each v.

Proposition A.69 (Order-statistic inversion)**.** *Let $w_1, \dots, w_{L_N}$ be i.i.d. prices from N-bidder auctions and let $0 < F(v) < 1$. Then $\hat{F}(v) \xrightarrow{p} F(v)$ and*

$$\sqrt{L_N}\left(\hat{F}(v) - F(v)\right) \xrightarrow{d} N\left(0,\ \frac{F_w(v)(1 - F_w(v))}{\phi_N'(F(v))^2}\right). \tag{A.91}$$

Proof. Consistency follows from Proposition A.68(i) and the continuity of ϕ_N^{-1}. The inverse function theorem gives $\frac{\mathrm{d}}{\mathrm{d}y}\phi_N^{-1}(y) = \frac{1}{\phi_N'(\phi_N^{-1}(y))}$, which is finite because $\phi_N'(F(v)) > 0$. The delta method (Theorem A.59) applied to Proposition A.68(ii) multiplies the asymptotic variance $F_w(1 - F_w)$ by the square of this derivative. □

The variance in (A.91) measures what is lost by observing one order statistic. If all N values of each auction were recorded, the empirical distribution function of the NL_N values would have asymptotic variance $\frac{F(1-F)}{N}$ per auction. With $N = 4$ and $F(v) = 0.5$, the price-only variance is 0.0955 against 0.0625, a ratio of 1.53. At $F(v) = 0.2$ the ratio is 4.49, and with $N = 6$ at the same point it reaches 40.6. The price is the second-highest value, so it carries little information about the lower tail, and the loss grows with N. These numbers come from `kernel_constants.py`.

Two extensions matter in practice. First, the inversion delivers one estimate of F for each N in the data. If participation varies independently of values, all these estimates must coincide, which is a testable restriction (Athey and Haile, 2002, Theorem 1). The estimates from different N are independent, so a Wald-type comparison at a point v divides their difference by the square root of the sum of the two variances in (A.91). Second, with a binding reserve price r the price is $\max\{v_{(N-1:N)}, r\}$, and F is identified only above r. Chapter 15 develops the identification argument, and Section A.11.6 returns to ascending auctions in which recorded bids are not values.

A.10.2 The kernel density estimator

A histogram estimates a density by counting observations in bins of width $2h$. It depends on the bin origin, and it is discontinuous. The kernel estimator centers a smooth bump on each observation instead (Rosenblatt, 1956; Parzen, 1962):

$$\hat{f}_h(x) = \frac{1}{nh}\sum_{i=1}^{n} \mathcal{K}\left(\frac{x - X_i}{h}\right) = \frac{1}{n}\sum_{i=1}^{n} \mathcal{K}_h(x - X_i). \tag{A.92}$$

With the uniform kernel $\mathcal{K}(u) = \frac{1}{2}\mathbf{1}\{|u| \le 1\}$, $\hat{f}_h(x)$ is the share of observations within h of x divided by $2h$, a histogram whose bin moves with x.

Definition A.70 (Second-order kernel)**.** A *second-order kernel* is a bounded function $\mathcal{K}$ with $\int \mathcal{K}(u)\,\mathrm{d}u = 1$, $\int u\mathcal{K}(u)\,\mathrm{d}u = 0$, $0 < \mu_2 = \int u^2\mathcal{K}(u)\,\mathrm{d}u < \infty$ and $\kappa_2 = \int \mathcal{K}(u)^2\,\mathrm{d}u < \infty$. A symmetric density with finite variance is a second-order kernel.

Assumption A.71 (Pointwise kernel asymptotics)**.** The draws $X_1, \dots, X_n$ are i.i.d. with density f. In a neighborhood of the point x, f is twice continuously differentiable with bounded second derivative. The kernel is second order, and the bandwidth satisfies $h \to 0$ and $nh \to \infty$.

Proposition A.72 (Bias and variance of the kernel density estimator)**.** *Under Assumption A.71,*

$$\mathbb{E}[\hat{f}_h(x)] - f(x) = \frac{h^2}{2}\mu_2 f''(x) + o(h^2), \qquad \operatorname{Var}(\hat{f}_h(x)) = \frac{f(x)\kappa_2}{nh} + o\left(\frac{1}{nh}\right). \tag{A.93}$$

Proof. Bias. The summands of (A.92) are i.i.d., so

$$\mathbb{E}[\hat{f}_h(x)] = \int \frac{1}{h}\mathcal{K}\Big(\frac{x-y}{h}\Big) f(y)\,\mathrm{d}y = \int \mathcal{K}(u) f(x-hu)\,\mathrm{d}u,$$

where we substituted $y = x - hu$ and $\mathrm{d}y = -h\,\mathrm{d}u$. A second-order Taylor expansion with mean-value point $\tilde{x}_u$ between x and $x - hu$ gives

$$f(x-hu) = f(x) - hu f'(x) + \frac{h^2u^2}{2} f''(\tilde{x}_u).$$

Integrating against $\mathcal{K}$, the first term returns $f(x)$ and the second vanishes because $\int u\mathcal{K} = 0$. The third equals $\frac{h^2}{2}\int u^2\mathcal{K}(u) f''(\tilde{x}_u)\,\mathrm{d}u$, which is $\frac{h^2}{2}\mu_2 f''(x) + o(h^2)$ by continuity of f'' and dominated convergence.

Variance. Again by independence,

$$\operatorname{Var}(\hat{f}_h(x)) = \frac{1}{n}\left\{\mathbb{E}\left[\mathcal{K}_h(x-X)^2\right] - (\mathbb{E}[\mathcal{K}_h(x-X)])^2\right\}.$$

The same substitution gives $\mathbb{E}[\mathcal{K}_h(x-X)^2] = \frac{1}{h}\int \mathcal{K}(u)^2 f(x-hu)\,\mathrm{d}u = \frac{f(x)\kappa_2}{h} + O(1)$. The squared mean is $f(x)^2 + O(h^2) = O(1)$. Hence $\operatorname{Var}(\hat{f}_h(x)) = \frac{f(x)\kappa_2}{nh} + O(\frac{1}{n})$, and $\frac{1}{n} = o(\frac{1}{nh})$ because $h \to 0$. □

The proposition displays the basic trade-off of nonparametric estimation. A small bandwidth averages few observations, so the variance is large. A large bandwidth averages over a region where f curves, so the bias is large. The variance is of order $\frac{1}{nh}$ because only about $2nhf(x)$ observations fall in the kernel window, which is slower than the parametric $\frac{1}{n}$. Under the same conditions a Lindeberg argument gives $\sqrt{nh}\,(\hat{f}_h(x) - \mathbb{E}[\hat{f}_h(x)]) \xrightarrow{d} N(0, f(x)\kappa_2)$.

Optimal bandwidth. The *mean integrated squared error* is $\operatorname{MISE}(h) = \mathbb{E}\int(\hat{f}_h(x) - f(x))^2\,\mathrm{d}x$, the integral of squared bias plus variance. Integrating the leading terms of (A.93) and using $\int f = 1$ gives the *asymptotic MISE*

$$\operatorname{AMISE}(h) = \frac{h^4}{4}\mu_2^2\mathcal{R}(f'') + \frac{\kappa_2}{nh}, \qquad \mathcal{R}(f'') = \int f''(x)^2\,\mathrm{d}x. \tag{A.94}$$

The first-order condition $h^3\mu_2^2\mathcal{R}(f'') - \frac{\kappa_2}{nh^2} = 0$ yields

$$h^* = \left[\frac{\kappa_2}{\mu_2^2\mathcal{R}(f'')\,n}\right]^{\frac{1}{5}}. \tag{A.95}$$

At h^* the squared-bias term equals one quarter of the variance term, so

$$\operatorname{AMISE}(h^*) = \frac{5}{4}\frac{\kappa_2}{nh^*} = \frac{5}{4}\left(\sqrt{\mu_2}\,\kappa_2\right)^{\frac{4}{5}}\mathcal{R}(f'')^{\frac{1}{5}}\,n^{-\frac{4}{5}}.$$

The optimal bandwidth shrinks like $n^{-\frac{1}{5}}$ and the error falls like $n^{-\frac{4}{5}}$, against n^{-1} for a correctly specified parametric model.

Silverman's rule of thumb. The unknown $\mathcal{R}(f'')$ in (A.95) can be replaced by its value for a reference density. Take f normal with variance σ^2 and the Gaussian kernel, for which $\mu_2 = 1$

and $\kappa_2 = \frac{1}{2\sqrt{\pi}}$. Write $f(x) = \frac{1}{\sigma}\phi(\frac{x}{\sigma})$ with ϕ the standard normal density. Then $f''(x) = \sigma^{-3}\phi''(\frac{x}{\sigma})$ and $\phi''(u) = (u^2 - 1)\phi(u)$, so

$$\mathcal{R}(f'') = \sigma^{-5} \int (u^2 - 1)^2 \phi(u)^2 \, \mathrm{d}u.$$

Now $\phi(u)^2 = \frac{1}{2\sqrt{\pi}}\,\psi(u)$, where ψ is the $N(0, \frac{1}{2})$ density. For $U \sim N(0, \frac{1}{2})$ we have $\mathbb{E}[U^2] = \frac{1}{2}$ and $\mathbb{E}[U^4] = \frac{3}{4}$, so $\mathbb{E}[(U^2 - 1)^2] = \frac{3}{4} - 1 + 1 = \frac{3}{4}$. Therefore

$$\mathcal{R}(f'') = \frac{3}{8\sqrt{\pi}\,\sigma^5}, \qquad (h^*)^5 = \frac{\frac{1}{2\sqrt{\pi}}}{\frac{3}{8\sqrt{\pi}\,\sigma^5}\,n} = \frac{4}{3}\,\frac{\sigma^5}{n},$$

and

$$h_{\mathrm{ROT}} = \left(\frac{4}{3}\right)^{\frac{1}{5}} \sigma n^{-\frac{1}{5}} \approx 1.06\,\sigma n^{-\frac{1}{5}}. \tag{A.96}$$

This is the *rule of thumb* of Silverman (1986), with σ replaced by the sample standard deviation. It is optimal for normal data and oversmooths densities with more curvature, such as multimodal ones, because those have larger $\mathcal{R}(f'')$.

Choice of kernel. The kernel enters (A.95) only through $\delta_{\mathcal{K}} = (\frac{\kappa_2}{\mu_2^2})^{\frac{1}{5}}$, and the minimized AMISE only through $\sqrt{\mu_2}\,\kappa_2$. Two consequences follow. A bandwidth rule derived for one kernel converts to another kernel by the factor $\frac{\delta_{\mathcal{K}}}{\delta_\phi}$, whatever f is. And kernels differ little in efficiency once their bandwidths are scaled correctly. Table A.10 reports the constants. The Epanechnikov kernel minimizes $\sqrt{\mu_2}\,\kappa_2$, and every other kernel in the table attains at least 93 percent of its efficiency.

Table A.10: Second-order kernels and their constants

Kernel	$\mathcal{K}(u)$	μ_2	κ_2	$\int \mathcal{K}'(u)^2 \mathrm{d}u$	$\int_0^\infty u\mathcal{K}(u)\mathrm{d}u$	$\frac{\delta_{\mathcal{K}}}{\delta_\phi}$	Efficiency
Uniform	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{2}$	n.a.	$\frac{1}{4}$	1.740	0.930
Epanechnikov	$\frac{3}{4}(1-u^2)$	$\frac{1}{5}$	$\frac{3}{5}$	$\frac{3}{2}$	$\frac{3}{16}$	2.214	1.000
Biweight	$\frac{15}{16}(1-u^2)^2$	$\frac{1}{7}$	$\frac{5}{7}$	$\frac{15}{7}$	$\frac{5}{32}$	2.623	0.994
Triweight	$\frac{35}{32}(1-u^2)^3$	$\frac{1}{9}$	$\frac{350}{429}$	$\frac{35}{11}$	$\frac{35}{256}$	2.978	0.987
Gaussian	$\phi(u)$	1	$\frac{1}{2\sqrt{\pi}}$	$\frac{1}{4\sqrt{\pi}}$	$\frac{1}{\sqrt{2\pi}}$	1.000	0.951

Notes: the first four kernels are zero outside $|u| \le 1$. The column $\frac{\delta_{\mathcal{K}}}{\delta_\phi}$ is the factor that converts a bandwidth rule for the Gaussian kernel into the corresponding rule for kernel $\mathcal{K}$, with $\delta_{\mathcal{K}} = (\frac{\kappa_2}{\mu_2^2})^{\frac{1}{5}}$. Efficiency is $\sqrt{\mu_2}\,\kappa_2$ of the Epanechnikov kernel divided by $\sqrt{\mu_2}\,\kappa_2$ of the kernel in the row. It is the ratio of sample sizes that gives the two kernels the same minimized AMISE. The derivative roughness $\int \mathcal{K}'^2$ enters the variance of density-derivative estimators (Proposition A.74). The uniform kernel is not differentiable. All constants are computed exactly with sympy in `kernel_constants.py`.

The auction literature uses the triweight kernel almost exclusively. It has compact support, so trimmed observations drop out of the estimate, and it is continuously differentiable on the whole line, including the end points of its support. Guerre et al. (2000, p. 532) chose it to satisfy

their kernel assumptions. Li et al. (2002, p. 180) and Krasnokutskaya (2011, Section 4.3)[10] give the differentiability at the boundary as the reason. These authors also illustrate the conversion factor. Li et al. and Krasnokutskaya set the bandwidth constant to $2.978 \times 1.06\,\hat{\sigma}$, and 2.978 is the triweight entry in the $\frac{\delta_{\mathcal{K}}}{\delta_{\phi}}$ column. Guerre et al. (2000, p. 532) and Asker (2010, p. 749) use $1.06\,\hat{\sigma}$ with the same kernel, a bandwidth about one third of the normal-reference rule for that kernel.

The exponents of the sample size also differ across these papers. GPV set $h_g = 1.06\,\hat{\sigma}_b (NL)^{-\frac{1}{5}}$ for the bid density, with $\hat{\sigma}_b$ the standard deviation of the bids and NL the number of bids (p. 532). Asker (2010, p. 749) uses $1.06\,\hat{\sigma} n^{-\frac{1}{6}}$ for densities and $1.06\,\hat{\sigma} n^{-\frac{1}{5}}$ for kernel-smoothed distribution functions. Krasnokutskaya (2011, Section 4.3) uses $2.978 \times 1.06\,\hat{\sigma} L^{-\frac{1}{6}}$, with L her sample size and $\hat{\sigma}$ the standard deviation of the log of one plus the bids, and says that she follows GPV. The rates of Section A.10.3 explain the pattern. With R derivatives of the value density and d continuous covariates, GPV's bandwidths for the bid distribution and the bid density shrink like $L^{-\frac{1}{2R+d+2}}$ and $L^{-\frac{1}{2R+d+3}}$, up to logarithms. With $R = 1$ and no covariates the density exponent is $-\frac{1}{5}$, GPV's own choice. With $R = 1$ and $d = 1$ the two exponents are $-\frac{1}{5}$ and $-\frac{1}{6}$, the pair that Asker uses. Neither Asker nor Krasnokutskaya derives an exponent. In a one-dimensional problem $L^{-\frac{1}{6}}$ shrinks more slowly than $L^{-\frac{1}{5}}$, so their bandwidths oversmooth slightly relative to GPV's rule. Oversmoothing lowers the variance of $\hat{g}$ at the cost of more bias.

Figure A.9 illustrates the trade-off with a bimodal density, $f = 0.6\,N(0,1) + 0.4\,N(2.5, 0.5^2)$, and $n = 200$. Panel (a) shows one sample. Halving the optimal bandwidth produces spurious bumps, and doubling it blurs the two modes into a plateau. Panel (b) plots the exact integrated squared bias, integrated variance and MISE against h, with Monte Carlo averages over 1,000 samples as markers. The exact MISE is minimized at $h^* = 0.291$, where the integrated squared bias is 0.0014 and the integrated variance 0.0039. The AMISE formula (A.95) gives 0.262. Its quartic bias term overstates the bias at large h, which pulls the AMISE minimizer to the left.

A.10.3 Smoothness, higher-order kernels and derivatives

The h^2 bias of Proposition A.72 comes from the second moment of the kernel. If f has more derivatives, kernels with more vanishing moments reduce the bias further.

Definition A.73 (Kernel of order R)**.** A kernel $\mathcal{K}$ is of *order* $R \geq 2$ if $\int \mathcal{K} = 1$, $\mu_j = \int u^j \mathcal{K}(u)\,\mathrm{d}u = 0$ for $j = 1, \ldots, R-1$, and $0 < |\mu_R| < \infty$.

If f has R bounded continuous derivatives near x and $\mathcal{K}$ is of order R, the expansion in the proof of Proposition A.72, carried to order R, gives

$$\mathbb{E}[\hat{f}_h(x)] - f(x) = \sum_{j=1}^{R} \frac{(-h)^j}{j!} \mu_j f^{(j)}(x) + o(h^R) = \frac{(-h)^R}{R!} \mu_R f^{(R)}(x) + o(h^R). \tag{A.97}$$

The variance is unchanged at order $\frac{1}{nh}$. Balancing h^{2R} against $\frac{1}{nh}$ gives $h \propto n^{-\frac{1}{2R+1}}$ and a root mean squared error of order $n^{-\frac{R}{2R+1}}$. Stone (1982) showed that $(\frac{n}{\log n})^{\frac{R}{2R+1}}$ is the best possible rate for estimating such a density uniformly over a compact set. The logarithm is the price of uniformity.

[10] We use the working-paper version of Krasnokutskaya (2011) dated May 24, 2004 (PIER Working Paper 05-006), and equation, section, lemma and proposition numbers refer to it.

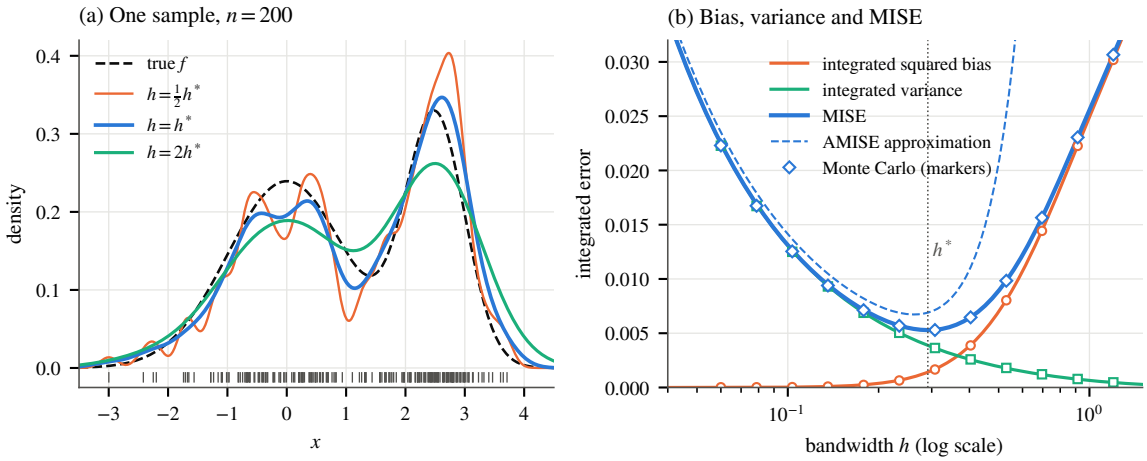

Figure A.9: Bandwidth choice for a kernel density estimator. The true density is $0.6\,N(0,1) + 0.4\,N(2.5, 0.5^2)$, the kernel is Gaussian and $n = 200$. (a) One sample (the median of 101 fresh samples by integrated squared error at h^*), with estimates at $\frac{1}{2}h^*$, h^* and $2h^*$, where $h^* = 0.291$ minimizes the exact MISE. (b) Exact integrated squared bias, integrated variance and MISE (solid lines), the AMISE approximation (A.94) (dashed) and Monte Carlo averages over 1,000 samples (markers). Seed 20261022, script `kde_demo.py`.

For $R > 2$ the kernel must take negative values, since $\mu_2 = 0$ is impossible for a nonnegative function. Density estimates can then be negative. In the auction setting this has a concrete cost. A negative estimated bid density produces pseudo-values below the corresponding bids, so Li et al. (2002, p. 180) keep second-order kernels in their three-bidder design even though their theory calls for order three.

Derivatives of a density. Differentiating (A.92) gives an estimator of the derivative,

$$\hat{f}_h'(x) = \frac{1}{nh^2} \sum_{i=1}^{n} \mathcal{K}'\left(\frac{x - X_i}{h}\right). \tag{A.98}$$

Proposition A.74 (Rate for a density derivative)**.** *Let $\mathcal{K}$ be a continuously differentiable kernel of order R that vanishes outside $[-1, 1]$, and let f have $R + 1$ bounded continuous derivatives near x. If $h \to 0$ and $nh^3 \to \infty$, then*

$$\mathbb{E}[\hat{f}_h'(x)] - f'(x) = \frac{(-h)^R}{R!}\mu_R f^{(R+1)}(x) + o(h^R), \qquad \operatorname{Var}(\hat{f}_h'(x)) = \frac{f(x)\int \mathcal{K}'(u)^2 \mathrm{d}u}{nh^3} + o\left(\frac{1}{nh^3}\right).$$

The mean squared error is minimized by $h \propto n^{-\frac{1}{2R+3}}$, and the root mean squared error is then of order $n^{-\frac{R}{2R+3}}$.

Proof. Bias. Substituting $y = x - hu$,

$$\mathbb{E}[\hat{f}_h'(x)] = \frac{1}{h}\int \mathcal{K}'(u) f(x - hu)\,\mathrm{d}u.$$

Integration by parts, with $\mathcal{K}(\pm 1) = 0$ and $\frac{\mathrm{d}}{\mathrm{d}u} f(x - hu) = -hf'(x - hu)$, turns this into $\int \mathcal{K}(u) f'(x - hu)\,\mathrm{d}u$. This is the expectation of a kernel estimator of f', and (A.97) applied to f' gives the bias.

Variance. Each summand of (A.98) is $\frac{1}{h^2}\mathcal{K}'(\frac{x-X_i}{h})$. Its second moment is

$$\frac{1}{h^4}\int \mathcal{K}'\Big(\frac{x-y}{h}\Big)^2 f(y)\,\mathrm{d}y = \frac{1}{h^3}\int \mathcal{K}'(u)^2 f(x-hu)\,\mathrm{d}u = \frac{f(x)\int \mathcal{K}'^2}{h^3} + o\left(\frac{1}{h^3}\right),$$

while its squared mean is $O(1)$. Dividing by n gives the variance.

Rate. The mean squared error is $c_1 h^{2R} + \frac{c_2}{nh^3}$ to first order. Its minimizer solves $2Rc_1 h^{2R-1} = \frac{3c_2}{nh^4}$, so $h \propto n^{-\frac{1}{2R+3}}$. Substituting back gives a mean squared error of order $n^{-\frac{2R}{2R+3}}$. □

The variance of a derivative estimate is larger by a factor h^{-2}, because differentiating the kernel divides by h once more. Every additional derivative costs two more powers of h in the variance and slows the rate.

Why first-price auctions converge slowly. The derivative result explains the rate of the estimator of Guerre et al. (2000). In the symmetric IPV first-price auction with N bidders, the inverse bid function is

$$\xi(b) = b + \frac{G(b)}{(N-1)g(b)}, \tag{A.99}$$

and the value distribution satisfies $G(b) = F(\xi(b))$ (Chapter 15). Differentiating gives $g(b) = f(\xi(b))\,\xi'(b)$, so the value density is

$$f(v) = \frac{g(\xi^{-1}(v))}{\xi'(\xi^{-1}(v))}, \qquad \xi'(b) = \frac{N}{N-1} - \frac{G(b)\,g'(b)}{(N-1)\,g(b)^2} \tag{A.100}$$

(Guerre et al., 2000, eq. (11)). The value density depends on the derivative of the bid density. GPV show that if f has R bounded continuous derivatives, then g has $R+1$ in the interior of its support (Guerre et al., 2000, Proposition 1). Estimating g' is then the problem of Proposition A.74, with R derivatives of g' available, and the best rate is $n^{-\frac{R}{2R+3}}$.

GPV make this heuristic exact. With d continuous auction covariates and L auctions, no estimator of the value density converges uniformly faster than $(\frac{L}{\log L})^{\frac{R}{2R+d+3}}$ (Guerre et al., 2000, Theorem 2). If values were observed, the best rate would be $(\frac{L}{\log L})^{\frac{R}{2R+d+1}}$. Their two-step estimator attains the bound (Guerre et al., 2000, Theorem 3) with bandwidths $h_G \propto (\frac{\log L}{L})^{\frac{1}{2R+d+2}}$ for the distribution, $h_g \propto (\frac{\log L}{L})^{\frac{1}{2R+d+3}}$ for the bid density, and $h_f \propto (\frac{\log L}{L})^{\frac{1}{2R+d+3}}$ for the value density (their Assumption A4). The first-step bandwidths are the optimal ones for G and g. The second-step bandwidth h_f is larger than the optimal bandwidth for observed values. GPV show that this oversmoothing is the only choice that attains the optimal rate given the first step. Pseudo-values away from the boundary converge uniformly at the faster rate $(\frac{L}{\log L})^{\frac{R+1}{2R+d+3}}$ of $\hat{g}$ (their Proposition 3), and the second step loses one power of the bandwidth when it smooths them.

A.10.4 Boundary bias and trimming

Kernel estimators are biased near the edge of the support. Bid and value distributions have compact supports, so this bias matters in every auction application.

Proposition A.75 (Boundary bias)**.** *Let f be zero below $\underline{x}$ and continuous on $[\underline{x}, \underline{x}+\eta)$ for some $\eta > 0$, with right limit $f(\underline{x}^+) > 0$. Let $\mathcal{K}$ be a kernel that vanishes outside $[-1, 1]$, and evaluate the estimator at $x = \underline{x} + ch$ with fixed $c \in [0, 1)$. Then as $h \to 0$,*

$$\mathbb{E}[\hat{f}_h(\underline{x} + ch)] \to f(\underline{x}^+) \int_{-1}^{c} \mathcal{K}(u)\,\mathrm{d}u.$$

For a symmetric kernel the limit at the boundary point itself ($c = 0$) is $\frac{1}{2} f(\underline{x}^+)$.

Proof. As in Proposition A.72, $\mathbb{E}[\hat{f}_h(x)] = \int \mathcal{K}(u) f(x - hu)\,\mathrm{d}u$. The density is zero unless $x - hu \geq \underline{x}$, that is, unless $u \leq c$. Hence $\mathbb{E}[\hat{f}_h(x)] = \int_{-1}^{c} \mathcal{K}(u) f(\underline{x} + h(c-u))\,\mathrm{d}u$. As $h \to 0$ the argument of f converges to $\underline{x}$ from above, and dominated convergence gives the limit. Symmetry gives $\int_{-1}^{0} \mathcal{K} = \frac{1}{2}$. □

The estimator does not converge to f anywhere in the boundary region of width h. Dividing by the known mass $\int_{-1}^{c} \mathcal{K}$ removes the leading term but leaves a bias of order h, against h^2 in the interior. Applied researchers use five remedies.

(a) *Reflection* adds the mirror image of the sample around $\underline{x}$, $\hat{f}_R(x) = \hat{f}_h(x) + \hat{f}_h(2\underline{x} - x)$ for $x \geq \underline{x}$. It removes the order-one bias. A bias of order h remains unless $f'(\underline{x}^+) = 0$.

(b) *Boundary kernels* change shape near the edge so that their moments of order zero and one over the available support are one and zero.

(c) *Transformation* estimates the density of a transformed variable whose support is unbounded and maps back by the change-of-variables formula. Li et al. (2002, footnote 13) recommend $\log(1 + b)$ when bids are very skewed.

(d) *Local linear density estimation* applies the boundary property of local linear regression (Proposition A.79) to a smoothed empirical distribution function.

(e) *Trimming* discards estimates within a bandwidth of the edge.

Trimming in the GPV estimator. GPV trim. Let ρ_g be the length of the support of the kernel used for $\hat{g}$, so $\rho_g = 2$ for the triweight kernel. By Proposition A.75, $\hat{g}$ is asymptotically biased within $\frac{\rho_g h_g}{2}$ of either end of the bid support. Since the minimum and maximum bids converge to the end points, GPV define the pseudo-value

$$\hat{V}_{il} = \begin{cases} B_{il} + \dfrac{\hat{G}(B_{il})}{(N-1)\,\hat{g}(B_{il})} & \text{if } B_{\min} + \frac{\rho_g h_g}{2} \leq B_{il} \leq B_{\max} - \frac{\rho_g h_g}{2}, \\ +\infty & \text{otherwise} \end{cases} \tag{A.101}$$

(Guerre et al., 2000, eq. (6)). With the triweight kernel the bids within h_g of the extreme bids are trimmed. An infinite pseudo-value contributes nothing to a second-step kernel estimate with compact support, so the device trims without changing the formula. With covariates, GPV trim observations within twice the bandwidths of the estimated boundary of the conditional support (their eq. (19)). Li et al. (2002, eq. (14)) use the window $[h_g, b_{\max} - h_g]$, since bids in their design are bounded below by zero, and Asker (2010, p. 749) follows the same practice. Trimming has a cost. The value density is estimated consistently only on an inner compact subset of its support, and the second-step estimate is itself biased within h_f of the trimmed region. Hickman and Hubbard (2015) propose boundary-corrected kernels for both steps in place of trimming.

A.10.5 Bandwidth choice and inference

Three families of bandwidth selectors are in use. The rule of thumb (A.96) is simple and stable but oversmooths curved densities. *Plug-in* selectors estimate $\mathcal{R}(f'')$ with a pilot kernel estimate and insert it into (A.95) (Sheather and Jones, 1991). *Least-squares cross-validation* (LSCV) estimates the integrated squared error directly. Expanding the square,

$$\int (\hat{f}_h - f)^2 = \int \hat{f}_h^2 - 2\int \hat{f}_h f + \int f^2.$$

The last term does not depend on h. The middle term is $2\mathbb{E}_X[\hat{f}_h(X)]$ for a new draw X, which the leave-one-out average estimates without bias. The criterion is

$$\mathrm{CV}(h) = \int \hat{f}_h(x)^2\,\mathrm{d}x - \frac{2}{n}\sum_{i=1}^{n} \hat{f}_{h,-i}(X_i), \qquad \hat{f}_{h,-i}(x) = \frac{1}{(n-1)h}\sum_{j\neq i} \mathcal{K}\!\left(\frac{x - X_j}{h}\right). \tag{A.102}$$

For the Gaussian kernel the first term has a closed form, $\int \hat{f}_h^2 = \frac{1}{n^2 h}\sum_i \sum_j \phi_{\sqrt{2}}(\frac{X_i - X_j}{h})$, where $\phi_{\sqrt{2}}$ is the $N(0, 2)$ density, because the convolution of two standard normal densities is the $N(0, 2)$ density.

The design of Figure A.9 shows the trade-offs (`kde_demo.py`, 1,000 samples). The population rule of thumb is 0.545, almost twice $h^* = 0.291$, because the mixture is bimodal. Its mean integrated squared error is 0.0103, about twice the 0.0053 attained at h^*. LSCV is centered correctly, with a mean of 0.294, but it is variable, with 10th and 90th percentiles of 0.199 and 0.376. Its mean integrated squared error is 0.0067.

Inference. Pointwise confidence intervals rest on the normal limit of Section A.10.2. At a bandwidth of order $n^{-\frac{1}{5}}$ the bias is of the same order as the standard deviation. Indeed, $\sqrt{nh}\cdot h^2 = \sqrt{nh^5}$ is bounded away from zero at such a bandwidth. An interval $\hat{f}_h(x) \pm 1.96\sqrt{\frac{\hat{f}_h(x)\kappa_2}{nh}}$ is then centered at the wrong point, and its coverage falls short of 95 percent. Two fixes are available. *Undersmoothing* takes $h = o(n^{-\frac{1}{5}})$ so that the bias vanishes relative to the standard deviation, at the cost of wider intervals. *Robust bias correction* subtracts an estimate of the bias and inflates the standard error to account for the estimated bias (Calonico et al., 2018).

Auction applications rarely follow either route. Athey and Haile (2007, Section 3.2.1, p. 21) report that data-driven bandwidth selection had not been explored there and that the asymptotic distribution of the two-step density estimator was largely unresolved.[11] For functionals that are asymptotically normal, such as quantiles of the value distribution, Haile et al. (2003) establish normality, and practitioners bootstrap. Bids within an auction may be dependent, so outside the independent private values model the bootstrap resamples whole auctions (Athey and Haile, 2007, Section 3.2.1, p. 21). Asker (2010) resamples auctions with 5,000 iterations (Section A.9.3 develops the cluster bootstrap).

A.10.6 Multivariate and conditional densities

With d-dimensional data the product kernel estimator is

$$\hat{f}_h(x) = \frac{1}{nh^d}\sum_{i=1}^{n}\prod_{k=1}^{d} \mathcal{K}\!\left(\frac{x_k - X_{ik}}{h}\right). \tag{A.103}$$

[11] We read the manuscript of May 6, 2005 of Athey and Haile (2007). Section, page, equation and footnote numbers refer to that manuscript and may differ from the published chapter. Its assessment of the literature dates from 2005.

The bias is still of order h^2. The variance becomes $\frac{f(x)\kappa_2^d}{nh^d}$ to first order, because the second moment of one summand is $\frac{1}{h^{2d}}\int \prod_k \mathcal{K}(\frac{x_k-y_k}{h})^2 f(y)\,\mathrm{d}y = \frac{1}{h^d}\kappa_2^d f(x) + o(h^{-d})$ after the substitution $y = x - hu$. Balancing h^4 against $\frac{1}{nh^d}$ gives $h \propto n^{-\frac{1}{4+d}}$ and a mean squared error of order $n^{-\frac{4}{4+d}}$. This is the *curse of dimensionality*. Ignoring constants, the accuracy that 100 observations deliver in one dimension requires $100^{\frac{4+d}{5}}$ observations in d dimensions, about 251 for $d = 2$, 631 for $d = 3$ and 3,981 for $d = 5$.

Conditional densities are ratios of joint and marginal densities, $f(y \mid x) = \frac{f(x,y)}{f(x)}$, and both terms can be estimated by (A.103). GPV estimate the conditional bid distribution given auction covariates X_l and the number of bidders N_l in this way. They rewrite the inverse bid function as $\xi(b,x,N) = b + \frac{1}{N-1}\frac{G(b,x,N)}{g(b,x,N)}$, where $G(b,x,N) = G(b \mid x,N) f_m(x,N)$ and $g(b,x,N) = g(b \mid x,N) f_m(x,N)$ share the marginal density f_m of the covariates, which cancels in the ratio (Guerre et al., 2000, eq. (12)). Both terms are estimated by kernels in the continuous covariates and in the discrete N (Guerre et al., 2000, eqs. (13)–(14)), and the optimal rate falls to $(\frac{L}{\log L})^{\frac{R}{2R+d+3}}$.

Affiliated private values. Li et al. (2002) extend the estimator to symmetric affiliated private values. The first-order condition involves the distribution of the highest rival bid M_{il} conditional on the bidder's own bid:

$$v = b + \frac{G_{M|B}(b \mid b)}{g_{M|B}(b \mid b)} = b + \frac{G_{M,B}(b,b)}{g_{M,B}(b,b)} \tag{A.104}$$

(Li et al., 2002, eq. (4)). Here $G_{M,B}(m,b) = G_{M|B}(m \mid b)\, g_B(b)$ is the derivative of the joint distribution of (M,B) in its second argument, and $g_{M,B}$ is the joint density. The marginal bid density g_B cancels, so the estimators

$$\hat{G}_{M,B}(b,b) = \frac{1}{L_n h_G}\sum_{l=1}^{L_n}\frac{1}{n}\sum_{i=1}^{n}\mathbf{1}\{M_{il} \le b\}\,\mathcal{K}_G\!\left(\frac{b - B_{il}}{h_G}\right), \tag{A.105}$$

$$\hat{g}_{M,B}(b,b) = \frac{1}{L_n h_g^2}\sum_{l=1}^{L_n}\frac{1}{n}\sum_{i=1}^{n}\mathcal{K}_g\!\left(\frac{b - M_{il}}{h_g}, \frac{b - B_{il}}{h_g}\right) \tag{A.106}$$

suffice (Li et al., 2002, eqs. (5)–(6)). Here n is the number of bidders, L_n the number of n-bidder auctions, $\mathcal{K}_G$ the triweight kernel and $\mathcal{K}_g$ a product of two triweight kernels. The second step estimates the n-dimensional joint density of the pseudo-values with a product kernel and averages it over the $n!$ permutations of its arguments to impose exchangeability. Their Proposition 2 gives uniform consistency at the rate $(\frac{L_n}{\log L_n})^{\frac{R(R+n-2)}{(R+n+1)(2R+2n-2)}}$ when $R > n-2$. With $R = 2$ and $n = 2$ this is $(\frac{L_n}{\log L_n})^{\frac{2}{15}}$, against Stone's $(\frac{L_n}{\log L_n})^{\frac{5}{15}}$ for observed values. The joint density is a higher-dimensional object and the first step involves a bivariate density, so the curse of dimensionality bites twice.

Their simulation guide is a template for practice. Values are $v_i = y + u_i$ with y uniform on $[0.25, 0.75]$ and u_i uniform on $[-0.25, 0.25]$, so the correlation between two values is 0.5. Each replication has 100 auctions with two bidders and 100 with three, and there are 1,000 replications (Li et al., 2002, pp. 178–179). Bandwidths are $h_G = c_G(nL)^{-\frac{1}{5}}$ and $h_g = c_g(nL)^{-\frac{1}{6}}$ for $n = 2$, and $(nL)^{-\frac{1}{7}}$ and $(nL)^{-\frac{1}{8}}$ for $n = 3$, with constants $2.978 \times 1.06\,\hat{\sigma}_b$ (Li et al., 2002, p. 180). The average bandwidths are 0.148 and 0.177 for $n = 2$ and 0.076 and 0.122 for $n = 3$ (Li et al., 2002, p. 182).

Homogenizing bids. Covariates can be removed before the nonparametric step when values scale multiplicatively with them. This reduces the dimension of every kernel estimate to one.

Proposition A.76 (Homogenization)**.** *Consider the symmetric IPV first-price auction with N bidders and a nonbinding reserve price. Suppose that values given covariates x satisfy $V = \Gamma(x)V^0$ with $\Gamma(x) > 0$, where the distribution F^0 of V^0 does not depend on x. Let β^0 be the equilibrium bid function when values are drawn from F^0. Then the equilibrium bid function given x is $\beta(v \mid x) = \Gamma(x)\beta^0(\frac{v}{\Gamma(x)})$, and $\ln B = \ln \Gamma(x) + \ln \beta^0(V^0)$.*

Proof. The equilibrium bid with value distribution $F(\cdot \mid x)$ and lower support point $\underline{v}(x)$ is $\beta(v \mid x) = v - \frac{\int_{\underline{v}(x)}^{v} F(u|x)^{N-1}\mathrm{d}u}{F(v|x)^{N-1}}$ (Chapter 14). Here $F(u \mid x) = F^0(\frac{u}{\Gamma(x)})$ and $\underline{v}(x) = \Gamma(x)\underline{v}^0$. Substituting $u = \Gamma(x)s$ and writing $v^0 = \frac{v}{\Gamma(x)}$,

$$\beta(v \mid x) = \Gamma(x)v^0 - \frac{\Gamma(x)\int_{\underline{v}^0}^{v^0} F^0(s)^{N-1}\mathrm{d}s}{F^0(v^0)^{N-1}} = \Gamma(x)\beta^0(v^0).$$

Taking logarithms of $B = \beta(V \mid x)$ gives the second claim. □

The proposition justifies a two-step procedure. Regress log bids on functions of the covariates, and apply the one-dimensional estimators to the residuals, the *homogenized bids* (Haile et al., 2003). Asker (2010) follows this route in the first step of his analysis of a bidding ring, regressing log knockout bids and target prices on lot characteristics (Chapter 13). The structure is restrictive. Covariates must shift the location of log values without changing the shape of their distribution, and the number of bidders must not depend on V^0. Unobserved heterogeneity with the same multiplicative structure leads to the deconvolution problem of Section A.11.5.

A.10.7 Worked application: the GPV estimator in a Monte Carlo

We replicate the Monte Carlo design of Guerre et al. (2000, Section 2.4). There are $L = 200$ auctions with $N = 5$ bidders, hence 1,000 bids per sample, and 1,000 replications. Values are log-normal with parameters zero and one, truncated to $[0.055, 2.5]$. The truncation keeps 81.8 percent of the log-normal mass, close to the "approximately 20%" that GPV report leaving out. The reserve price is not binding. We compute the equilibrium bid function $\beta(v) = v - \frac{\int_{0.055}^{v} F(u)^4\mathrm{d}u}{F(v)^4}$ on a grid of 200,001 points with the trapezoid rule. The bid support is $[0.055, 1.622]$.

Remark A.77 (The two-step estimator). Each replication runs the following steps (Guerre et al., 2000, eqs. (4)–(7)).

1. Draw NL values from F and compute the bids $B_{il} = \beta(V_{il})$.
2. Estimate the bid distribution by the empirical distribution function of all bids:

$$\hat{G}(b) = \frac{1}{NL}\sum_{l=1}^{L}\sum_{i=1}^{N}\mathbf{1}\{B_{il} \le b\}.$$

3. Estimate the bid density with the triweight kernel, $\hat{g}(b) = \frac{1}{NLh_g}\sum_l\sum_i \mathcal{K}(\frac{b-B_{il}}{h_g})$, with $h_g = 1.06\,\hat{\sigma}_b(NL)^{-\frac{1}{5}}$ and $\hat{\sigma}_b$ the standard deviation of the bids.

4. Compute the pseudo-values (A.101), trimming bids within h_g of the extreme bids.

5. Estimate the value density with the triweight kernel, $\hat{f}(v) = \frac{1}{NLh_f} \sum_l \sum_i \mathcal{K}(\frac{v-\hat{V}_{il}}{h_f})$, with $h_f = 1.06\,\hat{\sigma}_V (NL_T)^{-\frac{1}{5}}$. Here $\hat{\sigma}_V$ is the standard deviation of the finite pseudo-values. We read NL_T, which GPV define through "the number of auctions remaining after the trimming", as the number of untrimmed bids.

6. Evaluate $\hat{\xi}(b) = b + \frac{\hat{G}(b)}{(N-1)\hat{g}(b)}$ and $\hat{f}(v)$ at 500 equally spaced points of the bid and value supports, as GPV do.

GPV took $R = 1$, so the bandwidths are of order $L^{-\frac{1}{5}}$, and the factor N in the bandwidth reflects the N bids per auction. We also compute an infeasible estimate from the true values with the same kernel and rule. This isolates the cost of not observing values.

Figure A.10 reports the results. In panel (a) the pseudo-values of one replication scatter tightly around the true inverse bid function, with visible wiggles where $\hat{g}$ is noisy. The mean of $\hat{\xi}$ across replications is indistinguishable from the truth on the untrimmed region. It bends sharply upward near the top of the bid support, where $\hat{g}$ falls toward zero as Proposition A.75 predicts. On average 8.8 percent of the bids are trimmed. The average bandwidths are $h_g = 0.107$ and $h_f = 0.147$. In panel (b) the shaded regions lie outside the interval defined in GPV's footnote 9, the average of $\hat{\xi}(B_{\min} + h_g) + h_f$ to the average of $\hat{\xi}(B_{\max} - h_g) - h_f$. This interval is $[0.333, 2.138]$ in our replication, close to the vertical lines of GPV's Figure 2. Inside it, the mean of $\hat{f}$ deviates from f by at most 0.027, against a peak density of 0.80. The pointwise 5 to 95 percent band contains the true density at every grid point. These are the two features GPV emphasize.

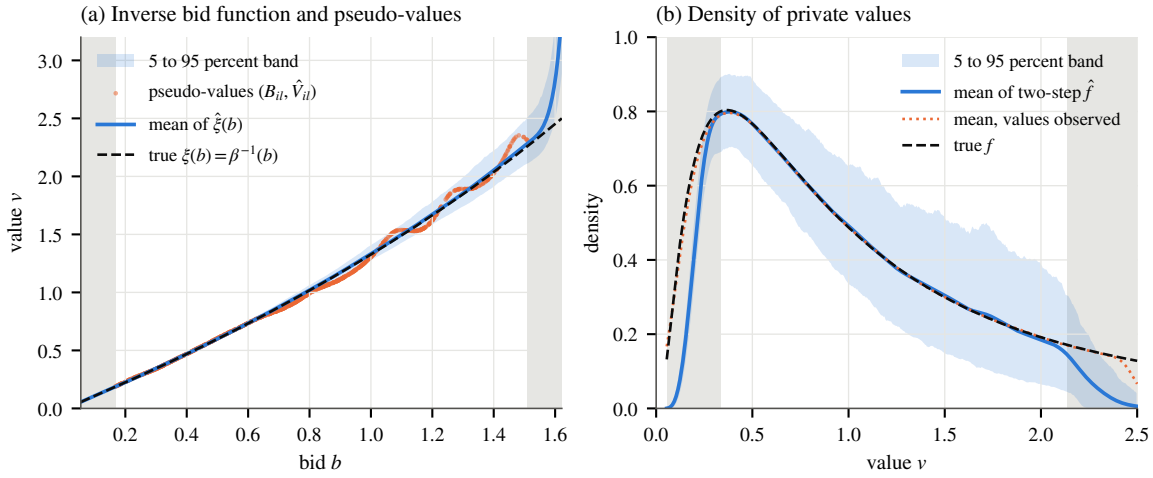

Figure A.10: The two-step estimator of Guerre et al. (2000) in their Monte Carlo design: 200 auctions with 5 bidders, values log-normal(0, 1) truncated to $[0.055, 2.5]$, triweight kernels, rule-of-thumb bandwidths, 1,000 replications. (a) True inverse bid function, mean and pointwise 5 to 95 percent band of $\hat{\xi}(b)$, and the pseudo-values of the first replication. The shaded bids are trimmed on average (within h_g of the extreme bids). (b) True value density, mean and pointwise 5 to 95 percent band of the two-step estimate, and the mean of the infeasible estimate from true values. The shaded regions lie outside GPV's interior region (their footnote 9). Seed 20261022, script `gpv_mc.py`. Design follows Guerre, Perrigne and Vuong (2000), Section 2.4.

The comparison with the infeasible estimator quantifies the price of inversion. On the interior region the mean integrated squared error of the two-step estimate is 0.0170, against 0.0035 when values are observed, a ratio of 4.9. The band in panel (b) is correspondingly wide, especially to the right of the mode, where the bid density is low and its estimation error is amplified by (A.99). Near the lower end the two-step estimate collapses toward zero. Its mean at $v = 0.055$ is 0.0003, against a true density of 0.132. This is the joint effect of trimming and boundary bias, and it is why GPV report results only on the interior region.

A.11 Nonparametric regression, deconvolution and bounds

This section estimates conditional means without functional form, combines nonparametric and parametric components, separates a common factor from idiosyncratic noise, and draws inferences when the data identify only a set. The tools build on Section A.10. Throughout, (y_i, x_i) are i.i.d., $m(x) = \mathbb{E}[y_i \mid x_i = x]$ is the regression function, $\sigma^2(x) = \mathrm{Var}(y_i \mid x_i = x)$, and f is the density of the scalar regressor x_i unless stated otherwise.

A.11.1 The Nadaraya-Watson estimator

The regression function is $m(x) = \frac{\int y f(x,y)\,\mathrm{d}y}{f(x)}$. Replacing the joint density by the product kernel estimate $\hat f(x,y) = \frac{1}{n}\sum_i \mathcal{K}_h(x - x_i)\mathcal{K}_h(y - y_i)$ and using $\int y\,\mathcal{K}_h(y - y_i)\,\mathrm{d}y = y_i$ for a symmetric kernel gives the *Nadaraya-Watson estimator* (Nadaraya, 1964; Watson, 1964):

$$\hat m_h(x) = \frac{\sum_{i=1}^n \mathcal{K}_h(x - x_i)\, y_i}{\sum_{i=1}^n \mathcal{K}_h(x - x_i)}. \tag{A.107}$$

It is a weighted average of the outcomes, with weights that decline with distance from x. It also solves $\min_a \sum_i \mathcal{K}_h(x - x_i)(y_i - a)^2$, so it is a *local constant* least squares fit.

Proposition A.78 (Bias and variance of Nadaraya-Watson)**.** *Let x be an interior point with $f(x) > 0$. Let f be continuously differentiable and m twice continuously differentiable near x, let σ^2 be continuous, and let $h \to 0$ and $nh \to \infty$. Then*

$$\mathbb{E}[\hat m_h(x)] - m(x) \approx h^2 \mu_2 \left(\frac{m''(x)}{2} + \frac{m'(x) f'(x)}{f(x)} \right), \qquad \mathrm{Var}(\hat m_h(x)) \approx \frac{\sigma^2(x) \kappa_2}{nh f(x)}, \tag{A.108}$$

where $\approx$ means equality of the leading terms.

Derivation. Write $\hat m_h(x) - m(x) = \frac{\hat A(x)}{\hat f(x)}$ with $\hat A(x) = \frac{1}{n}\sum_i \mathcal{K}_h(x - x_i)(y_i - m(x))$ and $\hat f(x) = \frac{1}{n}\sum_i \mathcal{K}_h(x - x_i)$. Since $\hat f(x) \xrightarrow{p} f(x)$, the leading terms of the bias and variance are those of $\frac{\hat A(x)}{f(x)}$.

Bias. Using $\mathbb{E}[y_i \mid x_i] = m(x_i)$ and substituting $x_i = x - hu$,

$$\mathbb{E}[\hat A(x)] = \int \mathcal{K}(u) \{ m(x - hu) - m(x) \} f(x - hu)\,\mathrm{d}u.$$

Expand $m(x-hu) - m(x) = -hum'(x) + \frac{h^2u^2}{2} m''(x) + o(h^2)$ and $f(x - hu) = f(x) - huf'(x) + o(h)$. The product is $-hum'f + h^2u^2(m'f' + \frac{1}{2}m''f) + o(h^2)$. The term linear in u integrates to zero, so $\mathbb{E}[\hat A(x)] = h^2\mu_2(m'(x)f'(x) + \frac{1}{2}m''(x)f(x)) + o(h^2)$. Dividing by $f(x)$ gives the bias.

Variance. The leading term is $\frac{1}{n}\mathbb{E}[\mathcal{K}_h(x-x_i)^2(y_i-m(x))^2] = \frac{1}{nh}\int \mathcal{K}(u)^2\{\sigma^2(x-hu)+(m(x-hu)-m(x))^2\}f(x-hu)\,\mathrm{d}u$, which equals $\frac{\kappa_2\sigma^2(x)f(x)}{nh}$ to first order. Dividing by $f(x)^2$ gives the variance. □

The bias has two parts. The curvature term $\frac{1}{2}m''$ is shared with every local smoother. The *design bias* $\frac{m'f'}{f}$ arises because, where the regressor density slopes, more observations sit on one side of x than on the other. The local average then leans toward the side with more data, and the slope of m converts the imbalance into bias.

At a boundary the problem is worse. Let the design have support $[0,\infty)$ with $f(0)>0$ and evaluate at $x=0$. Only $u\le 0$ contributes, so $\mathbb{E}[\hat{A}(0)] \approx -hm'(0)f(0)\int_{-\infty}^{0} u\mathcal{K}(u)\,\mathrm{d}u = hm'(0)f(0)\int_0^\infty u\mathcal{K}(u)\,\mathrm{d}u$, while $\hat{f}(0)\to\frac{1}{2}f(0)$. The bias is

$$\mathbb{E}[\hat{m}_h(0)]-m(0) \approx 2h\,m'(0)\int_0^\infty u\mathcal{K}(u)\,\mathrm{d}u = \frac{3}{8}\,h\,m'(0) \quad \text{(Epanechnikov kernel)}, \tag{A.109}$$

which is of order h against h^2 in the interior. The Epanechnikov value $\int_0^\infty u\mathcal{K}(u)\,\mathrm{d}u = \frac{3}{16}$ is taken from Table A.10. For the four compact kernels of that table the integral runs over $[0,1]$.

A.11.2 Local polynomial regression

The local constant fit ignores the slope of m. Fitting a line locally removes the design bias and the first-order boundary bias. The *local linear estimator* solves

$$(\hat{a},\hat{b}) = \arg\min_{a,b}\sum_{i=1}^{n}\mathcal{K}_h(x_i-x)\,\{y_i-a-b(x_i-x)\}^2, \qquad \hat{m}_{\mathrm{LL}}(x)=\hat{a}. \tag{A.110}$$

Let $S_j=\sum_i \mathcal{K}_h(x_i-x)(x_i-x)^j$. Solving the two normal equations gives

$$\hat{m}_{\mathrm{LL}}(x) = \frac{\sum_i w_i y_i}{\sum_i w_i}, \qquad w_i = \mathcal{K}_h(x_i-x)\{S_2-(x_i-x)S_1\}. \tag{A.111}$$

The weights satisfy $\sum_i w_i(x_i-x) = S_1S_2 - S_2S_1 = 0$. The estimator therefore reproduces any linear function exactly, whatever the design.

Proposition A.79 (Local linear regression)**.** *Let $\mathcal{K}$ vanish outside $[-1,1]$ and let m be twice continuously differentiable. Conditional on the regressors, and whenever $\sum_i w_i \neq 0$,*

$$\mathbb{E}[\hat{m}_{\mathrm{LL}}(x)\mid x_1,\dots,x_n]-m(x) = \frac{\sum_i w_i\,\frac{1}{2}m''(\tilde{x}_i)(x_i-x)^2}{\sum_i w_i},$$

with $\tilde{x}_i$ between x and x_i. At interior points the conditional bias is $\frac{h^2}{2}\mu_2 m''(x)+o_p(h^2)$, free of the design term. At boundary points it remains of order h^2. The interior variance is the Nadaraya-Watson variance $\frac{\sigma^2(x)\kappa_2}{nhf(x)}$ (Fan and Gijbels, 1996).

Derivation. Write $y_i = m(x)+m'(x)(x_i-x)+r_i+e_i$, where $r_i=\frac{1}{2}m''(\tilde{x}_i)(x_i-x)^2$ and $\mathbb{E}[e_i\mid x_i]=0$. Substituting into (A.111), the constant returns $m(x)$ and the linear term vanishes because $\sum_i w_i(x_i-x)=0$. What remains is $\frac{\sum_i w_i(r_i+e_i)}{\sum_i w_i}$, whose conditional mean is the displayed bias. Only observations with $|x_i-x|\le h$ receive weight, so $|r_i|\le\frac{1}{2}h^2\sup|m''|$ wherever x lies, and

the bias is $O_p(h^2)$ as long as $\frac{\sum_i |w_i|}{|\sum_i w_i|}$ stays bounded. That ratio is bounded at the boundary too, because $S_0 S_2 - S_1^2 > 0$ when the window contains data on a set of positive length. In the interior, $\frac{S_1}{S_0} = O_p(h^2)$ and $\frac{S_2}{S_0} = h^2\mu_2 + o_p(h^2)$, so the weights behave like $\mathcal{K}_h(x_i - x)$ to first order and the bias becomes $\frac{h^2}{2}\mu_2 m''(x)$. The variance argument is that of Proposition A.78. □

Fitting a polynomial of degree p in place of a line gives the *local polynomial* estimator. The coefficient on $(x_i - x)^k$ estimates $\frac{m^{(k)}(x)}{k!}$, so the slope $\hat{b}$ in (A.110) is a natural estimator of $m'(x)$. Odd degrees are preferred because they adapt automatically to the boundary (Fan and Gijbels, 1996).

Figure A.11 compares the two estimators with the same Epanechnikov kernel and bandwidth $h = 0.10$. The design density is $\frac{2}{3}(1+x)$ on $[0,1]$ and the regression function is $m(x) = 2e^{-5x} + 0.5x$, which is steep at the left boundary, with $m'(0) = -9.5$. With $n = 400$, noise standard deviation 0.25 and 1,000 samples, the bias of Nadaraya-Watson at $x = 0$ is -0.316. The approximation (A.109) gives -0.356, and the difference reflects the large curvature of m near zero. The local linear bias at $x = 0$ is -0.028. Its standard deviation there is larger, 0.105 against 0.064, because a line fitted at the edge extrapolates. In the interior both estimators share the curvature bias, which reaches 0.031 for local linear near $x = 0.1$, where $m'' = 50e^{-0.5} \approx 30$. Local fitting removes the design term and leaves the curvature term.

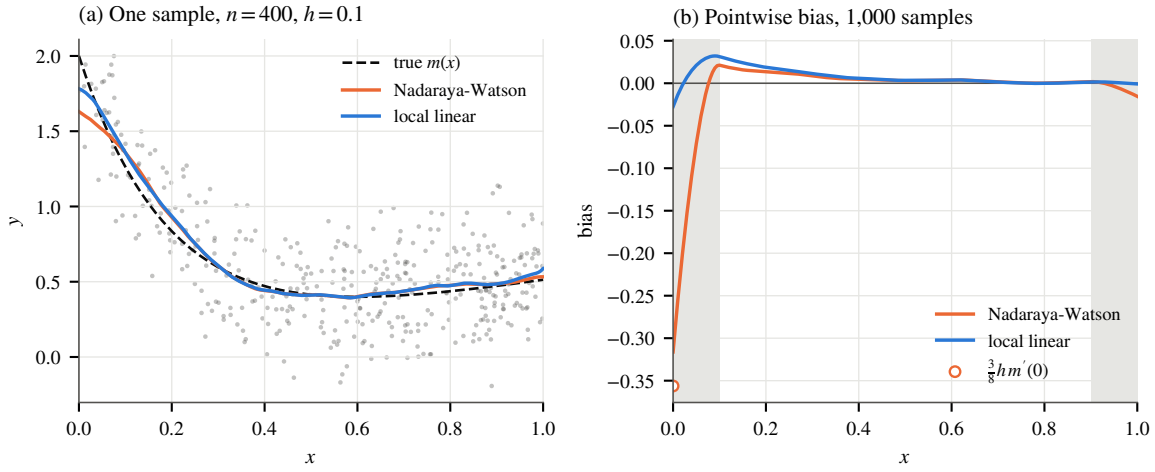

Figure A.11: Nadaraya-Watson and local linear regression with the same Epanechnikov kernel and bandwidth $h = 0.10$. The regressor has density $\frac{2}{3}(1+x)$ on $[0,1]$, $m(x) = 2e^{-5x} + 0.5x$, and the noise is $N(0, 0.25^2)$, $n = 400$. (a) One sample. (b) Pointwise bias over 1,000 samples. The shaded strips are within one bandwidth of the boundary, and the marker shows the boundary approximation $\frac{3}{8}hm'(0)$ of (A.109). Seed 20261022, script `npreg_demo.py`.

Applications in the book. Three applications use local regression. First, Hausman and Newey (1995) estimate demand $q(p, y)$ nonparametrically, as a function of price and income, and carry out the exact welfare analysis with it (Hausman, 1997, fn. 6). The exact analysis solves the differential equation of Hausman (1981). For a price change from p^0 to p^1, let $S(p) = e(p, u^0) - y$ be the extra income needed to keep utility at its initial level. Shephard's lemma and duality give

$$\frac{\mathrm{d}S(p)}{\mathrm{d}p} = q\big(p,\, y + S(p)\big), \qquad S(p^0) = 0, \tag{A.112}$$

and the compensating variation is $S(p^1)$ (Appendix B). Hausman (1997) solves the same differential equation for a parametric demand system for a new breakfast cereal. His exact welfare estimates and their standard errors use the method of Hausman and Newey (1995) (his fn. 24, Chapter 10). Second, Bajari and Benkard (2005, eq. (18)) recover each product's unobserved characteristic as a conditional quantile. Normalizing ξ to be uniform on $[0, 1]$ and independent of x, with price increasing in ξ, they set $\hat{\xi}_{jt} = \hat{F}_{p_t|x=x_j}(p_{jt})$. In their application a local linear kernel estimator (Fan and Gijbels, 1996) with a normal kernel worked best (Bajari and Benkard, 2005, Sections 5.1 and 6). Derivatives of the estimated hedonic price function then recover consumers' marginal valuations from their first-order conditions (Chapter 6). Third, conditional bid distributions given covariates can be estimated by local linear smoothing of indicator outcomes $\mathbf{1}\{B_{il} \le b\}$, which avoids the boundary problems of Section A.10.4 in the covariate dimension.

A.11.3 Series and sieve estimators

A *series estimator* approximates m by a linear combination of K_n known basis functions $\psi(x) = (\psi_1(x), \dots, \psi_{K_n}(x))^\top$, such as powers of x or regression splines. It fits the coefficients by least squares,

$$\hat{m}(x) = \psi(x)^\top \hat{\gamma}, \qquad \hat{\gamma} = (\Psi^\top \Psi)^{-1} \Psi^\top y. \tag{A.113}$$

Here Ψ is the $n \times K_n$ matrix with rows $\psi(x_i)^\top$. The number of terms plays the role of the inverse bandwidth. Its variance cost has an exact expression. With homoskedastic errors of variance σ^2, the fitted values are $P_\Psi y$ with $P_\Psi = \Psi(\Psi^\top \Psi)^{-1} \Psi^\top$, so

$$\frac{1}{n} \sum_{i=1}^{n} \operatorname{Var}(\hat{m}(x_i) \mid \Psi) = \frac{\sigma^2}{n} \operatorname{tr}(P_\Psi) = \frac{\sigma^2 K_n}{n}.$$

For a function with R derivatives and a polynomial or spline basis in one dimension, the squared approximation bias is of order K_n^{-2R}. Balancing the two gives $K_n \propto n^{\frac{1}{2R+1}}$ and the same mean squared error rate $n^{-\frac{2R}{2R+1}}$ as a kernel estimator (Newey, 1997). In practice K_n is chosen by cross-validation or an information criterion.

Series estimators are global. A misbehaving term affects the fit everywhere, and high-order polynomials are unstable at the boundary, which favors splines. In exchange, restrictions such as additivity, $m(x) = m_1(x_1) + m_2(x_2)$, are easy to impose by choosing the basis, and the estimator is a least squares regression whose inference is standard for fixed K_n. A *sieve* is the general version, an approximating parameter space that grows with n (Chen, 2007). Three uses appear in the book. Approximations to optimal instruments use series in the instruments (Section A.5.5). The marginal cost of an airline segment in Berry et al. (1996) is a cubic polynomial in leg distance and leg density, with two congestion shifters (WP Table 5, Section 9.7.4). It is a fixed low-order series. And Athey and Haile (2007, footnote 20) point to sieve estimation as a practical alternative to kernels in auctions with observed heterogeneity.

A.11.4 The partially linear model

Often only a few parameters are of interest, while a control variable enters in an unknown way. The *partially linear model* is

$$y_i = x_i^\top \beta + m(w_i) + e_i, \qquad \mathbb{E}[e_i \mid x_i, w_i] = 0, \tag{A.114}$$

with m unknown. Taking expectations conditional on w_i gives $\mathbb{E}[y_i \mid w_i] = \mathbb{E}[x_i \mid w_i]^\top \beta + m(w_i)$. Subtracting this from (A.114) eliminates m:

$$\tilde{y}_i = \tilde{x}_i^\top \beta + e_i, \qquad \tilde{y}_i = y_i - \mathbb{E}[y_i \mid w_i], \quad \tilde{x}_i = x_i - \mathbb{E}[x_i \mid w_i]. \tag{A.115}$$

Robinson (1988) estimates the two conditional means nonparametrically and regresses the residual of y on the residual of x by least squares. This is the *double-residual estimator*.

Proposition A.80 (Robinson's estimator)**.** *Suppose $\mathbb{E}[\tilde{x}_i \tilde{x}_i^\top]$ is positive definite, so no linear combination of x_i is a function of w_i alone. Suppose the first-step estimators of $\mathbb{E}[y \mid w]$ and $\mathbb{E}[x \mid w]$ converge in mean square faster than $n^{-\frac{1}{4}}$, with trimming and kernel order as in Robinson (1988). Then*

$$\sqrt{n}(\hat{\beta} - \beta) \xrightarrow{d} N\big(0,\ \mathbb{E}[\tilde{x}\tilde{x}^\top]^{-1}\mathbb{E}[e^2\tilde{x}\tilde{x}^\top]\mathbb{E}[\tilde{x}\tilde{x}^\top]^{-1}\big)\,,$$

the distribution of the infeasible regression with known conditional means.

Why the first step does not matter. The estimator solves the sample analogue of the moment $\mathbb{E}[(\tilde{y} - \tilde{x}^\top\beta)\tilde{x}] = 0$. Perturb the conditional means by functions $\delta_y(w)$ and $\delta_x(w)$, so the moment becomes $M(\delta) = \mathbb{E}[\{\tilde{y} - \delta_y(w) - (\tilde{x} - \delta_x(w))^\top\beta\}\{\tilde{x} - \delta_x(w)\}]$. Its derivative at $\delta = 0$ in the direction δ_y is $-\mathbb{E}[\delta_y(w)\tilde{x}]$, which is zero because $\mathbb{E}[\tilde{x} \mid w] = 0$. In the direction δ_x the derivative is $\mathbb{E}[\tilde{x}\,\delta_x(w)^\top]\beta - \mathbb{E}[e\,\delta_x(w)]$, and both terms vanish by $\mathbb{E}[\tilde{x} \mid w] = 0$ and $\mathbb{E}[e \mid w] = 0$. First-step errors therefore enter only through products of two errors, of order $\|\hat{\delta}\|^2$. If $\|\hat{\delta}\| = o_p(n^{-\frac{1}{4}})$, these products are $o_p(n^{-\frac{1}{2}})$, and the infeasible limit applies. □

The estimator is the nonparametric analogue of the Frisch-Waugh-Lovell theorem (Theorem A.9). If $m(w) = w^\top\gamma$, partialling out w by linear projection and regressing residual on residual reproduces the coefficient on x in the long regression. Robinson replaces the linear projection by the conditional expectation, which partials out every function of w. The insensitivity to the first step derived in the proof is the property now called *Neyman orthogonality*.

A simulation in `npreg_demo.py` shows what is at stake. Let w be uniform on $[0, 1]$, $x = \sin(2\pi w) + v$ and $y = x + 2\sin(2\pi w) + e$, with v and e standard normal, $n = 500$ and 1,000 samples. Least squares of y on a constant, x and w controls for w linearly. Its mean estimate is 1.327 against $\beta = 1$, and its nominal 95 percent interval never covers the truth. Robinson's estimator with local linear first steps ($h = 0.08$) has mean 0.999 and standard deviation 0.045, equal to the infeasible value $\frac{1}{\sqrt{500}} \approx 0.045$. Its interval covers in 94.1 percent of samples.

A.11.5 Deconvolution

Suppose two noisy measurements share a common component,

$$Y_1 = U + \epsilon_1, \qquad Y_2 = U + \epsilon_2, \tag{A.116}$$

with U, ϵ_1 and ϵ_2 mutually independent. In auctions, U is the log of a factor that scales all bids in an auction, known to the bidders and unobserved by us. The term ϵ_j is the log of the bid that bidder j would make if the factor were one. The goal is the distribution of each component from the joint distribution of (Y_1, Y_2).

Second moments show why two measurements help. Independence gives $\mathrm{Cov}(Y_1, Y_2) = \mathrm{Var}(U)$, so $\mathrm{Var}(\epsilon_j) = \mathrm{Var}(Y_j) - \mathrm{Cov}(Y_1, Y_2)$, and the normalization $\mathbb{E}[\epsilon_1] = 0$ gives $\mathbb{E}[U] = \mathbb{E}[Y_1]$. Variation across auctions identifies the spread of the common factor, and variation within auctions identifies the spread of the idiosyncratic parts. A theorem of Kotlarski (1966) extends this from second moments to whole distributions. Let $\varphi_U(t) = \mathbb{E}[e^{itU}]$ denote a characteristic function, where i is the imaginary unit, and let $\varphi_{Y_1Y_2}(t_1, t_2) = \mathbb{E}[e^{it_1Y_1 + it_2Y_2}]$.

Lemma A.81 (Kotlarski)**.** *In* (A.116)*, let* U*,* ϵ_1*,* ϵ_2 *be mutually independent with finite first moments and* $\mathbb{E}[\epsilon_1] = 0$*, and let* φ_U *and* φ_{ϵ_2} *never vanish. Then for every real* t*,*

$$\varphi_U(t) = \exp\left(\int_0^t \frac{\mathbb{E}\left[\mathrm{i}Y_1 e^{\mathrm{i}sY_2}\right]}{\mathbb{E}\left[e^{\mathrm{i}sY_2}\right]}\,\mathrm{d}s\right), \qquad \varphi_{\epsilon_1}(t) = \frac{\varphi_{Y_1Y_2}(t,0)}{\varphi_U(t)}, \qquad \varphi_{\epsilon_2}(t) = \frac{\varphi_{Y_1Y_2}(0,t)}{\varphi_U(t)}. \tag{A.117}$$

The joint distribution of (Y_1, Y_2) *therefore determines the distributions of* U*,* ϵ_1 *and* ϵ_2*.*

Proof. Independence factors the joint characteristic function:

$$\varphi_{Y_1Y_2}(t_1,t_2) = \mathbb{E}\left[e^{\mathrm{i}(t_1+t_2)U} e^{\mathrm{i}t_1\epsilon_1} e^{\mathrm{i}t_2\epsilon_2}\right] = \varphi_U(t_1+t_2)\,\varphi_{\epsilon_1}(t_1)\,\varphi_{\epsilon_2}(t_2).$$

Finite first moments make the characteristic functions continuously differentiable, with $\varphi_X'(0) = \mathrm{i}\mathbb{E}[X]$. Differentiating in t_1 and setting $t_1 = 0$, with $\varphi_{\epsilon_1}(0) = 1$ and $\varphi_{\epsilon_1}'(0) = \mathrm{i}\mathbb{E}[\epsilon_1] = 0$,

$$\frac{\partial \varphi_{Y_1Y_2}}{\partial t_1}(0,s) = \varphi_U'(s)\,\varphi_{\epsilon_2}(s).$$

The left side equals $\mathbb{E}[\mathrm{i}Y_1 e^{\mathrm{i}sY_2}]$, and $\varphi_{Y_1Y_2}(0,s) = \mathbb{E}[e^{\mathrm{i}sY_2}] = \varphi_U(s)\varphi_{\epsilon_2}(s) \neq 0$. Dividing, $\varphi_{\epsilon_2}(s)$ cancels:

$$\frac{\mathbb{E}[\mathrm{i}Y_1 e^{\mathrm{i}sY_2}]}{\mathbb{E}[e^{\mathrm{i}sY_2}]} = \frac{\varphi_U'(s)}{\varphi_U(s)} = \frac{\mathrm{d}}{\mathrm{d}s}\log\varphi_U(s),$$

where log is the continuous branch with $\log\varphi_U(0) = 0$, which exists because φ_U is continuous and never zero. Integrating from 0 to t and exponentiating gives the first formula. Setting $t_2 = 0$, and then $t_1 = 0$, in the factorization gives $\varphi_{Y_1Y_2}(t,0) = \varphi_U(t)\varphi_{\epsilon_1}(t)$ and $\varphi_{Y_1Y_2}(0,t) = \varphi_U(t)\varphi_{\epsilon_2}(t)$, and division gives the other two. A characteristic function determines its distribution. □

Each assumption has a role. Independence delivers the factorization. The nonvanishing condition allows the divisions and the logarithm. The zero mean of ϵ_1 is a location normalization, since a constant could otherwise move freely between U and the ϵ's. The lemma identifies distributions only. The realization of U in a given auction is not identified. Chapter 13 states the same result for Asker's application.

The nonvanishing condition deserves care. Krasnokutskaya (2011, Lemma 1) argues that a variable with bounded support has a characteristic function that extends to an entire function, so its zeros are isolated. Isolated zeros can still occur, as the uniform distribution shows, since its characteristic function $\frac{\sin t}{t}$ vanishes at multiples of π. Evdokimov and White (2012) show that identification survives some violations of the condition under additional restrictions.

The estimator. Li and Vuong (1998) replace each characteristic function by its sample analogue. With n independent pairs (Y_{1k}, Y_{2k}),

$$\hat{\varphi}_U(t) = \exp\left(\int_0^t \frac{\frac{1}{n}\sum_k \mathrm{i}Y_{1k} e^{\mathrm{i}sY_{2k}}}{\frac{1}{n}\sum_k e^{\mathrm{i}sY_{2k}}}\,\mathrm{d}s\right), \qquad \hat{f}_U(u) = \frac{1}{2\pi}\int_{-T}^{T} d_T(t)\, e^{-\mathrm{i}tu}\,\hat{\varphi}_U(t)\,\mathrm{d}t, \tag{A.118}$$

and analogously for ϵ_1 and ϵ_2. The density is recovered by the inverse Fourier transform, truncated at $\pm T$ and multiplied by a *damping factor* d_T that downweights high frequencies, such as $d_T(t) = \max\{1 - \frac{|t|}{T}, 0\}$ (Diggle and Hall, 1993). Since $\hat{\varphi}_U(-t)$ is the complex conjugate of $\hat{\varphi}_U(t)$, the estimate is real and equals $\frac{1}{\pi}\int_0^T d_T(t)\,\mathrm{Re}\{e^{-\mathrm{i}tu}\hat{\varphi}_U(t)\}\,\mathrm{d}t$. The truncation point T is the smoothing parameter, playing the role of an inverse bandwidth.

Deconvolution converges slowly. The empirical characteristic function has error of order $n^{-\frac{1}{2}}$ at each frequency, but the formulas divide by quantities that decay at high frequencies. The ratio in (A.118) divides by $\varphi_U(s)\varphi_{\epsilon_2}(s)$, and the formula for φ_{ϵ_1} divides by φ_U. The achievable rate depends on how fast the characteristic functions decay. It is polynomial in n for *ordinary smooth* distributions, whose characteristic functions decay like $|t|^{-\beta}$, and only logarithmic for *supersmooth* ones such as the normal (Fan, 1991). Li and Vuong (1998) establish uniform consistency under conditions of this kind. Krasnokutskaya's consistency result assumes ordinary smooth components with $\beta > 1$ (Krasnokutskaya, 2011, Proposition 5).

Figure A.12 implements (A.118) with U distributed Gamma with shape 4 and scale 0.25 (mean 1, standard deviation 0.5), $\epsilon_j \sim N(0, 0.4^2)$, $n = 1{,}000$ pairs and 200 samples. With $T = 8$ the median integrated squared error of $\hat{f}_U$ is 0.035. A kernel density estimate of Y_1 ignores the noise and has mean integrated squared error 0.058. Raising T to 10 lowers the median error to 0.029 but makes the estimator unstable, with a mean integrated squared error of 2.44 driven by a few samples. Too large a T divides by empirical characteristic functions that are pure noise.

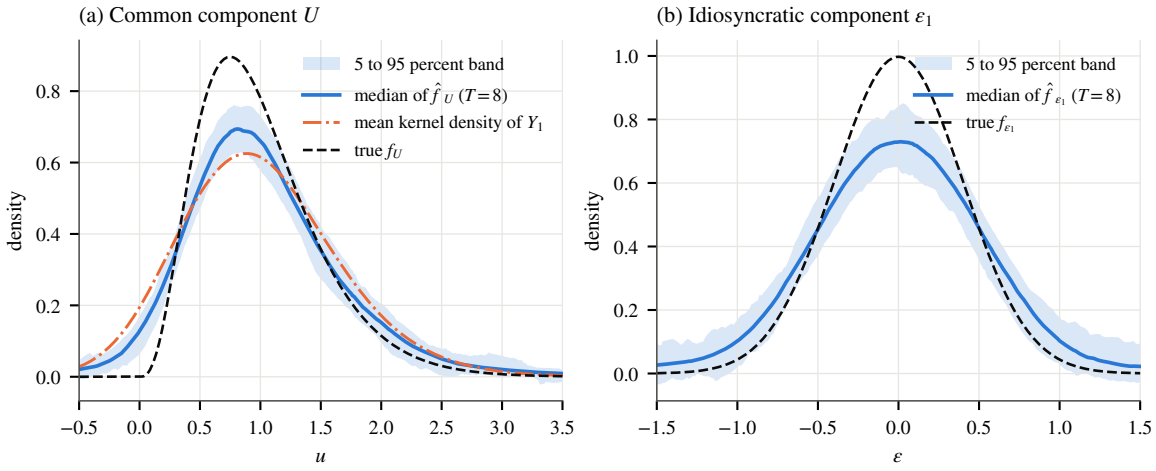

Figure A.12: Kotlarski deconvolution with the estimator of Li and Vuong (1998). $Y_j = U + \epsilon_j$ with $U \sim \text{Gamma}(4, 0.25)$ and $\epsilon_j \sim N(0, 0.4^2)$, $n = 1{,}000$ pairs, smoothing parameter $T = 8$, damping factor $1 - \frac{|t|}{T}$, 200 samples. (a) True density of U, pointwise median and 5 to 95 percent band of $\hat{f}_U$, and the mean rule-of-thumb kernel density estimate of Y_1. (b) The same for ϵ_1. Seed 20261022, script `npreg_demo.py`.

Krasnokutskaya's procurement auctions. Krasnokutskaya (2011) applies the lemma to first-price procurement auctions. A bidder's cost is the product of a project-level component Y, common knowledge among bidders and unobserved by us, and an individual component. The equilibrium bid inherits the product structure, $B_{ij} = y_j a_{ij}$, where a_{ij} is the bid at $y = 1$. For two bidders in the same auction, logs give $\log B_{i_1} = \log Y + \log A_{i_1}$ and $\log B_{i_2} = \log Y + \log A_{i_2}$. Her equation (3) is (A.117) for these variables.[12] The location is fixed by $\mathbb{E}[\log A_1] = 0$. Her estimator averages the empirical characteristic function over all pairs of bidders of the relevant types. It scales bids into $[0, 2]$ to reduce estimation error in the characteristic function. It uses the damping factor $1 - \frac{|t|}{T}$ and chooses T to match the means and variances of $\log Y$ and $\log A$ implied by the bids, which selects $T = 50$ in her application. The moment conditions behind

[12] Its equation (3) prints a logarithm where the exponential of (A.117) belongs. The estimator in its appendix uses the exponential.

the choice of T are the second-moment identities above. With identically distributed individual components, $\operatorname{Var}(\log A) = \frac{1}{2}\mathbb{E}[(\log B_1 - \log B_2)^2]$ and $\operatorname{Var}(\log Y) = \operatorname{Var}(\log B) - \operatorname{Var}(\log A)$ (Krasnokutskaya, 2011, Section 4.3). In a second step she draws pseudo-bids from the estimated density of the individual component by rejection sampling. She converts them to pseudo-costs through the asymmetric first-order condition. The densities in this step use a triweight kernel and the bandwidth $2.978 \times 1.06\,\hat{\sigma} L^{-\frac{1}{6}}$, where $\hat{\sigma}$ is the standard deviation of the log of one plus the bids. Confidence intervals come from the bootstrap. Independence also generates testable restrictions. The characteristic functions recovered from different pairs and triples of bidders must agree. A degenerate $\log Y$ gives the independent private values model, which can be tested within the same framework (her conditions W1 to W7). In Michigan highway procurement auctions she attributes about 75 percent of the variation in bidders' costs to factors known to all bidders. Only 25 percent comes from private information (abstract of the working paper). Hortaçsu and Perrigne (2021, p. 103) report the published estimate as 34 percent of the bid variation from private information. That figure refers to bids, while the working-paper figure refers to costs. Chapter 15 discusses the application.

Asker's knockout bids. Asker (2010) applies the same estimator to pairs of normalized knockout bids in a stamp-dealer ring, $\ln \hat{b}_{1k} = \ln(\varepsilon_k) + \ln \beta(v_{1k})$ and $\ln \hat{b}_{2k} = \ln(\varepsilon_k) + \ln \beta(v_{2k})$ (his eq. (4)). In his notation the common component of lot k is $\ln(\varepsilon_k)$, which plays the role of U in (A.116). He imposes $\mathbb{E}[\ln \beta(v_1)] = 0$ and independence (his Assumption U). The target-auction price supplies a third measurement of the common component. He averages the estimated characteristic functions from the two kinds of pairs, weighting by the number of observations of each, as Li and Vuong (1998) suggest. His damping factor is $\max\{1 - \frac{|t|}{\sqrt{2}T_n}, 0\}$. The smoothing parameter is $T_n = 50$ for the common component, whose estimate proved insensitive to it. For the strong members, the weak members and the highest non-ring value, the values 12.0, 3.0 and 8.3 minimize a criterion. The criterion matches naive damages and the ring's win probability and penalizes non-monotone bid functions (Asker, 2010, pp. 748–749). As with Krasnokutskaya, only distributions are identified, and the GPV inversion is applied to draws from the estimated distributions (Chapter 13).

A.11.6 Estimation and inference under partial identification

When the model and data restrict a parameter only to a set, the parameter is *partially identified* (Definition A.1). A common form is a set of moment inequalities,

$$\Theta_I = \{\theta \in \Theta : \ \mathbb{E}[m_j(W;\theta)] \geq 0, \ j = 1, \ldots, J\}, \tag{A.119}$$

where Θ_I is the *identified set*. Every point of Θ_I is consistent with the population distribution of the data, and no point outside it is. Estimation targets the set, and inference can target either the set or the true parameter inside it.

Bounds in English auctions. Haile and Tamer (2003) drop the button-auction model of ascending auctions, in which bidders exit at their values. They impose two behavioral assumptions. Bidders never bid more than their value, and bidders never let an opponent win at a price they would have been willing to beat. Let $G_{k:n}$ be the distribution of the k-th lowest bid in n-bidder auctions. Let $G^{\Delta}_{n:n}$ be the distribution of the winning bid plus the minimum increment Δ, and $\phi_{k:n}$ the map from F to $F_{(k:n)}$ in (A.90). The first assumption implies that the k-th lowest bid is at most the k-th lowest value, so $G_{k:n}(v) \geq \phi_{k:n}(F(v))$. The second implies that the second-highest value is at most the winning bid plus Δ, so $\phi_{n-1:n}(F(v)) \geq G^{\Delta}_{n:n}(v)$. Inverting the increasing

maps and combining all order statistics and all n gives (Athey and Haile, 2007, Section 4.3.1, eqs. (4.10)–(4.11))

$$F^-(v) = \max_n \ \phi^{-1}_{n-1:n}\big(G^{\Delta}_{n:n}(v)\big) \ \le \ F(v) \ \le \ F^+(v) = \min_n \min_{1\le k\le n} \ \phi^{-1}_{k:n}(G_{k:n}(v)) \,. \tag{A.120}$$

Chapter 15 develops the bounds and their use for reserve prices. Aradillas-López et al. (2013, pp. 493–499) derive bounds on expected profit, bidder surplus and the optimal reserve price when symmetric private values have nonnegative dependence. They use only the transaction price and, with values independent of the number of bidders, variation in that number across auctions. Asker (2010, footnote 37) discusses why he does not use the Haile-Tamer approach. Jump bidding was rare at the stamp auctions he observed, and bid increments were small relative to bids.

Plug-in estimation and the bias of extrema. The natural estimator of (A.120) replaces each G by an empirical distribution function. The minimum and maximum then create a finite-sample bias. The minimum is concave, so by Jensen's inequality $\mathbb{E}[\min_j \hat{a}_j] \le \min_j \mathbb{E}[\hat{a}_j]$. A worked case shows the size. Let $\hat{a}_1$ and $\hat{a}_2$ be independent $N(a, \sigma^2)$, both unbiased for the same bound a. Since $\min(a_1, a_2) = \frac{a_1+a_2}{2} - \frac{|a_1-a_2|}{2}$ and $\hat{a}_1 - \hat{a}_2 \sim N(0, 2\sigma^2)$ has mean absolute value $\frac{2\sigma}{\sqrt{\pi}}$,

$$\mathbb{E}\left[\min(\hat{a}_1, \hat{a}_2)\right] = a - \frac{\sigma}{\sqrt{\pi}}.$$

The estimated upper bound is too low and the estimated lower bound too high, so the estimated set is too narrow. The bias grows with the number of terms in the minimum. Haile and Tamer (2003) define the bounds in finite samples with smooth approximations to the max and min functions. In the words of Athey and Haile (2007, Section 4.3.1, p. 35), this "amounts to using weighted averages instead of the max or min." For example, the softmax-weighted average $\sum_j \hat{a}_j \frac{e^{\rho \hat{a}_j}}{\sum_k e^{\rho \hat{a}_k}}$ with $\rho < 0$ is a smooth minimum of this kind. It tends to $\min_j \hat{a}_j$ as $\rho \to -\infty$, and it lies above the minimum, which offsets the downward bias. We use it only as an illustration, and it need not be the weighting that Haile and Tamer choose.

The extrema also break standard inference. The functional $\min(a_1, a_2)$ is not differentiable where $a_1 = a_2$, so the delta method fails there, and the bootstrap can fail for the same reason (Proposition A.67).

Set estimators and confidence regions. Define the criterion $Q(\theta) = \sum_j (\min\{\mathbb{E}[m_j(W;\theta)], 0\})^2$, which is zero exactly on Θ_I. Its sample analogue Q_n is zero on the sample identified set, which may be empty or too small. Chernozhukov et al. (2007) estimate the set by $\{\theta : \ nQ_n(\theta) \le c_n\}$ with $c_n \to \infty$ and $\frac{c_n}{n} \to 0$, which is consistent in the Hausdorff distance. Confidence regions for Θ_I invert tests of $Q(\theta) = 0$, with cutoffs from subsampling or the bootstrap.

For an interval $[\theta_l, \theta_u]$ there is an important distinction. A region that covers the whole set with probability $1 - \alpha$ is larger than one that covers the true parameter with that probability. Imbens and Manski (2004) construct the second kind. With estimators $\hat{\theta}_l$ and $\hat{\theta}_u$, standard errors $\frac{\hat{\sigma}_l}{\sqrt{n}}$ and $\frac{\hat{\sigma}_u}{\sqrt{n}}$, and estimated length $\hat{\Delta} = \hat{\theta}_u - \hat{\theta}_l$, the interval is

$$\left[\hat{\theta}_l - c_n \frac{\hat{\sigma}_l}{\sqrt{n}}, \ \hat{\theta}_u + c_n \frac{\hat{\sigma}_u}{\sqrt{n}}\right], \qquad \Phi\left(c_n + \frac{\sqrt{n}\,\hat{\Delta}}{\max\{\hat{\sigma}_l, \hat{\sigma}_u\}}\right) - \Phi(-c_n) = 1 - \alpha. \tag{A.121}$$

When the set is long relative to sampling error, the true parameter can be near at most one end point. Only one tail then matters, and c_n approaches the one-sided value 1.645 for $\alpha = 0.05$.

When the set shrinks to a point, c_n rises to the two-sided 1.96. A region for the whole set needs both end points covered at once and uses a larger constant. Stoye (2009) refines the argument for sets whose length is near zero. Manski (2003) and Tamer (2010) survey the field.

A.12 Difference in differences and panel event studies

The last two sections of the appendix turn from estimators to research designs. Many questions in industrial organization concern a discrete change in a market. Two firms merge, a rival enters, a state raises a tax, or a patent is granted. A *retrospective* (or ex post) evaluation measures what the change did by comparing outcomes after it with outcomes before it. A *prospective* (or ex ante) evaluation predicts the effect before the change, with a model of demand, costs and conduct. This section develops the research designs behind retrospectives. They compare units exposed to the change with units that were not, before and after the change.

These designs are reduced form. They identify average effects of a change under assumptions about the outcomes that units would have had without it, and they need no model of conduct. The book uses them for merger retrospectives (Section 11.6), tax pass-through (Section 3.2), entry (Section 9.6.6) and patents (Section 5.10). We build on the potential-outcomes notation of Section A.1.3. Throughout this section i indexes units (products, markets, states, hospitals) and t indexes periods, and τ_t denotes a period fixed effect. In Section A.13 the symbol τ will index trading days instead.

A.12.1 The two-by-two design

We start with two groups and two periods. Units $i = 1, \dots, n$ are observed in periods $t \in \{0, 1\}$. The indicator Treat_i equals one for units in the *treated group*, which is exposed to the change between the two periods. The other units form the *control group*. Let $\mathit{Post}_t = \mathbf{1}\{t = 1\}$ and let $d_{it} = \mathit{Treat}_i \, \mathit{Post}_t$ be the treatment indicator. Each unit has two potential outcomes in each period, $y_{it}(1)$ with the treatment and $y_{it}(0)$ without it. We observe

$$y_{it} = y_{it}(0) + d_{it}\big[y_{it}(1) - y_{it}(0)\big].$$

Definition A.82 (Average effect of the treatment on the treated)**.** The *average treatment effect on the treated* in the post period, the panel version of the ATT of Section A.1.3, is

$$\mathrm{ATT} = \mathbb{E}\big[y_{i1}(1) - y_{i1}(0) \mid \mathit{Treat}_i = 1\big].$$

Two naive comparisons fail. The cross-sectional comparison of treated and control units in period 1 adds a selection term, the difference in untreated outcomes between the groups (Proposition A.8). The before-after comparison within the treated group adds the change that the treated units would have experienced anyway:

$$\mathbb{E}\big[y_{i1} - y_{i0} \mid \mathit{Treat}_i = 1\big] = \mathrm{ATT} + \mathbb{E}\big[y_{i1}(0) - y_{i0}(0) \mid \mathit{Treat}_i = 1\big],$$

provided that period-0 outcomes are untreated. A rise in input costs at the time of a merger, for example, is attributed to the merger. The *difference-in-differences* (DiD) estimator removes this change with the change in the control group. Let $\bar{y}_{T,t}$ and $\bar{y}_{C,t}$ denote the sample means of y_{it} in the treated and control groups in period t. Then

$$\hat{\beta}^{\mathrm{DD}} = \big(\bar{y}_{T,1} - \bar{y}_{T,0}\big) - \big(\bar{y}_{C,1} - \bar{y}_{C,0}\big). \tag{A.122}$$

Assumption A.83 (Identifying assumptions for DiD)**.**

(i) *No anticipation.* Period-0 outcomes are untreated: $y_{i0} = y_{i0}(0)$ for all i.

(ii) *Parallel trends.* Without the treatment, the mean outcome would have changed by the same amount in both groups:

$$\mathbb{E}\big[y_{i1}(0) - y_{i0}(0) \mid Treat_i = 1\big] = \mathbb{E}\big[y_{i1}(0) - y_{i0}(0) \mid Treat_i = 0\big].$$

(iii) *No interference.* The treatment of the treated group does not change the outcomes of control units: $y_{i1} = y_{i1}(0)$ when $Treat_i = 0$.

Proposition A.84 (Identification by DiD)**.** *Suppose the group means in* (A.122) *are unbiased for the corresponding population means. Under Assumption A.83,* $\mathbb{E}[\hat{\beta}^{\mathrm{DD}}] = \mathrm{ATT}$. *If the sample means are also consistent, then* $\hat{\beta}^{\mathrm{DD}} \xrightarrow{p} \mathrm{ATT}$.

Proof. Write $\mathbb{E}_1[\cdot]$ and $\mathbb{E}_0[\cdot]$ for expectations conditional on $Treat_i = 1$ and $Treat_i = 0$. For the treated group, the observed outcome in period 1 is $y_{i1}(1)$, and by (i) the period-0 outcome is $y_{i0}(0)$. Adding and subtracting $\mathbb{E}_1[y_{i1}(0)]$ gives

$$\begin{aligned}\mathbb{E}\big[\bar{y}_{T,1} - \bar{y}_{T,0}\big] &= \mathbb{E}_1\big[y_{i1}(1)\big] - \mathbb{E}_1\big[y_{i0}(0)\big] \\ &= \mathbb{E}_1\big[y_{i1}(1) - y_{i1}(0)\big] + \mathbb{E}_1\big[y_{i1}(0) - y_{i0}(0)\big] \\ &= \mathrm{ATT} + \mathbb{E}_1\big[y_{i1}(0) - y_{i0}(0)\big].\end{aligned}$$

For the control group, (iii) and (i) give $\mathbb{E}[\bar{y}_{C,1} - \bar{y}_{C,0}] = \mathbb{E}_0[y_{i1}(0) - y_{i0}(0)]$. By (ii) this equals the last term of the first display. Subtracting leaves ATT. Consistency follows from the continuous mapping theorem. □

The proof works for a panel, in which the same units appear in both periods, and for repeated cross sections. Two features of the assumptions deserve comment. First, parallel trends restricts changes in outcomes and leaves their levels free. Suppose untreated outcomes follow

$$y_{it}(0) = \mu_i + \tau_t + \varepsilon_{it}, \qquad \mathbb{E}\big[\varepsilon_{i1} - \varepsilon_{i0} \mid Treat_i\big] = 0. \tag{A.123}$$

Then $\mathbb{E}[y_{i1}(0) - y_{i0}(0) \mid Treat_i] = \tau_1 - \tau_0$ in both groups, so (ii) holds however strongly the unit effects μ_i are correlated with treatment. Firms that merge may have higher prices to begin with. What DiD needs is that their prices would not have grown faster.

Second, parallel trends depends on the scale of the outcome. Suppose the control mean of the untreated outcome rises from 10 to 11 and the treated mean would have risen from 20 to 21. Trends are parallel in levels. In logs the control change is $\ln \frac{11}{10} \approx 0.095$ and the treated change is $\ln \frac{21}{20} \approx 0.049$, so trends are not parallel. Merger retrospectives usually work with log prices. Their assumption is that, absent the merger, the proportional price changes of the two groups would have been equal.

Regression form. The same estimate comes from the regression

$$y_{it} = \alpha + \gamma\, Treat_i + \lambda\, Post_t + \beta^{\mathrm{DD}}\, Treat_i Post_t + e_{it}. \tag{A.124}$$

The four regressors span the four group-period cells, so OLS fits each cell mean exactly:

$$\begin{aligned}\hat{\alpha} &= \bar{y}_{C,0}, & \hat{\alpha} + \hat{\lambda} &= \bar{y}_{C,1}, \\ \hat{\alpha} + \hat{\gamma} &= \bar{y}_{T,0}, & \hat{\alpha} + \hat{\gamma} + \hat{\lambda} + \hat{\beta}^{\mathrm{DD}} &= \bar{y}_{T,1}.\end{aligned}$$

Subtract the second equation from the fourth and the first from the third. The difference of the two results is $\hat{\beta}^{\mathrm{DD}} = (\bar{y}_{T,1} - \bar{y}_{T,0}) - (\bar{y}_{C,1} - \bar{y}_{C,0})$. In a balanced panel we can replace $\alpha + \gamma\, Treat_i$ by unit fixed effects μ_i. Differencing the two periods then gives

$$y_{i1} - y_{i0} = \lambda + \beta^{\mathrm{DD}}\, Treat_i + (e_{i1} - e_{i0}).$$

The OLS slope on a binary regressor is the difference in group means of the dependent variable, which is again (A.122). The regression form is convenient for standard errors (Section A.12.4) and for adding covariates. With covariates, the assumption becomes *conditional parallel trends*: (ii) holds within cells of baseline covariates x_i. The regression then interacts x_i with $Post_t$. Covariates that the treatment itself changes should not be included, because they absorb part of the effect.

Figure A.13 shows the design with several periods on each side of the change. The pre-period paths are parallel. After adoption the treated path jumps. The dashed line continues the treated path at the slope of the control path, which is the counterfactual implied by parallel trends. The vertical gap between the observed and counterfactual paths is the ATT.

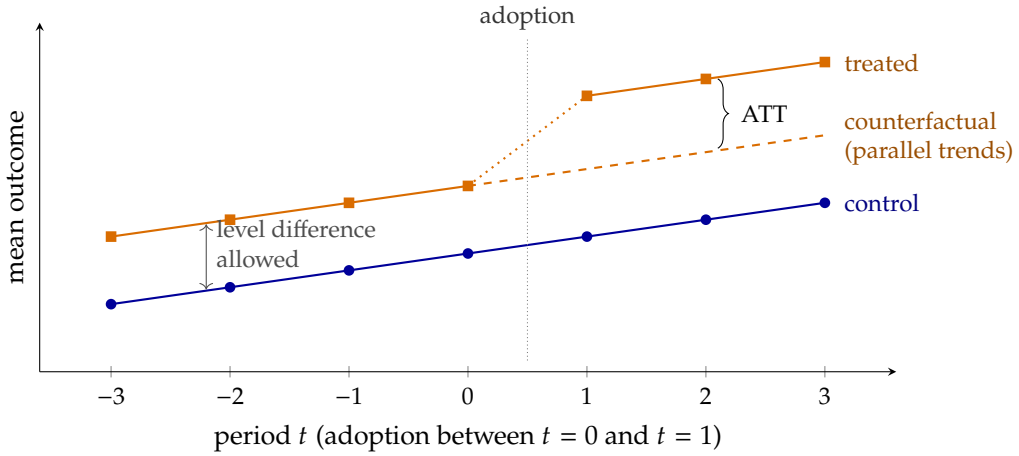

Figure A.13: The difference-in-differences design. Squares are the mean outcomes of the treated group and dots those of the control group. The dashed line is the treated group's untreated path implied by parallel trends. The vertical distance between the observed treated path and the dashed line is the average effect on the treated. Groups may differ in levels.

A.12.2 Two-way fixed effects and continuous treatment

With many periods, and possibly a treatment of varying intensity, the DiD regression generalizes to the *two-way fixed-effects* (TWFE) model

$$y_{it} = \mu_i + \tau_t + \beta\, d_{it} + e_{it}, \qquad i = 1, \dots, n, \quad t = 1, \dots, T, \tag{A.125}$$

where d_{it} may be binary or continuous. The unit effects μ_i absorb permanent differences across units, and the period effects τ_t absorb shocks common to all units in a period.

Let $\tilde{d}_{it}$ be the residual from regressing d_{it} on the unit and period dummies. By the Frisch-Waugh-Lovell theorem (Theorem A.9), the OLS estimate of β equals the slope of a regression of y_{it} on $\tilde{d}_{it}$:

$$\hat{\beta} = \frac{\sum_{i,t} \tilde{d}_{it}\, y_{it}}{\sum_{i,t} \tilde{d}_{it}^{2}}. \tag{A.126}$$

In a balanced panel the residual has the closed form already used in Section A.2.4. Let $\bar{d}_i$, $\bar{d}_t$ and $\bar{d}$ be the unit, period and overall means of d_{it}. Then

$$\tilde{d}_{it} = d_{it} - \bar{d}_i - \bar{d}_t + \bar{d}. \tag{A.127}$$

To verify (A.127), note two facts. The difference $d_{it} - \tilde{d}_{it} = \bar{d}_i + \bar{d}_t - \bar{d}$ is a unit term plus a period term, so it lies in the span of the dummies. And $\tilde{d}_{it}$ sums to zero over t for each i and over i for each t, so it is orthogonal to every dummy. These are the two properties that define the residual of a projection.

Identification. Substitute (A.125) into (A.126). The fixed effects drop out because $\sum_{i,t} \tilde{d}_{it}(\mu_i + \tau_t) = 0$, and $\sum_{i,t} \tilde{d}_{it} d_{it} = \sum_{i,t} \tilde{d}_{it}^2$ because $\tilde{d}_{it}$ is orthogonal to $d_{it} - \tilde{d}_{it}$. Hence

$$\hat{\beta} = \beta + \frac{\sum_{i,t} \tilde{d}_{it}\, e_{it}}{\sum_{i,t} \tilde{d}_{it}^2}.$$

Let $\mathbf{d}$ collect the treatments of all units in all periods. If $\mathbb{E}[e_{it} \mid \mathbf{d}] = 0$ for every i and t, then $\mathbb{E}[\hat{\beta} \mid \mathbf{d}] = \beta$. This *strict exogeneity* condition is the multi-period form of parallel trends and no anticipation. It allows treatment to be correlated with μ_i. It rules out treatment that responds to past or expected future shocks to the unit's outcome.

The variation that identifies β is the change in a unit's treatment relative to the average change across units. The two-unit, two-period case shows this transparently. Let units A and B be observed in two periods, and write $\Delta y_i = y_{i2} - y_{i1}$ and $\Delta d_i = d_{i2} - d_{i1}$. First differences remove μ_i:

$$\Delta y_i = (\tau_2 - \tau_1) + \beta\, \Delta d_i + \Delta e_i, \qquad i \in \{A, B\}.$$

Two equations in two unknowns fit exactly. Subtracting the equation for B from that for A gives

$$\hat{\beta} = \frac{\Delta y_A - \Delta y_B}{\Delta d_A - \Delta d_B}. \tag{A.128}$$

The estimate is the DiD in outcomes divided by the DiD in treatment. It has the form of a Wald estimator (Section A.3), with the change in treatment playing the role of the first stage.

Sumner's tax regression as a DiD with a continuous dose. The cigarette regression of Sumner (1981), written as (A.20) in Section A.2.4, is a TWFE regression with a continuous treatment, the specific tax t_{sy} of state s in year y. The pass-through ρ equals one under competition with constant marginal cost and exceeds one under market power with constant-elasticity demand (Section 3.2.1). By (A.128), a state that raises its tax by 10 cents more than another state identifies ρ from the difference in their price changes. Sumner states the identifying assumption directly. The remaining price variation "is assumed to be uncorrelated with R_{it}" (p. 1015), where R_{it} is his notation for the tax. He adds that the state dummies account for any stable pattern of state tax rates, such as an effect of the unchanging location of the tobacco industry (pp. 1015–1016).

Section A.2.4 reports his estimates. The two-way estimate of 1.074 falls to 1.029 when the year effects are replaced by the national price index and the state effects are dropped. Cross-state differences in tax levels and within-state tax changes therefore carry different information. The main threats to (A.20) are tax increases timed with changes in local demand or cost, and cross-border purchases that make legal sales respond to the tax gap with neighboring states. Sumner checks the second by adding a squared tax term to year-by-year regressions. It is insignificant in most years (n. 9, p. 1017). Section A.8.5 shows that the standard error of $\hat{\rho}$ more than doubles once dependence within states is allowed.

Remark A.85 (Heterogeneous pass-through). Suppose pass-through differs across states, so that $p_{sy} = \mu_s + \tau_y + \rho_s t_{sy} + e_{sy}$ with strictly exogenous errors. Repeating the steps above gives $\mathbb{E}[\hat{\rho} \mid \mathbf{t}] = \sum_s W_s \rho_s$ with

$$W_s = \frac{\sum_y \tilde{t}_{sy}\, t_{sy}}{\sum_{s',y} \tilde{t}^2_{s'y}}, \qquad \sum_s W_s = 1.$$

In a balanced panel $\sum_y \tilde{t}_{sy} = 0$, so we may replace t_{sy} by $t_{sy} - \bar{t}_s$, and $t_{sy} - \bar{t}_s = \tilde{t}_{sy} + (\bar{t}_y - \bar{t})$ by (A.127). Therefore

$$W_s = \frac{\sum_y \tilde{t}^2_{sy} + \sum_y \tilde{t}_{sy}\,(\bar{t}_y - \bar{t})}{\sum_{s',y} \tilde{t}^2_{s'y}}.$$

The first term is the state's share of the residual tax variation. The second term sums to zero across states, but it can be negative for a state whose tax deviations move against the national path. A weight can then be negative. Callaway et al. (2024) show that with a continuous dose the TWFE coefficient also mixes effects at different dose levels. Comparing units with different doses then needs a stronger assumption than parallel trends.

A.12.3 Control groups in IO retrospectives

A good control group satisfies two requirements. It is subject to the same shocks as the treated group, so that parallel trends is plausible. And it is unaffected by the treatment, so that no interference holds. In product markets these requirements pull in opposite directions. Products that share the demand and cost shocks of the merging products are their close substitutes, and close substitutes respond to the merger. With Bertrand competition prices are strategic complements, so rivals raise their prices when the merged firm raises its own. The next proposition shows what this does to the estimate.

Proposition A.86 (Partially affected controls)**.** *Let (i) and (ii) of Assumption A.83 hold, and suppose that the treatment raises the mean outcome of the control group by a fraction κ of the effect on the treated:*

$$\mathbb{E}\big[y_{i1} - y_{i1}(0) \mid \mathit{Treat}_i = 0\big] = \kappa \cdot \mathrm{ATT}.$$

Then $\mathbb{E}[\hat{\beta}^{\mathrm{DD}}] = (1-\kappa)\mathrm{ATT}$. If $0 \le \kappa < 1$, the expectation of the DiD estimate has the sign of the ATT and is no larger in magnitude. It is then a lower bound on the size of the effect. If $\kappa = 1$, the expectation is zero. If $\kappa < 0$, DiD overstates the effect.

Proof. The treated-group change is as in the proof of Proposition A.84: $\mathbb{E}[\bar{y}_{T,1} - \bar{y}_{T,0}] = \mathrm{ATT} + \mathbb{E}_1[y_{i1}(0) - y_{i0}(0)]$. For the control group, add and subtract $\mathbb{E}_0[y_{i1}(0)]$ and use (i):

$$\begin{aligned}\mathbb{E}\big[\bar{y}_{C,1} - \bar{y}_{C,0}\big] &= \mathbb{E}_0\big[y_{i1} - y_{i1}(0)\big] + \mathbb{E}_0\big[y_{i1}(0) - y_{i0}(0)\big] \\ &= \kappa \cdot \mathrm{ATT} + \mathbb{E}_0\big[y_{i1}(0) - y_{i0}(0)\big].\end{aligned}$$

Subtract the second display from the first and use (ii) to cancel the trends. The result is $(1-\kappa)\mathrm{ATT}$. For $0 \le \kappa \le 1$ the factor $1-\kappa$ lies in $[0,1]$, which gives the bound. For $\kappa < 0$ the factor exceeds one. □

The fraction κ has a structural interpretation. Consider a symmetric linear Bertrand oligopoly with N firms, two of which merge, with own-price demand slope b and cross-price slope d. Proposition 11.39 shows that each outsider raises its price by $\kappa = \frac{2d}{2b-(N-3)d}$ times the

insiders' increase. With three firms κ equals the diversion ratio between the merging products. The bias is therefore largest when the merging products are close substitutes, which is when the merger matters most. A negative κ arises for quantities. If the merged firm raises its prices, rivals gain sales, and a DiD in quantities with rivals as controls overstates the merging firms' loss.

The opposite choice, a distant control, has the opposite problem. Store brands (private labels) use the same inputs as branded products, and if they are supplied elastically their prices track costs while the merger leaves them alone, so $\kappa \approx 0$. But they may face different demand shocks. A rise in income can raise the demand for branded goods relative to store brands. Then (ii) fails and the private-label estimate is biased in an unknown direction. Reporting both control groups shows how much the conclusion depends on this trade-off. We now look at five designs from the book. Table A.11 summarizes them, with Sumner's design for comparison.

Ashenfelter and Hosken (2010): two control groups. Ashenfelter and Hosken (2010) study five consumer-product mergers that looked problematic from the public record (Section 11.6.7).[13] For each merging product and its control group they estimate, in logs,

$$p_{ijt} = \alpha_{ij} + \sum_{m=1}^{11} \delta_m M_{ijt} + \beta_1 \, Post_{ijt} + \beta_2 \, Post_{ijt} \times MergingParty_i + e_{ijt}, \tag{A.129}$$

for product i in city j and month t (their eq. 1, p. 24). Here α_{ij} is a product-city fixed effect and M_{ijt} are calendar-month indicators for seasonality. The coefficient β_2 is the DiD estimate of the proportional price change. The preferred control group is the private-label products closest to the merging brands. The alternative is branded close substitutes, which the authors expect to understate the effect for the reason in Proposition A.86 and treat mainly as a specification check (pp. 23–24). The preferred window has equal spans of data before and after the merger and drops the three months on each side of consummation (p. 22). Dropping those months avoids having to date the start of joint pricing. The symmetric window guards against transitory selection, a point first made by Heckman and Robb (1985) and used by Ashenfelter and Card (1985) (Proposition 11.43).

The aggregate effects in their Table 13 show that the control group matters (Table 11.16). With private-label controls, Pennzoil and Quaker State raised prices by 0.052 log points (s.e. 0.013), against 0.014 (0.011) with branded controls. For Procter and Gamble and Tambrands the figures are 0.070 (0.008) and 0.023 (0.007). Both patterns fit Proposition A.86 with κ between zero and one. For General Mills and the Chex brands the order reverses, 0.032 (0.005) against 0.057 (0.005). If private-label prices were unaffected and followed parallel trends, Proposition A.86 would make the branded estimate the smaller one. The reversal therefore means that at least one control group violates the assumptions, through different trends or through store-brand prices that responded to the merger.

Ashenfelter, Hosken and Weinberg (2013): composition and product turnover. Ashenfelter et al. (2013) study the 2006 Whirlpool-Maytag merger in major appliances (Section 11.6.8).[14] The treated categories are dishwashers, refrigerators, clothes washers and clothes dryers. The comparison categories are cooktops, freezers, ovens and ranges, restricted to brands not made

[13] We use the NBER working-paper version, Ashenfelter and Hosken (2008), for page and table numbers.

[14] We use the NBER working-paper version, Ashenfelter et al. (2011), for page numbers.

by either party, where the merger changed concentration little (p. 10). Their eq. (4) (p. 12) is

$$\ln p_{it} = \beta_1 \, Maytag_i \times Post_t + \beta_2 \, Whirlpool_i \times Post_t + \sum_k \gamma_k^T Age_{ikt}^T + \sum_k \gamma_k^C Age_{ikt}^C + \sum_l \lambda_l \, Month_{lt} + \alpha_i + e_{it}, \tag{A.130}$$

where i is a stock-keeping unit (SKU), a narrowly defined model, and α_i an SKU fixed effect. The age indicators are separate for treatment and comparison categories, because appliance prices fall with a model's age at category-specific rates. The month effects absorb common shocks.

Product turnover creates a composition problem with a sharp econometric form. For an SKU introduced after the merger, $Post_t = 1$ in every month it is observed. Its interaction $Maytag_i \times Post_t$ then equals the constant $Maytag_i$ and is absorbed by α_i. With SKU effects, the merger effect is identified only from SKUs sold both before and after the merger (p. 13). Since most models live about a year, this discards the products introduced after the merger, whose prices the merged firm chose. The authors' eq. (5) replaces α_i by observed characteristics and brand dummies, so new SKUs contribute. On SKUs introduced within a year of the merger, eqs. (4) and (5) give nearly identical effects (pp. 14–15). The authors read this agreement as evidence that unobserved SKU quality is not correlated with the post-merger indicators, given the characteristics. The preferred results show price increases for new products in two categories. New Whirlpool dryers rose by 13 to 17 percent, depending on the comparison category, and new Maytag dishwashers by 5 to 7 percent (p. 16). Standard errors are clustered by SKU (p. 14).

Björnerstedt and Verboven (2016): merging firms against rivals. Björnerstedt and Verboven (2016) evaluate the acquisition of AstraZeneca Tika (AZT) by GlaxoSmithKline (GSK) in the Swedish market for painkillers (Section 11.7).[15] The two firms were the only sellers of paracetamol, and the Swedish Competition Authority cleared the merger on April 3, 2009 (WP pp. 4 and 6). Their retrospective regression, in the spirit of (A.129), is

$$\ln p_{gt} = \alpha_g + \beta_g \, PostMerger_t + e_{gt},$$

where p_{gt} is the average price of product group g in month t (eq. 1, p. 134, and WP eq. 18). Each group has its own post-merger change. Ashenfelter and Hosken (2010) instead give all control products a common change (WP p. 27, n. 16). The difference between the merging group's β_g and a rival group's β_g is a DiD estimate. The authors note that the merger may also raise rival prices, and the difference is then a lower bound for the merger effect (p. 134). This is the case $0 < \kappa < 1$ of Proposition A.86.

The two versions of the paper use different windows. The published article defines groups by substance and by substance and firm. It compares one year before with one year after the merger, "to exclude possible changes after the deregulation" of the Swedish pharmacy monopoly (p. 134). The working paper compares April 2007 to April 2009 with May 2009 to May 2011, and reports groups by substance and by firm (WP pp. 27–28). In that longer window the paracetamol price drifts down near the end, "perhaps associated with new entry threats following the deregulation" (WP p. 27). The one-year window of the published article leaves out these months.

[15] Only pp. 134, 137 and 147 of the published article were available to us. References marked WP are to the January 2013 working paper, Björnerstedt and Verboven (2013). Its printed page numbers equal its PDF page numbers minus one.

The regression table of the published article (its Table 4, one-year window) was not available to us. We therefore report WP Table 7, which uses the two-year window and robust standard errors. The published estimates may differ. In log points, the post-merger change is 0.351 (0.007) for paracetamol, 0.001 (0.005) for ibuprofen and 0.100 (0.004) for acetylsalicylic acid (ASA, sold as aspirin). The merging firms moved together, with 0.356 (0.006) for AZT and 0.379 (0.009) for GSK. With ibuprofen as the control group, the DiD estimate is 0.350 log points, or 42 percent. With ASA as the control, it is 0.251, or 29 percent (WP p. 29). Pooling the two rival substances into one control gives 0.30, or 35 percent (WP p. 29, n. 17). The abstract of the working paper reports these figures as an increase of 42 percent in absolute terms and 35 percent relative to rivals. The ASA increase fits $\kappa > 0$, which makes the ASA-based estimate the smaller one. The authors offer a second reason, a mandated cut in ASA package sizes (WP p. 29). That reason is a failure of parallel trends instead. Both reasons lower the ASA-based estimate, and the design cannot separate them.

Dafny (2009): rival exposure, an instrument and placebo periods. Dafny (2009) measures the effect of hospital mergers on the prices of rival hospitals (Section 11.6.9). Section A.3.1 sets out her design. Read as a panel design, it is a first-differenced TWFE model with a continuous treatment. The unit is a hospital that did not merge, and the outcome is the long difference in log price from 1988 to 1997. The treatment is the number of rival mergers between 1989 and 1996, as in (A.31). Strict exogeneity fails here. Hospitals with merging rivals had slower price growth before the merger wave (Section A.1.3), so mergers happened in markets on different paths. The co-location instrument restores identification, and Table A.2 reports the first stage, the reduced form and the IV and OLS estimates.

The design borrows the event-study logic of Section A.12.5 through placebo periods. If co-location affected price growth through channels other than mergers, it would also predict growth before and after the merger wave. The reduced-form coefficient is −0.016 (0.010) for 1985–1988 and −0.008 (0.013) for 1997–2000 (panel B of Table A.2). These are tests of the exclusion restriction in the spirit of pre-trend tests.

Whinston and Collins (1992): two cohorts as each other's controls. Whinston and Collins (1992) study incumbent responses to entry by People Express on routes out of Newark (Section 9.6.6). Markets entered in 1984 and markets entered in 1985 are observed in the first quarters of 1984, 1985 and 1986. Let $D_{my} = 1$ if market m has been entered by year y, and consider

$$\ln P_{my} = \mu_m + \nu_y + \beta\, D_{my} + e_{my}.$$

For the 1984 cohort D is $(0, 1, 1)$ across the three years, and for the 1985 cohort it is $(0, 0, 1)$. In 1984–1985 the 1985 cohort, not yet entered, is the control for the 1984 cohort. In 1985–1986 the 1984 cohort, already entered, is the control for the 1985 cohort. The incumbents' mean price fell 33 percent (s.d. 26) in the 1984 cohort and rose 2 percent (24) in the 1985 cohort during 1984–1985, with a two-sample t statistic of 2.5. In 1985–1986 the changes were 0 percent (15) and −35 percent (21), with $t = 3.5$ (Table 3, p. 459). The second comparison uses an already treated group as control. It is valid only if the 1984 cohort's effect stayed constant in its second year. The flat 1984 cohort change in 1985–1986 supports that assumption. Section A.12.6 shows why this condition matters in staggered designs. The authors also caution that demand or cost conditions may have changed in the entered markets, and could even have caused entry (pp. 458–459).

Remark A.87 (DiD inside a structural model). Miller and Weinberg (2017, pp. 1779–1780) estimate a supply model for beer that allows a departure from Nash-Bertrand after the merger.

ABI and MillerCoors may then partly or fully internalize the effect of their prices on each other's profits. The instrument that identifies the departure is an indicator for ABI and MillerCoors products after the merger. A separate post-merger cost shifter for MillerCoors isolates the comparison between ABI and the imported brands of Modelo and Heineken. Identification therefore rests on a DiD comparison of implied marginal costs, which Proposition 11.57 makes exact. Parallel trends is then an assumption about the unobserved costs of ABI and of the imported brands.

Table A.11: Difference-in-differences designs in the book

Study	Treatment	Control	Window	Inference	Main threat
Sumner (1981)	state-year cigarette tax (continuous)	tax changes in other states, via state and year effects	annual, 1954–1978	conventional, and random effects	taxes timed with local shocks, cross-border sales
Ashenfelter and Hosken (2010)	five consumer-product mergers	private labels (preferred) or branded substitutes	symmetric, 3 months dropped on each side	clustered by month	rival responses, store-brand demand shocks
Ashenfelter et al. (2013)	Whirlpool-Maytag, four appliance categories	cooktops, freezers, ovens, ranges of other brands	SKUs in their first year, monthly	clustered by SKU	product turnover and composition
Björnerstedt and Verboven (2016)	paracetamol merger, Sweden, 2009	ibuprofen and ASA groups	one year before and after (published), two years (WP)	robust s.e. (WP Table 7)	rival responses, ASA package sizes, deregulation
Dafny (2009)	number of rival hospital mergers, 1989–1996	hospitals with fewer rival mergers, with a co-location instrument	long difference 1988–1997, placebos 1985–1988 and 1997–2000	IV, Hausman test	co-location related to price growth
Whinston and Collins (1992)	People Express entry, Newark markets	markets entered in the other year	first quarters 1984, 1985, 1986	two-sample t, 13 d.f.	entry timed with market shocks, changing effects

Notes: Entries are taken from the papers' text and tables, cited in the main text. ASA is acetylsalicylic acid. For Björnerstedt and Verboven, the one-year window is that of the published article (p. 134). The two-year window and the inference come from the January 2013 working paper (WP).

Which mergers are studied. A retrospective estimates the effect of one merger. Conclusions about mergers in general also depend on which mergers are studied, and Asker and Nocke (2021, pp. 255–256) list three filters. The studied mergers were consummated, so an antitrust authority had usually cleared them, and blocked or deterred mergers are missing. They come from industries with good data, mostly consumer-facing ones, and few concern intermediate goods. They also tend to be large or to illustrate a phenomenon of interest. In potential-outcomes terms, an average over studied mergers is an ATT for a selected population. It need not equal the effect of a merger that the authority would have blocked. Their survey of retrospectives published from 2000 to 2020 finds a wide range of price effects. Some prices rose sharply, some did not move and some fell (pp. 256–257).

A.12.4 Inference

DiD data are panels, and panel errors are dependent. Outcomes of a unit are correlated over time, and outcomes of units in the same period share common shocks. Which dependence matters depends on the regressors in the model. We treat serial correlation first.

Proposition A.88 (DiD as a comparison of unit-level changes)**.** *Consider a balanced panel with T_0 pre-periods and T_1 post-periods, a common adoption date, n_1 treated and n_0 control units. Let $\Delta_i = \bar{y}_{i,\text{post}} - \bar{y}_{i,\text{pre}}$ be unit i's change in mean outcome. The TWFE estimate of β in (A.125) with $d_{it} = \mathit{Treat}_i \mathit{Post}_t$ equals*

$$\hat{\beta} = \bar{\Delta}_1 - \bar{\Delta}_0,$$

the difference between the mean changes of treated and control units. If units are independent, then $\operatorname{Var}(\hat{\beta} \mid \mathit{Treat}) = \frac{\sigma^2_{\Delta,1}}{n_1} + \frac{\sigma^2_{\Delta,0}}{n_0}$, with $\sigma^2_{\Delta,g}$ the variance of Δ_i in group g, whatever the serial correlation within units.

Proof. Let $p = \frac{n_1}{n}$ and $q = \frac{T_1}{T}$. With a common adoption date, $\bar{d}_i = q\,\mathit{Treat}_i$, $\bar{d}_t = p\,\mathit{Post}_t$ and $\bar{d} = pq$. By (A.127),

$$\tilde{d}_{it} = \mathit{Treat}_i \mathit{Post}_t - q\,\mathit{Treat}_i - p\,\mathit{Post}_t + pq = (\mathit{Treat}_i - p)(\mathit{Post}_t - q).$$

The denominator of (A.126) is $\sum_i (\mathit{Treat}_i - p)^2 \sum_t (\mathit{Post}_t - q)^2 = np(1-p) \cdot Tq(1-q)$. For the numerator, first sum over periods:

$$\sum_t (\mathit{Post}_t - q)\, y_{it} = T_1(1-q)\,\bar{y}_{i,\text{post}} - T_0\, q\,\bar{y}_{i,\text{pre}} = Tq(1-q)\,\Delta_i,$$

using $T_1 = qT$ and $T_0 = (1-q)T$. Then sum over units: $\sum_i (\mathit{Treat}_i - p)\Delta_i = np\bar{\Delta}_1 - p(np\bar{\Delta}_1 + n(1-p)\bar{\Delta}_0) = np(1-p)(\bar{\Delta}_1 - \bar{\Delta}_0)$. Dividing gives $\hat{\beta} = \bar{\Delta}_1 - \bar{\Delta}_0$. The variance follows because the Δ_i are independent across units. □

The proposition gives the right standard error in two equivalent ways. We may collapse the data to one change per unit and compare means, or cluster the TWFE regression by unit (Section A.8.2). Conventional OLS standard errors treat the nT errors as independent, and they are too small when errors are positively autocorrelated. Suppose the errors of each unit follow a stationary AR(1) process with coefficient r and variance σ^2. The variance of a mean of m consecutive errors is

$$\operatorname{Var}\left(\frac{1}{m}\sum_{t=1}^{m} e_{it}\right) = \frac{\sigma^2}{m^2}\left[m + 2\sum_{h=1}^{m-1}(m-h)\,r^h\right] \approx \frac{\sigma^2}{m}\cdot\frac{1+r}{1-r}$$

for large m, since $\sum_{h=-\infty}^{\infty} r^{|h|} = \frac{1+r}{1-r}$. The covariance between the pre-period and post-period means is of order $\frac{1}{m^2}$ and becomes negligible. The independence formula therefore understates the variance of Δ_i by a factor of about $\frac{1+r}{1-r}$, which is 9 when $r = 0.8$. The standard error is then too small by a factor of 3. This is the mechanism behind the placebo evidence of Bertrand et al. (2004) discussed in Section A.8.2. Clustering by state or collapsing to pre and post means fixes the problem when there are many states.

Few treated units. Cluster-robust inference relies on many clusters, and in particular on many treated clusters. Retrospectives often have one merger, or a handful of treated markets. Conley and Taber (2011) use the control units' residuals to estimate the distribution of the treated

units' errors, which gives valid inference with few treated groups and many controls. A related approach is *randomization inference*. We reassign the treatment to each control unit in turn, or to each possible set of units. For each placebo assignment g we recompute the estimate $\hat{\beta}_g$. The p-value is

$$\hat{p} = \frac{1}{|\mathcal{G}|} \sum_{g \in \mathcal{G}} \mathbf{1}\{|\hat{\beta}_g| \geq |\hat{\beta}|\},$$

where $\mathcal{G}$ is the set of assignments, including the actual one. The test is exact under the null of no effect for any unit when treatment was assigned at random among the units, and approximate otherwise. The wild cluster bootstrap of Remark A.57 is a further option, with the caveats noted there for few treated clusters.

Common shocks and the choice of cluster. In (A.129) the regressor $Post_{ijt}$ takes the same value for all products and cities in a month, and the model has no month effects beyond calendar-month seasonality. Common monthly shocks then make the errors of a month correlated. As a result, the conventional variance understates the variance of $\hat{\beta}_1$ and $\hat{\beta}_2$ by the Moulton factor (Moulton, 1987, 1990) of Proposition A.56 and Lemma 11.44. Ashenfelter and Hosken therefore cluster on the time period, "because we are observing the prices of the same products in many different markets in each time period" (Ashenfelter and Hosken, 2008, p. 25). The number of clusters is then the number of months in the window, so it is modest. Equation (A.130) instead includes a full set of month effects, which absorb common monthly shocks. The remaining dependence is within an SKU over time, and Ashenfelter, Hosken and Weinberg cluster by SKU. When both forms of dependence matter, two-way clustering is available (Section A.8.2). Whinston and Collins compare cohort means of market-level changes with a two-sample t test with 13 degrees of freedom. That test treats markets as independent and is exact under normality with equal variances.

A.12.5 Event-study specifications

A single DiD coefficient averages the effect over all post-treatment periods. An *event study* estimates the path of the effect by relative time. Let E_i be the period in which unit i adopts the treatment, with $E_i = \infty$ for units never treated, and let $k = t - E_i$ be relative time. The canonical specification is

$$y_{it} = \mu_i + \tau_t + \sum_{k \neq -1} \phi_k \, \mathbf{1}\{t - E_i = k\} + e_{it}. \tag{A.131}$$

The coefficients ϕ_k for $k \geq 0$ (the *lags*) trace the effect k periods after adoption. The coefficients for $k \leq -2$ (the *leads*) measure differences before adoption, relative to the omitted period $k = -1$. Suppose parallel trends and no anticipation hold, effects are the same for all adoption cohorts, and every relative period has its own dummy. Suppose also that the sample contains never-treated units, or that a second lead is omitted (Proposition A.89). Then $\phi_k = 0$ for $k < 0$, and ϕ_k equals the average effect at relative time k for $k \geq 0$. Section A.12.6 shows what goes wrong when effects differ across cohorts.

The choice of omitted period changes the meaning of every coefficient. With $k = -1$ omitted, ϕ_k is measured relative to the last pre-treatment period. The patent event study in Section 5.10 omits the grant period $k = 0$ instead (Equation (5.152)). Its post-grant coefficients are then changes relative to the grant period, net of any effect that occurred within it.

Proposition A.89 (Collinearity without never-treated units)**.** *Suppose every unit is treated at some finite date and* (A.131) *includes a dummy for every relative period observed in the data. Then the unit*

effects, the period effects and the relative-time dummies are linearly dependent even after one relative period is omitted, and ϕ is not identified without a second normalization.

Proof. For every observation exactly one relative-time dummy equals one, so

$$\sum_k (k+1)\,\mathbf{1}\{t - E_i = k\} = t - E_i + 1.$$

The term with $k = -1$ has coefficient zero, so the left side involves only included dummies. The right side is a period term (t) plus a unit term ($1 - E_i$), which lies in the span of the period and unit dummies. A nontrivial linear combination of the regressors is therefore zero, and the regressor matrix does not have full column rank. □

The proposition shows that a linear trend in relative time cannot be told apart from a linear trend in calendar time and a cohort effect. Researchers resolve it by omitting a second lead, usually the earliest, or by including never-treated units. For a never-treated unit all dummies are zero while $t - E_i$ is undefined, so the identity fails and the collinearity disappears.

Binning. Relative periods far from adoption are observed only for a few cohorts. Many studies therefore *bin* the end points: one dummy collects all $k \le \underline{k}$ and another all $k \ge \bar{k}$, as in the patent event study of Section 5.10. Binning assumes that the effect is constant within each bin. If effects keep growing beyond $\bar{k}$, the misspecification contaminates the other coefficients, including the leads. Figure A.14 shows the result in a simulated panel.

Leads as tests of parallel trends. Estimated leads near zero are evidence for parallel trends and no anticipation. A joint Wald test of $\phi_k = 0$ for all leads is a formal version (Section A.2.6). Two cautions apply. Pre-trend tests often have low power against violations large enough to matter for the lags. And reporting the event study only when the test passes distorts the distribution of the reported estimates, sometimes making the bias worse (Roth, 2022). Rambachan and Roth (2023) replace the exact assumption with bounds on post-treatment violations of parallel trends. One version, the *relative magnitudes* restriction, assumes that the change in the violation between consecutive post-periods is at most $\bar{M}$ times the largest such change in the pre-period. The identified set for the effect then widens with $\bar{M}$, and we can report the largest $\bar{M}$ at which the conclusion survives.

The placebo regressions of Dafny (2009) are leads in long-difference form. The checks in Whinston and Collins (1992) play the same role. The 1985 cohort's price rose 2 percent in the year before its entry, which supports parallel trends. The 1984 cohort's price was flat in the year after its entry, which supports a constant effect.

A.12.6 Staggered adoption with heterogeneous effects

In many applications units adopt at different dates. Patents are granted molecule by molecule, mergers close at different dates, and states change taxes in different years. This *staggered adoption* design seems a natural case for the TWFE regression (A.125) with $d_{it} = \mathbf{1}\{t \ge E_i\}$. The TWFE coefficient can badly misrepresent the average effect when effects vary over time or across cohorts. A literature that began with Goodman-Bacon (2021) and de Chaisemartin and D'Haultfœuille (2020) shows this. Roth et al. (2023) survey the literature.

Let e index adoption cohorts and define the *cohort-time average effect*

$$\mathrm{ATT}_e(k) = \mathbb{E}\big[y_{it}(1) - y_{it}(0) \mid E_i = e,\ t - E_i = k\big], \qquad k \ge 0.$$

We maintain parallel trends for all cohorts, including the never-treated, in all periods, and no anticipation: $y_{it} = y_{it}(0)$ for $t < E_i$. Equivalently, untreated outcomes follow (A.123) with strictly exogenous errors.

Proposition A.90 (TWFE as a weighted average of cell effects)**.** *Let $y_{it} = y_{it}(0) + d_{it}\Delta_{it}$, where $\Delta_{it} = y_{it}(1) - y_{it}(0)$ and untreated outcomes satisfy (A.123) with $\mathbb{E}[\varepsilon_{it} \mid \mathbf{d}, \Delta] = 0$. Then*

$$\mathbb{E}\big[\hat{\beta} \mid \mathbf{d}, \Delta\big] = \sum_{(i,t):\, d_{it}=1} w_{it}\, \Delta_{it}, \qquad w_{it} = \frac{\tilde{d}_{it}}{\sum_{(j,s):\, d_{js}=1} \tilde{d}_{js}}, \qquad \sum_{(i,t):\, d_{it}=1} w_{it} = 1.$$

In a balanced panel the weight of a treated cell is proportional to $1 - \bar{d}_i - \bar{d}_t + \bar{d}$, which is negative when $\bar{d}_i + \bar{d}_t > 1 + \bar{d}$.

Proof. Substitute the outcome into (A.126). The terms $\mu_i + \tau_t$ drop out because $\tilde{d}_{it}$ is orthogonal to the unit and period dummies. The error term has conditional mean zero. What remains is

$$\mathbb{E}\big[\hat{\beta} \mid \mathbf{d}, \Delta\big] = \frac{\sum_{i,t} \tilde{d}_{it}\, d_{it}\, \Delta_{it}}{\sum_{i,t} \tilde{d}_{it}^2}.$$

As shown in Section A.12.2, $\sum_{i,t} \tilde{d}_{it}^2 = \sum_{i,t} \tilde{d}_{it} d_{it} = \sum_{d_{it}=1} \tilde{d}_{it}$. This gives the weights and shows that they sum to one. The balanced-panel expression follows from (A.127) with $d_{it} = 1$. □

The weights are negative for treated cells of units that are treated for many periods ($\bar{d}_i$ large) in periods when most units are treated ($\bar{d}_t$ large). These are early adopters late in the sample. A negative weight means that a larger effect in such a cell lowers the TWFE coefficient. The next result shows where the negative weights come from, in the smallest staggered design.

Proposition A.91 (Three groups and three periods)**.** *Let periods be $t = 1, 2, 3$. An early group E adopts in period 2, a late group L adopts in period 3, and a group U is never treated, with population shares ω_E, ω_L and ω_U. Let $S = \omega_E\omega_L + \omega_E\omega_U + \omega_L\omega_U$. Define four two-by-two DiD estimators from the group-period means $\bar{y}_{gt}$:*

$$\begin{aligned}
\hat{\beta}_{EU} &= \left(\frac{\bar{y}_{E2} + \bar{y}_{E3}}{2} - \bar{y}_{E1}\right) - \left(\frac{\bar{y}_{U2} + \bar{y}_{U3}}{2} - \bar{y}_{U1}\right),\\
\hat{\beta}_{LU} &= \left(\bar{y}_{L3} - \frac{\bar{y}_{L1} + \bar{y}_{L2}}{2}\right) - \left(\bar{y}_{U3} - \frac{\bar{y}_{U1} + \bar{y}_{U2}}{2}\right),\\
\hat{\beta}^{E}_{EL} &= \left(\bar{y}_{E2} - \bar{y}_{E1}\right) - \left(\bar{y}_{L2} - \bar{y}_{L1}\right),\\
\hat{\beta}^{L}_{EL} &= \left(\bar{y}_{L3} - \bar{y}_{L2}\right) - \left(\bar{y}_{E3} - \bar{y}_{E2}\right).
\end{aligned}$$

The first two compare each adopting group with the never-treated group. The third compares the early group with the late group before the late group adopts. The fourth compares the late group with the early group after the early group has adopted. Then the TWFE estimate is

$$\hat{\beta} = \frac{\omega_E\omega_U}{S}\,\hat{\beta}_{EU} + \frac{\omega_L\omega_U}{S}\,\hat{\beta}_{LU} + \frac{\omega_E\omega_L}{2S}\,\hat{\beta}^{E}_{EL} + \frac{\omega_E\omega_L}{2S}\,\hat{\beta}^{L}_{EL},$$

and the four weights sum to one.

Proof. Normalize $\omega_E + \omega_L + \omega_U = 1$. Because treatment varies only by group and period, (A.126) can be computed from group-period means: $\hat{\beta} = \frac{\sum_{g,t} \omega_g \tilde{d}_{gt} \bar{y}_{gt}}{\sum_{g,t} \omega_g \tilde{d}_{gt}^2}$, with $\tilde{d}_{gt} = d_{gt} - \bar{d}_g - \bar{d}_t + \bar{d}$. We prove the identity in three steps.

Step 1: both sides ignore additive effects. Adding $a_g + b_t$ to every $\bar{y}_{gt}$ leaves $\hat{\beta}$ unchanged, because $\tilde{d}_{gt}$ is orthogonal to group and period terms. It leaves each two-by-two estimator unchanged, because each is a difference of changes over the same periods.

Step 2: a basis. Any array of cell means can be written as $\bar{y}_{gt} = (\bar{y}_{g1} + \bar{y}_{Ut} - \bar{y}_{U1}) + r_{gt}$, where $r_{gt} = \bar{y}_{gt} - \bar{y}_{g1} - \bar{y}_{Ut} + \bar{y}_{U1}$. The first part is additive, and $r_{gt} = 0$ in row U and in column $t = 1$. So r is a combination of the four indicator arrays of the cells $(E,2)$, $(E,3)$, $(L,2)$ and $(L,3)$. By Step 1 and linearity, it suffices to check the identity for these four indicator arrays. If $\omega_U = 0$, the cells of row U enter neither side, and we may give them any values.

Step 3: the four checks. The group means of treatment are $\bar{d}_E = \frac{2}{3}$, $\bar{d}_L = \frac{1}{3}$ and $\bar{d}_U = 0$. The period means are $\bar{d}_1 = 0$, $\bar{d}_2 = \omega_E$ and $\bar{d}_3 = \omega_E + \omega_L$, and $\bar{d} = \frac{2\omega_E + \omega_L}{3}$. Hence

$$\tilde{d}_{E2} = \frac{1 - \omega_E + \omega_L}{3}, \qquad \tilde{d}_{E3} = \frac{1 - \omega_E - 2\omega_L}{3},$$
$$\tilde{d}_{L2} = \frac{-1 - \omega_E + \omega_L}{3}, \qquad \tilde{d}_{L3} = \frac{2 - \omega_E - 2\omega_L}{3}.$$

The denominator equals $\sum_{g,t} \omega_g \tilde{d}_{gt} d_{gt}$, a sum over the treated cells:

$$\omega_E\big(\tilde{d}_{E2} + \tilde{d}_{E3}\big) + \omega_L \tilde{d}_{L3} = \frac{2\omega_E + 2\omega_L - 2\omega_E^2 - 2\omega_E\omega_L - 2\omega_L^2}{3} = \frac{2S}{3},$$

where the last step uses $S = \omega_E\omega_L + (\omega_E + \omega_L)(1 - \omega_E - \omega_L)$. For the indicator of cell (h,s) the left side is $\frac{\omega_h \tilde{d}_{hs}}{\frac{2S}{3}}$. For the indicator of $(E,2)$ the left side is $\frac{\omega_E(1-\omega_E+\omega_L)}{2S}$. On the right side $\hat{\beta}_{EU} = \frac{1}{2}$, $\hat{\beta}_{LU} = 0$, $\hat{\beta}^E_{EL} = 1$ and $\hat{\beta}^L_{EL} = 1$, so the right side is

$$\frac{\omega_E\omega_U}{2S} + \frac{\omega_E\omega_L}{2S} + \frac{\omega_E\omega_L}{2S} = \frac{\omega_E(\omega_U + 2\omega_L)}{2S} = \frac{\omega_E(1 - \omega_E + \omega_L)}{2S}.$$

For $(E,3)$ the two-by-two values are $\frac{1}{2}$, 0, 0 and -1, so both sides equal $\frac{\omega_E(\omega_U-\omega_L)}{2S} = \frac{\omega_E(1-\omega_E-2\omega_L)}{2S}$. For $(L,3)$ the values are 0, 1, 0 and 1, so the right side is $\frac{2\omega_L\omega_U+\omega_E\omega_L}{2S} = \frac{\omega_L(2-\omega_E-2\omega_L)}{2S}$, which equals the left side. For $(L,2)$ the values are 0, $-\frac{1}{2}$, -1 and -1, so the right side is $-\frac{\omega_L(\omega_U+2\omega_E)}{2S} = \frac{\omega_L(-1-\omega_E+\omega_L)}{2S}$, which again equals the left side. Finally, the weights sum to $\frac{2\omega_E\omega_U+2\omega_L\omega_U+2\omega_E\omega_L}{2S} = 1$. □

The proposition says that TWFE is a weighted average of all two-by-two comparisons in the data. Three of them are clean, in the sense that the control group is untreated in both periods compared. The fourth, $\hat{\beta}^L_{EL}$, uses the already treated early group as the control. Its expectation reveals the problem.

Corollary A.92 (Weights on the cohort effects)**.** *Under parallel trends and no anticipation, in the design of Proposition A.91,*

$$\mathbb{E}\big[\hat{\beta}^L_{EL}\big] = \mathrm{ATT}_L(0) - \big[\mathrm{ATT}_E(1) - \mathrm{ATT}_E(0)\big],$$
$$\mathbb{E}\big[\hat{\beta}\big] = \frac{\omega_E(\omega_U + 2\omega_L)}{2S}\,\mathrm{ATT}_E(0) + \frac{\omega_E(\omega_U - \omega_L)}{2S}\,\mathrm{ATT}_E(1) + \frac{\omega_L(2\omega_U + \omega_E)}{2S}\,\mathrm{ATT}_L(0).$$

With equal shares the weights are $\frac{1}{2}$, 0 and $\frac{1}{2}$. Without a never-treated group ($\omega_U = 0$) they are 1, $-\frac{1}{2}$ and $\frac{1}{2}$.

Proof. Under the assumptions, the expected cell means are additive effects plus $\mathrm{ATT}_E(0)$ in cell $(E,2)$, $\mathrm{ATT}_E(1)$ in cell $(E,3)$ and $\mathrm{ATT}_L(0)$ in cell $(L,3)$. The additive effects drop out of every estimator. The expectation of $\hat{\beta}^L_{EL}$ is $\mathrm{ATT}_L(0) - 0$ for the late group minus $\mathrm{ATT}_E(1) - \mathrm{ATT}_E(0)$ for the early group. The weights on the three effects are the left sides computed in Step 3 of the proof of Proposition A.91 for the three treated cells. Setting $\omega_E = \omega_L = \omega_U = \frac{1}{3}$ gives $S = \frac{1}{3}$ and the weights $\frac{1}{2}$, 0, $\frac{1}{2}$. Setting $\omega_U = 0$ gives $S = \omega_E \omega_L$ and the weights 1, $-\frac{1}{2}$, $\frac{1}{2}$. □

The forbidden comparison subtracts the growth of the early group's effect. If effects are constant over time, $\mathrm{ATT}_E(1) = \mathrm{ATT}_E(0)$ and every comparison is unbiased for some average effect. If effects grow, the comparison is biased downward and can be negative even though every effect is positive. Without a never-treated group the extreme case is stark. Let $\mathrm{ATT}_E(0) = \mathrm{ATT}_L(0) = 0$ and $\mathrm{ATT}_E(1) = 1$, so that the treatment works with a one-period lag. Then $\mathbb{E}[\hat{\beta}] = -\frac{1}{2}$, although no unit is harmed. This is the situation Whinston and Collins guard against by checking that the 1984 cohort's effect was constant.

Theorem A.93 (Goodman-Bacon decomposition)**.** *Consider a balanced panel with periods $t = 1, \dots, T$, adoption cohorts k with shares ω_k that adopt at different dates, and possibly a never-treated group U with share ω_U. Let $\bar{d}_k$ be the fraction of periods in which cohort k is treated, and $\hat{V}^d = \frac{1}{nT}\sum_{i,t} \tilde{d}^2_{it}$. Then*

$$\hat{\beta} = \sum_k s_{kU} \hat{\beta}_{kU} + \sum_k \sum_{\ell : \bar{d}_\ell < \bar{d}_k} \left(s^k_{k\ell} \hat{\beta}^k_{k\ell} + s^\ell_{k\ell} \hat{\beta}^\ell_{k\ell} \right),$$

where $\hat{\beta}_{kU}$ compares cohort k with the never-treated over all periods. The estimator $\hat{\beta}^k_{k\ell}$ compares the earlier cohort k with the later cohort ℓ before ℓ adopts, and $\hat{\beta}^\ell_{k\ell}$ compares ℓ with k after k has adopted. The weights

$$s_{kU} = \frac{\omega_k \omega_U \bar{d}_k (1 - \bar{d}_k)}{\hat{V}^d}, \qquad s^k_{k\ell} = \frac{\omega_k \omega_\ell (\bar{d}_k - \bar{d}_\ell)(1 - \bar{d}_k)}{\hat{V}^d}, \qquad s^\ell_{k\ell} = \frac{\omega_k \omega_\ell \, \bar{d}_\ell (\bar{d}_k - \bar{d}_\ell)}{\hat{V}^d}$$

are positive and sum to one.

We state the weights of Goodman-Bacon (2021), Theorem 1, after simplifying the products of group shares. In the design of Proposition A.91, $\bar{d}_E = \frac{2}{3}$, $\bar{d}_L = \frac{1}{3}$ and $\hat{V}^d = \frac{2S}{9}$, and the formulas reproduce its weights. On the simulated panel below, the script also checks that the weights sum to one and that the weighted sum of the nine two-by-two estimates equals $\hat{\beta}$ to six decimals. The weights grow with group size and with the variance of treatment within each comparison. Comparisons in which treatment switches in the middle of the window receive the most weight. The decomposition shows that the TWFE coefficient is a variance-weighted average of comparisons. Some of these use already treated units as controls. Every weight is positive, yet the implied weights on the cohort effects can be negative, as in Corollary A.92.

Event studies under heterogeneity. The dynamic specification (A.131) has a related problem. Sun and Abraham (2021) show that each TWFE coefficient ϕ_k equals a weighted average of cohort effects at relative time k plus a weighted sum of cohort effects at other relative times. The second set of weights sums to zero across cohorts. Contamination therefore vanishes when effects are the same in every cohort, and it appears when they differ. Binned or omitted relative periods with nonzero effects add more contamination. Leads can then look like pre-trends even when parallel trends holds.

Heterogeneity-robust estimators. The remedy is to estimate each cohort-time effect from clean comparisons and then average with chosen weights.

- Callaway and Sant'Anna (2021) estimate the group-time effect of cohort e in period $t \geq e$ by a two-by-two comparison with base period $e-1$. The estimator is

$$\widehat{\mathrm{ATT}}(e,t) = \left(\bar{y}_{e,t} - \bar{y}_{e,e-1}\right) - \left(\bar{y}_{C,t} - \bar{y}_{C,e-1}\right),$$

  where C is the never-treated group or the units not yet treated by period t. Under parallel trends and no anticipation, the expected change of the control group equals the change cohort e would have had without treatment, so the estimator is unbiased for $\mathrm{ATT}_e(t-e)$. Event-study estimates average these effects across cohorts at each relative time, $\hat{\phi}_k = \sum_e w_e(k)\widehat{\mathrm{ATT}}(e, e+k)$, with $w_e(k)$ the cohort shares among the cohorts observed at k. Leads are computed the same way for $t < e$.

- Sun and Abraham (2021) estimate a saturated regression with a dummy for each cohort and relative period, using never-treated or last-treated units as controls, and average the coefficients with cohort shares. In a balanced panel without covariates and with never-treated controls, their estimates coincide with those of Callaway and Sant'Anna. Our simulation below confirms this to machine precision.

- Borusyak et al. (2024) propose an *imputation* estimator. It estimates μ_i and τ_t from untreated observations only, imputes $\hat{y}_{it}(0) = \hat{\mu}_i + \hat{\tau}_t$ for treated observations, and averages $y_{it} - \hat{y}_{it}(0)$ over the cells of interest. It uses all pre-treatment periods, which makes it efficient when errors are homoskedastic and serially uncorrelated. It leans more on parallel trends in early periods.

- *Stacked* DiD (Cengiz et al., 2019) builds one dataset per cohort, containing the cohort and units not treated within a window around its adoption date. It stacks the datasets and estimates an event study with dataset-specific unit and period effects.

These estimators differ in the control group, the base period and the weights. Each removes the forbidden comparisons.

A simulated illustration. Figure A.14 reports a Monte Carlo experiment. A balanced panel has 400 units observed for 20 periods. Cohorts of 100 units adopt in periods 5, 10 and 15, and 100 units are never treated. Untreated outcomes follow (A.123), so parallel trends and no anticipation hold exactly. The effect k periods after adoption is $\gamma_e(k+1)$, with γ_e equal to 0.10, 0.06 and 0.03 for the three cohorts. Effects therefore grow with time since adoption and are larger for early cohorts. The average effect over all treated unit-periods is 0.551. The static TWFE coefficient averages 0.126 across 500 replications (standard deviation 0.020), less than a quarter of the average effect.

Panel (b) shows why. The Goodman-Bacon decomposition of the expected TWFE coefficient puts a total weight of 0.497 on comparisons with the never-treated group, whose weighted average is 0.400. Comparisons of earlier cohorts with not-yet-treated cohorts receive 0.211 and average 0.344. Comparisons of later cohorts with already treated ones receive 0.292 and average −0.501. The three comparisons in this last group are all negative. Their controls are early cohorts whose effects keep rising, and the rise is subtracted from the late cohorts' effects.

Panel (a) shows the event study. The TWFE specification, with binned end points beyond ±5, produces leads that rise to 0.110 at $k = -5$, a spurious pre-trend. Its lags are too low at adoption and from $k = 3$ on, reaching 0.263 at $k = 5$ where the true value is 0.380. The Callaway-Sant'Anna and imputation estimators are centered on the truth, at 0.384 and 0.383 for $k = 5$. Their 5th to 95th percentile ranges at $k = 5$ are $[0.293, 0.478]$ and $[0.314, 0.454]$. The imputation

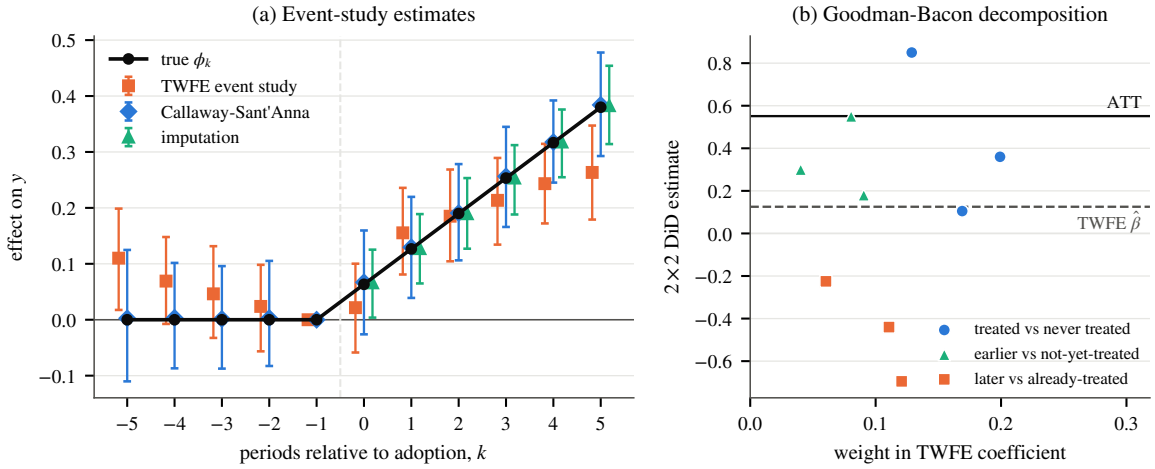

Figure A.14: Staggered adoption with effects that grow over time and differ across cohorts. (a) Mean estimates of the event-time effects over 500 replications, with bars from the 5th to the 95th percentile. The black line is the true effect, averaged over the cohorts observed at each relative time. The TWFE event study includes dummies for $k = -5, \ldots, 5$ (omitting $k = -1$) and binned end points. (b) Goodman-Bacon decomposition of the expected static TWFE coefficient (dashed line). Each marker is one two-by-two comparison. The solid line is the average effect over all treated unit-periods. The design has 400 units, 20 periods, adoption in periods 5, 10 and 15 plus a never-treated group. Numbers from `staggered_did.py`, seed 20261022.

estimator is more precise here because the errors are independent and homoskedastic, which is the case in which it is efficient.

The lesson for applied work is direct. When treatment timing varies and effects may change with exposure, we should report heterogeneity-robust estimates alongside, or instead of, TWFE. The Goodman-Bacon decomposition is a useful diagnostic, because it shows how much weight the forbidden comparisons receive. In merger retrospectives that pool mergers closing at different dates, and in patent or entry studies with staggered timing, the issue arises whenever the effect builds up gradually.

A.12.7 Related designs

Synthetic control. Many IO questions concern a single treated unit, such as the local market of one merger or one state's regulation. With one treated unit, the choice of control group carries the whole design. The *synthetic control* method (Abadie and Gardeazabal, 2003; Abadie et al., 2010) builds the control as a weighted average of untreated units. Let unit 1 be treated after period T_0 and units $2, \ldots, J+1$ be potential controls. Let X_1 be a vector of pre-treatment characteristics of the treated unit, including pre-period outcomes, and X_0 the matrix of the same characteristics for the controls. The weights solve

$$\min_{w} \left\| X_1 - X_0 w \right\|_V \quad \text{subject to} \quad w_j \geq 0, \ \sum_{j=2}^{J+1} w_j = 1,$$

for a positive definite weighting matrix V chosen to fit pre-period outcomes. The estimated effect in period $t > T_0$ is $y_{1t} - \sum_j w_j y_{jt}$. The constraints rule out extrapolation, because the

synthetic unit lies in the convex hull of the controls. The method is credible when the synthetic unit tracks the treated unit closely over a long pre-period. Inference uses placebo assignments, applying the method to each control unit in turn and comparing the treated unit's post-period gap with the placebo gaps. Abadie (2021) discusses data requirements and practice.

Triple differences. When the control group may face different trends, a third difference can remove them. Suppose a merger affects product category A in region 1, and region 2 and category B are unaffected. The *triple difference* is

$$\hat{\beta}^{\mathrm{DDD}} = \big[\Delta\bar{y}_{A1} - \Delta\bar{y}_{A2}\big] - \big[\Delta\bar{y}_{B1} - \Delta\bar{y}_{B2}\big],$$

where $\Delta\bar{y}_{cr}$ is the change in the mean outcome of category c in region r. The first bracket is a regional DiD for category A. The second removes region-specific trends that also appear in category B. The identifying assumption is that the gap between the regional trends would have been the same in both categories. This is weaker than parallel trends for either DiD alone.

Regression discontinuity. When treatment is assigned by a known rule based on a running variable z_i, with $d_i = \mathbf{1}\{z_i \geq c\}$, units just above and just below the cutoff c are comparable. If potential outcomes are continuous in z at c, the jump $\lim_{z \downarrow c} \mathbb{E}[y_i \mid z_i = z] - \lim_{z \uparrow c} \mathbb{E}[y_i \mid z_i = z]$ identifies the average effect at the cutoff. Estimation uses local linear regression on each side (Section A.11.2). Lee and Lemieux (2010) survey the design. Athey et al. (2011) discuss a deterministic rule for the format of timber sales, such as an open auction whenever timber volume exceeds a threshold. Under such a rule their comparison would be identified in a manner analogous to a regression discontinuity design (n. 13, p. 229).

Selection on observables and matching. A different design drops the panel. It assumes *unconfoundedness*, that treatment is as good as random given observed covariates: $(y_i(0), y_i(1)) \perp d_i \mid x_i$. It also assumes *overlap*, $0 < \psi(x) < 1$, where $\psi(x) = \mathbb{P}(d_i = 1 \mid x_i = x)$ is the *propensity score*. Rosenbaum and Rubin (1983) show that unconfoundedness given x_i implies unconfoundedness given $\psi(x_i)$. The proof is short. By iterated expectations,

$$\mathbb{P}\big(d_i = 1 \mid y_i(0), y_i(1), \psi(x_i)\big) = \mathbb{E}\big[\mathbb{P}(d_i = 1 \mid y_i(0), y_i(1), x_i) \mid y_i(0), y_i(1), \psi(x_i)\big] = \psi(x_i),$$

because the inner probability equals $\psi(x_i)$ by unconfoundedness. Comparisons may therefore condition on the scalar ψ instead of the whole vector x. Estimators include regression adjustment, inverse propensity weighting and matching. A matching estimator imputes each unit's missing potential outcome by the average outcome of its M nearest neighbors in the other treatment group. Abadie and Imbens (2006) derive its large-sample distribution and a consistent variance estimator. Imbens and Rubin (2015) give a full treatment.

Athey et al. (2011) use these tools to compare sealed-bid and open timber auctions held by the US Forest Service (Chapter 15). Their sales took place between 1982 and 1990 in the Northern forests and between 1982 and 1989 in California. For an outcome Y they write $Y = f(SEALED, X, N, \epsilon)$ and target the average effect $\Delta Y = \mathbb{E}[f(1, X, N, \epsilon) - f(0, X, N, \epsilon)]$ (eq. 5, p. 229). The identifying assumption is that the auction format is independent of ϵ given the covariates. It holds by design for sales whose format was randomized, and for other sales if the format was chosen on information in their data. They estimate a logit propensity score of the sealed-bid format on tract characteristics and drop sales with predicted probabilities below 0.075 or above 0.925 to enforce overlap (p. 227). Their matching estimator is

$$\widehat{\Delta Y} = \frac{1}{T} \sum_{t \text{ sealed}} \big(Y_t - \hat{Y}_t\big) + \frac{1}{T} \sum_{t \text{ open}} \big(\hat{Y}_t - Y_t\big)$$

(eq. 7, p. 230). Here T is the number of sales, and $\hat{Y}_t$ is the average outcome of the $M = 4$ sales of the other format with the closest propensity scores. Standard errors follow Abadie and Imbens (2006). Table A.12 compares the matching estimates with two regression estimates. In the Northern forests the three estimators agree closely. Sealed bidding raises logger entry by about 10 percent and the sale price by 9 to 12 percent. In California the price effects are small and insignificant, and the matching estimates are imprecise. Trimming for overlap kept only a third of the California sales (p. 227). The authors also report similar estimates on the 378 Northern sales whose format was randomized (p. 226).

Table A.12: Effect of sealed bidding on timber sale outcomes: regression and matching

	Northern forests (N = 1,071)		California (N = 707)	
Estimator	ln(logger entry)	ln(price)	ln(logger entry)	ln(price)
OLS, no interactions	0.089	0.094	0.101	0.027
	(0.036)	(0.038)	(0.045)	(0.051)
OLS with sealed × covariate interactions	0.097	0.099	0.099	0.026
	(0.036)	(0.039)	(0.044)	(0.050)
Propensity-score matching, $M = 4$	0.100	0.118	0.106	−0.038
	(0.048)	(0.064)	(0.062)	(0.127)

Notes: Each entry is the estimated effect of the sealed-bid format, with robust standard errors in parentheses (Abadie-Imbens standard errors for matching). Regressions control for the Forest Service appraisal variables, sale characteristics and year, quarter and location dummies. Samples exclude sales with propensity scores outside [0.075, 0.925]. A.13 Financial event studies

A financial *event study* measures the effect of a discrete piece of news on the market value of firms. The method goes back to Fama et al. (1969), and MacKinlay (1997) surveys it. Industrial organization uses it to learn about profits that we cannot observe directly. A merger that raises market power should raise the value of the merging firms' rivals, and entry into a profitable market should lower the value of incumbents. This section develops the method in general form. Section 9.6.1 applies it in full to the entry study of Whinston and Collins (1992), and Section 11.6.6 applies it to mergers.

A.13.1 Premise

The method rests on *market efficiency*. The equity value of a firm equals the expected present value of the cash flows to its shareholders, given all public information. When news changes expected future profits, the share price adjusts as soon as the news becomes public. The return on the announcement day, net of the return the stock would have earned anyway, then measures the revision in the expected value of the firm to its shareholders. A study of a few days of returns can thus reveal a change in discounted profits over many years. The price of this economy is a set of assumptions about information, timing and the model of normal returns, which we make explicit below.

A.13.2 Normal returns and abnormal returns

Index firms by f and trading days by τ, with the announcement on day $\tau = 0$ of *event time*. Let $R_{f\tau}$ be the return on firm f's stock, including dividends, R^m_τ the return on a market index and R^0_τ the risk-free rate. The *normal return* is the return expected without the event. Three models are common. The *constant-mean model* sets $R_{f\tau} = \mu_f + u_{f\tau}$. The *market model* sets

$$R_{f\tau} = a_f + b_f R^m_\tau + u_{f\tau}, \qquad \mathbb{E}[u_{f\tau} \mid R^m] = 0, \quad \operatorname{Var}(u_{f\tau} \mid R^m) = \sigma^2_f, \tag{A.132}$$

with errors uncorrelated across days. The *excess-return* form of the capital asset pricing model replaces returns by returns in excess of the risk-free rate, $R_{f\tau} - R^0_\tau = a_f + b_f(R^m_\tau - R^0_\tau) + u_{f\tau}$, as in Section 9.6.1. The market model removes the part of the return due to market-wide news, which reduces the variance of the abnormal return and raises power.

The model is estimated on an *estimation window* of T_e trading days that ends some days before the event, so that the event cannot affect the estimates. The *event window* is $[\tau_1, \tau_2]$, which contains day 0 and has $L = \tau_2 - \tau_1 + 1$ days. Days before the announcement allow for leakage, and days after it allow for slow absorption. Figure A.15 shows the layout.

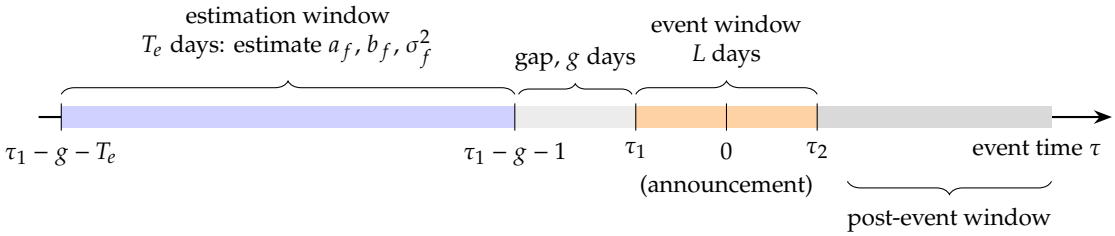

Figure A.15: Windows in a financial event study. The normal-return model is estimated on the estimation window, which ends g days before the event window so that the event cannot affect the estimates. Abnormal returns are computed on the event window $[\tau_1, \tau_2]$ around the announcement on day 0. A post-event window can be used to check for slow adjustment.

Definition A.94 (Abnormal and cumulative abnormal returns)**.** Let $(\hat a_f, \hat b_f)$ be the OLS estimates of (A.132) on the estimation window. The *abnormal return* on an event-window day is the prediction error $AR_{f\tau} = R_{f\tau} - \hat a_f - \hat b_f R^m_\tau$. The *cumulative abnormal return* is $CAR_f(\tau_1, \tau_2) = \sum_{\tau=\tau_1}^{\tau_2} AR_{f\tau}$.

The variance of abnormal returns has a compact matrix form. Stack the estimation-window data as y_e ($T_e \times 1$) and $X_e = [\iota,\ R^m_e]$ ($T_e \times 2$), and the event-window data as y^* ($L \times 1$) and X^* ($L \times 2$). Let AR^* be the $L \times 1$ vector of abnormal returns.

Proposition A.95 (Variance of abnormal returns)**.** *Suppose that* (A.132) *holds on both windows under the null hypothesis of no event effect. Let the errors be independent of the market returns and uncorrelated across days, with variance* σ^2_f*. Then, conditional on the market returns,*

$$\mathbb{E}\big[AR^*\big] = 0, \qquad \operatorname{Var}\big(AR^*\big) = \sigma^2_f \Big[I_L + X^* (X_e^\top X_e)^{-1} X^{*\top} \Big].$$

For a single day,

$$\operatorname{Var}\big(AR_{f\tau}\big) = \sigma^2_f \left[1 + \frac{1}{T_e} + \frac{(R^m_\tau - \hat\mu_m)^2}{\sum_s (R^m_s - \hat\mu_m)^2} \right],$$

where $\hat\mu_m$ *is the mean market return over the estimation window and the sum runs over it. For the cumulative abnormal return,* $\operatorname{Var}(CAR_f) = \iota^\top \operatorname{Var}(AR^*)\, \iota$.

Proof. Write $\theta_f = (a_f, b_f)^\top$ and $\hat{\theta}_f = (X_e^\top X_e)^{-1} X_e^\top y_e$. Under the null, $y^* = X^* \theta_f + u^*$, so

$$AR^* = y^* - X^* \hat{\theta}_f = u^* - X^*(\hat{\theta}_f - \theta_f) = u^* - X^*(X_e^\top X_e)^{-1} X_e^\top u_e.$$

Both terms have mean zero. The event-window errors u^* are uncorrelated with the estimation-window errors u_e, so the variance is the sum of $\mathrm{Var}(u^*) = \sigma_f^2 I_L$ and

$$X^*(X_e^\top X_e)^{-1} X_e^\top \mathrm{Var}(u_e) X_e (X_e^\top X_e)^{-1} X^{*\top} = \sigma_f^2 X^*(X_e^\top X_e)^{-1} X^{*\top}.$$

For a single day with regressor row $x_\tau = (1, R_\tau^m)$, write $Q = \sum_s (R_s^m - \hat{\mu}_m)^2$. The inverse is

$$(X_e^\top X_e)^{-1} = \frac{1}{T_e Q} \begin{pmatrix} \sum_s (R_s^m)^2 & -\sum_s R_s^m \\ -\sum_s R_s^m & T_e \end{pmatrix}.$$

Then $x_\tau (X_e^\top X_e)^{-1} x_\tau^\top = \frac{\sum_s (R_s^m)^2 - 2R_\tau^m \sum_s R_s^m + T_e (R_\tau^m)^2}{T_e Q}$. Substituting $\sum_s (R_s^m)^2 = Q + T_e \hat{\mu}_m^2$ and $\sum_s R_s^m = T_e \hat{\mu}_m$, the numerator becomes $Q + T_e (R_\tau^m - \hat{\mu}_m)^2$. Dividing by $T_e Q$ gives $\frac{1}{T_e} + \frac{(R_\tau^m - \hat{\mu}_m)^2}{Q}$. The variance of the cumulative abnormal return is the variance of $\iota^\top AR^*$. □

The term $X^*(X_e^\top X_e)^{-1} X^{*\top}$ is estimation error in the normal-return model. It vanishes as T_e grows, and with a typical estimation window of a year of trading days it is small. Its off-diagonal elements are not zero, so abnormal returns on different event-window days are correlated through the common estimation error.

Test statistics. Replacing σ_f^2 by the residual variance $\hat{\sigma}_f^2 = \frac{1}{T_e - 2} \sum_s \hat{u}_{fs}^2$ gives the *standardized cumulative abnormal return*

$$SCAR_f = \frac{CAR_f(\tau_1, \tau_2)}{\widehat{\mathrm{sd}}\big(CAR_f\big)}.$$

Under normal errors and the null it has a t distribution with $T_e - 2$ degrees of freedom, and it is approximately standard normal for long estimation windows. With N events on different calendar dates the abnormal returns are independent across events. Two aggregate statistics are standard. The first divides the average CAR, $\overline{CAR} = \frac{1}{N} \sum_f CAR_f$, by $\frac{1}{N} (\sum_f \widehat{\mathrm{Var}}(CAR_f))^{\frac{1}{2}}$. The second averages the standardized values. A t variable with $T_e - 2$ degrees of freedom has variance $\frac{T_e - 2}{T_e - 4}$, so

$$\left(\frac{N(T_e - 4)}{T_e - 2} \right)^{\frac{1}{2}} \frac{1}{N} \sum_{f=1}^{N} SCAR_f \xrightarrow{d} N(0, 1)$$

as N grows. The second statistic weights events with volatile stocks less.

Power and the length of the window. A short window raises power. Suppose an event moves the value by a fraction A spread over an L-day window, and ignore estimation error. The expected standardized CAR of one event is about $\frac{A}{\sigma_f \sqrt{L}}$. With daily volatility $\sigma_f = 0.02$ and $A = 0.01$, it is 0.5 for a one-day window. With $N = 50$ independent events the aggregate statistic is about $0.5\sqrt{50} \approx 3.5$. With an eleven-day window the same effect gives about $\frac{3.5}{\sqrt{11}} \approx 1.07$, which is insignificant. Brown and Warner (1985) study the properties of these tests with daily data.

Events on the same date. When several firms are hit by the same news, their abnormal returns are correlated. Industry news that the market index does not absorb moves them together.

Suppose N firms share an event date, each CAR has variance v, and each pair has correlation ρ. Then

$$\operatorname{Var}\left(\overline{CAR}\right) = \frac{1}{N^2}\left[Nv + N(N-1)\rho v\right] = \frac{v}{N}\left[1 + (N-1)\rho\right],$$

the same inflation factor as in clustered regressions (Proposition A.56). One remedy is the *portfolio approach*. We form an equally weighted portfolio of the affected firms, estimate the market model for the portfolio return, and compute its abnormal return. The portfolio residual variance estimates $\frac{1}{N^2}\iota^\top \Sigma \iota$ directly, so the covariance is accounted for. The other remedy, a system of regressions, follows.

A.13.3 Regression form

The two-step procedure has an equivalent one-step form. We estimate the market model on the estimation and event windows together and add one indicator for each event-window day:

$$R_{f\tau} = a_f + b_f R^m_\tau + \sum_{s=\tau_1}^{\tau_2} \gamma_{fs}\, \mathbf{1}\{\tau = s\} + u_{f\tau}. \tag{A.133}$$

Proposition A.96 (Dummy-variable form)**.** *OLS on* (A.133) *gives the estimation-window estimates* $(\hat{a}_f, \hat{b}_f)$*, and* $\hat{\gamma}_{fs} = AR_{fs}$ *for every event-window day* s*. Under the assumptions of Proposition A.95, the conventional OLS variance of* $(\hat{\gamma}_{f\tau_1}, \dots, \hat{\gamma}_{f\tau_2})$ *equals* $\operatorname{Var}(AR^*)$*.*

Proof. Order the observations with the estimation window first. The regressor matrix and the dummy matrix are

$$X = \begin{pmatrix} X_e \\ X^* \end{pmatrix}, \qquad Q_d = \begin{pmatrix} 0 \\ I_L \end{pmatrix}.$$

By the Frisch-Waugh-Lovell theorem (Theorem A.9), the coefficients on X equal those from regressing $M_Q y$ on $M_Q X$, where $M_Q = I - Q_d(Q_d^\top Q_d)^{-1}Q_d^\top$. This annihilator sets the event-window rows to zero and leaves the estimation-window rows unchanged. The regression therefore uses only estimation-window data, and its coefficients are $(\hat{a}_f, \hat{b}_f)$. The dummy coefficients solve the remaining normal equations, $Q_d^\top(y - X\hat{\theta}_f - Q_d\hat{\gamma}_f) = 0$, which give $\hat{\gamma}_f = y^* - X^*\hat{\theta}_f = AR^*$. Each dummy fits its observation exactly.

For the variance, the FWL theorem gives the conventional variance of $\hat{\gamma}_f$ as $\sigma_f^2(Q_d^\top M_X Q_d)^{-1}$, with $M_X = I - X(X^\top X)^{-1}X^\top$. Now $Q_d^\top M_X Q_d = I_L - X^*(X^\top X)^{-1}X^{*\top}$ and $X^\top X = X_e^\top X_e + X^{*\top}X^*$. The Woodbury identity gives

$$\left[I_L - X^*\left(X_e^\top X_e + X^{*\top}X^*\right)^{-1}X^{*\top}\right]^{-1} = I_L + X^*(X_e^\top X_e)^{-1}X^{*\top}.$$

So the conventional variance equals $\sigma_f^2[I_L + X^*(X_e^\top X_e)^{-1}X^{*\top}]$, which is $\operatorname{Var}(AR^*)$. □

The regression form has three advantages. The sum of the dummy coefficients is the CAR, and its standard error comes from the regression. A single dummy for all window days estimates the average daily abnormal return directly, and L times it estimates the cumulative effect. And the event effect can depend on firm and event characteristics, which lets many firms and events be estimated jointly. Proposition 9.47 gives the scalar version used by Whinston and Collins.

Systems of firms. With M firms observed on the same days, we stack the firm equations for day τ as $y_\tau = X_\tau\theta + u_\tau$. The vector θ may contain parameters common to all firms, such as the effect of an event per unit of exposure. A system of *seemingly unrelated regressions* (SUR) allows errors to be correlated across firms on the same day and uncorrelated across days, $\mathbb{E}[u_\tau u_\tau^\top] = \Sigma$ (Zellner, 1962). Feasible GLS estimates Σ from first-stage residuals (Section A.2.5). Binder (1985, pp. 170–173) applies this system, which he calls the multivariate regression model, to regulatory events that affect many firms at once. GLS reduces to equation-by-equation OLS when every equation has the same regressors and no parameter is shared (Proposition A.13). Binder's system meets both conditions, since each firm has its own abnormal returns and all equations share one regressor matrix. In his system the GLS point estimates therefore equal OLS, and SUR matters for his tests across firms, whose statistics use $\hat{\Sigma}$ (p. 173). Neither condition holds when the event effect is a common parameter scaled by firm-specific exposure, and SUR then gains efficiency and gives standard errors that account for same-day correlation. Whinston and Collins (1992) estimate such a system for a panel of 20 airlines, People Express included, "allowing the $\{\epsilon_{it}\}$ to be contemporaneously correlated across firms" (p. 449).

Dollar abnormal values. An abnormal return measures the event's effect relative to the firm's value. The *dollar abnormal value* on day τ is $V_{f,\tau-1}AR_{f\tau}$, where $V_{f,\tau-1}$ is the equity value at the previous close. Summing over the window gives the change in shareholder wealth. The choice between returns and dollars is a modelling choice about the event. If the event changes the firm's value by a fixed dollar amount Δ_f, its return effect is $\frac{\Delta_f}{V_{f,\tau-1}}$. A model with a common abnormal return across firms would then force larger firms to have proportionally larger dollar effects. Whinston and Collins argue that the loss from being an incumbent in one entered market should not scale with the carrier's size (p. 449). They therefore model dollar effects, with the return equation

$$R_{f\tau} - R^0_\tau = \frac{a_f}{V_{f,\tau-1}} + b_f\left(R^m_\tau - R^0_\tau\right) + \frac{\Delta_f(Z_\tau)}{V_{f,\tau-1}} + u_{f\tau},$$

where $\Delta_f(Z_\tau)$ is the dollar effect of the events on day τ (Equation (9.42)). Estimating in return units keeps the error homoskedastic. The equivalent dollar regression would have errors with variance $V^2_{f,\tau-1}\sigma^2_f$. Their simplest specification makes the dollar loss proportional to the incumbent's annualized seatmiles on the entered route. The estimated loss per seatmile is -0.0109 (s.e. 0.0035) for a one-day window, -0.0147 (0.0049) for two days and -0.0191 (0.0061) for three days (Table 1, p. 453). These are total changes over each window. They imply losses of \$3.7 million to \$6.5 million per incumbent (p. 452). Table 9.10 reports the full results.

A.13.4 Identification and pitfalls

An abnormal return equals the change in expected shareholder value caused by the event only under several conditions. Each can fail in IO applications.

Dating and leakage. The event must be dated by the first public report. News often leaks before formal announcements, through rumors, regulatory filings or trade press. Longer windows capture leakage but add the noise of unrelated news on each extra day, and by the power calculation above they dilute the test. Whinston and Collins date each event by the earliest report in the trade or financial press, and use one-, two- and three-day windows ending on that day (p. 450).

Anticipation. Markets price events before they happen when they expect them. The next result makes the consequence precise.

Proposition A.97 (Partial anticipation)**.** *Suppose that before the announcement the market assigns probability π to an event that would change the firm's value by ΔV, and that the announcement resolves the uncertainty. If the event is announced, the measured value change is $(1-\pi)\Delta V$. If the announcement reveals that the event will not happen, the measured change is $-\pi\Delta V$.*

Proof. Let V^0 be the value without the event. Before the announcement the value is the expectation $V^0 + \pi\Delta V$. If the event is announced, the value becomes $V^0 + \Delta V$, and the change is $(V^0 + \Delta V) - (V^0 + \pi\Delta V) = (1 - \pi)\Delta V$. If the event is ruled out, the value becomes V^0, and the change is $-\pi\Delta V$. □

Announcement returns therefore understate the value of events that were partly expected, and the bias is larger the more predictable the event. Dividing by $1 - \pi$ corrects the estimate if π is known. Malatesta and Thompson (1985, pp. 240–241) show that π need not be known when events of constant expected value recur with a constant probability per period. Repeated acquisition attempts by one firm are an example. They regress the firm's dollar excess return on a market term and a dummy for periods with an event. The intercept then estimates $-\pi\Delta V$, and the dummy coefficient estimates ΔV itself. A merger announcement raises the probability of the merger, and an antitrust complaint lowers it. Under Proposition A.97 the two events move the rivals' values in opposite directions with magnitudes that depend on the prior probabilities. This is the logic behind the rival tests in Table 11.15.

Information revealed by the event. An event can reveal information beyond its direct effect. A merger announcement may reveal that scale economies are available to the whole industry, or that rivals are attractive targets. Rivals' values then rise for reasons other than market power. Entry by one firm may reveal its plans for further expansion. Whinston and Collins find industry-wide losses that they cannot fully attribute, and list such informational effects among the possible sources (p. 448).

Confounding events and calendar clustering. Other news inside the window that is correlated with exposure to the event biases the estimate. Events that cluster on the same dates create the cross-sectional dependence discussed above. Event-induced changes in volatility make the estimation-window variance too small. A test that standardizes each abnormal return and then uses the cross-sectional variance of the standardized values guards against this (Boehmer et al., 1991).

Thin trading. Stocks that trade infrequently have stale prices, which biases estimated betas and spreads the response over several days. Estimators that use leads and lags of the market return correct the betas (Scholes and Williams, 1977).

Who captures the change. Equity values measure only the shareholders' part of a change in firm value. Part of the rents from market power can accrue to debtholders, to workers through rent sharing, or to managers. Whinston and Collins note that misdating, partial anticipation, and value changes felt by debtholders or workers all bias their estimates toward zero (p. 453). Effects on consumers do not appear in stock prices at all, so an event study measures only producer gains and losses.

A.13.5 Uses in industrial organization

Mergers. The value created for the merging firms combines market power and efficiencies, so it cannot tell them apart. The returns of rivals can. A merger that raises prices raises rivals' profits, while a merger that creates a more efficient competitor lowers them. Eckbo (1983) and Stillman (1983) compare rivals' abnormal returns at the merger announcement and at the antitrust complaint. Under the market-power hypothesis the two returns have opposite signs, positive and then negative. Table 11.15 lists the predictions, including the information hypothesis that weakens the test. The design also needs rivals that are publicly traded and for which the affected market is a large part of value. Section 11.6.6 discusses applications and their limits. Asker and Nocke (2021, p. 231, n. 137) report that most authors doubt that an event study can reveal the competitive effects of one specific merger. In their reading the method works best for patterns across large samples of mergers.

Entry and contestability. Incumbents' value losses at an entry announcement reveal profits or sunk costs on the entered route, which perfect contestability rules out. Whinston and Collins (1992) use differences in exposure across carriers to separate three sources of loss (Section 9.6). These are incumbency on the entered airport pair, presence at other airports of the same city pair, and general effects felt by all carriers. The panel DiD of Section A.12.3 then checks the mechanism with prices, quantities and capacity.

Regulation. Regulatory events change the profits of whole industries at once. Whinston and Collins (1992, p. 448, n. 5) cite Schwert (1981) and Rose (1985) as earlier uses of the event study in industrial organization. Their titles are "Using Financial Data to Measure the Effects of Regulation" (Schwert) and "The Incidence of Regulatory Rents in the Motor Carrier Industry" (Rose). Binder (1985, pp. 168–169) applies the multivariate regression model to 20 major regulatory changes between 1887 and 1978. News about each change came out in 5.6 announcements on average, spread over 18.5 months (p. 170). His tests reject the null of no abnormal returns only slightly more often than chance would predict (p. 174). He concludes that the formal announcements were generally anticipated (p. 181). Because regulatory news is often anticipated and spread over many dates, Proposition A.97 and the dating problem are especially relevant here.

The financial event study and the panel DiD answer related questions with different data. The first measures expected changes in producer value at the moment of the news. The second measures realized changes in prices and quantities over months or years. Studies that use both, as Whinston and Collins do, can check one against the other.

A.14 Bibliographic notes

Several textbooks cover the material of this appendix in more depth. Hayashi (2000), Wooldridge (2010) and Hansen (2022) treat least squares, instrumental variables, panel data and GMM at the level of Sections A.2, A.3 and A.5. Cameron and Trivedi (2005) add many microeconometric applications. Newey and McFadden (1994) remains the standard reference for the large-sample theory of extremum estimators. It covers the consistency and normality theorems of Section A.4, two-step estimators and the efficiency of GMM. Andrews et al. (2019) survey weak instruments and robust inference. Angrist and Pischke (2009) and Imbens and Rubin (2015) present the potential-outcomes approach to instruments and treatment effects that underlies Sections A.1.3, A.3.7 and A.12.

For simulation, Gourieroux and Monfort (1996) develop the asymptotic theory of simulated moments, simulated likelihood and indirect inference, and Train (2009) is a practical guide to simulation in discrete choice models. Cameron and Miller (2015) is the standard practitioner's guide to clustered standard errors, and Abadie et al. (2023) restate the case for clustering in design-based terms. For the bootstrap, Efron and Tibshirani (1993) give an accessible introduction, Hall (1992) develops the theory of asymptotic refinements, and Horowitz (2001) surveys the method for econometricians. Silverman (1986) is the classic introduction to density estimation. Fan and Gijbels (1996) cover local polynomial regression, and Li and Racine (2007) give a comprehensive treatment of nonparametric econometrics, including series estimators and the partially linear model.

Roth et al. (2023) survey the recent literature on differences in differences, with staggered adoption, robust estimators and violations of parallel trends. Abadie (2021) discusses synthetic control in practice, and MacKinlay (1997) remains the standard introduction to financial event studies. For partial identification, Manski (2003) develops the general approach and Tamer (2010) surveys its use in econometrics.

For systems of demand equations, Deaton and Muellbauer (1980b, Section 3.3, pp. 67–75) explain which restrictions of demand theory can be tested and review the early tests on Dutch and British data (Sections A.2.5 and A.2.6). Davies (1977) and Hansen (1992) treat tests in which a parameter is identified only under the alternative, the problem behind Porter's test for regime switching (Section A.6.7).

Several surveys connect these tools to industrial organization. Ackerberg et al. (2007) cover demand estimation, production functions and dynamic models, with particular attention to GMM, simulation and instruments for differentiated-products demand. Athey and Haile (2007) do the same for auctions, from nonparametric identification to the practical choices of kernels, trimming and bootstrap. Two chapters of the fifth volume of the Handbook of Industrial Organization (Ho et al., 2021a) survey the later applications. Hortaçsu and Perrigne (2021) review empirical work on auctions. Their sections on timber and procurement auctions (pp. 86–123) cover two methods of this appendix. The entry model of Athey et al. (2011) appears on pp. 90–91 (Sections A.6.5 and A.12.7). The deconvolution estimator of Krasnokutskaya (2011) appears on p. 103 (Section A.11.5). Asker and Nocke (2021) review collusion and mergers. Their Section 2.3 (pp. 209–210) covers statistical tests for bid rigging from Porter and Zona (1993) on. Their Section 3.7 (pp. 255–257) and their appendix table (pp. 261–265) cover merger retrospectives, the designs of Section A.12. Einav and Levin (2010, p. 158) argue that structural and design-based work are often complementary, even for the same question.

A.15 Exercises

1. *Simultaneity with correlated shocks.* Take the market of Assumption A.4, but let the demand and supply shocks have covariance σ_{ds}.

   (a) Show that the slope of the OLS regression of q_t on p_t converges to

   $$\frac{c\,\sigma_d^2 - b\,\sigma_s^2 + (b-c)\,\sigma_{ds}}{\sigma_d^2 + \sigma_s^2 - 2\sigma_{ds}}.$$

   Check the result by computing $\mathrm{Cov}(q_t, p_t)$ twice, once from the supply equation as in the proof of Proposition A.5 and once from the demand equation.

(b) Let $\sigma_{ds} = 0$. Find the limit of the slope of the reverse regression of p_t on q_t. Show that it equals the inverse demand slope $-\frac{1}{b}$ only when $\sigma_d^2 = 0$ or $c = 0$, and interpret both cases.

(c) Add the cost shifter w_t of Corollary A.6. Show that IV with instrument w_t is consistent for $-b$ whatever the value of σ_{ds}. Which assumption about w_t does the argument use?

(d) In the design of Figure A.1, compute the concentration parameter μ^2 of (A.37) for samples of 200 markets. Use (A.38) to compare it with the mean first-stage F statistic of 331 reported in the caption.

2. *Two-stage least squares and specification tests.*

(a) Let $L = K$ and let A be any nonsingular $L \times L$ matrix. Show that IV with instruments ZA gives the same estimate as IV with Z. Explain why the choice among linear combinations of the instruments matters only when $L > K$.

(b) Consider one endogenous regressor, exogenous controls and excluded instruments. In the control-function regression of Proposition A.17, show that the coefficient on the first-stage residual is zero if and only if the regressor is uncorrelated with the structural error. Explain why a heteroskedasticity-robust t test of this coefficient remains valid when OLS is not efficient.

(c) For the 80th percentile fare in Borenstein (1989), the route-share coefficient is 0.1259 (0.0349) by OLS and 0.2238 (0.0784) by 2SLS (Section A.3.6). Compute the Hausman statistic (A.42) for this coefficient alone, and compare it with the 5 percent cutoff of χ^2_1.

(d) Borenstein reports that Hausman tests reject the exogeneity of route share and the route Herfindahl index. Give two reasons why a statistic for one coefficient in one percentile regression need not agree with the tests he reports.

(e) In the Rotterdam system (A.23), show that adding up and symmetry together imply homogeneity. Explain why OLS estimates satisfy adding up whatever the data (Proposition A.14), why homogeneity can be tested one equation at a time, and why a test of symmetry needs the whole system.

3. *A two-step estimator.* Let (x_i, y_i) be independent and identically distributed with $\mathbb{E}[x_i] = \mu \neq 0$, and let $\theta = \frac{\mathbb{E}[y_i]}{\mu}$. The first step estimates $\hat{\mu} = \bar{x}$, and the second solves $\frac{1}{n}\sum_i (y_i - \theta\hat{\mu}) = 0$.

(a) Write the two steps as the moments $m(w;\mu) = x - \mu$ and $g(w;\theta,\mu) = y - \theta\mu$. Use Proposition A.36 to show that $V_\theta = \frac{\operatorname{Var}(y_i - \theta x_i)}{\mu^2}$.

(b) Show that the delta method (Theorem A.59) applied to $\frac{\bar{y}}{\bar{x}}$ gives the same variance.

(c) The naive variance treats $\hat{\mu}$ as known. Show that it equals $\frac{\operatorname{Var}(y_i)}{\mu^2}$, and find the condition on $\operatorname{Cov}(x_i, y_i)$ under which it understates the true variance.

(d) Relate the result to the generated regressand of Section A.5.6, in which every implied markup depends on the estimated price coefficient.

4. *EM and regime persistence.* Let $y_t = \mu_1 I_t + \mu_0(1 - I_t) + \sigma\varepsilon_t$ for $t = 1, \dots, T$, with ε_t independent standard normal and I_t independent Bernoulli with $\mathbb{P}(I_t = 1) = \lambda$.

(a) Write the likelihood and the posterior probability $w_t = \mathbb{P}(I_t = 1 \mid y_t)$ used in the E step.

(b) Show that the M step gives $\lambda = \frac{1}{T}\sum_t w_t$, $\mu_1 = \frac{\sum_t w_t y_t}{\sum_t w_t}$ and $\mu_0 = \frac{\sum_t (1-w_t) y_t}{\sum_t (1-w_t)}$. Derive the update for σ^2.

(c) Show that if the algorithm starts with $\mu_1 = \mu_0$, every posterior equals λ and the algorithm never leaves the set $\{\mu_1 = \mu_0\}$. Relate this to the random start in Figure A.5.

(d) Let I_t instead follow a Markov chain with $\mathbb{P}(I_{t+1} = 1 \mid I_t = 1) = p_1$ and $\mathbb{P}(I_{t+1} = 1 \mid I_t = 0) = p_0$. Derive the stationary probability of the collusive regime and the expected length of a spell in each regime. Evaluate them at Ellison's estimates $p_1 = 0.975$ and $p_0 = 0.067$, and compare with Section A.6.6.

(e) Return to the model of (a). The null of a single regime is $\mu_1 = \mu_0$. Show that the likelihood does not depend on λ under this null. Use the result to explain why the likelihood ratio statistic for this null has no χ^2_1 limit. Discuss whether Porter's statistic of 554.1 (Section A.6.7) leaves any doubt about his rejection.

5. *Simulation estimators.* A binary outcome has $\mathbb{P}(y_i = 1 \mid x_i) = \int \Lambda(x_i^\top \beta_\nu)\, \mathrm{d}F(\nu)$, where Λ is the logistic distribution function and β_ν is a random coefficient vector.

(a) A frequency simulator draws n_s latent utilities per observation and records the share of draws with positive utility. Show that SML with this simulator evaluates the log of zero with positive probability. Show that MSM with the moment $\mathbb{E}[z_i(y_i - \tilde{P}_i)] = 0$ has no such problem.

(b) For the smooth simulator, use Proposition A.54(i) to explain why the bias of SML is largest for observations whose observed outcome is unlikely under the model.

(c) In the auction estimator of Section A.7.4, suppose a researcher drops the correction term from (A.81). Use (A.80) to explain the direction in which the estimated spread of values moves when the simulator variance $\omega_I(\theta)$ increases with that spread.

6. *Inference in a state-year panel.*

(a) Let $y_{ic} = \alpha + \beta x_c + a_c + \varepsilon_{ic}$, with a regressor x_c that is constant within state c, independent state effects a_c with variance σ_a^2, and independent ε_{ic} with variance σ_ε^2. Use Proposition A.56 to compute the ratio of the true to the conventional standard error of $\hat{\beta}$ when each state has 25 years and $\frac{\sigma_a^2}{\sigma_a^2 + \sigma_\varepsilon^2} = 0.3$.

(b) Now let the regressor vary within states, and add state fixed effects. Show that the within transformation removes a_c, so that conventional standard errors are valid in this model. Use Example A.58 to explain why clustering by state still raised the standard error in row (1) of Table A.8.

(c) In that row, $\hat{\rho} = 1.075$ with a state-clustered standard error of 0.034. Build a 95 percent interval for $\ln(\rho - 1)$ by the delta method, with the t_{47} quantile 2.012. Map it into an interval for the elasticity $\frac{\rho}{\rho - 1}$.

(d) Compare your interval with the intervals in Table A.9. Which parametrization makes the normal approximation more accurate here, and why?

7. *Kernel bandwidths and boundaries.*

(a) Use (A.95) and the normal reference value of $\mathcal{R}(f'')$ to derive the rule of thumb for the Epanechnikov kernel, $h = (40\sqrt{\pi})^{\frac{1}{5}} \sigma n^{-\frac{1}{5}} \approx 2.34\, \sigma n^{-\frac{1}{5}}$. Check the conversion factor reported in Table A.10.

(b) Guerre et al. (2000) use the constant 1.06 with the triweight kernel, whose normal-reference constant is 2.978×1.06. By what factor does their bandwidth differ from the normal-reference rule? What does the difference imply for the bias and the variance of $\hat{g}$?

(c) Let f have support $[0, \infty)$ with $f(0^+) > 0$ and $f'(0^+) \neq 0$. Show that the reflection estimator $\hat{f}_h(x) + \hat{f}_h(-x)$ has bias of order h at $x = 0$. Find its leading term for a symmetric kernel.

(d) Use Proposition A.75 and (A.99) to explain why pseudo-values computed near the upper end of the bid support are biased upward.

8. *Control groups, staggered adoption and anticipation.*

(a) Extend Proposition A.86 to a control group that is partly affected and also violates parallel trends by $\delta = \mathbb{E}_1[y_{i1}(0) - y_{i0}(0)] - \mathbb{E}_0[y_{i1}(0) - y_{i0}(0)]$. Show that $\mathbb{E}[\hat{\beta}^{\mathrm{DD}}] = (1 - \kappa)\mathrm{ATT} + \delta$.

(b) For Pennzoil and Quaker State, Ashenfelter and Hosken (2010) estimate 0.052 with private-label controls and 0.014 with branded controls. Suppose private labels satisfy $\kappa = 0$ and $\delta = 0$, and branded substitutes satisfy $\delta = 0$. What fraction κ of the merging firms' price increase did branded rivals match? Repeat the calculation for General Mills and Chex (0.032 and 0.057), and explain what the answer implies.

(c) In the design of Proposition A.91, let $(\omega_E, \omega_L, \omega_U) = (\tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{2})$. Compute the weights that Corollary A.92 places on $\mathrm{ATT}_E(0)$, $\mathrm{ATT}_E(1)$ and $\mathrm{ATT}_L(0)$. For which shares is the weight on $\mathrm{ATT}_E(1)$ negative?

(d) A merger announcement raises the market's probability that a merger will be completed from zero to π, and a later antitrust challenge lowers it back to zero. Following Proposition A.97, show that a rival's abnormal values at the two dates are $\pi \Delta V$ and $-\pi \Delta V$. Explain why the sum of the two can test the information hypothesis of Section A.13.4.

Appendix B

Mathematical Toolkit

Empirical industrial organization uses a small set of mathematical tools again and again. Pass-through formulas come from the implicit function theorem, and Shephard's lemma and Roy's identity come from the envelope theorem. Logit demand comes from the algebra of the Gumbel distribution. The identification of auction models comes from the distribution theory of order statistics. This appendix states each tool with its assumptions, gives or locates a proof, and shows how the chapters use it.

The appendix serves two kinds of reader. A reader who meets a tool in a chapter can come here for a precise statement, a proof, a worked example and the usual pitfalls. A reader who wants a systematic treatment can read the appendix from start to finish, because each section builds on the earlier ones. Several chapters prove a tool in the context of one application. For those results we usually restate the theorem and refer to the chapter that proves it. We give full proofs for the tools that no chapter proves and for the parts of a result that go beyond the chapter's version. Worked applications, such as pass-through in Section B.2.3, keep their derivations because they show a tool at work.

The sections follow the logic of the tools. Section B.1 collects calculus, matrix and probability facts. Sections B.2 and B.3 develop the two workhorses of comparative statics, the implicit function theorem and the envelope theorem. Section B.4 applies the envelope theorem to consumer and producer theory, and Section B.5 derives the logit family from the extreme value distribution. Section B.6 turns to order statistics, the language of auction data. Section B.7 treats fixed points: the inversion of market shares, and the existence, uniqueness and computation of price equilibria. Sections B.8 and B.9 study the shape restrictions that make equilibria exist, comparative statics signable and auction models tractable. These are log-concavity, supermodularity and affiliation. Table B.1 maps each tool to its section and to the chapters that use it.

Notation follows the rest of the book, with a few generic symbols. A generic parameter is $a \in A \subseteq \mathbb{R}^m$ and a generic choice is $x \in X \subseteq \mathbb{R}^n$. We never use θ for a generic parameter, because θ denotes conduct and (θ_1, θ_2) denote demand parameters elsewhere. Euler's constant is γ_E, the modulus of a contraction is κ, and the curvature of inverse demand is $\chi = -\frac{qP''}{P'}$, as in Chapter 2. Symbols that matter in one section only are introduced there. In Section B.4, for instance, I denotes income and r a vector of input prices, while r is a reserve price in the auction applications.

Table B.1: The tools of this appendix and where the book uses them

Tool	Section	Main result	Where the book uses it
Implicit function theorem	B.2	$D_a x = -[D_x \Psi]^{-1} D_a \Psi$ (Theorem B.27)	Pass-through (Chapters 2 and 3), best-response slopes (Chapter 2), gradient of the share inversion (Chapter 8), merger price effects (Chapter 11)
Envelope theorem	B.3	$V'(a) = f_a(x^*(a), a)$ (Theorem B.46)	Shephard's and Hotelling's lemmas (Chapters 1 and 5), entry and profits (Chapter 2), bidder rents and revenue equivalence (Chapter 14)
Duality	B.4	Shephard's lemma, Roy's identity, the Slutsky equation, virtual and shadow prices	Almost ideal demand system (Chapter 5), new goods (Chapter 10), cost functions (Chapters 3 and 9)
Extreme value and logit algebra	B.5	Max-stability, the log-sum $\ln \Lambda + \gamma_E$, GEV shares (Propositions B.89 and B.93 and Theorem B.103)	Logit, nested logit and random coefficients demand (Chapters 4 and 6 to 8), applications (Chapters 9 to 11)
Order statistics	B.6	$F_{(k:n)} = \phi_{k:n} \circ F$, competing risks (Propositions B.112 and B.121)	Equilibrium bids and revenues (Chapter 14), identification of value distributions (Chapter 15)
Contraction mapping	B.7	Unique fixed point and geometric convergence (Theorem B.127)	Share inversion (Chapters 8, 9 and 11), computation of equilibria (Chapters 4 and 11, Appendix C)
Log-concavity	B.8	Preserved by products, marginals and integration (Propositions B.155 and B.156 and Theorem B.158)	Monopoly pricing and pass-through (Chapters 2 and 3), existence of price equilibrium (Chapter 4), auctions (Chapters 14 and 15)
Supermodularity and affiliation	B.9	Topkis's theorem, supermodular games, MLRP and association (Theorems B.177, B.187 and B.197)	Strategic complements (Chapters 2 and 11), the vertical model (Chapter 6), affiliated values (Chapters 14 and 15)

Notes: Each section states the general result. It proves the result, proves the case the book uses, or refers to the chapter or source that proves it. The chapters listed carry the economic applications.

B.1 Notation and analytical preliminaries

This section collects the calculus, matrix and probability facts that the rest of the appendix uses. Each fact comes with a short proof or a precise reference. We state the facts in the form in which the chapters apply them, and we point to those applications as we go.

B.1.1 Vectors, derivatives and norms

Vectors are columns unless they are rows of product characteristics, and $^\top$ denotes the transpose. For $x, y \in \mathbb{R}^n$ we write $x \geq y$ if $x_k \geq y_k$ for every k, and $x \gg y$ if every inequality is strict. The vector of ones is $\mathbf{1}$, the k-th unit vector is e_k, and the identity matrix is I_n, or I when the size is clear. The indicator function is $\mathbf{1}\{\cdot\}$. The generic parameter a and the generic choice x follow the conventions stated at the start of the appendix.

Derivatives follow one convention. For a differentiable $f : \mathbb{R}^n \to \mathbb{R}$, the *gradient* $\nabla f(x)$ is the column vector with entries $\frac{\partial f}{\partial x_k}$. For a differentiable map $\Psi : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$, written $\Psi(x, a)$,

the *Jacobian* $D_x\Psi$ is the $n \times n$ matrix with (j,k) element $\frac{\partial \Psi_j}{\partial x_k}$. Similarly, $D_a\Psi$ is the $n \times m$ matrix with (j,l) element $\frac{\partial \Psi_j}{\partial a_l}$. Row j of a Jacobian collects the derivatives of the j-th equation. The *Hessian* $D^2_{xx} f$ has (k,l) element $\frac{\partial^2 f}{\partial x_k \partial x_l}$, and $D^2_{xa} f$ has (k,l) element $\frac{\partial^2 f}{\partial x_k \partial a_l}$. A function is C^r if it has continuous partial derivatives up to order r. The Hessian of a C^2 function is symmetric by Young's theorem.

The chain rule takes a compact matrix form. Suppose $x(a)$ is differentiable and $h(a) = \Psi(x(a), a)$. Let $D_a x$ be the $n \times m$ matrix with (k,l) element $\frac{\partial x_k}{\partial a_l}$. Then

$$D_a h(a) = D_x \Psi\big(x(a), a\big)\, D_a x(a) + D_a \Psi\big(x(a), a\big). \tag{B.1}$$

Element by element, (B.1) reads $\frac{\partial h_j}{\partial a_l} = \sum_k \frac{\partial \Psi_j}{\partial x_k} \frac{\partial x_k}{\partial a_l} + \frac{\partial \Psi_j}{\partial a_l}$.

Two matrices of share derivatives recur in the book. For mean utilities $\delta = (\delta_1, \ldots, \delta_J)^\top$, the matrix $\frac{\partial s}{\partial \delta^\top}$ has (j,k) element $\frac{\partial s_j}{\partial \delta_k}$. For prices, the matrix Δ has (j,k) element $\Delta_{jk} = \frac{\partial s_j}{\partial p_k}$. Both follow the Jacobian convention, so row j describes how product j's share responds to every mean utility or every price.

The orientation of Δ matters in the multiproduct pricing condition. Firm f owns the products in $\mathcal{J}_f$ and earns $M \sum_{k \in \mathcal{J}_f} (p_k - mc_k) s_k(p)$, where M is market size. After division by M, the first-order condition for the price of product $j \in \mathcal{J}_f$ is

$$s_j(p) + \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j}(p) = 0. \tag{B.2}$$

The derivative $\frac{\partial s_k}{\partial p_j}$ is the (k,j) element of Δ, which is the (j,k) element of $\Delta^\top$. Let Ω be the ownership matrix, with $\Omega_{jk} = 1$ if j and k have the same owner and $\Omega_{jk} = 0$ otherwise. The *Hadamard* (element-wise) *product* of two matrices of the same size is $(A \odot B)_{jk} = A_{jk} B_{jk}$. Row j of $(\Omega \odot \Delta^\top)(p - mc)$ is then

$$\big[(\Omega \odot \Delta^\top)(p - mc)\big]_j = \sum_{k=1}^{J} \Omega_{jk} \frac{\partial s_k}{\partial p_j}(p_k - mc_k) = \sum_{k \in \mathcal{J}_f} (p_k - mc_k) \frac{\partial s_k}{\partial p_j},$$

because Ω_{jk} keeps exactly the products of j's owner. Stacking the J conditions (B.2) gives

$$s(p) + \big(\Omega \odot \Delta(p)^\top\big)(p - mc) = 0. \tag{B.3}$$

With single-product firms, $\Omega = I$ and row j reads $s_j + (p_j - mc_j)\frac{\partial s_j}{\partial p_j} = 0$. Solving,

$$p_j - mc_j = -s_j \Big(\frac{\partial s_j}{\partial p_j}\Big)^{-1} = \Big(-\frac{\partial \ln s_j}{\partial p_j}\Big)^{-1},$$

so the dollar markup is the inverse of the own semi-elasticity of demand. Section 4.2.3 develops (B.3) in full.

Remark B.1 (Two errors in the matrix condition). The ordinary product $\Omega\Delta^\top$ has (j,k) element $\sum_l \Omega_{jl} \frac{\partial s_k}{\partial p_l}$. This sum adds up the effects on s_k of every price that j's owner sets, and it has no economic meaning. The second error transposes Δ. The matrix $\Omega \odot \Delta$ places $\frac{\partial s_j}{\partial p_k}$, the effect of a

sibling's price on j's share, where the condition needs $\frac{\partial s_k}{\partial p_j}$. When utility is linear in price, Δ is symmetric and this error is invisible. That is the case for the logit and for random coefficients on price, where $\frac{\partial s_j}{\partial p_k} = \int \alpha_i s_{ij} s_{ik} \, \mathrm{d}F(\nu_i)$ for $k \neq j$ (Proposition 8.4). With the utility $\alpha \ln(y_i - p_j)$ of Berry et al. (1995), the marginal utility of money $\frac{\alpha}{y_i - p_k}$ depends on the product. Then Δ is asymmetric, and a transposed Δ produces wrong markups.

Norms measure the size of vectors and matrices. The *sup norm* of $x \in \mathbb{R}^n$ is $\|x\|_\infty = \max_k |x_k|$. A matrix A inherits the *induced norm*

$$\|A\|_\infty = \sup_{x \neq 0} \frac{\|Ax\|_\infty}{\|x\|_\infty}.$$

By construction $\|Ax\|_\infty \leq \|A\|_\infty \|x\|_\infty$. Applying this twice gives $\|ABx\|_\infty \leq \|A\|_\infty \|B\|_\infty \|x\|_\infty$, so $\|AB\|_\infty \leq \|A\|_\infty \|B\|_\infty$. We drop the subscript ∞ when no confusion can arise.

Lemma B.2 (Row-sum formula)**.** *For every real $n \times m$ matrix A, $\|A\|_\infty = \max_j \sum_k |A_{jk}|$.*

Proof. Let $R = \max_j \sum_k |A_{jk}|$. For any x and any row j,

$$|(Ax)_j| = \Big| \sum_k A_{jk} x_k \Big| \leq \sum_k |A_{jk}| \, |x_k| \leq \Big(\sum_k |A_{jk}| \Big) \|x\|_\infty \leq R \, \|x\|_\infty .$$

Taking the maximum over j gives $\|Ax\|_\infty \leq R \|x\|_\infty$, so $\|A\|_\infty \leq R$. For the reverse inequality, let row j^* attain the maximum. Set $x_k = 1$ if $A_{j^*k} \geq 0$ and $x_k = -1$ otherwise. Then $\|x\|_\infty = 1$ and $(Ax)_{j^*} = \sum_k |A_{j^*k}| = R$, so $\|A\|_\infty \geq R$. □

The lemma turns a contraction property of a differentiable map into a condition on the row sums of its Jacobian (Proposition B.131). This is why the uniqueness conditions of Berry (1994) and the contraction conditions of Berry et al. (1995) are both stated as row sums.

B.1.2 Concavity, quasi-concavity and homogeneity

Definition B.3 (Concave and quasi-concave functions)**.** Let $X \subseteq \mathbb{R}^n$ be convex and $f : X \to \mathbb{R}$. The function f is *concave* if $f(\lambda x + (1-\lambda)y) \geq \lambda f(x) + (1-\lambda) f(y)$ for all $x, y \in X$ and $\lambda \in [0,1]$. It is *strictly concave* if the inequality is strict whenever $x \neq y$ and $\lambda \in (0,1)$. It is *convex* if $-f$ is concave. It is *quasi-concave* if $f(\lambda x + (1-\lambda)y) \geq \min\{f(x), f(y)\}$, and *strictly quasi-concave* if this inequality is strict whenever $x \neq y$ and $\lambda \in (0,1)$.

Quasi-concavity is equivalent to convexity of every upper contour set $\{x \in X : f(x) \geq u\}$. Every concave function is quasi-concave, since $\lambda f(x) + (1-\lambda) f(y) \geq \min\{f(x), f(y)\}$. The converse fails, because every monotone function of one variable is quasi-concave.

Proposition B.4 (Second-order characterization)**.** *Let X be open and convex and $f \in C^2$ on X.*

(a) The function f is concave if and only if $D^2_{xx} f(x)$ is negative semidefinite at every $x \in X$.

(b) If $D^2_{xx} f(x)$ is negative definite at every $x \in X$, then f is strictly concave.

The converse of (b) fails.

Proof. A function is concave if and only if its restriction to every segment is concave. For $x \in X$ and a direction h, let $g(t) = f(x + th)$ on the interval of t for which $x + th \in X$. The chain rule gives $g''(t) = h^\top D^2_{xx} f(x + th)\, h$. A C^2 function of one variable is concave if and only if g' is

nonincreasing, that is, if and only if $g'' \le 0$. So f is concave if and only if $h^\top D^2_{xx} f\, h \le 0$ for all x and h, which is (a). Under the hypothesis of (b), $g'' < 0$ for every $h \neq 0$. Then g' is strictly decreasing, g is strictly concave, and so is f. The function $f(x) = -x^4$ is strictly concave, yet $f''(0) = 0$. □

Lemma B.5 (First-order bound)**.** *Let f be differentiable and concave on an open convex set X. Then $f(y) \le f(x) + \nabla f(x)^\top (y - x)$ for all $x, y \in X$. In particular, a point x^* with $\nabla f(x^*) = 0$ maximizes f on X.*

Proof. For $\lambda \in (0, 1]$, concavity gives $f(x + \lambda(y - x)) \ge f(x) + \lambda[f(y) - f(x)]$. Rearranging,

$$\frac{f(x + \lambda(y - x)) - f(x)}{\lambda} \ge f(y) - f(x).$$

As $\lambda \to 0$ the left side converges to the directional derivative $\nabla f(x)^\top (y - x)$. □

Lemma B.6 (Minimum of affine functions)**.** *Let Z be convex and let $\{\ell_x : x \in X\}$ be any family of affine functions $\ell_x(z) = b_x + c_x^\top z$ on Z. If $g(z) = \inf_{x \in X} \ell_x(z)$ is finite on Z, then g is concave. If $\bar{g}(z) = \sup_{x \in X} \ell_x(z)$ is finite on Z, then $\bar{g}$ is convex.*

Proof. Take $z, z' \in Z$ and $\lambda \in [0, 1]$. For every x, affinity and the definition of g give

$$\ell_x(\lambda z + (1 - \lambda) z') = \lambda \ell_x(z) + (1 - \lambda) \ell_x(z') \ge \lambda g(z) + (1 - \lambda) g(z').$$

Taking the infimum over x on the left gives $g(\lambda z + (1 - \lambda) z') \ge \lambda g(z) + (1 - \lambda) g(z')$. The statement for $\bar{g}$ follows by applying the first one to the family $-\ell_x$. □

The lemma gives curvature properties of value functions without any differentiability. The expenditure function $e(p, u) = \min_q \{p^\top q : U(q) \ge u\}$ is a minimum of functions that are linear in p, so it is concave in p (Section B.4). The cost function is concave in input prices for the same reason, and the profit function is convex in prices because it is a maximum of linear functions (Example B.53).

Lemma B.7 (Maximizers of quasi-concave functions)**.** *If f is quasi-concave on a convex set X, its set of maximizers on X is convex. If f is strictly quasi-concave, it has at most one maximizer.*

Proof. Let $V^* = \max_{x \in X} f(x)$, and let x and y be maximizers. For $\lambda \in [0, 1]$, quasi-concavity gives $f(\lambda x + (1 - \lambda) y) \ge \min\{f(x), f(y)\} = V^*$, so $\lambda x + (1 - \lambda) y$ is a maximizer. If f is strictly quasi-concave and $x \neq y$, the midpoint satisfies $f\left(\frac{1}{2} x + \frac{1}{2} y\right) > V^*$, which is impossible. □

Best responses of a player with a quasi-concave payoff are therefore convex-valued. This is the property that Kakutani's fixed-point theorem needs to deliver existence of a pricing equilibrium (Theorem B.147, Section B.8).

Definition B.8 (Homogeneity)**.** A function f defined on a cone $X \subseteq \mathbb{R}^n$ is *homogeneous of degree r* if $f(tx) = t^r f(x)$ for every $x \in X$ and every $t > 0$.

Proposition B.9 (Euler's theorem)**.** *Let f be differentiable and homogeneous of degree r on an open cone. Then*

(a) $\sum_{k=1}^n x_k \frac{\partial f}{\partial x_k}(x) = r f(x)$ *for every x, and*

(b) every partial derivative $\frac{\partial f}{\partial x_k}$ *is homogeneous of degree $r - 1$.*

Proof. Fix x and differentiate the identity $f(tx) = t^r f(x)$ with respect to t:

$$\sum_k x_k \frac{\partial f}{\partial x_k}(tx) = r t^{r-1} f(x).$$

Setting $t = 1$ gives (a). For (b), differentiate the same identity with respect to x_k:

$$t\,\frac{\partial f}{\partial x_k}(tx) = t^r \frac{\partial f}{\partial x_k}(x).$$

Dividing by t gives $\frac{\partial f}{\partial x_k}(tx) = t^{r-1}\frac{\partial f}{\partial x_k}(x)$. □

Euler's theorem produces the adding-up identities of demand theory (Section B.4). The expenditure function $e(p,u)$ is homogeneous of degree one in p, so $\sum_i p_i \frac{\partial e}{\partial p_i} = e$. Hicksian demand $h(p,u)$ is homogeneous of degree zero in p, so $\sum_j p_j \frac{\partial h_i}{\partial p_j} = 0$, which says that the Slutsky matrix annihilates the price vector. Marshallian demand $q_i(p,I)$ is homogeneous of degree zero in (p,I), so

$$\sum_j p_j \frac{\partial q_i}{\partial p_j} + I\,\frac{\partial q_i}{\partial I} = 0.$$

Dividing by q_i turns this into the statement that price and income elasticities of each good sum to zero.

Corollary B.10 (Translation invariance)**.** *Let $f : \mathbb{R}^n \to \mathbb{R}$ be differentiable with $f(x + c\mathbf{1}) = f(x)$ for all x and all $c \in \mathbb{R}$. Then*

$$\sum_{k=1}^{n} \frac{\partial f}{\partial x_k}(x) = \nabla f(x)^\top \mathbf{1} = 0.$$

Proof. The function $c \mapsto f(x + c\mathbf{1})$ is constant, so its derivative at $c = 0$ is zero. By the chain rule that derivative is $\nabla f(x)^\top \mathbf{1}$. □

The corollary is Euler's theorem in disguise. With $y_k = e^{x_k}$, translation invariance of f is homogeneity of degree zero of $\tilde{f}(y) = f(\ln y_1, \dots, \ln y_n)$. Euler's theorem then gives $0 = \sum_k y_k \frac{\partial \tilde{f}}{\partial y_k} = \sum_k \frac{\partial f}{\partial x_k}$.

Example B.11 (Shares depend only on utility differences)**.** In an additive random utility model, consumer i obtains $\delta_k + \epsilon_{ik}$ from alternative $k = 0, 1, \dots, J$. Adding the same constant to every δ_k, the outside good's δ_0 included, leaves every consumer's choice unchanged. Hence $s_j(\delta + c\mathbf{1}) = s_j(\delta)$ for $\delta = (\delta_0, \dots, \delta_J)$, and Corollary B.10 gives

$$\sum_{k=0}^{J} \frac{\partial s_j}{\partial \delta_k} = 0. \tag{B.4}$$

If the outside good is a substitute for j, so that $\frac{\partial s_j}{\partial \delta_0} < 0$, then

$$\sum_{k=1}^{J} \frac{\partial s_j}{\partial \delta_k} = -\frac{\partial s_j}{\partial \delta_0} > 0.$$

This is the step on which Berry (1994, p. 261) builds his uniqueness argument (Example B.22). In the logit, $\frac{\partial s_j}{\partial \delta_k} = s_j(\mathbf{1}\{j = k\} - s_k)$ for $k = 0, \dots, J$, and the sum in (B.4) is $s_j\big(1 - \sum_{k=0}^{J} s_k\big) = 0$.

B.1.3 Mean values, integrals and transformations of random variables

The scalar mean value theorem says that a function differentiable on (u, u') and continuous on $[u, u']$ satisfies $g(u') - g(u) = g'(\tau)(u' - u)$ for some $\tau \in (u, u')$. For vector-valued maps there is no single intermediate point, and the right tool is an integral.

Proposition B.12 (Integral form of the mean value theorem)**.** *Let $U \subseteq \mathbb{R}^d$ be open, let $\Psi : U \to \mathbb{R}^n$ be C^1, and suppose the segment $[x, x'] = \{x + t(x' - x) : t \in [0, 1]\}$ lies in U. Then*

$$\Psi(x') - \Psi(x) = \Big[\int_0^1 D\Psi\big(x + t(x' - x)\big)\, \mathrm{d}t \Big](x' - x), \tag{B.5}$$

where the integral of a matrix is taken element by element.

Proof. For each j, the function $g_j(t) = \Psi_j(x + t(x' - x))$ is C^1 on $[0, 1]$. The chain rule gives

$$g_j'(t) = \sum_k \frac{\partial \Psi_j}{\partial x_k}\big(x + t(x' - x)\big)(x_k' - x_k).$$

By the fundamental theorem of calculus, $\Psi_j(x') - \Psi_j(x) = g_j(1) - g_j(0) = \int_0^1 g_j'(t)\, \mathrm{d}t$. Stacking the n rows gives (B.5). □

A single intermediate point does not exist in general. The map $\Psi(t) = (\cos t, \sin t)^\top$ satisfies $\Psi(2\pi) - \Psi(0) = 0$, while its derivative $(-\sin t, \cos t)^\top$ never vanishes.

Corollary B.13 (Mean value inequality)**.** *Under the assumptions of Proposition B.12,*

$$\|\Psi(x') - \Psi(x)\|_\infty \le \sup_{z \in [x, x']} \|D\Psi(z)\|_\infty \, \|x' - x\|_\infty.$$

Proof. Write $z_t = x + t(x' - x)$. Row j of (B.5) gives

$$|\Psi_j(x') - \Psi_j(x)| \le \int_0^1 \sum_k \Big|\frac{\partial \Psi_j}{\partial x_k}(z_t)\Big| \, |x_k' - x_k| \, \mathrm{d}t \le \int_0^1 \sum_k \Big|\frac{\partial \Psi_j}{\partial x_k}(z_t)\Big| \, \mathrm{d}t \; \|x' - x\|_\infty.$$

By Lemma B.2 the row sum inside the integral is at most $\|D\Psi(z_t)\|_\infty$. Bounding it by the supremum over the segment and maximizing over j gives the claim. □

Example B.14 (The mean value step in the BLP contraction)**.** Berry et al. (1995, Appendix I, p. 887) study a C^1 map $f : \mathbb{R}^J \to \mathbb{R}^J$ whose partial derivatives are nonnegative and whose row sums $\sum_k \frac{\partial f_j}{\partial x_k}$ are below one. Their operator is $f(\delta) = \delta + \ln s^{obs} - \ln s(\delta)$, equation (6.8) on p. 865. Take two points x, x' in a bounded box and let $\lambda = \|x - x'\|_\infty$, so that $x' \le x + \lambda \mathbf{1}$. Suppose $f_j(x') \ge f_j(x)$. Monotonicity and (B.5) along the direction $\mathbf{1}$ give

$$f_j(x') - f_j(x) \le f_j(x + \lambda \mathbf{1}) - f_j(x) = \int_0^\lambda \Big[\sum_{k=1}^J \frac{\partial f_j}{\partial x_k}(x + z\mathbf{1}) \Big] \mathrm{d}z \le \kappa \lambda,$$

where $\kappa < 1$ is the largest row sum over the compact set of points that the segments can reach. The same bound follows from Corollary B.13, because with nonnegative partials $\|D f\|_\infty$ is the largest row sum. This step makes the truncated map a contraction. The full theorem and its proof are in Theorem 8.15.

Proposition B.15 (Leibniz's rule). *(a) Let $g(x,a)$ and $g_a(x,a) = \frac{\partial g}{\partial a}(x,a)$ be continuous on $[x_L, x_U] \times [a_L, a_U]$, and let $l(a)$ and $m(a)$ be differentiable with values in $[x_L, x_U]$. Then $\Gamma(a) = \int_{l(a)}^{m(a)} g(x,a)\,\mathrm{d}x$ satisfies, for $a \in (a_L, a_U)$,*

$$\Gamma'(a) = g\big(m(a),a\big)m'(a) - g\big(l(a),a\big)l'(a) + \int_{l(a)}^{m(a)} g_a(x,a)\,\mathrm{d}x. \tag{B.6}$$

(b) Let μ be a measure, such as the distribution F of a taste shock. Suppose $g(\cdot,a)$ is μ-integrable for each a in an open interval N and that $g_a(x,a)$ exists there. Suppose also that an integrable function $b(x)$ satisfies $|g_a(x,a)| \le b(x)$ for all x and all $a \in N$. Then for $a \in N$,

$$\frac{\mathrm{d}}{\mathrm{d}a}\int g(x,a)\,\mathrm{d}\mu(x) = \int g_a(x,a)\,\mathrm{d}\mu(x).$$

Proof. We prove (b) first. For $h \neq 0$ small, the scalar mean value theorem gives $\frac{g(x,a+h)-g(x,a)}{h} = g_a(x, a+\tau_x h)$ for some $\tau_x \in (0,1)$. This difference quotient is bounded by $b(x)$, and it converges to $g_a(x,a)$ as $h \to 0$. Dominated convergence lets us pass the limit through the integral.

For (a), define $G(u,w,a) = \int_w^u g(x,a)\,\mathrm{d}x$. The fundamental theorem of calculus gives $\frac{\partial G}{\partial u} = g(u,a)$ and $\frac{\partial G}{\partial w} = -g(w,a)$. Part (b), with μ the Lebesgue measure on $[x_L, x_U]$ and b the maximum of $|g_a|$ on the compact rectangle, gives $\frac{\partial G}{\partial a} = \int_w^u g_a(x,a)\,\mathrm{d}x$. These partial derivatives are continuous, so G is C^1. The chain rule applied to $\Gamma(a) = G(m(a), l(a), a)$ gives (B.6). □

Example B.16 (Share derivatives with random coefficients)**.** In the random coefficients logit, consumer i with taste draw ν_i buys j with probability $s_{ij}(p,\nu_i) = \frac{\exp(\delta_j+\mu_{ij})}{1+\sum_k \exp(\delta_k+\mu_{ik})}$. Her price coefficient is α_i, so $\frac{\partial(\delta_k+\mu_{ik})}{\partial p_k} = -\alpha_i$. The logit derivative $\frac{\partial s_{ij}}{\partial(\delta_k+\mu_{ik})} = s_{ij}(\mathbf{1}\{j=k\} - s_{ik})$ and the chain rule give

$$\frac{\partial s_{ij}}{\partial p_k} = \alpha_i\, s_{ij}\big(s_{ik} - \mathbf{1}\{j=k\}\big).$$

Market shares are $s_j(p) = \int s_{ij}(p,\nu)\,\mathrm{d}F(\nu)$. Because shares lie in $[0,1]$, the integrand's derivative satisfies $|\alpha_i s_{ij}(s_{ik} - \mathbf{1}\{j=k\})| \le |\alpha_i|$ at every price vector. If $\mathbb{E}|\alpha_i| < \infty$, Proposition B.15(b) applies with $b = |\alpha_i|$ and

$$\frac{\partial s_j}{\partial p_k} = \int \alpha_i\, s_{ij}\big(s_{ik} - \mathbf{1}\{j=k\}\big)\,\mathrm{d}F(\nu_i). \tag{B.7}$$

With B simulation draws the integral becomes an average over draws (Proposition 8.4).

A second application has a variable limit of integration. In first-price auctions with n bidders, values drawn from F, and reserve price r, the function $\int_r^v F(t)^{n-1}\,\mathrm{d}t$ has derivative $F(v)^{n-1}$ by (B.6) with $l' = 0$, $m(v) = v$ and $g_a = 0$. Example B.57 uses this step, and Section B.6 uses Leibniz's rule to derive the densities of order statistics.

Lemma B.17 (Tail formula for the mean)**.** *If $X \ge 0$ has CDF F, then $\mathbb{E}[X] = \int_0^\infty \big(1 - F(x)\big)\,\mathrm{d}x$, where both sides may be infinite.*

Proof. Write $X = \int_0^\infty \mathbf{1}\{x < X\}\,\mathrm{d}x$. Take expectations and exchange the order of integration, which Tonelli's theorem allows because the integrand is nonnegative:

$$\mathbb{E}[X] = \int_0^\infty \mathbb{E}\big[\mathbf{1}\{x < X\}\big]\,\mathrm{d}x = \int_0^\infty \mathbb{P}(X > x)\,\mathrm{d}x = \int_0^\infty \big(1 - F(x)\big)\,\mathrm{d}x. \qquad \square$$

The same exchange of integrals is integration by parts, $\int_u^{u'} \varphi \, \mathrm{d}\psi = \varphi(u')\psi(u') - \varphi(u)\psi(u) - \int_u^{u'} \psi \, \mathrm{d}\varphi$, in probabilistic form. Auction theory uses it to write bids as conditional expectations.

Example B.18 (The first-price bid as a conditional expectation)**.** Let Y_1 be the highest of $n-1$ rival values, drawn independently from F, so its CDF is F^{n-1}. For $v > r$, consider $\mathbb{E}[\max\{Y_1, r\} \mid Y_1 < v]$. The event $Y_1 \le r$ has probability $F(r)^{n-1}$ and contributes r, so

$$\mathbb{E}[\max\{Y_1, r\} \mid Y_1 < v] = \frac{rF(r)^{n-1} + \int_r^v t \, \mathrm{d}\big[F(t)^{n-1}\big]}{F(v)^{n-1}}.$$

Integration by parts with $\varphi(t) = t$ and $\psi(t) = F(t)^{n-1}$ gives

$$\int_r^v t \, \mathrm{d}\big[F(t)^{n-1}\big] = vF(v)^{n-1} - rF(r)^{n-1} - \int_r^v F(t)^{n-1} \, \mathrm{d}t.$$

The boundary terms in r cancel, and

$$\mathbb{E}[\max\{Y_1, r\} \mid Y_1 < v] = v - \frac{\int_r^v F(t)^{n-1} \, \mathrm{d}t}{F(v)^{n-1}}. \tag{B.8}$$

The right side is the equilibrium bid of the symmetric first-price auction (Riley and Samuelson, 1981), derived in Example B.57 and in Section 14.5.3.

Lemma B.19 (Probability integral transform)**.** *(a) If X has a continuous CDF F, then $F(X)$ is uniformly distributed on $[0,1]$.*

(b) For any CDF F, define the generalized inverse $F^{-1}(u) = \inf\{x : F(x) \ge u\}$ for $u \in (0,1)$. If U is uniform on $[0,1]$, then $F^{-1}(U)$ has CDF F.

Proof. Right continuity of F implies that $F^{-1}(u) \le x$ if and only if $u \le F(x)$. For (b), $\mathbb{P}(F^{-1}(U) \le x) = \mathbb{P}(U \le F(x)) = F(x)$. For (a), fix $u \in (0,1)$. The same equivalence shows that $F(X) \ge u$ if and only if $X \ge F^{-1}(u)$. Continuity of F gives $\mathbb{P}(X \ge x) = 1 - F(x)$ and $F(F^{-1}(u)) = u$. Hence

$$\mathbb{P}\big(F(X) \ge u\big) = \mathbb{P}\big(X \ge F^{-1}(u)\big) = 1 - F\big(F^{-1}(u)\big) = 1 - u,$$

so $\mathbb{P}(F(X) < u) = u$ for every $u \in (0,1)$, which is the uniform distribution. □

Part (b) is how simulation draws are produced. The standard Gumbel CDF $\exp(-e^{-x})$ has inverse $-\ln(-\ln u)$, so $-\ln(-\ln U)$ is a standard Gumbel draw (Section B.5). Part (a) maps order statistics of any continuous distribution into order statistics of uniforms (Section B.6).

B.1.4 Matrix facts

A symmetric matrix A is *negative semidefinite* if $x^\top A x \le 0$ for every x, and *negative definite* if $x^\top A x < 0$ for every $x \ne 0$. Equivalently, all eigenvalues of A are nonpositive in the first case and negative in the second. Positive (semi)definiteness is defined with the inequalities reversed. Second-order conditions for maximization and the negativity of the Slutsky matrix (Section B.4) are statements of this kind. In practice they are checked with determinants.

Proposition B.20 (Principal minors)**.** *Let A be a symmetric $n \times n$ matrix and let A_k be its leading $k \times k$ submatrix.*

(a) *A is negative definite if and only if $(-1)^k \det A_k > 0$ for $k = 1, \dots, n$.*

(b) *A is negative semidefinite if and only if $(-1)^k \det A_S \geq 0$ for every principal submatrix A_S of order k, formed from any k rows and the same k columns, for every k.*

Simon and Blume (1994) prove both parts. For $n = 2$, part (a) says that $\left(\begin{smallmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{smallmatrix}\right)$ is negative definite if and only if $a_{11} < 0$ and $a_{11}a_{22} - a_{12}^2 > 0$. Part (b) needs every principal minor, including those that are not leading. The matrix $\left(\begin{smallmatrix} 0 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ has leading minors 0 and 0, which satisfy the weak sign conditions. Yet it is not negative semidefinite, and its principal minor of order one in the second position equals 1.

Lemma B.21 (Diagonal dominance)**.** *Let A be a real $n \times n$ matrix.*

(a) *(Gershgorin) Every eigenvalue z of A, real or complex, satisfies $|A_{jj} - z| \leq \sum_{k \neq j} |A_{jk}|$ for at least one row j.*

(b) *(Levy-Desplanques) If A is* strictly diagonally dominant*, that is, $|A_{jj}| > \sum_{k \neq j} |A_{jk}|$ for every row j, then A is nonsingular.*

(c) *If A is symmetric, strictly diagonally dominant and has a negative diagonal, then A is negative definite.*

Proof. For (a), let $Ax = zx$ with $x \neq 0$, and pick j with $|x_j| = \|x\|_\infty > 0$. Row j of the eigenvalue equation reads $(A_{jj} - z)x_j = -\sum_{k \neq j} A_{jk}x_k$. Taking absolute values and dividing by $|x_j|$,

$$|A_{jj} - z| \leq \sum_{k \neq j} |A_{jk}| \frac{|x_k|}{|x_j|} \leq \sum_{k \neq j} |A_{jk}|.$$

For (b), $z = 0$ would require $|A_{jj}| \leq \sum_{k \neq j} |A_{jk}|$ for some row, which strict dominance rules out. So 0 is not an eigenvalue and A is nonsingular. For (c), the eigenvalues of a symmetric matrix are real. By (a) each lies within $\sum_{k \neq j} |A_{jk}| < |A_{jj}| = -A_{jj}$ of some $A_{jj} < 0$, so each is negative. □

Example B.22 (The share Jacobian is invertible)**.** Assume, with Berry (1994, p. 260), that $\frac{\partial s_j}{\partial \delta_j} > 0$ and $\frac{\partial s_j}{\partial \delta_k} < 0$ for every $k \neq j$, the outside good included. By Example B.11,

$$\frac{\partial s_j}{\partial \delta_j} - \sum_{k \geq 1, k \neq j} \left| \frac{\partial s_j}{\partial \delta_k} \right| = \sum_{k=1}^{J} \frac{\partial s_j}{\partial \delta_k} = -\frac{\partial s_j}{\partial \delta_0} > 0.$$

So the $J \times J$ matrix $\frac{\partial s}{\partial \delta^\top}$ of inside goods is strictly diagonally dominant at every δ. By Lemma B.21 it is nonsingular. This is Berry's condition (A2), and in the logit the margin of dominance is $s_j s_0$. The implicit function theorem then delivers the derivatives of the inverse share function (Example B.41).

Lemma B.23 (Neumann series)**.** *Let $\|\cdot\|$ be an induced matrix norm and $\|A\| < 1$. Then $I - A$ is nonsingular,*

$$(I - A)^{-1} = \sum_{h=0}^{\infty} A^h, \qquad \text{and} \qquad \left\|(I - A)^{-1}\right\| \leq \frac{1}{1 - \|A\|}.$$

Proof. Let $S_H = \sum_{h=0}^{H} A^h$. Submultiplicativity gives $\|A^h\| \le \|A\|^h$, so for $H' > H$,

$$\|S_{H'} - S_H\| \le \sum_{h=H+1}^{H'} \|A\|^h \le \frac{\|A\|^{H+1}}{1 - \|A\|} \to 0.$$

The partial sums are therefore Cauchy and converge to a matrix S. Telescoping gives $(I-A)S_H = I - A^{H+1}$, and $A^{H+1} \to 0$. Taking limits, $(I - A)S = I$, and $S(I - A) = I$ in the same way. The bound follows from $\|S_H\| \le \sum_{h \le H} \|A\|^h \le \frac{1}{1-\|A\|}$. □

The lemma is the linear case of the contraction mapping theorem (Theorem B.127). The affine map $\Phi(x) = Ax + b$ contracts with modulus $\|A\|$, and its iterates from $x^{(0)} = 0$ are $x^{(H)} = S_{H-1}b$. They converge to the fixed point $(I - A)^{-1}b$. Proposition B.31 reads the series as rounds of strategic responses.

Lemma B.24 (Sherman-Morrison formula)**.** *Let B be nonsingular and u, v vectors with $1-v^\top B^{-1}u \neq 0$. Then*

$$\left(B - uv^\top\right)^{-1} = B^{-1} + \frac{B^{-1}uv^\top B^{-1}}{1 - v^\top B^{-1}u}. \tag{B.9}$$

Proof. Write $\tau = 1 - v^\top B^{-1}u$ and multiply $B - uv^\top$ by the right side of (B.9):

$$\begin{aligned}\left(B - uv^\top\right)\left(B^{-1} + \frac{B^{-1}uv^\top B^{-1}}{\tau}\right) &= I + \frac{uv^\top B^{-1}}{\tau} - uv^\top B^{-1} - \frac{u\,(v^\top B^{-1}u)\,v^\top B^{-1}}{\tau} \\ &= I + uv^\top B^{-1}\,\frac{1 - \tau - v^\top B^{-1}u}{\tau} = I,\end{aligned}$$

because $1 - \tau = v^\top B^{-1}u$. The scalar $v^\top B^{-1}u$ can be moved in front of $v^\top B^{-1}$ because it is a number. □

Example B.25 (The logit Jacobian, its inverse, and logit markups)**.** In the logit, $s_j = \frac{e^{\delta_j}}{\Lambda}$ with $\Lambda = 1 + \sum_{k=1}^{J} e^{\delta_k}$ and $s_0 = \frac{1}{\Lambda}$. Since $\frac{\partial \Lambda}{\partial \delta_k} = e^{\delta_k}$, the quotient rule gives

$$\frac{\partial s_j}{\partial \delta_j} = \frac{e^{\delta_j}\Lambda - e^{\delta_j}e^{\delta_j}}{\Lambda^2} = s_j(1 - s_j), \qquad \frac{\partial s_j}{\partial \delta_k} = -\frac{e^{\delta_j}e^{\delta_k}}{\Lambda^2} = -s_j s_k \quad (k \neq j).$$

In matrix form, with $s = (s_1, \dots, s_J)^\top$,

$$\frac{\partial s}{\partial \delta^\top} = \operatorname{diag}(s) - ss^\top. \tag{B.10}$$

This is a diagonal matrix minus a rank-one matrix, so Lemma B.24 applies with $B = \operatorname{diag}(s)$ and $u = v = s$. Two facts do the work:

$$\operatorname{diag}(s)^{-1}s = \mathbf{1}, \qquad s^\top \operatorname{diag}(s)^{-1}s = s^\top \mathbf{1} = \sum_{k=1}^{J} s_k = 1 - s_0.$$

The denominator in (B.9) is $1 - (1 - s_0) = s_0 > 0$, and the numerator is $\mathbf{1}\mathbf{1}^\top$. Hence

$$\left[\operatorname{diag}(s) - ss^\top\right]^{-1} = \operatorname{diag}\left(\frac{1}{s_1}, \dots, \frac{1}{s_J}\right) + \frac{1}{s_0}\mathbf{1}\mathbf{1}^\top. \tag{B.11}$$

A direct check confirms (B.11). The logit inversion $\delta_j = \ln s_j - \ln s_0$ with $s_0 = 1 - \sum_k s_k$ has $\frac{\partial \delta_j}{\partial s_k} = \frac{\mathbf{1}\{j=k\}}{s_j} + \frac{1}{s_0}$, which is the (j,k) element of (B.11), as the inverse function theorem requires.

Markups follow in a few lines. With $\delta_j = \tilde{\delta}_j - \alpha p_j$, the price Jacobian is $\Delta = -\alpha\big[\operatorname{diag}(s) - ss^\top\big]$, which is symmetric. Write $m = p - mc$, so (B.3) gives $m = -(\Omega \odot \Delta^\top)^{-1} s$.

(i) Single-product firms. With $\Omega = I$, the matrix $\Omega \odot \Delta^\top$ is diagonal with entries $-\alpha s_j(1 - s_j)$. Hence $m_j = \frac{s_j}{\alpha s_j(1-s_j)} = \frac{1}{\alpha(1-s_j)}$.

(ii) One owner of all inside goods. With $\Omega = \mathbf{1}\mathbf{1}^\top$, we have $\Omega \odot \Delta^\top = \Delta$, and (B.11) gives

$$m = \frac{1}{\alpha}\Big[\operatorname{diag}\Big(\frac{1}{s_1}, \ldots, \frac{1}{s_J}\Big) + \frac{1}{s_0}\mathbf{1}\mathbf{1}^\top\Big] s = \frac{1}{\alpha}\Big[\mathbf{1} + \frac{1 - s_0}{s_0}\mathbf{1}\Big] = \frac{1}{\alpha s_0}\mathbf{1}.$$

Every product carries the same markup $\frac{1}{\alpha s_0}$.

(iii) A multiproduct firm. Order products by owner, so that Ω is block diagonal. Then $\Omega \odot \Delta^\top$ is block diagonal with blocks $-\alpha\big[\operatorname{diag}(s_f) - s_f s_f^\top\big]$, where s_f collects the shares of firm f. Lemma B.24 with $v^\top B^{-1} u = \sum_{k \in \mathcal{J}_f} s_k \equiv S_f$ inverts each block as $\operatorname{diag}(s_f)^{-1} + \frac{1}{1 - S_f}\mathbf{1}\mathbf{1}^\top$. The same computation as in (ii) gives the common markup

$$m_k = \frac{1}{\alpha}\Big[1 + \frac{S_f}{1 - S_f}\Big] = \frac{1}{\alpha(1 - S_f)} \qquad \text{for every } k \in \mathcal{J}_f.$$

Case (iii) contains (i) with $S_f = s_j$ and (ii) with $S_f = 1 - s_0$. Proposition 4.7 derives the same formula from the scalar conditions, and Section B.5.5 reuses the example.

B.2 The implicit function theorem and comparative statics

Equilibrium conditions rarely solve for the endogenous variables in closed form. First-order conditions, market-clearing conditions and share equations define prices, quantities or mean utilities only implicitly, as solutions x of a system $\Psi(x, a) = 0$. Yet we need to know how the solution moves with costs, taxes, ownership or demand parameters. The implicit function theorem says when the solution is a differentiable function $x(a)$, and it gives the derivative without solving the system.

B.2.1 Statement and proof

Theorem B.26 (Implicit function theorem, scalar case)**.** *Let $\Psi : \mathbb{R} \times \mathbb{R}^m \to \mathbb{R}$ be C^1 near (x_0, a_0), with $\Psi(x_0, a_0) = 0$ and $\Psi_x(x_0, a_0) \neq 0$. Then there are open neighborhoods N_a of a_0 and N_x of x_0, and a unique function $x : N_a \to N_x$, such that $\Psi(x(a), a) = 0$ for every $a \in N_a$. The function $x(\cdot)$ is C^1, and*

$$\frac{\partial x}{\partial a_l}(a) = -\frac{\Psi_{a_l}\big(x(a), a\big)}{\Psi_x\big(x(a), a\big)}, \qquad l = 1, \ldots, m. \tag{B.12}$$

Proof. We proceed in five steps.

Step 1. Replacing Ψ by $-\Psi$ if necessary, assume $\Psi_x(x_0, a_0) > 0$. By continuity of Ψ_x there are $\epsilon > 0$ and $\eta > 0$ with $\Psi_x(x, a) > 0$ whenever $|x - x_0| \le \epsilon$ and $\|a - a_0\| \le \eta$. For each such a, the function $\Psi(\cdot, a)$ is strictly increasing on $[x_0 - \epsilon, x_0 + \epsilon]$.

Step 2. Since $\Psi(x_0, a_0) = 0$ and $\Psi(\cdot, a_0)$ is strictly increasing, $\Psi(x_0 - \epsilon, a_0) < 0 < \Psi(x_0 + \epsilon, a_0)$. By continuity of Ψ in a, there is $\eta' \in (0, \eta]$ such that $\Psi(x_0 - \epsilon, a) < 0 < \Psi(x_0 + \epsilon, a)$ for all $\|a - a_0\| < \eta'$.

Step 3. Let $N_a = \{a : \|a - a_0\| < \eta'\}$ and $N_x = (x_0 - \epsilon, x_0 + \epsilon)$. For $a \in N_a$, the intermediate value theorem gives a root $x(a) \in N_x$. Strict monotonicity makes it the only root in N_x.

Step 4. The function $x(\cdot)$ is continuous. At any $a_1 \in N_a$, repeat Steps 1 to 3 around $(x(a_1), a_1)$ with an arbitrary $\epsilon' > 0$ in place of ϵ. For a close enough to a_1, the unique root then lies within ϵ' of $x(a_1)$.

Step 5. Fix $a \in N_a$ and l, let $a' = a + he_l$, and write $\Delta x = x(a') - x(a)$. Apply the scalar mean value theorem to $\tau \mapsto \Psi(x(a) + \tau\Delta x, a + \tau h e_l)$ on $[0, 1]$. Since Ψ vanishes at both ends,

$$0 = \Psi(x(a'), a') - \Psi(x(a), a) = \Psi_x(\xi)\,\Delta x + \Psi_{a_l}(\xi)\,h$$

for a point ξ on the segment between $(x(a), a)$ and $(x(a'), a')$. Hence $\frac{\Delta x}{h} = -\frac{\Psi_{a_l}(\xi)}{\Psi_x(\xi)}$. As $h \to 0$, Step 4 gives $\Delta x \to 0$, so $\xi \to (x(a), a)$. Continuity of the partial derivatives yields (B.12). The right side of (B.12) is continuous in a, so $x(\cdot)$ is C^1. □

Figure B.1 illustrates the theorem with $\Psi(x, a) = x^2 + a^2 - 1$, whose zero set is the unit circle. Here $\Psi_x = 2x$ and $\Psi_a = 2a$. At $(a_0, x_0) = (0.6, 0.8)$ we have $\Psi_x = 1.6 \neq 0$. The theorem gives the local solution $x(a) = \sqrt{1 - a^2}$ with slope

$$x'(a_0) = -\frac{\Psi_a}{\Psi_x} = -\frac{2a_0}{2x_0} = -\frac{3}{4},$$

which matches the direct derivative $-\frac{a_0}{\sqrt{1-a_0^2}}$. At $(1, 0)$, by contrast, $\Psi_x = 0$. In every box around that point there are two solutions $\pm\sqrt{1 - a^2}$ for a slightly below one and none for $a > 1$.

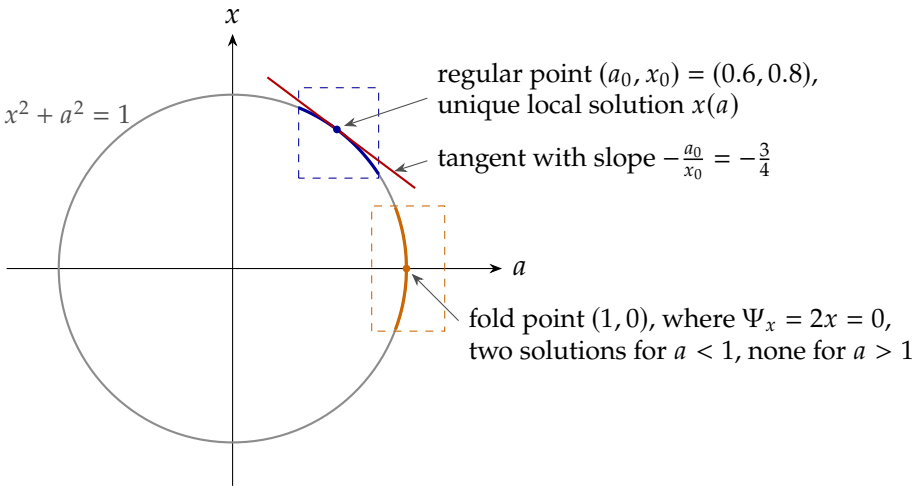

Figure B.1: The implicit function theorem for $\Psi(x, a) = x^2 + a^2 - 1$. Near the regular point $(0.6, 0.8)$ the zero set is the graph of a unique C^1 function, whose slope $-\frac{\Psi_a}{\Psi_x} = -\frac{3}{4}$ is the slope of the tangent. Near the fold point $(1, 0)$, where $\Psi_x = 0$, no box contains the graph of a unique function of a.

Theorem B.27 (Implicit function theorem)**.** *Let $\Psi : U \to \mathbb{R}^n$ be C^1 on an open set $U \subseteq \mathbb{R}^n \times \mathbb{R}^m$. Let $(x_0, a_0) \in U$ satisfy $\Psi(x_0, a_0) = 0$, with $D_x\Psi(x_0, a_0)$ nonsingular. Then there are $\epsilon > 0$ and $\eta > 0$ with the following property. For every a with $\|a - a_0\| < \eta$, the system $\Psi(x, a) = 0$ has exactly one solution $x(a)$ with $\|x(a) - x_0\| \le \epsilon$. The function $x(\cdot)$ is C^1, and*

$$D_a x(a) = -\big[D_x\Psi\big(x(a), a\big)\big]^{-1} D_a\Psi\big(x(a), a\big). \tag{B.13}$$

Proof. All norms are sup norms and their induced matrix norms. We first derive (B.13) assuming that a differentiable solution exists, and then prove existence, uniqueness and differentiability.

The derivative formula. The function $h(a) = \Psi(x(a), a)$ is identically zero, so its Jacobian is zero. By the chain rule (B.1),

$$\begin{aligned} 0 &= D_a h(a) \\ &= D_x\Psi\big(x(a), a\big)\, D_a x(a) + D_a\Psi\big(x(a), a\big). \end{aligned}$$

Moving the second term to the left and premultiplying by $[D_x\Psi]^{-1}$ gives (B.13).

Existence and uniqueness. Let $J_0 = D_x\Psi(x_0, a_0)$ and define

$$\Phi_a(x) = x - J_0^{-1}\Psi(x, a).$$

Since J_0^{-1} is nonsingular, x is a fixed point of Φ_a exactly when $\Psi(x, a) = 0$. The Jacobian of Φ_a is

$$D\Phi_a(x) = I - J_0^{-1} D_x\Psi(x, a) = J_0^{-1}\big[J_0 - D_x\Psi(x, a)\big],$$

which vanishes at (x_0, a_0). By continuity of $D_x\Psi$, choose $\epsilon > 0$ and $\eta_1 > 0$ such that $\|D\Phi_a(x)\| \le \frac{1}{2}$ whenever $\|x - x_0\| \le \epsilon$ and $\|a - a_0\| \le \eta_1$. On the closed ball $B_\epsilon = \{x : \|x - x_0\| \le \epsilon\}$, which is convex, Corollary B.13 gives

$$\|\Phi_a(x) - \Phi_a(x')\| \le \frac{1}{2}\|x - x'\| \qquad \text{for all } x, x' \in B_\epsilon. \tag{B.14}$$

The map also sends B_ϵ into itself for a close to a_0. For $x \in B_\epsilon$,

$$\|\Phi_a(x) - x_0\| \le \|\Phi_a(x) - \Phi_a(x_0)\| + \|\Phi_a(x_0) - x_0\| \le \frac{\epsilon}{2} + \big\|J_0^{-1}\Psi(x_0, a)\big\|.$$

The last term is zero at $a = a_0$ and continuous in a. So there is $\eta \in (0, \eta_1]$ with $\|J_0^{-1}\Psi(x_0, a)\| \le \frac{\epsilon}{2}$ for $\|a - a_0\| < \eta$. For such a, Φ_a maps the complete set B_ϵ into itself and contracts with modulus $\frac{1}{2}$. The contraction mapping theorem (Theorem B.127) gives a unique fixed point $x(a) \in B_\epsilon$.

Continuity. For two parameter values a, a', add and subtract $\Phi_a(x(a'))$ and use (B.14):

$$\|x(a) - x(a')\| \le \frac{1}{2}\|x(a) - x(a')\| + \big\|J_0^{-1}\big[\Psi(x(a'), a) - \Psi(x(a'), a')\big]\big\|.$$

Hence $\|x(a) - x(a')\| \le 2\|J_0^{-1}\| \sup_{y \in B_\epsilon} \|\Psi(y, a) - \Psi(y, a')\|$. The supremum vanishes as $a' \to a$, because Ψ is uniformly continuous on compact sets.

Differentiability. Fix a, write $x = x(a)$ and $x' = x(a')$, and let z_t be the point $(x + t(x' - x), a + t(a' - a))$. Proposition B.12, applied to Ψ as a function of the stacked vector (x, a), gives

$$0 = \Psi(x', a') - \Psi(x, a) = M_x\,(x' - x) + M_a\,(a' - a),$$

where $M_x = \int_0^1 D_x\Psi(z_t)\,\mathrm{d}t$ and $M_a = \int_0^1 D_a\Psi(z_t)\,\mathrm{d}t$. The points z_t stay in the region where $\|I - J_0^{-1}D_x\Psi\| \le \frac{1}{2}$, so $\|I - J_0^{-1}M_x\| \le \frac{1}{2}$. Lemma B.23 makes $J_0^{-1}M_x$, and hence M_x, nonsingular. Therefore $x' - x = -M_x^{-1}M_a(a' - a)$. As $a' \to a$, continuity gives $x' \to x$, $M_x \to D_x\Psi(x, a)$ and $M_a \to D_a\Psi(x, a)$. So $x(\cdot)$ is differentiable with derivative (B.13), which is continuous in a. □

Remark B.28 (The theorem is local). The theorem guarantees a unique solution only near (x_0, a_0). It says nothing about solutions far from x_0. Several price equilibria, for instance, can each be locally unique, with a nonsingular Jacobian at each one. Global uniqueness needs other tools, such as contractions or dominant-diagonal conditions (Section B.7). The theorem also fails where $D_x\Psi$ is singular. At such fold points a small change in a can make solutions appear, disappear or jump, as at $(1, 0)$ in Figure B.1.

B.2.2 Comparative statics of optima and equilibria

Proposition B.29 (Comparative statics of an optimum)**.** *Let $f(x, a)$ be C^2 with x in an open set $X \subseteq \mathbb{R}^n$. Suppose x_0 is an interior maximizer at a_0 with $\nabla_x f(x_0, a_0) = 0$ and $D^2_{xx} f(x_0, a_0)$ negative definite. Then near a_0 there is a C^1 function $x^*(a)$ of strict local maximizers with $x^*(a_0) = x_0$, and*

$$D_a x^*(a) = -\left[D^2_{xx} f(x^*(a), a)\right]^{-1} D^2_{xa} f(x^*(a), a). \tag{B.15}$$

In the scalar case $\frac{\mathrm{d}x^*}{\mathrm{d}a} = -\frac{f_{xa}}{f_{xx}}$, which has the sign of the cross partial f_{xa}.

Proof. Apply Theorem B.27 to $\Psi(x, a) = \nabla_x f(x, a)$. Its Jacobian $D_x\Psi = D^2_{xx} f$ is negative definite, hence nonsingular, and $D_a\Psi = D^2_{xa} f$. This gives a C^1 solution of the first-order conditions and the formula (B.15). The leading principal minors of the Hessian are continuous, so by Proposition B.20 the Hessian stays negative definite near (x_0, a_0). The second-order sufficient condition therefore holds along the solution. In the scalar case $f_{xx} < 0$, so $-\frac{f_{xa}}{f_{xx}}$ has the sign of f_{xa}. □

The cross partial f_{xa} measures complementarity between the choice and the parameter. When $f_{xa} > 0$, a higher a raises the marginal return to x, and the optimal x rises. Section B.9 obtains the same monotonicity without differentiability or concavity, by Topkis's theorem.

Example B.30 (Monopoly price and cost)**.** A monopolist with constant marginal cost c chooses p to maximize $f(p, c) = (p - c)Q(p)$. The derivatives are

$$f_p = Q + (p - c)Q', \qquad f_{pp} = 2Q' + (p - c)Q'', \qquad f_{pc} = -Q' > 0.$$

So the price rises with cost whenever the second-order condition $f_{pp} < 0$ holds. The magnitude is $\frac{\mathrm{d}p^*}{\mathrm{d}c} = -\frac{f_{pc}}{f_{pp}} = \frac{Q'}{2Q' + (p-c)Q''}$, the monopoly pass-through rate that Section B.2.3 studies in detail.

Games add strategic feedback. Each player's first-order condition depends on the others' choices, so a parameter change moves every player's best response and then moves it again through the rivals' reactions.

Proposition B.31 (Comparative statics of a Nash equilibrium)**.** *Players $i = 1, \dots, N$ choose x_i in open intervals, with C^2 payoffs $\pi_i(x, a)$ and a scalar parameter a. Let x^* be an interior Nash equilibrium at a_0, so that $\Psi_i(x, a) \equiv \frac{\partial \pi_i}{\partial x_i}(x, a) = 0$ for every i. Let $D_x\Psi$ be the $N \times N$ matrix with (i, j) element $\frac{\partial^2 \pi_i}{\partial x_i \, \partial x_j}$.*

(a) If $D_x\Psi(x^*, a_0)$ is nonsingular, the first-order conditions have a locally unique solution $x^*(a)$ through x^*. It is C^1 with $\frac{\mathrm{d}x^*}{\mathrm{d}a} = -[D_x\Psi]^{-1} D_a\Psi$. It remains a Nash equilibrium for a near a_0 if each π_i is concave in x_i.

(b) Suppose also that $\frac{\partial^2 \pi_i}{\partial x_i^2} < 0$ *for every* i*. Define the best-response slopes and the direct effects*

$$R_{ij} = -\Big(\frac{\partial^2 \pi_i}{\partial x_i^2}\Big)^{-1} \frac{\partial^2 \pi_i}{\partial x_i \, \partial x_j} \quad (j \neq i), \qquad R_{ii} = 0, \qquad c_i = -\Big(\frac{\partial^2 \pi_i}{\partial x_i^2}\Big)^{-1} \frac{\partial^2 \pi_i}{\partial x_i \, \partial a}.$$

Then $\frac{\mathrm{d}x^*}{\mathrm{d}a} = (I - R)^{-1} c$*. If* $\|R\|_\infty < 1$*, then* $\frac{\mathrm{d}x^*}{\mathrm{d}a} = \sum_{h=0}^{\infty} R^h c$*.*

Proof. Part (a) is Theorem B.27 applied to Ψ. Nonsingularity alone does not keep each $x_i^*(a)$ a best response to $x_{-i}^*(a)$. Concavity of π_i in x_i does, because a stationary point of a concave function is a global maximizer. For (b), write π_{ij} for $\frac{\partial^2 \pi_i}{\partial x_i \, \partial x_j}$ and π_{ia} for $\frac{\partial^2 \pi_i}{\partial x_i \, \partial a}$. Row i of $D_x \Psi \frac{\mathrm{d}x^*}{\mathrm{d}a} + D_a \Psi = 0$ reads

$$\pi_{ii} \frac{\mathrm{d}x_i^*}{\mathrm{d}a} + \sum_{j \neq i} \pi_{ij} \frac{\mathrm{d}x_j^*}{\mathrm{d}a} + \pi_{ia} = 0.$$

Dividing by $-\pi_{ii} > 0$ and rearranging,

$$\frac{\mathrm{d}x_i^*}{\mathrm{d}a} = \sum_{j \neq i} R_{ij} \frac{\mathrm{d}x_j^*}{\mathrm{d}a} + c_i.$$

Stacking gives $(I - R)\frac{\mathrm{d}x^*}{\mathrm{d}a} = c$. Since $I - R = \operatorname{diag}(\pi_{11}, \ldots, \pi_{NN})^{-1} D_x \Psi$, the matrix $I - R$ is nonsingular, and the series form follows from Lemma B.23. □

The objects in (b) have direct interpretations. Apply Theorem B.26 to player i's own first-order condition. Then R_{ij} is the slope of i's best response to x_j. Likewise, c_i is the shift of that best response when a moves with rivals held fixed. The series says that the equilibrium response is the direct effect c, plus the rivals' reactions Rc to it, plus the reactions $R^2 c$ to those reactions, and so on.

Remark B.32 (Stability and the correspondence principle). The condition $\|R\|_\infty < 1$ has a dynamic reading. Near x^*, best-response dynamics $x^{(h+1)} = BR(x^{(h)})$ are approximately $x^{(h+1)} - x^* = R(x^{(h)} - x^*)$. If every absolute row sum of R is below one, deviations shrink and the equilibrium is locally stable. With strategic complements (Definition B.182), $R \geq 0$, so $(I - R)^{-1} = \sum_h R^h \geq 0$ element by element. A shock that raises every direct effect then raises every equilibrium action. Stability thus delivers sign restrictions on comparative statics. This is the correspondence principle of Samuelson (1947), which Dixit (1986) applies to oligopoly. With strategic substitutes, as in Cournot, the terms of the series alternate in sign, and stability alone signs fewer responses.

B.2.3 Application: pass-through

The *pass-through* rate $\rho = \frac{\mathrm{d}p}{\mathrm{d}c}$ is the response of an equilibrium price to a shift in marginal cost, or $\frac{\mathrm{d}p}{\mathrm{d}t}$ for a specific tax t. It governs tax incidence, the price effects of mergers, and tests of market power (Section 2.8, Chapter 3, Chapter 11). Every formula below comes from one recipe. We write the equilibrium condition as $\Psi(\text{price or quantity}, \text{cost}) = 0$ and apply the implicit function theorem.

The formulas depend on the curvature of demand. As in (2.60), the *curvature* of inverse demand $P(q)$ is

$$\chi(q) = -\frac{qP''(q)}{P'(q)}. \tag{B.16}$$

Since $P' < 0$, χ has the sign of P''. Linear inverse demand has $\chi = 0$, concave inverse demand has $\chi \le 0$, and convex inverse demand has $\chi \ge 0$.

Proposition B.33 (Monopoly pass-through)**.** *A monopolist has constant marginal cost c and faces a C^2 demand $Q(p)$ with $Q' < 0$. Its optimal price $p(c)$ is interior and satisfies the first-order condition $Q'(p)(p-c) + Q(p) = 0$ and the strict second-order condition $(p-c)Q''(p) + 2Q'(p) < 0$. Let $P = Q^{-1}$ be inverse demand and $q = Q(p)$. Then*

$$\rho = \frac{\mathrm{d}p}{\mathrm{d}c} = \frac{Q'}{(p-c)Q'' + 2Q'} = \frac{1}{2 - \frac{QQ''}{(Q')^2}} = \frac{1}{2 - \chi(q)} > 0, \tag{B.17}$$

and in particular $\frac{QQ''}{(Q')^2} = \chi(q)$.

Proof. Let $\Psi(p, c) = Q'(p)(p-c) + Q(p)$. Its partial derivatives are

$$\begin{aligned} \Psi_p &= Q''(p)(p-c) + Q'(p) + Q'(p) = (p-c)Q'' + 2Q', \\ \Psi_c &= -Q'(p). \end{aligned}$$

The second-order condition gives $\Psi_p < 0$, so Theorem B.26 applies:

$$\rho = -\frac{\Psi_c}{\Psi_p} = \frac{Q'}{(p-c)Q'' + 2Q'}.$$

Both numerator and denominator are negative, so $\rho > 0$. The same result follows from differentiating the identity $Q'(p(c))(p(c) - c) + Q(p(c)) \equiv 0$ term by term, which gives $\rho(p - c)Q'' + (\rho - 1)Q' + \rho Q' = 0$.

For the second form, the first-order condition gives $p - c = -\frac{Q}{Q'}$. Substituting,

$$\rho = \frac{Q'}{-\frac{QQ''}{Q'} + 2Q'}.$$

Dividing numerator and denominator by Q' gives $\rho = \left[2 - \frac{QQ''}{(Q')^2}\right]^{-1}$.

For the third form, differentiate the identity $Q(P(q)) = q$ twice:

$$\begin{aligned} Q'(P(q))\,P'(q) &= 1, \\ Q''(P(q))\,P'(q)^2 + Q'(P(q))\,P''(q) &= 0. \end{aligned}$$

The first line gives $Q' = \frac{1}{P'}$. The second then gives $Q'' = -\frac{Q'P''}{(P')^2} = -\frac{P''}{(P')^3}$. Hence

$$\frac{QQ''}{(Q')^2} = q \cdot \left(-\frac{P''}{(P')^3}\right) \cdot (P')^2 = -\frac{qP''}{P'} = \chi(q).$$

The quantity-space route gives the same answer. The condition $P(q) + qP'(q) = c$ has derivative $2P' + qP''$ in q, so $\frac{\mathrm{d}q}{\mathrm{d}c} = \frac{1}{2P' + qP''}$ and $\rho = P'\frac{\mathrm{d}q}{\mathrm{d}c} = \frac{P'}{2P' + qP''} = \frac{1}{2 - \chi}$. □

Corollary B.34 (Pass-through and log-concavity)**.** *Under the assumptions of Proposition B.33, monopoly pass-through is below one if and only if demand is strictly log-concave at p, that is, $(\ln Q)''(p) < 0$. It equals one if and only if $(\ln Q)''(p) = 0$, and it exceeds one if and only if $(\ln Q)''(p) > 0$ (Bulow and Pfleiderer, 1983).*

Proof. Differentiating $\ln Q$ twice,

$$(\ln Q)'' = \left(\frac{Q'}{Q}\right)' = \frac{QQ'' - (Q')^2}{Q^2} = \frac{(Q')^2}{Q^2}(\chi - 1),$$

by Proposition B.33. The second-order condition makes $2 - \chi > 0$. So $\rho < 1$ if and only if $2 - \chi > 1$, that is $\chi < 1$, which is $(\ln Q)'' < 0$. The other two cases are identical with the inequalities replaced. □

The same corollary appears in Corollary 2.71. With unit demand, $Q(p) = M[1 - F(p)]$ for a CDF F of valuations, so demand is log-concave exactly when the survival function $1 - F$ is. Proposition B.160 develops this reading and extends the corollary from a local to a global statement.

Example B.35 (Pass-through for common demand curves)**.** Each case applies (B.17), and Table 2.5 collects the results. The symbols a, b, A and γ follow Chapter 2 and are local to this example and to Proposition B.161.

(i) *Power inverse demand*, $P(q) = a - bq^\gamma$ with $b\gamma > 0$ and $\gamma > -1$. Then $P' = -b\gamma q^{\gamma-1}$ and $P'' = -b\gamma(\gamma - 1)q^{\gamma-2}$, so $\frac{qP''}{P'} = \gamma - 1$ and $\chi = 1 - \gamma$. Directly, marginal revenue is $a - b(1 + \gamma)q^\gamma$. Substituting $bq^\gamma = a - p$ gives marginal revenue $(1 + \gamma)p - \gamma a$. Setting it equal to c,

$$p = \frac{c + \gamma a}{1 + \gamma}, \qquad \rho = \frac{1}{1 + \gamma} = \frac{1}{2 - \chi}.$$

Linear demand is $\gamma = 1$, with $\rho = \frac{1}{2}$.

(ii) *Exponential demand*, $P(q) = a - b \ln q$ with $b > 0$, or $Q(p) = e^{\frac{a-p}{b}}$, whose semi-elasticity is the constant $\frac{1}{b}$. Then $P' = -\frac{b}{q}$, $P'' = \frac{b}{q^2}$ and $\chi = 1$. Marginal revenue is $P + qP' = p - b$, so $p = c + b$ and $\rho = 1$. A monopolist facing this demand passes through exactly the cost change, as a competitive industry with flat marginal cost would. A pass-through test cannot tell the two apart.

(iii) *Constant elasticity*, $Q(p) = Ap^{-\varepsilon}$ with $\varepsilon > 1$, so $P(q) = (\frac{q}{A})^{-\frac{1}{\varepsilon}}$. Then $P' = -\frac{P}{\varepsilon q}$ and $P'' = \frac{1}{\varepsilon}(1 + \frac{1}{\varepsilon})\frac{P}{q^2}$, so $\chi = 1 + \frac{1}{\varepsilon}$ and

$$\rho = \frac{1}{1 - \frac{1}{\varepsilon}} = \frac{\varepsilon}{\varepsilon - 1} > 1.$$

This matches the pricing rule $p = \frac{\varepsilon}{\varepsilon - 1}c$. In the notation of case (i) it is the power family with a zero intercept, $b = -A^{\frac{1}{\varepsilon}}$ and $\gamma = -\frac{1}{\varepsilon}$.

(iv) *Logit, one product, rivals' prices fixed*. The share is $s(p) = \frac{e^{\xi - \alpha p}}{\Lambda_{-j} + e^{\xi - \alpha p}}$, where $\Lambda_{-j} = 1 + \sum_{k \neq j} e^{\delta_k}$ does not depend on p. Then $s' = -\alpha s(1 - s)$, and the first-order condition is $p - c = m(p)$ with $m(p) = \frac{1}{\alpha(1 - s(p))}$. Differentiating m,

$$m'(p) = \frac{1}{\alpha}\frac{s'(p)}{(1 - s)^2} = -\frac{s}{1 - s}.$$

Differentiating $p - c = m(p)$ in c gives $\rho - 1 = m'(p)\rho$, so

$$\rho = \frac{1}{1 - m'(p)} = \frac{1}{1 + \frac{s}{1 - s}} = 1 - s.$$

Equivalently, $s'' = \alpha^2 s(1-s)(1-2s)$ gives $\chi = \frac{ss''}{(s')^2} = \frac{1-2s}{1-s} < 1$, and $\frac{1}{2-\chi} = 1 - s$. Logit demand is log-concave, since $(\ln s)'' = -\alpha^2 s(1-s) < 0$.

By Corollary B.34, demand is log-concave exactly when $\chi < 1$. Linear and logit demand are log-concave, the power family is log-concave when $\gamma > 0$, exponential demand is log-linear, and constant-elasticity demand is log-convex.

We now allow imperfect competition of any degree and rising marginal cost. Consider a symmetric homogeneous-good industry with conduct parameter $\theta \in [0, 1]$, where $\theta = 0$ is price taking, $\theta = \frac{1}{N}$ is symmetric Cournot and $\theta = 1$ is joint monopoly. Industry output Q satisfies the supply relation of Section 2.7 with a specific tax t added to marginal cost $mc(Q)$:

$$P(Q) + \theta Q P'(Q) = mc(Q) + t. \tag{B.18}$$

Three elasticities summarize the primitives at the equilibrium. The demand elasticity is $\varepsilon = -\frac{P}{QP'}$. The elasticity of the effective marginal cost curve is $\varepsilon_S = \frac{mc+t}{Q\,mc'}$, defined relative to marginal cost including the tax and infinite when marginal cost is flat. The *marginal consumer surplus* is $ms(q) = -qP'(q)$, the surplus that one more unit hands to inframarginal buyers, and $\varepsilon_{ms} = \frac{ms}{q\,ms'}$ is its elasticity.

Proposition B.36 (Pass-through under conduct and rising marginal cost)**.** *Let P be C^2 with $P' < 0$, let mc be C^1 with $mc' \geq 0$, and let θ not vary with t. Suppose $Q(t) > 0$ solves (B.18) and the stability condition $(1+\theta)P' + \theta QP'' - mc' < 0$ holds. Then*

$$\rho = \frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{1 + \theta(1-\chi) - \frac{mc'}{P'}} = \frac{1}{1 + \frac{\theta}{\varepsilon_{ms}} + \frac{\varepsilon - \theta}{\varepsilon_S}}, \tag{B.19}$$

with $\frac{1}{\varepsilon_{ms}} = 1 - \chi$, and the denominator is positive.

Proof. Let $\Psi(Q, t) = P(Q) + \theta QP'(Q) - mc(Q) - t$. Its partial derivatives are

$$\begin{aligned} \Psi_Q &= P' + \theta P' + \theta QP'' - mc' = (1+\theta)P' + \theta QP'' - mc', \\ \Psi_t &= -1. \end{aligned}$$

Stability gives $\Psi_Q < 0$, so by Theorem B.26 $\frac{\mathrm{d}Q}{\mathrm{d}t} = -\frac{\Psi_t}{\Psi_Q} = \frac{1}{\Psi_Q} < 0$. Price moves along the demand curve, so

$$\rho = P'(Q)\frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{P'}{(1+\theta)P' + \theta QP'' - mc'}.$$

Dividing numerator and denominator by P' and using $\frac{QP''}{P'} = -\chi$,

$$\rho = \frac{1}{1 + \theta - \theta\chi - \frac{mc'}{P'}} = \frac{1}{1 + \theta(1-\chi) - \frac{mc'}{P'}}.$$

This is the first form. The ratio $\frac{P'}{\Psi_Q}$ is positive because both terms are negative.

For the second form, the supply relation (B.18) gives

$$mc + t = P + \theta QP' = P\left(1 + \theta\frac{QP'}{P}\right) = P\left(1 - \frac{\theta}{\varepsilon}\right).$$

The definition of ε_S gives $mc' = \frac{mc+t}{Q\varepsilon_S} = \frac{P}{Q\varepsilon_S}\left(1 - \frac{\theta}{\varepsilon}\right)$. Therefore

$$-\frac{mc'}{P'} = \left(-\frac{P}{QP'}\right)\frac{1}{\varepsilon_S}\left(1 - \frac{\theta}{\varepsilon}\right) = \frac{\varepsilon}{\varepsilon_S}\left(1 - \frac{\theta}{\varepsilon}\right) = \frac{\varepsilon - \theta}{\varepsilon_S}.$$

Finally, $ms'(q) = -P' - qP'' = -P'\left(1 + \frac{qP''}{P'}\right) = -P'(1-\chi)$, so

$$\frac{1}{\varepsilon_{ms}} = \frac{q\,ms'}{ms} = \frac{-qP'(1-\chi)}{-qP'} = 1-\chi.$$

Substituting both expressions into the first form gives the second. □

The second form of (B.19) is the representation of Weyl and Fabinger (2013). It requires ε_S to be defined relative to marginal cost, as above. Proposition 2.76 states the same result and derives its incidence consequences.

Corollary B.37 (Special cases)**.** *Under the assumptions of Proposition B.36, the following special cases hold.*

(a) With flat marginal cost ($\varepsilon_S = \infty$), $\rho = \frac{1}{1+\theta(1-\chi)}$.

(b) With price taking ($\theta = 0$), $\rho = \frac{1}{1+\frac{\varepsilon}{\varepsilon_S}} = \frac{\varepsilon_S}{\varepsilon_S+\varepsilon} \leq 1$.

(c) With monopoly and flat marginal cost, $\rho = \frac{1}{2-\chi}$, as in Proposition B.33.

(d) With linear demand and flat marginal cost, $\rho = \frac{1}{1+\theta}$.

(e) With symmetric Cournot ($\theta = \frac{1}{N}$) and flat marginal cost, $\rho = \frac{N}{N+1-\chi}$.

Proof. Each case substitutes into (B.19). For (b), $\theta = 0$ removes the curvature term and leaves $\frac{\varepsilon-0}{\varepsilon_S}$. For (c), $\theta = 1$ gives $1 + 1 - \chi = 2 - \chi$. For (d), $\chi = 0$. For (e), multiply numerator and denominator of $\frac{1}{1+\frac{1-\chi}{N}}$ by N. □

The corollary shows what a pass-through estimate can and cannot reveal. Under price taking, $\rho \leq 1$ for every demand curve, so an estimate above one rejects competition whatever the curvature. A pass-through of one, however, fits three different worlds. It fits competition with flat cost, monopoly with exponential demand, and monopoly with log-convex demand and rising cost. With flat cost, rearranging (a) gives $\theta(\chi - 1) = 1 - \frac{1}{\rho}$. One estimate identifies only this product of conduct and curvature. Conduct is identified only jointly with the curvature of demand and the slope of marginal cost (Corollary 2.78, Chapter 3). Measured price indices add a composition effect when the product mix shifts, which Chapter 3 discusses. Figure 2.10 plots case (a) against curvature for four values of conduct. With linear demand, case (a) gives pass-through of $\frac{1}{2}$, $\frac{2}{3}$ and $\frac{4}{5}$ for $\theta = 1, \frac{1}{2}, \frac{1}{4}$. With constant elasticity $\varepsilon = 2$ ($\chi = \frac{3}{2}$), it gives 2, $\frac{4}{3}$ and $\frac{8}{7}$.

With differentiated products, cost shocks to one product move every price, and pass-through becomes a matrix.

Proposition B.38 (Pass-through matrix)**.** *Let shares $s(p)$ be C^2, let c be the vector of constant marginal costs, and let the equilibrium satisfy*

$$\Psi(p, c) = s(p) + \left(\Omega \odot \Delta(p)^\top\right)(p - c) = 0.$$

If $D_p\Psi$ is nonsingular at the equilibrium, then

$$\frac{\partial p}{\partial c^\top} = \left[D_p\Psi\right]^{-1}\left(\Omega \odot \Delta^\top\right), \qquad \left(D_p\Psi\right)_{jl} = \frac{\partial s_j}{\partial p_l} + \Omega_{jl}\frac{\partial s_l}{\partial p_j} + \sum_k \Omega_{jk}(p_k - c_k)\frac{\partial^2 s_k}{\partial p_j\,\partial p_l}. \tag{B.20}$$

Proof. Row j of Ψ is $\Psi_j = s_j + \sum_k \Omega_{jk}\frac{\partial s_k}{\partial p_j}(p_k - c_k)$. Differentiating in c_l gives $-\Omega_{jl}\frac{\partial s_l}{\partial p_j}$, so $D_c\Psi = -(\Omega \odot \Delta^\top)$. Differentiating in p_l with the product rule gives

$$\frac{\partial \Psi_j}{\partial p_l} = \frac{\partial s_j}{\partial p_l} + \sum_k \Omega_{jk}\Big[\frac{\partial^2 s_k}{\partial p_j\,\partial p_l}(p_k - c_k) + \frac{\partial s_k}{\partial p_j}\mathbf{1}\{k = l\}\Big],$$

which is the stated element. Theorem B.27 gives $\frac{\partial p}{\partial c^\top} = -[D_p\Psi]^{-1}D_c\Psi = [D_p\Psi]^{-1}(\Omega \odot \Delta^\top)$. □

The last term of $D_p\Psi$ contains second derivatives of demand. Multiproduct pass-through therefore depends on the curvature of demand, as in the scalar case. With one product and $\Omega = 1$, (B.20) reduces to $\frac{s'}{2s' + (p-c)s''}$, which is (B.17) with s in place of Q. The matrix also includes rivals' responses. Consider a logit duopoly of single-product firms. Holding the rival's price fixed, firm 1's pass-through is $1 - s_1$ (Example B.35), which is the first entry of the vector of direct effects in Proposition B.31. The equilibrium own pass-through is $\frac{1-s_1}{1-R_{12}R_{21}} \geq 1 - s_1$, because logit best-response slopes lie in $[0, 1)$. The difference reflects strategic complementarity.

Remark B.39 (Upward pricing pressure as a cost shock). Pass-through converts merger incentives into price predictions. Suppose single-product firms A and B merge. Evaluated at pre-merger prices, A's new first-order condition is $s_A + (p_A - c_A)\frac{\partial s_A}{\partial p_A} + (p_B - c_B)\frac{\partial s_B}{\partial p_A} = 0$. Divide it by $-\frac{\partial s_A}{\partial p_A} > 0$ and let $D_{AB} = -\frac{\partial s_B}{\partial p_A}\big(\frac{\partial s_A}{\partial p_A}\big)^{-1}$ be the diversion ratio. The condition becomes

$$p_A - \big[c_A + (p_B - c_B)D_{AB}\big] = -s_A\Big(\frac{\partial s_A}{\partial p_A}\Big)^{-1}.$$

The merger thus acts like an increase in A's marginal cost by the *upward pricing pressure* $\mathrm{UPP}_A = (p_B - c_B)D_{AB}$, net of any efficiency credit. Farrell and Shapiro (2010) credit the merger with a proportional cut E in each product's marginal cost. Net pressure on A's price is then upward when $D_{AB}(p_B - c_B) > Ec_A$, their inequality (1) on p. 12 of the November 2008 working paper. To first order the price change is the pass-through matrix of the post-merger conditions applied to the vector of these cost shifts, an approach that Jaffe and Weyl (2013) develop. Holding the partner's price fixed, the single-product version is $\Delta p_A \approx \rho_A\,\mathrm{UPP}_A$. With logit demand $\rho_A = 1 - s_A$, and with linear demand $\rho_A = \frac{1}{2}$. The same upward pressure therefore predicts different price effects under different curvatures (Chapter 11).

B.2.4 Further applications

Example B.40 (Slope of a Cournot best response)**.** Firm i chooses q_i given rivals' output Q_{-i}, with first-order condition

$$\Psi(q_i, Q_{-i}) = P(q_i + Q_{-i}) + q_iP'(q_i + Q_{-i}) - C_i'(q_i) = 0.$$

The partial derivatives are $\Psi_{q_i} = 2P' + q_iP'' - C_i''$ and $\Psi_{Q_{-i}} = P' + q_iP''$. By Theorem B.26,

$$BR_i'(Q_{-i}) = -\frac{P' + q_iP''}{2P' + q_iP'' - C_i''} = -\frac{P' + q_iP''}{(P' + q_iP'') + (P' - C_i'')}.$$

Suppose $P' + q_iP'' < 0$, so marginal revenue falls with rivals' output, and $C_i'' \geq 0$. Write $u = -(P' + q_iP'') > 0$ and $w = C_i'' - P' > 0$. Then $BR_i' = -\frac{u}{u+w} \in (-1, 0)$. Quantities are strategic substitutes (Definition B.182), because a rival's expansion lowers firm i's marginal profit. Firm i offsets that expansion only in part (Section 2.4.2). Example B.181 obtains the sign of the slope without the second-order condition.

Example B.41 (Gradient of the share inversion)**.** In the random coefficients logit, mean utilities $\delta(\theta_2)$ solve $s(\delta(\theta_2), \theta_2) = s^{obs}$, where θ_2 collects the nonlinear parameters. The Jacobian $\frac{\partial s}{\partial \delta^\top}$ is nonsingular by Example B.22. Theorem B.27 then gives

$$\frac{\partial \delta}{\partial \theta_2^\top} = -\left[\frac{\partial s}{\partial \delta^\top}\right]^{-1} \frac{\partial s}{\partial \theta_2^\top}.$$

This formula supplies the analytic gradient of the GMM objective (Proposition 8.22). Without random coefficients, the inverse is available in closed form from (B.11).

Example B.42 (Berry's element-by-element inverse)**.** Berry (1994, p. 260, eq. (A1)) defines an element-by-element inverse. Holding the other mean utilities fixed, $r_j(\delta, s_j)$ is the mean utility of product j that makes its predicted share equal to its observed share s_j:

$$s_j = s_j\big(\delta_1, \ldots, \delta_{j-1}, r_j(\delta, s_j), \delta_{j+1}, \ldots, \delta_J\big).$$

A vector δ inverts the share system exactly when $\delta = r(\delta, s)$. Since $\frac{\partial s_j}{\partial \delta_j} > 0$, Theorem B.26 gives, for $k \neq j$,

$$\frac{\partial r_j}{\partial \delta_k} = -\frac{\partial s_j}{\partial \delta_k}\left(\frac{\partial s_j}{\partial \delta_j}\right)^{-1} > 0,$$

the expression on p. 261. The row sum $\sum_{k \neq j} \frac{\partial r_j}{\partial \delta_k}$ is below one exactly when the dominance condition of Example B.22 holds. In the logit, $r_j = \ln s_j - \ln(1 - s_j) + \ln\left(1 + \sum_{k \neq j} e^{\delta_k}\right)$, and at the solution $\frac{\partial r_j}{\partial \delta_k} = \frac{s_k}{1 - s_j}$. This is the logit diversion ratio from j to k, and the row sum is $\frac{1 - s_j - s_0}{1 - s_j} < 1$. Section B.7.4 uses these properties to prove existence and uniqueness of the inverse.

B.3 Constrained optimization and the envelope theorem

Many objects in this book are value functions: maximized profits, minimized costs, indirect utility, a bidder's equilibrium payoff. The envelope theorem gives their derivatives. Its message is that, at an optimum, the indirect effect of a parameter through the reoptimized choice vanishes to first order. Only the direct effect remains. We begin with the first-order conditions of constrained problems, which the constrained version of the theorem needs.

B.3.1 Lagrange and Kuhn-Tucker conditions

Consider the problem

$$V(a) = \max_{x \in X} f(x, a) \quad \text{subject to} \quad g_k(x, a) \geq 0, \quad k = 1, \ldots, K, \tag{B.21}$$

with $X \subseteq \mathbb{R}^n$ open. The *Lagrangian* is

$$\mathcal{L}(x, \lambda, a) = f(x, a) + \sum_{k=1}^{K} \lambda_k g_k(x, a),$$

and the λ_k are *multipliers*. A constraint is *binding* at x if $g_k(x, a) = 0$ and *slack* if $g_k(x, a) > 0$.

Theorem B.43 (Kuhn-Tucker conditions)**.** *Let f and $g_1, \dots, g_K$ be C^1 in x, and let x^* be a local maximizer in* (B.21)*. Suppose the gradients $\nabla_x g_k(x^*, a)$ of the binding constraints are linearly independent. Then there are multipliers $\lambda_1^*, \dots, \lambda_K^*$ such that*

(i) (stationarity) $\nabla_x f(x^*, a) + \sum_k \lambda_k^* \nabla_x g_k(x^*, a) = 0$,

(ii) (primal feasibility) $g_k(x^*, a) \geq 0$ for every k,

(iii) (dual feasibility) $\lambda_k^* \geq 0$ for every k,

(iv) (complementary slackness) $\lambda_k^* g_k(x^*, a) = 0$ for every k.

For an equality constraint $g_k = 0$, the same holds with λ_k^* unrestricted in sign.

The theorem is due to Kuhn and Tucker (1951), and Mas-Colell et al. (1995, Mathematical Appendix) give a proof. Stationarity says that the gradient of f is a nonnegative combination of the vectors $-\nabla_x g_k$ of the binding constraints. Every feasible direction therefore lowers f to first order. Complementary slackness sets the multipliers of slack constraints to zero.

The linear independence condition is a *constraint qualification*, and it cannot be dropped. Maximize $f(x) = x$ subject to $g(x) = -x^3 \geq 0$. The feasible set is $x \leq 0$ and the maximizer is $x^* = 0$. Yet $g'(0) = 0$, so stationarity would require $1 + \lambda \cdot 0 = 0$, which no λ satisfies.

Proposition B.44 (Sufficiency under concavity)**.** *Let X be convex and let $f(\cdot, a)$ and every $g_k(\cdot, a)$ be concave and differentiable. If (x^*, λ^*) satisfies conditions (i) to (iv) of Theorem B.43, then x^* is a global maximizer in* (B.21)*.*

Proof. Since $\lambda^* \geq 0$, the function $x \mapsto \mathcal{L}(x, \lambda^*, a)$ is a nonnegative combination of concave functions and hence concave. Stationarity says its gradient vanishes at x^*, so by Lemma B.5 x^* maximizes it. For any feasible x, the terms $\lambda_k^* g_k(x, a)$ are nonnegative, and complementary slackness makes them zero at x^*. Hence

$$f(x, a) \leq \mathcal{L}(x, \lambda^*, a) \leq \mathcal{L}(x^*, \lambda^*, a) = f(x^*, a). \qquad \square$$

Concavity of f can be weakened to quasi-concavity, with quasi-concave constraints and a nonvanishing gradient of f at x^* (Arrow and Enthoven, 1961). Utility maximization fits either version, because the budget constraint is linear.

Example B.45 (Cobb-Douglas utility)**.** A consumer with income I faces prices $p \in \mathbb{R}^n_{++}$ for goods $i = 1, \dots, n$ and solves

$$\max_q \sum_{i=1}^n a_i \ln q_i \quad \text{subject to} \quad I - p^\top q \geq 0, \qquad a_i > 0, \ \sum_i a_i = 1.$$

The nonnegativity constraints are slack, because $\ln q_i \to -\infty$ as $q_i \to 0$. The Lagrangian is $\mathcal{L} = \sum_i a_i \ln q_i + \lambda(I - p^\top q)$, and stationarity gives

$$\frac{a_i}{q_i} - \lambda p_i = 0 \quad \Longrightarrow \quad q_i = \frac{a_i}{\lambda p_i}.$$

Since $\frac{a_i}{q_i} > 0$, we need $\lambda > 0$, and complementary slackness makes the budget bind. Substituting into the budget,

$$I = \sum_i p_i q_i = \sum_i \frac{a_i}{\lambda} = \frac{1}{\lambda},$$

so $\lambda = \frac{1}{I}$ and the Marshallian demands are

$$q_i(p, I) = \frac{a_i I}{p_i}. \tag{B.22}$$

The consumer spends the share a_i of income on good i. Substituting the demands into the objective gives the indirect utility function

$$v(p, I) = \sum_i a_i \ln \frac{a_i I}{p_i} = \Big(\sum_i a_i\Big) \ln I + \sum_i a_i(\ln a_i - \ln p_i) = \ln I + \sum_i a_i(\ln a_i - \ln p_i). \tag{B.23}$$

The objective is concave and the constraint linear, so Proposition B.44 confirms the solution. Two checks anticipate later results. First, $\frac{\partial v}{\partial I} = \frac{1}{I} = \lambda$, so the multiplier is the marginal utility of income (Corollary B.51). Second, $-\frac{\partial v}{\partial p_i}\big(\frac{\partial v}{\partial I}\big)^{-1} = \frac{a_i}{p_i} I$ recovers (B.22), which is Roy's identity. The utility $\prod_i q_i^{a_i} = \exp(\sum_i a_i \ln q_i)$ is a monotone transformation and has the same demands, with indirect utility $I \prod_i \big(\frac{a_i}{p_i}\big)^{a_i}$. Section B.4.2 continues this example.

B.3.2 The envelope theorem

We start without constraints. Let $V(a) = \max_{x \in X} f(x, a)$, where the choice set X does not depend on a, and let $x^*(a)$ denote a maximizer.

Theorem B.46 (Envelope theorem)**.** *Let $X \subseteq \mathbb{R}^n$ be open and f be C^1. Suppose the maximizer $x^*(a)$ is differentiable in a. Then for every l,*

$$\frac{\partial V}{\partial a_l}(a) = \frac{\partial f}{\partial a_l}\big(x^*(a), a\big). \tag{B.24}$$

Proof. Write $V(a) = f(x^*(a), a)$ and apply the chain rule:

$$\frac{\partial V}{\partial a_l} = \sum_{k=1}^{n} \frac{\partial f}{\partial x_k}\big(x^*(a), a\big) \frac{\partial x_k^*}{\partial a_l} + \frac{\partial f}{\partial a_l}\big(x^*(a), a\big).$$

At an interior maximizer every $\frac{\partial f}{\partial x_k}$ vanishes, so the sum is zero. □

The indirect effect through x^* is zero because the choice was already optimal. A small change in x around the optimum has no first-order effect on f, whatever caused it.

Corollary B.47 (Curvature of the value function)**.** *Let x and a be scalars, f be C^2, and $f_{xx}(x^*(a), a) < 0$. Then*

$$V''(a) = f_{aa} - \frac{f_{xa}^2}{f_{xx}} \geq f_{aa},$$

with all derivatives evaluated at $(x^*(a), a)$.

Proof. Differentiate $V'(a) = f_a(x^*(a), a)$ once more and substitute $\frac{\mathrm{d}x^*}{\mathrm{d}a} = -\frac{f_{xa}}{f_{xx}}$ from Proposition B.29:

$$V''(a) = f_{aa} + f_{ax} \frac{\mathrm{d}x^*}{\mathrm{d}a} = f_{aa} - \frac{f_{xa}^2}{f_{xx}}.$$

The last term is nonnegative because $f_{xx} < 0$. □

The corollary says that reoptimization makes the value function more convex than the objective. If f is linear in a, then $f_{aa} = 0$ and V is convex. This is the differential version of Lemma B.6.

Theorem B.46 assumes a differentiable maximizer. Many applications violate that assumption. In auctions the choice is a bid that may jump, and in discrete choice the maximizer is an alternative from a finite set. The next two results, due to Milgrom and Segal (2002), need neither differentiability of x^* nor any structure on X.

Theorem B.48 (Envelope theorem for arbitrary choice sets)**.** *Let X be any set, a a scalar in an open interval, and $x^* \in X$ a maximizer of $f(\cdot, a)$. Suppose $f(x^*, \cdot)$ is differentiable at a.*

(a) If V is differentiable at a, then $V'(a) = f_a(x^*, a)$.

(b) If V has one-sided derivatives at a, then $V'(a^+) \geq f_a(x^*, a) \geq V'(a^-)$.

Proof. For every a', $V(a') \geq f(x^*, a')$, with equality at $a' = a$. So the function $h(a') = V(a') - f(x^*, a')$ is nonnegative and attains its minimum value zero at $a' = a$. For $a' > a$, $\frac{h(a')-h(a)}{a'-a} \geq 0$. Letting $a' \downarrow a$ gives $V'(a^+) - f_a(x^*, a) \geq 0$. For $a' < a$ the quotient is nonpositive, which gives $V'(a^-) - f_a(x^*, a) \leq 0$. This proves (b), and (a) follows because the one-sided derivatives coincide. □

The proof is the tangency picture of Figure B.2. For a fixed choice x^*, the function $f(x^*, \cdot)$ lies below V and touches it at a. Where both are differentiable, they must share the slope there. A by-product of (a) is that $f_a(x^*, a)$ takes the same value at every maximizer whenever V is differentiable.

Theorem B.49 (Integral form of the envelope theorem)**.** *Let X be any set and $a \in [a_L, a_U]$. Suppose that $f(x, \cdot)$ is absolutely continuous and differentiable for every x. Suppose also that an integrable function b satisfies $|f_a(x, a)| \leq b(a)$ for all x and almost all a, and that a maximizer $x^*(a)$ exists for almost every a. Then V is absolutely continuous, and for any selection of maximizers*

$$V(a) = V(a_L) + \int_{a_L}^{a} f_a\big(x^*(t), t\big)\,\mathrm{d}t. \tag{B.25}$$

Proof sketch. For $a < a'$ and any x, $f(x, a') - V(a) \leq f(x, a') - f(x, a)$. Taking the supremum over x, and repeating with a and a' exchanged,

$$|V(a') - V(a)| \leq \sup_x |f(x, a') - f(x, a)| = \sup_x \left| \int_a^{a'} f_a(x, t)\,\mathrm{d}t \right| \leq \int_a^{a'} b(t)\,\mathrm{d}t.$$

Summing over finitely many disjoint intervals shows that V is absolutely continuous. An absolutely continuous function is differentiable almost everywhere and equals the integral of its derivative. At almost every t, V is differentiable and a maximizer exists, so Theorem B.48 gives $V'(t) = f_a(x^*(t), t)$. Integrating yields (B.25). Milgrom and Segal (2002) give the details. □

The integral form is the version used in mechanism design and auctions. There the payoff of the marginal type is pinned down by a participation condition, and (B.25) then determines every type's payoff (Example B.57).

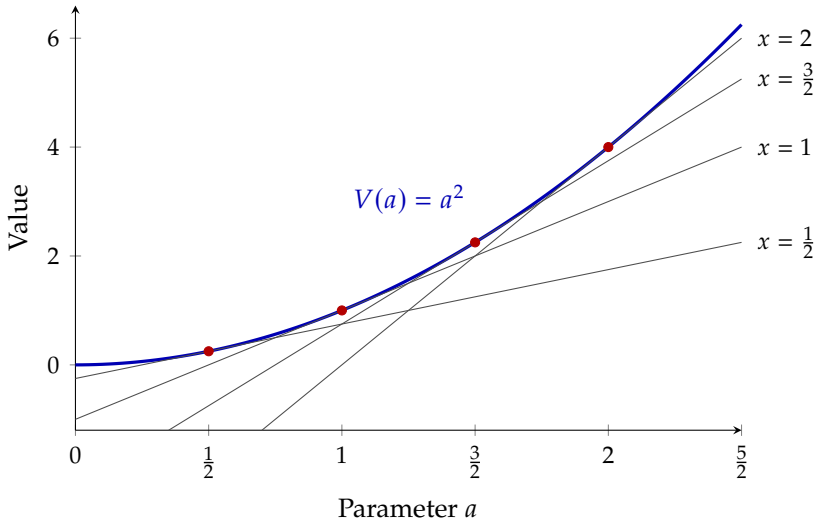

Figure B.2: The envelope theorem. Each thin line is $f(x,a) = 2xa - x^2$ for a fixed choice $x \in \{\frac{1}{2}, 1, \frac{3}{2}, 2\}$. The value function $V(a) = \max_x f(x,a) = a^2$, attained at $x^*(a) = a$, is their upper envelope. Each line touches the envelope at $a = x$ (dots), so $V'(a) = \frac{\partial f}{\partial a}(x^*(a), a) = 2x^*(a) = 2a$. The envelope is convex because it is a maximum of functions linear in a.

B.3.3 The envelope theorem with constraints

Theorem B.50 (Envelope theorem with constraints)**.** *In problem (B.21) with scalar a, let f and the g_k be C^1 in (x,a). Suppose that near a the solution $x^*(a)$ and multipliers $\lambda^*(a)$ are differentiable, satisfy the conditions of Theorem B.43, and that the set of binding constraints does not change. Then*

$$V'(a) = \frac{\partial \mathcal{L}}{\partial a}\big(x^*(a), \lambda^*(a), a\big) = f_a\big(x^*(a), a\big) + \sum_k \lambda_k^*(a)\, \frac{\partial g_k}{\partial a}\big(x^*(a), a\big). \tag{B.26}$$

Proof. Write $V(a) = f(x^*(a), a)$ and differentiate:

$$V'(a) = \nabla_x f^{\top} \frac{\mathrm{d}x^*}{\mathrm{d}a} + f_a.$$

Stationarity replaces $\nabla_x f$ by $-\sum_k \lambda_k^* \nabla_x g_k$:

$$V'(a) = -\sum_k \lambda_k^* \nabla_x g_k^{\top} \frac{\mathrm{d}x^*}{\mathrm{d}a} + f_a.$$

A binding constraint satisfies $g_k(x^*(a), a) = 0$ on a neighborhood of a. Differentiating this identity gives $\nabla_x g_k^{\top} \frac{\mathrm{d}x^*}{\mathrm{d}a} = -\frac{\partial g_k}{\partial a}$. A slack constraint has $\lambda_k^* = 0$ on a neighborhood. Substituting both facts yields (B.26). □

Corollary B.51 (Multipliers as shadow prices)**.** *If a constraint takes the form $h(x) \le b$, the derivative of the value with respect to b equals its multiplier, $\frac{\partial V}{\partial b} = \lambda^*$.*

Proof. Write the constraint as $g(x,b) = b - h(x) \ge 0$. Then $\frac{\partial g}{\partial b} = 1$, the objective does not depend on b, and (B.26) gives $V'(b) = \lambda^*$. □

In Example B.45, the budget constraint is $p^\top q \le I$, and indeed $\frac{\partial v}{\partial I} = \frac{1}{I} = \lambda$. The multiplier on a budget is the marginal utility of income, and the multiplier on an output constraint in cost minimization is marginal cost (Example B.54).

Remark B.52 (The Le Chatelier principle). Split the choice into $x = (y, z)$, where z is fixed at $\bar{z}$ in the short run. The long-run value $V^L(a) = \max_{y,z} f(y, z, a)$ is at least the short-run value $V^S(a) = \max_y f(y, \bar{z}, a)$, with equality at the a_0 for which $\bar{z}$ is optimal. The difference $V^L - V^S$ is therefore minimized at a_0. Its first derivative vanishes there and its second derivative is nonnegative, so $V^{L\prime}(a_0) = V^{S\prime}(a_0)$ and $V^{L\prime\prime}(a_0) \ge V^{S\prime\prime}(a_0)$. When V' is a supply or demand function, as with Hotelling's lemma below, long-run responses are at least as large as short-run ones (Samuelson, 1947). For costs the inequality flips. Long-run cost is the lower envelope of short-run cost curves and touches the one with the optimal capital stock. At that output, long-run and short-run marginal cost coincide, and long-run marginal cost is flatter. This is one reason why accounting measures of cost can differ from the economic marginal cost that pricing theory needs (Chapter 1).

Rationing gives a concrete case in consumer theory (Deaton and Muellbauer, 1980b, Section 4.3, pp. 110–112). Let good 1 be rationed at the quantity the consumer would choose freely, $z = h_1(p, u)$, where h is Hicksian demand and $S_{jk} = \frac{\partial h_j}{\partial p_k}$ (Section B.4.2). Write $h_j^*(p_{-1}, u, z)$ for the restricted Hicksian demand for good $j \neq 1$ (Remark B.75). It does not depend on p_1, and $h_j^*(p_{-1}, u, h_1(p, u)) = h_j(p, u)$ for all p (their eq. 3.3). Section 5.7.2 differentiates this identity with respect to p_1 and p_j and uses Slutsky symmetry (Proposition B.66). With $S_{11} < 0$, the restricted own-price effect is

$$S_{jj}^* \equiv \frac{\partial h_j^*}{\partial p_j} = S_{jj} - \frac{S_{j1}^2}{S_{11}} \ge S_{jj},$$

their eq. 3.6 (p. 112). Both sides are nonpositive, so rationing good 1 weakly reduces the absolute compensated own-price effect of every other good. The reduction is zero only when $S_{j1} = 0$.

B.3.4 Applications

Example B.53 (Hotelling's lemma)**.** A price-taking firm with production function $\varphi(x)$, output price p and input prices r earns

$$\pi(p, r) = \max_x \; p\,\varphi(x) - r^\top x.$$

Theorem B.46 gives

$$\frac{\partial \pi}{\partial p} = \varphi(x^*) = q^*, \qquad \frac{\partial \pi}{\partial r_\ell} = -x_\ell^*,$$

so supply and input demands are derivatives of the profit function (Hotelling, 1932). For each x, the objective is linear in (p, r). By Lemma B.6, π is convex in (p, r). Its second derivatives therefore give $\frac{\partial q^*}{\partial p} = \frac{\partial^2 \pi}{\partial p^2} \ge 0$ and $\frac{\partial x_\ell^*}{\partial r_\ell} = -\frac{\partial^2 \pi}{\partial r_\ell^2} \le 0$: supply curves slope up and input demand curves slope down.

Example B.54 (Shephard's lemma and marginal cost)**.** The cost function is $C(r, q) = \min_x\{r^\top x : \varphi(x) \ge q\}$. Write it as the maximization problem $-C(r, q) = \max_x\{-r^\top x : \varphi(x) - q \ge 0\}$, with Lagrangian $-r^\top x + \lambda(\varphi(x) - q)$. Theorem B.50 gives

$$\frac{\partial C}{\partial r_\ell} = x_\ell(r, q), \qquad \frac{\partial C}{\partial q} = \lambda^*,$$

the first being Shephard's lemma for costs (Shephard, 1953). The multiplier on the output constraint is marginal cost. Stationarity reads $r_\ell = \lambda^* \frac{\partial \varphi}{\partial x_\ell}$, so each input price equals marginal cost times the input's marginal product. Multiplying by $\frac{x_\ell}{q}$ for a freely adjustable input ℓ and dividing the output price p by λ^*,

$$\frac{p}{\lambda^*} = \Big(\frac{\partial \varphi}{\partial x_\ell}\frac{x_\ell}{q}\Big)\frac{pq}{r_\ell x_\ell}.$$

The markup ratio equals the output elasticity of the flexible input times the ratio of revenue to spending on that input. This is the production approach to markups (Proposition 1.30, De Loecker and Warzynski, 2012). Concavity of C in r follows from Lemma B.6.

Example B.55 (Monopoly profit, cost and taxes)**.** A monopolist with constant marginal cost c and specific tax t earns $\pi^*(t) = \max_p (p - c - t)Q(p)$. The envelope theorem gives $\frac{\mathrm{d}\pi^*}{\mathrm{d}t} = -Q(p^*)$. To first order, profit falls by the quantity sold whatever the pass-through rate. Consumer surplus $\int_{p^*}^{\infty} Q(u)\,\mathrm{d}u$ falls at rate $Q\frac{\mathrm{d}p^*}{\mathrm{d}t} = \rho Q$ by Leibniz's rule. The ratio of consumer to producer burden under monopoly is therefore ρ, the case $\theta = 1$ of Proposition 2.80.

Example B.56 (Entry lowers incumbents' Cournot profits)**.** Firm i's profit given rivals' output is $V_i(Q_{-i}) = \max_{q_i}\big[P(q_i + Q_{-i})q_i - C_i(q_i)\big]$. By the envelope theorem,

$$V_i'(Q_{-i}) = q_i\,P'(Q) < 0 \qquad \text{whenever } q_i > 0.$$

The firm's own output response has no first-order effect. In a symmetric equilibrium with N firms, rivals' output is $Q_{-i} = Q - q$, and entry raises it, since $\frac{\mathrm{d}Q}{\mathrm{d}N} > 0$ and $\frac{\mathrm{d}q}{\mathrm{d}N} < 0$ (Proposition 2.33). Treating N as continuous,

$$\frac{\mathrm{d}\pi}{\mathrm{d}N} = q\,P'(Q)\Big(\frac{\mathrm{d}Q}{\mathrm{d}N} - \frac{\mathrm{d}q}{\mathrm{d}N}\Big) < 0.$$

Example B.57 (Bidder rents in the first-price auction)**.** There are n bidders with independent private values drawn from F, and a reserve price r. Rivals use a strictly increasing bid function β with $\beta(r) = r$. A bidder with value $v \geq r$ who bids $\beta(z)$ wins when every rival value is below z, with probability $F(z)^{n-1}$. Her equilibrium payoff is

$$\pi(v) = \max_z\ \big(v - \beta(z)\big)F(z)^{n-1},$$

and in equilibrium $z = v$ is optimal. For each z the objective is affine in v with slope $F(z)^{n-1}$. So π is a maximum of affine functions, hence convex and absolutely continuous, and Theorem B.49 applies:

$$\pi'(v) = F(v)^{n-1} \text{ almost everywhere}, \qquad \pi(r) = \big(r - \beta(r)\big)F(r)^{n-1} = 0.$$

Integrating from r gives $\pi(v) = \int_r^v F(t)^{n-1}\,\mathrm{d}t$. The payoff is also the winning probability times the surplus when winning, $\pi(v) = (v - \beta(v))F(v)^{n-1}$. Equating the two expressions,

$$\beta(v) = v - \frac{\int_r^v F(t)^{n-1}\,\mathrm{d}t}{F(v)^{n-1}},$$

which is (B.8). With uniform values on $[0,1]$ and $r = 0$, $\beta(v) = \frac{n-1}{n}v$.

The first-order route reaches the same formula with more work. Differentiating the objective in z at $z = v$ gives $-\beta'(v)F(v)^{n-1} + (v - \beta(v))(n-1)F(v)^{n-2}f(v) = 0$. Rearranged, this is the differential equation

$$\frac{\mathrm{d}}{\mathrm{d}v}\Big[\beta(v)F(v)^{n-1}\Big] = v\,\frac{\mathrm{d}}{\mathrm{d}v}\Big[F(v)^{n-1}\Big].$$

Integrating from r and applying the integration by parts of Example B.18 gives the bid again. The envelope route needs neither the differential equation nor differentiability of β. It also shows that the payoff $\pi(v)$ depends only on who wins and on the zero payoff of type r. Any format with the same allocation and $\pi(r) = 0$ therefore yields the same expected payments, which is revenue equivalence (Myerson, 1981; Riley and Samuelson, 1981). Section 14.5.3 develops these results.

Example B.58 (Expected maximum utility)**.** Let $\mathcal{W}(\delta) = \mathbb{E}[\max_k(\delta_k + \epsilon_k)]$ in an additive random utility model with continuously distributed errors. For each realization of ϵ, the maximum is the value of a choice over a finite set. Its derivative in δ_j is $\mathbf{1}\{j \text{ is the maximizer}\}$ wherever the maximizer is unique, which holds with probability one. This is the envelope theorem for a finite choice set. Taking expectations,

$$\frac{\partial \mathcal{W}}{\partial \delta_j} = \mathbb{P}(j \text{ is chosen}) = s_j(\delta).$$

The exchange of derivative and expectation needs a domination argument, which the Williams-Daly-Zachary theorem (Theorem B.94) supplies. In the logit, $\mathcal{W} = \ln \sum_k e^{\delta_k}$ plus a constant, and $\frac{\partial}{\partial \delta_j} \ln \sum_k e^{\delta_k} = s_j$.

B.4 Duality in consumer and producer theory

Duality theory studies an optimization problem through its value function. Under convexity the value function summarizes the problem completely, and its derivatives deliver the demand or supply functions. The envelope theorem of Section B.3 computes those derivatives, so this section applies it repeatedly. Empirical IO uses this in three ways. It builds demand systems from an expenditure function, as in the almost ideal demand system of Chapter 5. It measures welfare exactly from estimated demand, as in the valuation of new goods in Chapter 10. It recovers marginal cost from a cost function, as in the conduct and airline studies of Chapter 3 and Chapter 9. Section 5.2 proves the consumer-theory results that the AIDS needs. This section restates them for reference and points to those proofs. It adds five tools: the envelope-theorem proof of Shephard's lemma, the properties of indirect utility, the integrability method of Hausman (1981), quasi-linear utility and producer duality.

There are n goods indexed by $i, j = 1, \ldots, n$, with prices $p \in \mathbb{R}^n_{++}$. In this section $I > 0$ denotes the consumer's income (total expenditure), not the number of consumers. We write U for the utility function and u for a utility level. Marshallian demand is $q(p, I)$ and Hicksian demand is $h(p, u)$. The indirect utility function is $v(p, I)$ and the expenditure function is $e(p, u)$. The budget share of good i is $w_i = \frac{p_i q_i}{I}$, the income elasticity is $\eta_i = \frac{\partial \ln q_i}{\partial \ln I}$, and the Slutsky matrix S has elements $S_{ij} = \frac{\partial h_i}{\partial p_j}$. In this section only, ε_{ij} denotes the signed Marshallian elasticity $\frac{\partial \ln q_i}{\partial \ln p_j}$, as in Chapter 5.

B.4.1 The utility maximization and expenditure minimization problems

Assumption B.59 (Preferences)**.** The utility function $U : \mathbb{R}^n_+ \to \mathbb{R}$ is continuous, strictly increasing and strictly quasi-concave. Prices satisfy $p \gg 0$, meaning that every component is positive, and income satisfies $I > 0$.

The *utility maximization problem* (UMP) and the *expenditure minimization problem* (EMP) are

$$v(p, I) = \max_{q \geq 0} \{U(q) : p^\top q \leq I\}, \qquad e(p, u) = \min_{q \geq 0} \{p^\top q : U(q) \geq u\}. \tag{B.27}$$

The maximizer $q(p, I)$ is the *Marshallian demand*, and the minimizer $h(p, u)$ is the *Hicksian* (compensated) *demand*. In the EMP we take utility levels $u > U(0)$ in the range of U. Both problems have solutions. The budget set is compact because $p \gg 0$, and a continuous function attains its maximum on a compact set. For the EMP, pick any bundle $\bar{q}$ with $U(\bar{q}) \geq u$ and minimize over the compact set $\{q \geq 0 : U(q) \geq u,\ p^\top q \leq p^\top \bar{q}\}$. The solutions are unique. If two distinct bundles solved the UMP, their midpoint would be affordable and, by strict quasi-concavity, strictly better. The argument for the EMP is the same after scaling the midpoint down slightly. Both constraints bind. A bundle that leaves money unspent can be enlarged, which raises utility because U is strictly increasing.

Proposition B.60 (Indirect utility function)**.** *Under Assumption B.59, $v(p, I)$ has four properties.*

(i) It is homogeneous of degree zero in (p, I).

(ii) It is strictly increasing in I and nonincreasing in each p_i.

(iii) It is quasi-convex in p: for every $\bar{v}$, the set $\{p : v(p, I) \leq \bar{v}\}$ is convex.

(iv) It is continuous in (p, I).

Proof. Write $B(p, I) = \{q \geq 0 : p^\top q \leq I\}$ for the budget set. (i) For $\lambda > 0$, $B(\lambda p, \lambda I) = B(p, I)$, so the two maxima coincide. (ii) If $I' > I$, the bundle $q(p, I)$ costs $I < I'$, so $q(p, I) + \epsilon \mathbf{1}$ is affordable at I' for small $\epsilon > 0$ and is strictly better. If $p' \geq p$, then $B(p', I) \subseteq B(p, I)$, so $v(p', I) \leq v(p, I)$. (iii) Let $p'' = \lambda p + (1 - \lambda)p'$ with $\lambda \in [0, 1]$. Any q with $p''^\top q \leq I$ satisfies $p^\top q \leq I$ or $p'^\top q \leq I$, because otherwise $p''^\top q > I$. Hence $B(p'', I) \subseteq B(p, I) \cup B(p', I)$ and

$$v(p'', I) \leq \max\{v(p, I), v(p', I)\}.$$

If both $v(p, I)$ and $v(p', I)$ are at most $\bar{v}$, so is $v(p'', I)$. (iv) The objective is continuous and the budget correspondence is continuous and compact-valued when $p \gg 0$, so the theorem of the maximum applies (Mas-Colell et al., 1995, ch. 3). □

Proposition B.61 (Expenditure function)**.** *Under Assumption B.59, $e(p, u)$ has four properties.*

(i) It is homogeneous of degree one in p.

(ii) It is strictly increasing in u and nondecreasing in each p_i.

(iii) It is concave in p.

(iv) It is continuous in (p, u).

Proposition 5.5 proves the four properties. Concavity is the key one. For each feasible bundle q the map $p \mapsto p^\top q$ is linear, and $e(\cdot, u)$ is the minimum of this family, which is concave by Lemma B.6.

Proposition B.62 (Duality identities)**.** *Under Assumption B.59, for all $p \gg 0$, $I > 0$ and $u > U(0)$ in the range of U,*

$$e(p, v(p, I)) = I, \qquad v(p, e(p, u)) = u, \tag{B.28}$$

$$q(p, I) = h(p, v(p, I)), \qquad h(p, u) = q(p, e(p, u)). \tag{B.29}$$

Lemma 5.4 proves the identities. The argument uses monotonicity and continuity of U to show that each constraint binds, and uniqueness of the solutions to match the two demands.

The identities let us move between the two problems. The functions $v(p, \cdot)$ and $e(p, \cdot)$ are inverses of each other for fixed prices, and Marshallian and Hicksian demands coincide when income and utility are linked by them. Every result below uses one of the four identities.

Deaton and Muellbauer (1980b, ch. 2) build demand analysis on the same duality. They write the expenditure function as the *cost function* $c(u, p)$ and income as total outlay x. Their Section 2.3 (pp. 37–42) states the properties of Proposition B.61 and derives Shephard's lemma and Roy's identity (their eqs. 3.9 and 3.16, pp. 40–41). Section 2.4 (pp. 43–46) derives adding up, homogeneity, symmetry, negativity and the Slutsky equation (eqs. 4.1–4.6). Section 2.5 (pp. 47–50) turns to the integrability problem of Section B.4.3.

B.4.2 Shephard's lemma, Roy's identity and the Slutsky equation

Proposition B.63 (Shephard's lemma, Shephard, 1953)**.** *Under Assumption B.59, if $e(\cdot, u)$ is differentiable at p^0, then*

$$h_i(p^0, u) = \frac{\partial e(p^0, u)}{\partial p_i}, \qquad i = 1, \ldots, n. \tag{B.30}$$

In share form, at $u = v(p, I)$,

$$w_i = \frac{\partial \ln e(p, u)}{\partial \ln p_i}. \tag{B.31}$$

Proposition 5.6 proves the lemma with a supporting-hyperplane argument and derives the share form by the chain rule. Here we give the second route, through the envelope theorem.

Proof (envelope theorem). Suppose U is twice continuously differentiable and the solution $(h(p, u), \mu(p, u))$ of the EMP and its multiplier are differentiable in p. The Lagrangian is $\mathcal{L}(q, \mu, p) = p^\top q - \mu\,[U(q) - u]$. The envelope theorem with constraints (Theorem B.50) says that the derivative of the value function equals the partial derivative of the Lagrangian, evaluated at the solution:

$$\frac{\partial e(p, u)}{\partial p_i} = \frac{\partial \mathcal{L}}{\partial p_i}\Big|_{q = h(p,u),\, \mu = \mu(p,u)} = h_i(p, u).$$

The indirect effects through q and μ vanish by the first-order conditions and the binding constraint. The share form follows by the chain rule, as in Section 5.2.3. □

The supporting-hyperplane proof of Proposition 5.6 needs neither derivatives of U nor differentiability of h. Fix p^0 and let $q^0 = h(p^0, u)$. The bundle q^0 is feasible at every price vector, so $e(p, u) \le p^\top q^0$, with equality at p^0. The gradient of $p^\top q^0 - e(p, u)$ therefore vanishes at its minimizer p^0. This is the proof of Deaton and Muellbauer (1980b, eqs. 3.10–3.11, p. 40), whose function $Z(p)$ is $p^\top q^0 - e(p, u)$. It also shows more. The same argument works for any bundle q in the Hicksian demand set. So every such bundle is a *supergradient* of the concave function

$e(\cdot, u)$ at p^0, that is, $e(p, u) \le e(p^0, u) + q^\top (p - p^0)$ for every p. When indifference curves have flat segments, the Hicksian demand is a set and e has a kink. Figure B.3 draws the argument. Figure 2.9 of Deaton and Muellbauer (1980b, p. 39) draws the same concave cross section, with a chord in place of the supporting lines. Deaton and Muellbauer (1980a) state the share form (B.31) as their equation (5) on p. 313, with the cost function written $c(u, p)$. Logarithmic differentiation of an expenditure function then yields budget shares as functions of prices and utility, which is how they derive the AIDS.

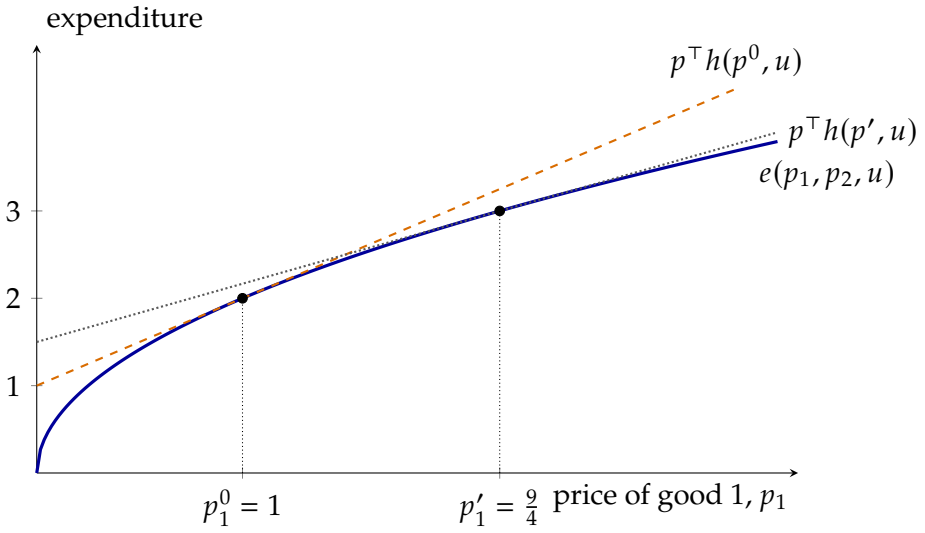

Figure B.3: Shephard's lemma as a supporting hyperplane. Cobb-Douglas utility $U = q_1^{\frac{1}{2}} q_2^{\frac{1}{2}}$ with $p_2 = 1$ and $u = 1$ gives $e(p_1, 1, 1) = 2\sqrt{p_1}$, which is concave in p_1. The cost of the fixed bundle $h(p^0, u) = (1, 1)$ is the line $p_1 + 1$. It lies above e and touches it at $p_1^0 = 1$, so its slope $h_1(p^0, u) = 1$ equals the slope of e there. The dotted line repeats the construction at $p_1' = \frac{9}{4}$, where $h(p', u) = (\frac{2}{3}, \frac{3}{2})$. The expenditure function is the lower envelope of all such lines.

Proposition B.64 (Roy's identity, Roy, 1947)**.** *Under Assumption B.59, if v is differentiable at (p, I) with $\frac{\partial v}{\partial I} > 0$ and $e(\cdot, u)$ is differentiable at p for $u = v(p, I)$, then*

$$q_i(p, I) = -\frac{\partial v(p, I)}{\partial p_i} \left[\frac{\partial v(p, I)}{\partial I} \right]^{-1}. \tag{B.32}$$

Proposition 5.7 proves the identity, together with its share form. The proof differentiates the identity $v(p, e(p, u)) = u$ of (B.28) with respect to p_i, substitutes Shephard's lemma, and evaluates at $u = v(p, I)$.

Roy's identity is invariant to increasing transformations of v, because a transformation multiplies both derivatives by the same positive factor. Section B.5.4 shows that the Williams-Daly-Zachary theorem is the discrete-choice version of the identity.

Proposition B.65 (Slutsky equation, Slutsky, 1915)**.** *Under Assumption B.59 and differentiability of q and h, at $u = v(p, I)$,*

$$\frac{\partial q_i(p, I)}{\partial p_j} = \frac{\partial h_i(p, u)}{\partial p_j} - q_j(p, I) \frac{\partial q_i(p, I)}{\partial I}. \tag{B.33}$$

In elasticity form, $\varepsilon_{ij}^h = \varepsilon_{ij} + \eta_i w_j$, where $\varepsilon_{ij}^h = \frac{\partial \ln h_i}{\partial \ln p_j}$ is the Hicksian elasticity.

Proposition 5.8(i) proves the equation by differentiating $h_i(p,u) = q_i(p, e(p,u))$ with respect to p_j and applying Shephard's lemma. Proposition 5.9(a) derives the elasticity form.

The first term on the right of (B.33) is the *substitution effect*, which holds utility fixed. The second is the *income effect*, the response to the loss of purchasing power. The remaining elasticity identities (Engel and Cournot aggregation, homogeneity, symmetry in share form) are derived in Section 5.2.6.

Proposition B.66 (Slutsky matrix)**.** *Suppose $e(\cdot, u)$ is twice continuously differentiable. Then the Slutsky matrix $S(p,u)$ satisfies:*

(i) S is symmetric: $S_{ij} = S_{ji}$.

(ii) S is negative semidefinite. In particular $S_{ii} \le 0$.

(iii) $Sp = 0$ and $p^\top S = 0$. Hence S has rank at most $n-1$.

Proof. By Shephard's lemma, S is the Hessian of $e(\cdot, u)$. Parts (ii) to (iv) of Proposition 5.8 prove symmetry, negative semidefiniteness and $Sp = 0$ from Young's theorem, concavity and Euler's theorem (Proposition B.9). Symmetry then gives $p^\top S = 0$. The vector p is nonzero and lies in the null space, so the rank of S is at most $n-1$. □

Corollary B.67 (Net substitutes)**.** *If $n \ge 2$ and $S_{ii} < 0$, then $S_{ij} > 0$ for at least one $j \ne i$. Every good with a strictly negative compensated own-price effect has at least one net substitute.*

Proof. Row i of $Sp = 0$ reads $\sum_{j \ne i} S_{ij} p_j = -S_{ii} p_i > 0$. Since every $p_j > 0$, at least one S_{ij} with $j \ne i$ must be positive. □

Negative semidefiniteness is the compensated law of demand. It is the only sign restriction that consumer theory places on demand. Marshallian own-price effects can have either sign, because the income effect in (B.33) can dominate.

Example B.68 (Cobb-Douglas duality, continuing Example B.45)**.** Let $U(q) = \prod_i q_i^{a_i}$ with $a_i > 0$ and $\sum_i a_i = 1$. This is an increasing transformation of $\sum_i a_i \ln q_i$, so Marshallian demand is again $q_i = \frac{a_i I}{p_i}$. Substituting demand into U,

$$v(p,I) = \prod_i \left(\frac{a_i I}{p_i} \right)^{a_i} = I \prod_i \left(\frac{a_i}{p_i} \right)^{a_i}.$$

Setting $v(p,e) = u$ and solving for e gives the expenditure function

$$e(p,u) = u \prod_i \left(\frac{p_i}{a_i} \right)^{a_i}.$$

It is homogeneous of degree one in p because the exponents sum to one. Shephard's lemma gives $h_i(p,u) = \frac{\partial e}{\partial p_i} = \frac{a_i}{p_i} e(p,u)$. At $u = v(p,I)$ we have $e = I$, so $h_i = \frac{a_i I}{p_i} = q_i$, as (B.29) requires. Roy's identity also recovers demand:

$$\frac{\partial v}{\partial p_i} = -\frac{a_i}{p_i} v, \qquad \frac{\partial v}{\partial I} = \frac{v}{I}, \qquad -\frac{\partial v}{\partial p_i} \left[\frac{\partial v}{\partial I} \right]^{-1} = \frac{a_i I}{p_i}.$$

For the Slutsky equation with $i \ne j$, the compensated cross effect is $S_{ij} = \frac{a_i}{p_i} \frac{\partial e}{\partial p_j} = \frac{a_i a_j e}{p_i p_j}$, which is symmetric in (i,j). The Marshallian cross effect is zero, and the income term is $q_j \frac{\partial q_i}{\partial I} = \frac{a_j I}{p_j} \cdot \frac{a_i}{p_i}$.

At $e = I$ the two sides of (B.33) agree. The own effect is $S_{ii} = \frac{a_i}{p_i} \cdot \frac{a_i e}{p_i} - \frac{a_i e}{p_i^2} = -\frac{a_i(1-a_i)e}{p_i^2} < 0$, and row i of Sp is $\frac{a_i e}{p_i}\left(\sum_j a_j - 1\right) = 0$.

Example B.69 (PIGLOG preferences, Deaton and Muellbauer, 1980a)**.** The *PIGLOG* (price-independent generalized logarithmic) class of Deaton and Muellbauer (1980a, eq. 1, p. 313) has

$$\ln e(p,u) = (1-u)\ln a(p) + u \ln b(p).$$

Here $a(p)$ and $b(p)$ are positive and homogeneous of degree one. They are interpreted as the costs of subsistence ($u = 0$) and bliss ($u = 1$). The share form of Shephard's lemma gives

$$w_i = \frac{\partial \ln a}{\partial \ln p_i} + u\left(\frac{\partial \ln b}{\partial \ln p_i} - \frac{\partial \ln a}{\partial \ln p_i}\right).$$

Inverting $\ln e(p,u) = \ln I$ gives the indirect utility function $u = \frac{\ln I - \ln a(p)}{\ln b(p) - \ln a(p)}$. Substituting it into the share equation shows that budget shares are linear in $\ln I$, with coefficients that depend on prices. The AIDS chooses a translog $\ln a(p)$ and $\ln b(p) = \ln a(p) + \beta_0 \prod_k p_k^{\beta_k}$ (Deaton and Muellbauer, 1980a, eqs. 2–4). Section 5.3 carries out that specialization.

B.4.3 Integrability and recovering preferences from demand

Demand is usually estimated before anything is known about preferences. Two questions follow. Is the estimated system generated by some utility function? If so, can we recover the expenditure function from it, so that welfare can be measured exactly? The first question is answered by the integrability theorem. The second is answered by a differential equation.

Proposition B.70 (Integrability, Hurwicz and Uzawa, 1971)**.** *Let $q(p,I)$ be continuously differentiable on $\mathbb{R}^n_{++} \times \mathbb{R}_{++}$. Suppose it satisfies adding up, $p^\top q(p,I) = I$, and homogeneity of degree zero in (p,I). Suppose also that the matrix with elements $S_{ij} = \frac{\partial q_i}{\partial p_j} + q_j \frac{\partial q_i}{\partial I}$ is symmetric and negative semidefinite at every (p,I). Then, under regularity conditions, there is an increasing and quasi-concave utility function whose Marshallian demand is q.*

We omit the proof. Its logic is short. We look for a function $e(p,u)$ that satisfies the system of partial differential equations

$$\frac{\partial e(p,u)}{\partial p_i} = q_i\big(p, e(p,u)\big), \qquad i = 1,\dots,n, \tag{B.34}$$

which combines Shephard's lemma with (B.29). Differentiate the i-th equation with respect to p_j:

$$\frac{\partial^2 e}{\partial p_j \partial p_i} = \frac{\partial q_i}{\partial p_j} + \frac{\partial q_i}{\partial I} \cdot \frac{\partial e}{\partial p_j} = \frac{\partial q_i}{\partial p_j} + \frac{\partial q_i}{\partial I} q_j = S_{ij}.$$

Mixed partial derivatives must be equal, so a solution can exist only if $S_{ij} = S_{ji}$. This is the integrability condition of Deaton and Muellbauer (1980b, eqs. 5.2–5.3, p. 50). Frobenius's theorem says that symmetry is also sufficient for a local solution. Negative semidefiniteness then makes the solution concave in p, so it is a valid expenditure function (Mas-Colell et al., 1995, ch. 3). The practical message is that an estimated demand system which satisfies the four restrictions supports exact welfare analysis (Chapter 5).

When only one price changes, (B.34) reduces to an ordinary differential equation. This is the method of Hausman (1981). Fix the other prices p_{-1} and, for each utility level u, let $\tilde{e}_u(p_1) = e(p_1, p_{-1}, u)$. Shephard's lemma and (B.29) give

$$\frac{\mathrm{d}\tilde{e}_u(p_1)}{\mathrm{d}p_1} = h_1(p_1, p_{-1}, u) = q_1\big(p_1, p_{-1}, \tilde{e}_u(p_1)\big). \tag{B.35}$$

The right side is known once q_1 has been estimated, so (B.35) is a first-order differential equation in the scalar $\tilde{e}_u$. Each solution curve is one indifference level. We label the curve by its initial condition. The curve through (p_1^0, I^0) belongs to the utility level $u^0 = v(p_1^0, p_{-1}, I^0)$, so $\tilde{e}_{u^0}(p_1^0) = I^0$. If q_1 is Lipschitz in income, that is, $|q_1(p, I) - q_1(p, I')| \leq K|I - I'|$ for a constant K, the Picard-Lindelöf theorem gives a unique solution. Its standard proof is a contraction argument (Theorem B.127). The labeling of utility is arbitrary because utility is ordinal. Money measures such as the compensating variation do not depend on it.

Hausman (1981) solves (B.35) in closed form for common parametric demands. Hausman (1997, eq. 3, p. 212) uses the solution as the "(partial) expenditure function" that values a new cereal brand. The word partial reflects that only the new good's price varies. Under the usual separability assumptions only the demand curve of the new good needs to be estimated (Hausman, 1997, fn. 7).

Example B.71 (Exact welfare from linear demand)**.** Let the demand for good 1 be linear in its own price and income,

$$q_1 = c_0 + c_1 p_1 + c_2 I, \qquad c_1 < 0,\ c_2 \neq 0,$$

with the other prices fixed and absorbed in c_0. Equation (B.35) becomes the linear equation

$$\frac{\mathrm{d}e}{\mathrm{d}p_1} = c_0 + c_1 p_1 + c_2 e.$$

Homogeneous part. The equation $\frac{\mathrm{d}e}{\mathrm{d}p_1} = c_2 e$ has the solutions $Ke^{c_2 p_1}$ for any constant K.

Particular solution. Try $e = A + Bp_1$. Substituting gives $B = c_0 + c_1 p_1 + c_2 A + c_2 B p_1$ for all p_1. Matching the coefficients on p_1 gives $0 = c_1 + c_2 B$, so $B = -\frac{c_1}{c_2}$. Matching the constants gives $B = c_0 + c_2 A$, so

$$A = \frac{B - c_0}{c_2} = -\frac{1}{c_2}\left(c_0 + \frac{c_1}{c_2}\right).$$

General solution. Adding the two parts and using the constant of integration as the utility index,

$$e(p_1, u) = u\, e^{c_2 p_1} - \frac{1}{c_2}\left(c_0 + c_1 p_1 + \frac{c_1}{c_2}\right). \tag{B.36}$$

To verify, differentiate: $\frac{\partial e}{\partial p_1} = c_2 u\, e^{c_2 p_1} - \frac{c_1}{c_2}$. The right side of the differential equation is $c_0 + c_1 p_1 + c_2 u\, e^{c_2 p_1} - \left(c_0 + c_1 p_1 + \frac{c_1}{c_2}\right)$, which is the same. Inverting $e(p_1, u) = I$ gives the indirect utility function

$$v(p_1, I) = e^{-c_2 p_1}\left[I + \frac{1}{c_2}\left(c_0 + c_1 p_1 + \frac{c_1}{c_2}\right)\right],$$

and Roy's identity returns q_1. The Hicksian demand is $h_1(p_1, u) = c_2 u\, e^{c_2 p_1} - \frac{c_1}{c_2}$.

Compensating variation of a price change. Let the price rise from p_1^0 to $p_1^0 + \Delta$ at income I^0, and write $q^0 = c_0 + c_1 p_1^0 + c_2 I^0$ for initial demand. The initial utility satisfies $u^0 e^{c_2 p_1^0} = I^0 + \frac{1}{c_2}\left(c_0 + c_1 p_1^0 + \frac{c_1}{c_2}\right) = \frac{q^0}{c_2} + \frac{c_1}{c_2^2}$. Substituting into $CV = e(p_1^0 + \Delta, u^0) - I^0$ and collecting terms,

$$CV = \left(\frac{q^0}{c_2} + \frac{c_1}{c_2^2}\right)\left(e^{c_2\Delta} - 1\right) - \frac{c_1}{c_2}\Delta. \tag{B.37}$$

Expanding $e^{c_2\Delta}$ to third order shows that $CV \to q^0\Delta + \frac{c_1}{2}\Delta^2$ as $c_2 \to 0$. The limit is the Marshallian surplus loss $\int_{p_1^0}^{p_1^0+\Delta}(c_0 + c_1 t + c_2 I^0)\,\mathrm{d}t$. Without income effects the two measures coincide.

Virtual price and the value of the good. The virtual price p_1^V is the price at which compensated demand falls to zero (Definition B.73). The Hicksian slope at the initial point is $\frac{\partial h_1}{\partial p_1} = c_1 + c_2 q^0$, the Slutsky term. Negativity requires $c_1 + c_2 q^0 \le 0$, and we assume the strict inequality. Setting $h_1(p_1^V, u^0) = 0$ and using the expression for u^0 gives

$$e^{c_2(p_1^V - p_1^0)} = \frac{c_1}{c_1 + c_2 q^0}, \qquad \text{so} \qquad p_1^V - p_1^0 = \frac{1}{c_2}\ln\frac{c_1}{c_1 + c_2 q^0}.$$

Substituting $\Delta = p_1^V - p_1^0$ into (B.37), the first term becomes $\frac{c_2 q^0 + c_1}{c_2^2} \cdot \frac{-c_2 q^0}{c_1 + c_2 q^0} = -\frac{q^0}{c_2}$. The compensating variation of removing the good is therefore

$$CV^V = -\frac{q^0}{c_2} - \frac{c_1}{c_2^2}\ln\frac{c_1}{c_1 + c_2 q^0}.$$

As $c_2 \to 0$, $p_1^V - p_1^0 \to -\frac{q^0}{c_1}$, the Marshallian choke price, and $CV^V \to \frac{(q^0)^2}{2|c_1|}$, the Marshallian triangle. For a numerical illustration take $c_0 = 4$, $c_1 = -2$, $c_2 = 0.01$, $I^0 = 100$ and $p_1^0 = 1$. Then $q^0 = 3$, the budget share is 3 percent and the income elasticity is $\frac{1}{3}$. The Hicksian virtual price is 2.511, against a Marshallian choke price of 2.5. The exact value of the good is $CV^V = 2.273$, about 1 percent above the Marshallian triangle of 2.25. Doubling the price costs $CV = 2.012$, against a Marshallian loss of 2. For a normal good the exact measure exceeds the Marshallian one, as Proposition 5.12 predicts, and the gap is small when the good is a small part of the budget (Willig, 1976).

B.4.4 Welfare measures and virtual prices

Definition B.72 (Compensating and equivalent variation)**.** Let prices change from p^0 to p^1 at fixed income I, and let $u^0 = v(p^0, I)$ and $u^1 = v(p^1, I)$. The *compensating variation* and the *equivalent variation* are

$$CV = e(p^1, u^0) - I, \qquad EV = I - e(p^0, u^1). \tag{B.38}$$

This is Definition 5.11. With these signs both measures are positive for a welfare loss.

The CV is the extra income that restores the old utility at the new prices. The EV is the income the consumer would give up at the old prices to be as badly off as after the change.

Section 5.2.7 uses Shephard's lemma to write each measure as an area to the left of a Hicksian demand curve,

$$CV = \int_{p_i^0}^{p_i^1} h_i(t, p_{-i}, u^0)\,\mathrm{d}t, \qquad EV = \int_{p_i^0}^{p_i^1} h_i(t, p_{-i}, u^1)\,\mathrm{d}t, \tag{B.39}$$

when only p_i changes. When several prices change, the CV is a line integral of Hicksian demands that does not depend on the path (5.14). For a normal good the Marshallian surplus lies between EV and CV (Proposition 5.12).

Definition B.72 follows Deaton and Muellbauer (1980b, Section 7.4, eqs. 4.1–4.2, p. 186), who also sign both measures so that they are positive for a loss. Two bounds use only observed prices and quantities. Let $q^0 = q(p^0, I)$ and $q^1 = q(p^1, I)$ be the bundles chosen before and after the change. The old bundle reaches u^0 and costs $p^{1\top}q^0$ at the new prices, so $e(p^1, u^0) \le p^{1\top}q^0$. The new bundle reaches u^1 and costs $p^{0\top}q^1$ at the old prices, so $e(p^0, u^1) \le p^{0\top}q^1$. Since $I = p^{0\top}q^0 = p^{1\top}q^1$,

$$CV \le q^{0\top}(p^1 - p^0), \qquad EV \ge q^{1\top}(p^1 - p^0). \tag{B.40}$$

The Laspeyres variation $q^{0\top}(p^1 - p^0)$ overstates the compensation the consumer needs. The Paasche variation $q^{1\top}(p^1 - p^0)$ understates the equivalent loss. To first order in $p^1 - p^0$ both bounds hold with equality (their eq. 4.3, p. 187). The ratio forms of the same objects are *true cost-of-living indices*. At a reference utility u^R the index is

$$\mathrm{COL}(p^1, p^0; u^R) = \frac{e(p^1, u^R)}{e(p^0, u^R)}$$

(their Section 7.1, eq. 1.2, p. 170). The argument behind (B.40) bounds $\mathrm{COL}(p^1, p^0; u^0)$ above by the Laspeyres index $\frac{p^{1\top}q^0}{p^{0\top}q^0}$. It bounds $\mathrm{COL}(p^1, p^0; u^1)$ below by the Paasche index $\frac{p^{1\top}q^1}{p^{0\top}q^1}$ (their eqs. 1.3–1.4, p. 172).

A new good, or a good that disappears, is a price change of a special kind. The good is absent in one of the two situations. Hicks (1940) proposed to treat the missing good as available at a price that would "just make the demands for these commodities (from the whole community) equal to zero." The passage is on p. 144 and is quoted by Hausman (1997, p. 211). Rothbarth (1941) called such prices the virtual price system.

Definition B.73 (Virtual price)**.** Given the other prices p_{-i} and the utility level u, the *virtual* (reservation) *price* of good i is the lowest p_i^V with $h_i(p_i^V, p_{-i}, u) = 0$, as in Definition 5.44. If $h_i > 0$ at every finite price, we set $p_i^V = \infty$.

Hausman (1997, eqs. 1–2, p. 211) writes the condition with the Marshallian demand, $0 = g(p_1, \ldots, p_{n-1}, p_n^*, y)$. He then replaces income by the expenditure function at the post-introduction utility, so that the virtual price is computed on the Hicksian demand (his footnote 5).

Proposition B.74 (Valuing the removal of a good)**.** *Let $e_{-i}(p_{-i}, u) = \min\{p_{-i}^\top q_{-i} : U(0, q_{-i}) \ge u\}$ be the expenditure function when good i is unavailable. Under Assumption B.59:*

(i) $e(p_i, p_{-i}, u) \le e_{-i}(p_{-i}, u)$ for every p_i, and e is nondecreasing in p_i.

(ii) If $p_i^V < \infty$, then $e(p_i^V, p_{-i}, u) = e_{-i}(p_{-i}, u)$.

(iii) If $p_i^V = \infty$, then $e(p_i, p_{-i}, u) \to e_{-i}(p_{-i}, u)$ as $p_i \to \infty$.

(iv) In both cases the compensating variation of removing good i at prices p^0 is

$$CV = e_{-i}(p^0_{-i}, u^0) - e(p^0, u^0) = \int_{p_i^0}^{p_i^V} h_i(t, p^0_{-i}, u^0)\,\mathrm{d}t. \tag{B.41}$$

Proof. Parts (i) and (ii) are Proposition 5.45, and monotonicity is Proposition B.61. (iii) By (i) the limit L exists and $L \le e_{-i}$. Write $h(p_i)$ for $h(p_i, p_{-i}, u)$. Since $p_i h_i(p_i) \le e(p_i, p_{-i}, u) \le e_{-i}$, we have $h_i(p_i) \to 0$. The bundles $h(p_i)$ are bounded, so a subsequence converges to some $\bar{q}$ with $\bar{q}_i = 0$ and, by continuity of U, $U(\bar{q}) \ge u$. Then $e_{-i} \le p^\top_{-i}\bar{q}_{-i} = \lim p^\top_{-i} h_{-i}(p_i) \le L$. (iv) Combine (ii) or (iii) with Shephard's lemma and the fundamental theorem of calculus. □

Remark B.75 (Rationing and shadow prices). Virtual prices are a special case of the theory of rationing in Deaton and Muellbauer (1980b, Section 4.3, pp. 109–114). Suppose the consumer must buy exactly z units of good i, and let $e^*(p, u, z) = \min_q\{p^\top q : U(q) \ge u,\ q_i = z\}$ be the *restricted expenditure function*. The *shadow price* $p_i^*(p_{-i}, u, z)$ is the price at which the consumer would choose z freely, so $h_i(p_i^*, p_{-i}, u) = z$. Section 5.7.2 derives two identities, their eqs. 3.12 and 3.7 (pp. 112–114):

$$e^*(p, u, z) = e(p_i^*, p_{-i}, u) + (p_i - p_i^*)z, \qquad \frac{\partial e^*}{\partial z} = p_i - p_i^*.$$

A marginal unit of the ration costs p_i, and it saves p_i^* of spending on other goods at constant utility. Their Figure 4.6 (p. 113) reads p_i^* off the tangent to the indifference curve at the rationed bundle. An unavailable good is the ration $z = 0$. When the virtual price of Definition B.73 is finite, it is the shadow price of this ration. The first identity then gives $e^*(p, u, 0) = e(p_i^V, p_{-i}, u)$, which is part (ii) of Proposition B.74. Integrating $\frac{\partial e^*}{\partial z}$ from 0 to $z^0 = h_i(p^0, u^0)$ gives

$$CV = e^*(p^0, u^0, 0) - e^*(p^0, u^0, z^0) = \int_0^{z^0} \left[p_i^*(p^0_{-i}, u^0, z) - p_i^0\right] \mathrm{d}z.$$

The integrand is the inverse compensated demand curve minus the price. The integral is therefore the area of (B.41), measured along the quantity axis. Cross derivatives of e^* give symmetry results for shadow prices that parallel Slutsky symmetry (their eqs. 3.8–3.10, pp. 113–114). Remark B.52 uses the restricted demands to show that a ration dampens the compensated price responses of the other goods.

The ratio $\frac{e(p_i^V, p_{-i}, u^0)}{e(p^0, u^0)}$ is the exact cost-of-living index that corrects for the availability of the good (Hausman, 1997, eq. 4, p. 212). It is COL at $u^R = u^0$, with the price of good i raised to its virtual price. Hausman labels the period in which the good is available as period 1. He therefore evaluates the index at the post-introduction utility u^1, as $\frac{y^*}{y}$ with $y^* = e(p_1, \ldots, p_{n-1}, p_n^*, u^1)$. Our u^0 is the utility when the good is available, so the two ratios coincide. The value of a good is the area under its compensated demand curve from the actual price up to the virtual price. Functional form therefore matters a great deal. In the AIDS a budget share reaches zero at a finite log price, so the virtual price is finite and depends on the estimated own and cross effects (Chapter 5). In the CES and logit models demand is positive at every finite price, so $p_i^V = \infty$. For the CES, the expenditure function is $e(p, u) = P(p)\,u$ with $P(p)^{1-\sigma_{\text{CES}}} = \sum_j a_j p_j^{1-\sigma_{\text{CES}}}$ and $\sigma_{\text{CES}} > 1$. Removing good i gives

$$P_{-i}^{1-\sigma_{\text{CES}}} = P^{1-\sigma_{\text{CES}}} - a_i p_i^{1-\sigma_{\text{CES}}} = P^{1-\sigma_{\text{CES}}}(1 - w_i),$$

where $w_i = a_i \left(\frac{p_i}{P}\right)^{1-\sigma_{\text{CES}}}$ is the budget share. Since e is linear in P,

$$\frac{CV}{I} = \frac{P_{-i}}{P} - 1 = (1 - w_i)^{\frac{1}{1-\sigma_{\text{CES}}}} - 1 > 0.$$

The logit analogue is $-\frac{1}{\alpha}\ln(1 - s_i)$ per consumer (Proposition B.95). In both models the loss depends only on the share and one substitution parameter. The value of variety is built into the functional form. Hausman (1997, p. 210) instead estimates a flexible demand system for cereal and finds a virtual price for Apple-Cinnamon Cheerios about twice its actual price (Chapter 10).

Proposition B.76 (Quasi-linear utility)**.** *Let there be a numeraire good* 0 *with price one, and let* $U(q_0, q) = q_0 + \tilde{u}(q)$ *with* $q \in \mathbb{R}^n_+$*. The function* $\tilde{u}$ *is twice continuously differentiable and strictly increasing, with a negative definite Hessian (hence strictly concave). Suppose the solution is interior, with* $q_0 > 0$ *and* $q \gg 0$*. Then:*

(i) Marshallian demand $q(p)$ *for goods* $1, \dots, n$ *solves* $\nabla\tilde{u}(q) = p$ *and does not depend on income, so* $\frac{\partial q_i}{\partial I} = 0$ *for* $i \geq 1$*.*

(ii) $v(p, I) = I + CS(p)$ *and* $e(p, u) = u - CS(p)$*, where* $CS(p) = \max_q\{\tilde{u}(q) - p^\top q\}$*.*

(iii) Hicksian and Marshallian demands coincide, $h(p, u) = q(p)$*, and the Slutsky matrix equals* $\frac{\partial q}{\partial p^\top} = [D^2\tilde{u}(q)]^{-1}$*.*

(iv) For any change from p^0 *to* p^1*,*

$$CV = EV = CS(p^0) - CS(p^1) = \int_0^1 \sum_{i=1}^{n} q_i(p(t))\,\dot{p}_i(t)\,\mathrm{d}t, \tag{B.42}$$

the change in Marshallian consumer surplus, along any path $p(t)$ *from* p^0 *to* p^1*.*

Proof. (i) Substitute the budget constraint $q_0 = I - p^\top q$ into utility. The consumer maximizes $I - p^\top q + \tilde{u}(q)$ over q. The first-order conditions are $\frac{\partial\tilde{u}}{\partial q_i} = p_i$, and strict concavity makes the solution unique. Income does not appear. (ii) Substituting the solution, $v(p, I) = I - p^\top q(p) + \tilde{u}(q(p)) = I + CS(p)$. Setting $v(p, e) = u$ and solving gives $e = u - CS(p)$. (iii) By the envelope theorem, $\frac{\partial CS}{\partial p_i} = -q_i(p)$. Shephard's lemma then gives $h_i = \frac{\partial e}{\partial p_i} = q_i(p)$. Differentiating the identity $\nabla\tilde{u}(q(p)) = p$ gives $D^2\tilde{u} \cdot \frac{\partial q}{\partial p^\top} = I_n$, where I_n is the identity matrix. (iv) From (ii),

$$\begin{aligned} CV &= e(p^1, u^0) - e(p^0, u^0) = CS(p^0) - CS(p^1), \\ EV &= e(p^0, u^0) - e(p^0, u^1) = u^0 - u^1 = CS(p^0) - CS(p^1). \end{aligned}$$

The line integral follows from $\nabla CS = -q$ and the fundamental theorem of calculus. It is path independent because q is a gradient. □

Proposition B.76 is the reason why welfare in discrete-choice models with utility linear in income is exact. There the utility of alternative j is $\alpha(y_i - p_j) + \tilde{\delta}_j + \epsilon_{ij}$, and every alternative has the same marginal utility of income α. The expected surplus formula of Proposition B.95 therefore measures CV and EV at once (Chapter 7, Chapter 10). The interiority condition $q_0 > 0$ matters. If the numeraire hits zero, income effects reappear.

Remark B.77 (Income effects in discrete choice). With income effects, for example utility $\alpha \ln(y_i - p_j)$ as in random-coefficients models of car demand, the marginal utility of income depends on the alternative chosen. The expected maximum utility is then not a money measure, and the compensating variation has no closed form. It must be computed consumer by consumer, by solving for the income that restores each consumer's expected utility (Chapter 10).

Remark B.78 (Aggregation). Suppose we want a representative consumer whose expenditure function is the sum of the individual ones, for every distribution of income. This is possible if and only if individual expenditure functions have the *Gorman polar form* $e_h(p, u_h) = a_h(p) + b(p)u_h$ with a common $b(p)$ (Gorman, 1953, 1961). Roy's identity gives individual demands $q_i^h = \frac{\partial a_h}{\partial p_i} + \frac{\partial \ln b}{\partial p_i}(I_h - a_h(p))$, so every household has the same marginal propensity to spend on good i, and aggregate demand depends only on total income. Quasi-linear preferences are of Gorman form, with $a_h(p) = -CS_h(p)$ and $b(p) = 1$. This is why consumer surplus can be summed across consumers in discrete-choice welfare analysis.

Deaton and Muellbauer (1980b, Section 6.1, pp. 149–153) reach the Gorman form from the demand side. Average demand depends only on average expenditure if and only if Engel curves are linear with slopes common to all households (their eq. 1.4, p. 150). With utility maximization this forces the Gorman polar form (their eq. 1.6, p. 151). Their Section 6.2 (pp. 154–157) aggregates budget shares instead. Let there be H households, write $\bar{I}$ for mean income and $\omega_h = \frac{I_h}{H\bar{I}}$ for household h's share of total income. The aggregate budget share is the income-weighted mean $\bar{w}_i = \sum_h \omega_h w_i^h$ (their eq. 2.1). Under PIGLOG preferences common to all households, Example B.69 gives $w_i^h = A_i(p) + B_i(p)\ln I_h$, with coefficients that depend only on prices. Hence

$$\bar{w}_i = A_i(p) + B_i(p)\ln I_0, \qquad \ln I_0 = \sum_h \omega_h \ln I_h.$$

A single consumer with the *representative income* I_0 reproduces the aggregate shares. Substitute $I_h = \omega_h H\bar{I}$ and use $\sum_h \omega_h = 1$:

$$\ln I_0 = \ln \bar{I} + \ln H + \sum_h \omega_h \ln \omega_h = \ln \bar{I} + \ln H - \ln Z,$$

where $\ln Z = -\sum_h \omega_h \ln \omega_h$ is Theil's entropy of the income shares, which Deaton and Muellbauer (1980b, p. 157) call an entropy measure of dispersion. So $I_0 = \frac{H}{Z}\bar{I}$, their eq. 2.15 (p. 157). The index Z reaches its maximum H when all incomes are equal. Representative income therefore exceeds mean income whenever incomes differ, and it moves with the distribution of income. The wider class of *price-independent generalized linear* (PIGL) preferences gives a similar formula (their eqs. 2.7–2.13). Sections 5.4.2 and 5.4.3 prove these results and apply them to the AIDS.

B.4.5 Producer duality

The firm's problems have the same structure as the consumer's, with one simplification: there are no income effects. A single-output firm has a production function $\varphi : \mathbb{R}^L_+ \to \mathbb{R}_+$, which is continuous and increasing. It buys inputs $x = (x_1, \ldots, x_L)$ at prices $r \in \mathbb{R}^L_{++}$ and sells output at price $p > 0$. (Here r is an input price vector, not a reserve price.) The *profit function* and the *cost function* are

$$\pi(p, r) = \max_{x \geq 0} \left\{ p\varphi(x) - r^\top x \right\}, \qquad C(r, q) = \min_{x \geq 0} \left\{ r^\top x : \varphi(x) \geq q \right\}. \tag{B.43}$$

We assume that the profit maximum exists and is attained at a unique input vector $x^*(p, r)$, with supply $q^*(p, r) = \varphi(x^*(p, r))$. This requires decreasing returns at large scale. The cost minimizer is the vector of *conditional factor demands* $x(r, q)$.

Proposition B.79 (Profit function and Hotelling's lemma, Hotelling, 1932)**.** *The profit function has the following properties.*

(i) It is homogeneous of degree one in (p, r).

(ii) It is convex in (p, r)*, nondecreasing in* p *and nonincreasing in* r.

(iii) Where it is differentiable, $\frac{\partial \pi}{\partial p} = q^*(p, r)$ *and* $\frac{\partial \pi}{\partial r_\ell} = -x^*_\ell(p, r)$.

(iv) Where it is twice continuously differentiable, $\frac{\partial q^*}{\partial p} \geq 0$, $\frac{\partial x^*_\ell}{\partial r_\ell} \leq 0$, $\frac{\partial x^*_\ell}{\partial r_m} = \frac{\partial x^*_m}{\partial r_\ell}$ *and* $\frac{\partial q^*}{\partial r_\ell} = -\frac{\partial x^*_\ell}{\partial p}$.

Proof. (i) Scaling (p, r) by $\lambda > 0$ scales the objective by λ for every x. (ii) For each x, the map $(p, r) \mapsto p\varphi(x) - r^\top x$ is linear, and the maximum of linear functions is convex. The monotonicity is immediate. (iii) Fix (p^0, r^0) and $x^0 = x^*(p^0, r^0)$. For every (p, r),

$$\pi(p, r) \geq p\varphi(x^0) - r^\top x^0,$$

with equality at (p^0, r^0). The difference between the two sides is minimized at (p^0, r^0), so its gradient vanishes there. This is the mirror image of the supporting-hyperplane proof of Shephard's lemma (Proposition 5.6). Example B.53 obtained the same result from the envelope theorem. (iv) The Hessian of π is symmetric and positive semidefinite by convexity. By (iii) its entries are $\frac{\partial^2 \pi}{\partial p^2} = \frac{\partial q^*}{\partial p}$, $\frac{\partial^2 \pi}{\partial r_\ell^2} = -\frac{\partial x^*_\ell}{\partial r_\ell}$, $\frac{\partial^2 \pi}{\partial r_\ell \partial r_m} = -\frac{\partial x^*_\ell}{\partial r_m}$ and $\frac{\partial^2 \pi}{\partial p \, \partial r_\ell} = \frac{\partial q^*}{\partial r_\ell}$. Nonnegative diagonal elements and symmetry give the four statements. □

Supply curves slope up and factor demands slope down for every technology. The consumer analogue holds only for compensated demand. The difference is the absence of an income effect.

Proposition B.80 (Cost function and Shephard's lemma for costs)**.** *The cost function has the following properties.*

(i) It is homogeneous of degree one and concave in r*, and nondecreasing in* r *and in* q.

(ii) Where it is differentiable in r, $x_\ell(r, q) = \frac{\partial C(r,q)}{\partial r_\ell}$.

(iii) Where the cost minimizer and its multiplier μ *are differentiable,* $mc(r, q) \equiv \frac{\partial C(r,q)}{\partial q} = \mu(r, q)$.

(iv) Where C *is twice continuously differentiable,* $\frac{\partial x_\ell}{\partial r_m} = \frac{\partial x_m}{\partial r_\ell}$*, the matrix* $\left[\frac{\partial x_\ell}{\partial r_m}\right]$ *is negative semidefinite, and* $\sum_m r_m \frac{\partial x_\ell}{\partial r_m} = 0$.

Proof. The cost function is the expenditure function with U replaced by φ, u by q and p by r. The proofs of Proposition 5.5, Proposition 5.6 and Proposition 5.8 apply word for word, which gives (i), (ii) and (iv). Monotonicity in q holds because a higher target shrinks the feasible set. Part (iii) is Example B.54: the partial derivative of the Lagrangian $r^\top x - \mu[\varphi(x) - q]$ with respect to q is μ, and the envelope theorem with constraints (Theorem B.50) gives the result. □

Profit maximization can be done in two steps. First minimize the cost of each output level. Then choose output to maximize $pq - C(r, q)$. At an interior optimum with C convex in q, the second step gives $p = mc(r, q^*)$, and $\pi(p, r) = \max_q \{pq - C(r, q)\}$.

Remark B.81 (Returns to scale). If φ is homogeneous of degree $B > 0$, then $C(r, q) = q^{\frac{1}{B}} C(r, 1)$. To see this, note that $\varphi(x) \geq 1$ holds if and only if $\varphi(q^{\frac{1}{B}} x) = q\varphi(x) \geq q$. The map $x \mapsto q^{\frac{1}{B}} x$ is therefore a bijection between the feasible sets for outputs 1 and q, and it multiplies cost by $q^{\frac{1}{B}}$. Marginal cost is $mc = \frac{1}{B} q^{\frac{1}{B}-1} C(r, 1)$. It is constant under constant returns ($B = 1$), rising under decreasing returns ($B < 1$) and falling under increasing returns ($B > 1$). The ratio of average to marginal cost equals B.

Example B.82 (Fixed proportions)**.** Let $\varphi(x) = \min_\ell \frac{x_\ell}{b_\ell}$ with input requirements $b_\ell > 0$. Producing q requires $x_\ell \geq b_\ell q$ for every ℓ. Any excess input raises cost because $r \gg 0$, so the cost minimizer is $x_\ell(r, q) = b_\ell q$ and

$$C(r, q) = q \sum_{\ell=1}^{L} b_\ell r_\ell, \qquad mc = \sum_{\ell=1}^{L} b_\ell r_\ell.$$

Shephard's lemma holds, $\frac{\partial C}{\partial r_\ell} = b_\ell q = x_\ell$, although φ is not differentiable. Only the differentiability of C matters, as in the supporting-hyperplane proof of Proposition 5.6. Conditional factor demands do not respond to input prices, so the substitution matrix is zero. Marginal cost is constant in output and linear in input prices. Suppose one input is a raw material with requirement k per unit of output and price p^{raw}, and the other inputs cost c_0 per unit of output. Then $mc = c_0 + k\, p^{\text{raw}}$, the form of a refiner's marginal cost used in Chapter 3.

Flexible cost functions play the role in production that flexible expenditure functions play in demand. The translog cost function of Christensen et al. (1973) specifies $\ln C(r, q)$ as a second-order polynomial in $\ln r$ and $\ln q$. Shephard's lemma in share form gives the cost shares $w_\ell^C = \frac{\partial \ln C}{\partial \ln r_\ell} = a_\ell + \sum_m \gamma_{\ell m} \ln r_m + \gamma_{\ell q} \ln q$, which are linear in logs like the AIDS share equations. Homogeneity of degree one in r requires $\sum_\ell a_\ell = 1$ and $\sum_\ell \gamma_{\ell m} = \sum_\ell \gamma_{\ell q} = 0$. Network cost functions with hub economies, as in Chapter 9, are built in the same spirit. Table B.2 collects the four problems of this section.

Table B.2: Four optimization problems and their value functions

Problem	Value	Homogeneity	Curvature	Derivative identity
UMP: $\max_q \{U(q) : p^\top q \leq I\}$	$v(p, I)$	degree 0 in (p, I)	quasi-convex in p	Roy: $q_i = -\frac{\partial v}{\partial p_i} \left[\frac{\partial v}{\partial I}\right]^{-1}$
EMP: $\min_q \{p^\top q : U(q) \geq u\}$	$e(p, u)$	degree 1 in p	concave in p	Shephard: $h_i = \frac{\partial e}{\partial p_i}$, $w_i = \frac{\partial \ln e}{\partial \ln p_i}$
Profit: $\max_x \{p\varphi(x) - r^\top x\}$	$\pi(p, r)$	degree 1 in (p, r)	convex in (p, r)	Hotelling: $q^* = \frac{\partial \pi}{\partial p}$, $x_\ell^* = -\frac{\partial \pi}{\partial r_\ell}$
Cost: $\min_x \{r^\top x : \varphi(x) \geq q\}$	$C(r, q)$	degree 1 in r	concave in r	Shephard: $x_\ell = \frac{\partial C}{\partial r_\ell}$, $mc = \frac{\partial C}{\partial q}$

Notes: UMP and EMP are the utility maximization and expenditure minimization problems. Symmetric second derivatives of each value function give Slutsky symmetry (EMP) and the reciprocity relations $\frac{\partial x_\ell}{\partial r_m} = \frac{\partial x_m}{\partial r_\ell}$ (profit and cost). Curvature gives the sign restrictions: a negative semidefinite Slutsky matrix, upward-sloping supply and downward-sloping factor demands.

B.5 Extreme value distributions and logit algebra

Discrete-choice demand rests on one distributional assumption, the type-I extreme value distribution of the idiosyncratic taste shock. This section collects everything about that

distribution and its multivariate generalization that Chapter 4, Chapter 6, Chapter 7, Chapter 8, Chapter 9, Chapter 10 and Chapter 11 use. Chapter 6 proves the core results: max-stability, the logit formula, the log-sum, the Williams-Daly-Zachary theorem and the GEV theorem. Chapter 7 proves the nested-logit formulas. We restate these results with references to their proofs, and we prove the remaining results here.

The notation is local to this section. Alternatives are $j = 0, 1, \dots, J$, with $j = 0$ the outside good. Mean utilities are δ_j, normalized by $\delta_0 = 0$ when an outside good is present. The logit denominator is $\Lambda = 1 + \sum_{k \geq 1} e^{\delta_k}$, which equals $\sum_{k=0}^{J} e^{\delta_k}$ under the normalization. The expected maximum utility is $\mathcal{W}(\delta) = \mathbb{E}[\max_j(\delta_j + \epsilon_j)]$. Euler's constant is $\gamma_E \approx 0.5772$. We never write a bare γ, which denotes AIDS coefficients. The GEV generating function is $H(y_0, \dots, y_J)$ with $y_j = e^{\delta_j}$, the nesting parameter is σ, and W_0 is the principal branch of the Lambert function. Elasticities follow the global notation: the own-price elasticity is a positive number, and cross elasticities are signed.

B.5.1 Random utility and choice probabilities

Assumption B.83 (Additive random utility)**.** Consumer i obtains utility $u_{ij} = \delta_j + \epsilon_{ij}$ from alternative $j = 0, \dots, J$ and chooses the alternative with the highest utility. The vector $\epsilon_i = (\epsilon_{i0}, \dots, \epsilon_{iJ})$ is independent of δ, has an absolutely continuous distribution F, and has finite means, $\mathbb{E}|\epsilon_{ij}| < \infty$.

The *acceptance set* of alternative j is the set of shocks for which j is chosen,

$$A_j(\delta) = \left\{\epsilon : \delta_j + \epsilon_j \geq \delta_k + \epsilon_k \text{ for all } k\right\}.$$

The choice probability, which equals the market share in a large population of consumers with independent shocks, is

$$s_j(\delta) = \mathbb{P}\big(\epsilon_i \in A_j(\delta)\big) = \int \mathbf{1}\{\epsilon \in A_j(\delta)\}\, \mathrm{d}F(\epsilon). \tag{B.44}$$

A tie between j and k requires $\epsilon_j - \epsilon_k = \delta_k - \delta_j$, a hyperplane of Lebesgue measure zero. Ties therefore have probability zero under an absolutely continuous F, the acceptance sets overlap only on a null set, and $\sum_{j=0}^{J} s_j = 1$. Consumer heterogeneity in tastes is handled by replacing δ_j with $\delta_j + \mu_{ij}$ and applying every result conditional on the consumer's type.

Proposition B.84 (Normalizations)**.** *Under Assumption B.83:*

(i) (Location) $s(\delta + c\mathbf{1}) = s(\delta)$ for every scalar c.

(ii) (Scale) The shares generated by the utilities $\lambda\delta_j + \lambda\epsilon_{ij}$ equal those generated by $\delta_j + \epsilon_{ij}$ for every $\lambda > 0$.

Proof. (i) Adding c to every δ_k leaves every inequality defining A_j unchanged. (ii) Multiplying every utility by $\lambda > 0$ preserves their ranking. □

Location invariance means that only utility differences are identified, so we set $\delta_0 = 0$. Scale invariance means that the variance of ϵ must be fixed. In the logit model it is fixed at $\frac{\pi^2}{6}$. Suppose true utility is $\tilde{\delta}_j - \alpha^* p_j + b\,\epsilon_{ij}$ with a standard Gumbel ϵ_{ij} and an unknown scale $b > 0$. Dividing by b gives an observationally equivalent model with price coefficient

$\alpha = \frac{\alpha^*}{b}$. Estimated coefficients are therefore measured relative to the scale of the shock. Ratios of coefficients, such as the willingness to pay $\frac{\beta_k}{\alpha}$ for characteristic k, are scale free.

The outside good does more than fix the location. Suppose there were no outside good and all inside prices rose by the same amount c. Every δ_j would fall by αc, and by location invariance no share would change. Aggregate demand for the category would be perfectly inelastic, and a monopolist owning every product could raise prices without limit. With an outside good whose utility is fixed at $\delta_0 = 0$, a common price increase moves consumers out of the market. The outside good also lets a new product draw consumers from not buying, which welfare analysis of new goods needs. In the data it requires a definition of the market size M, which is an assumption. Figure B.4 draws the acceptance sets with two inside goods.

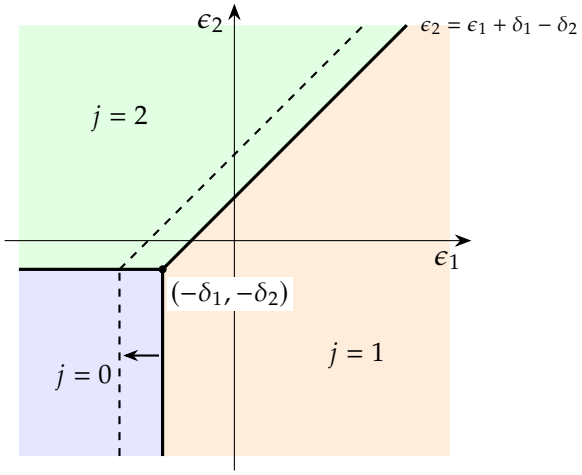

Figure B.4: Choice regions in the space of taste shocks, with two inside goods and an outside good. The shocks are measured relative to the outside good, $\epsilon_j \equiv \epsilon_{ij} - \epsilon_{i0}$. The consumer buys nothing in the lower-left quadrant. She buys good 1 to the right of the vertical boundary and below the 45-degree ray, and good 2 above the horizontal boundary and above the ray. Each share is the probability mass of its region under the joint density of the shocks. Raising δ_1 moves the corner to the left (dashed lines), and region 1 grows at the expense of both other regions. The figure uses $\delta_1 = 1$ and $\delta_2 = 0.4$.

B.5.2 The Gumbel distribution

Definition B.85 (Type-I extreme value distribution)**.** A random variable has the *type-I extreme value* (or *Gumbel*) distribution $\mathrm{EV}(a, b)$, with location $a \in \mathbb{R}$ and scale $b > 0$, if its CDF and density are

$$F(x) = \exp\left(-e^{-\frac{x-a}{b}}\right), \qquad f(x) = \frac{1}{b}\, e^{-\frac{x-a}{b}} \exp\left(-e^{-\frac{x-a}{b}}\right). \tag{B.45}$$

The *standard* Gumbel distribution has $a = 0$ and $b = 1$, with CDF $F_{\mathrm{EV}}(\epsilon) = \exp(-e^{-\epsilon})$ and density $e^{-\epsilon}\exp(-e^{-\epsilon})$.

If ϵ is standard Gumbel, then $a + b\epsilon \sim \mathrm{EV}(a, b)$. Every fact about $\mathrm{EV}(a, b)$ therefore follows from the standard case.

Lemma B.86 (Gumbel from exponential)**.** *If E has the unit exponential distribution, $\mathbb{P}(E > t) = e^{-t}$ for $t \geq 0$, then $-\ln E$ is standard Gumbel. If U is uniform on $(0, 1)$, then $-\ln(-\ln U)$ is standard Gumbel.*

Proof. For every x,

$$\mathbb{P}(-\ln E \le x) = \mathbb{P}(\ln E \ge -x) = \mathbb{P}(E \ge e^{-x}) = \exp(-e^{-x}).$$

For the second claim, $-\ln U$ is unit exponential because $\mathbb{P}(-\ln U > t) = \mathbb{P}(U < e^{-t}) = e^{-t}$. This is also the probability integral transform (Lemma B.19) applied to the inverse CDF $F_{\mathrm{EV}}^{-1}(u) = -\ln(-\ln u)$. □

Proposition B.87 (Moments and shape)**.** *Let ϵ be standard Gumbel. Then $\mathbb{E}[\epsilon] = \gamma_E$, $\mathrm{Var}(\epsilon) = \frac{\pi^2}{6}$, the mode is 0 and the median is $-\ln\ln 2 \approx 0.367$. The distribution is skewed to the right, with skewness about 1.14. For $\mathrm{EV}(a, b)$ the mean is $a + b\gamma_E$ and the variance is $\frac{b^2\pi^2}{6}$.*

Proof. By Lemma B.86 write $\epsilon = -\ln E$. For $t < 1$ the moment generating function is

$$\mathbb{E}\left[e^{t\epsilon}\right] = \mathbb{E}\left[E^{-t}\right] = \int_0^\infty x^{-t} e^{-x}\,\mathrm{d}x = \Gamma(1-t),$$

where Γ is the gamma function. We use two standard facts about it, $\Gamma'(1) = -\gamma_E$ and $\Gamma''(1) = \gamma_E^2 + \frac{\pi^2}{6}$. The first two moments are

$$\mathbb{E}[\epsilon] = \frac{\mathrm{d}}{\mathrm{d}t}\Gamma(1-t)\Big|_{t=0} = -\Gamma'(1) = \gamma_E, \qquad \mathbb{E}[\epsilon^2] = \Gamma''(1) = \gamma_E^2 + \frac{\pi^2}{6},$$

so $\mathrm{Var}(\epsilon) = \frac{\pi^2}{6}$. The density has derivative $f'(x) = f(x)(e^{-x} - 1)$, which is positive for $x < 0$ and negative for $x > 0$, so the mode is 0. The median solves $\exp(-e^{-m}) = \frac{1}{2}$, which gives $m = -\ln\ln 2$. The skewness equals $\frac{12\sqrt{6}\,\zeta(3)}{\pi^3} \approx 1.14$, where ζ is the Riemann zeta function. We state this value without proof. The location and scale results follow from $a + b\epsilon \sim \mathrm{EV}(a, b)$. □

Remark B.88 (Why "extreme value"). The Gumbel distribution is a limit law for maxima. Let $X_1, \dots, X_n$ be independent unit exponential draws and $X_{(n:n)}$ their maximum (Section B.6). For $x > -\ln n$,

$$\mathbb{P}\left(X_{(n:n)} - \ln n \le x\right) = \left(1 - e^{-x-\ln n}\right)^n = \left(1 - \frac{e^{-x}}{n}\right)^n \longrightarrow \exp(-e^{-x}).$$

More generally, the centered and scaled maximum of independent draws from any distribution with exponential-type tails, the normal included, converges to a Gumbel (Fisher and Tippett, 1928; Gnedenko, 1943). If the taste shock is read as the best of many independent unobserved attributes, this offers a heuristic justification. The real attraction of the distribution is the closed forms it delivers.

B.5.3 Max-stability and the logit formula

The Gumbel family is closed under maxima with a common scale. This single property delivers the logit formula, the log-sum and the nested logit.

Proposition B.89 (Max-stability)**.** *Let $\epsilon_0, \dots, \epsilon_J$ be independent $\mathrm{EV}(0, b)$ and let $\delta_0, \dots, \delta_J$ be constants. Then*

$$\max_j(\delta_j + \epsilon_j) \sim \mathrm{EV}\left(b \ln \sum_{j=0}^{J} e^{\frac{\delta_j}{b}},\ b\right). \tag{B.46}$$

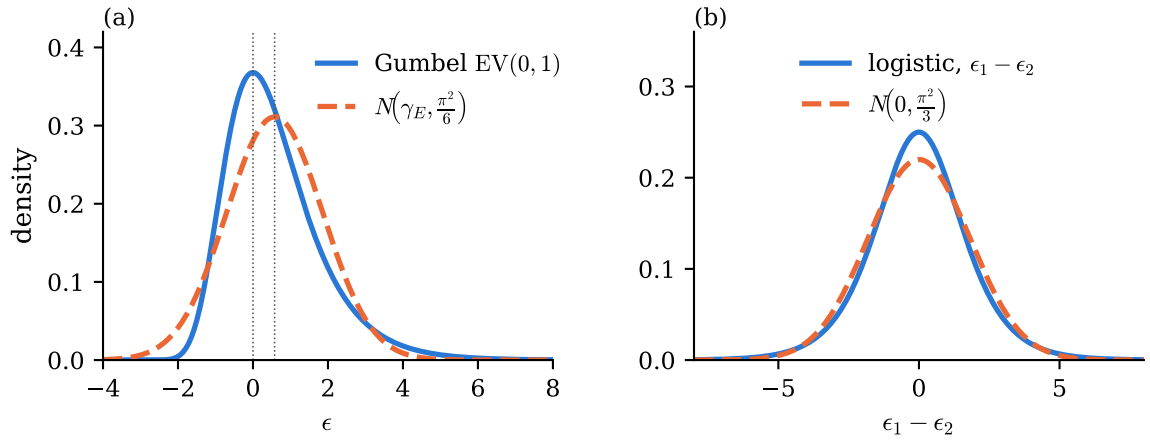

Figure B.5: Panel (a): the standard Gumbel density and the normal density with the same mean γ_E and variance $\frac{\pi^2}{6}$. The dotted lines mark the mode 0 and the mean γ_E. The Gumbel is skewed to the right. Panel (b): the standard logistic density, which is the density of the difference of two independent standard Gumbels (Proposition B.90), and the normal density with mean 0 and variance $\frac{\pi^2}{3}$. The logistic is symmetric and close to the normal, with slightly fatter tails.

Lemma 6.9 proves the case $b = 1$, and the text after it extends the proof to scale b. The proof multiplies the independent Gumbel CDFs $\exp(-e^{-\frac{x-\delta_j}{b}})$ and collects the exponents.

Proposition B.90 (Logistic differences)**.** *If ϵ_1 and ϵ_2 are independent standard Gumbels, then $\epsilon_1 - \epsilon_2$ has the standard logistic distribution,*

$$\mathbb{P}(\epsilon_1 - \epsilon_2 \le x) = \frac{1}{1 + e^{-x}},$$

with density $\frac{e^{-x}}{(1+e^{-x})^2}$, mean zero and variance $\frac{\pi^2}{3}$.

Lemma 6.10 proves the result by conditioning on ϵ_2 and substituting $t = e^{-\epsilon_2}$.

Theorem B.91 (Multinomial logit, McFadden, 1974)**.** *Let $u_{ij} = \delta_j + \epsilon_{ij}$ with $\epsilon_{i0}, \ldots, \epsilon_{iJ}$ independent standard Gumbels. Then*

$$s_j(\delta) = \frac{e^{\delta_j}}{\sum_{k=0}^{J} e^{\delta_k}} = \frac{e^{\delta_j}}{1 + \sum_{k=1}^{J} e^{\delta_k}} \quad \text{when } \delta_0 = 0. \tag{B.47}$$

With EV$(0, b)$ *shocks,*

$$s_j(\delta) = \frac{\exp\left(\frac{\delta_j}{b}\right)}{\sum_{k=0}^{J} \exp\left(\frac{\delta_k}{b}\right)}.$$

McFadden (1984, eqs. 3.14–3.15, pp. 1411–1412) states the result and notes that it follows by a straightforward integration. Proposition 6.11 gives two proofs. The first carries out that integration, conditioning on ϵ_{ij} and substituting $t = e^{-\epsilon_{ij}}$. The second combines the two previous propositions. By Proposition B.89, the best rival utility is $\ln \sum_{k \neq j} e^{\delta_k}$ plus a standard

Gumbel shock independent of ϵ_{ij}. By Proposition B.90, the difference of the two shocks is logistic.

The scale b governs how deterministic choice is. As $b \to 0$, the alternative with the highest δ_j is chosen with probability one. As $b \to \infty$, all shares tend to $\frac{1}{J+1}$.

Proposition B.92 (The chosen maximum)**.** *In the logit model of Theorem B.91, with* $\Lambda = \sum_{k=0}^{J} e^{\delta_k}$,

$$\mathbb{P}\Big(\max_k u_{ik} \le x,\ j \text{ chosen} \Big) = s_j \exp\big(- e^{-x} \Lambda \big). \tag{B.48}$$

Hence the distribution of the maximal utility conditional on choosing j *is* $\mathrm{EV}(\ln \Lambda, 1)$ *for every* j*, the identity of the chosen alternative is independent of the maximal utility, and*

$$\mathbb{E}\big[\epsilon_{ij} \mid j \text{ chosen} \big] = \gamma_E - \ln s_j. \tag{B.49}$$

Proof. By Proposition 6.13, the joint probability factors as $s_j \mathbb{P}(\max_k u_{ik} \le x)$, which is (6.22). Its proof repeats the direct integration of Proposition 6.11 with the extra restriction $\delta_j + \epsilon_{ij} \le x$. By Proposition B.89, $\mathbb{P}(\max_k u_{ik} \le x) = \exp(-e^{-x}\Lambda)$, which gives (B.48). Dividing by s_j gives the conditional CDF $\exp(-e^{-(x - \ln \Lambda)})$, which does not depend on j. Its mean is $\ln \Lambda + \gamma_E$. On the event that j is chosen, $\epsilon_{ij} = \max_k u_{ik} - \delta_j$, so $\mathbb{E}[\epsilon_{ij} \mid j \text{ chosen}] = \ln \Lambda + \gamma_E - \delta_j = \gamma_E - \ln s_j$. □

Equation (B.49) quantifies selection. Consumers who choose a product with a small share have, on average, a large taste shock for it. Corrections for selection in models that combine a discrete choice with a continuous outcome use this formula (Dubin and McFadden, 1984). The independence of the winner and the winning value is also the key step in the nest-by-nest derivation of the nested logit (Proposition B.107).

Independence of irrelevant alternatives (IIA) is the property that the ratio of two choice probabilities does not depend on any third alternative. From (B.47),

$$\frac{s_j}{s_k} = e^{\delta_j - \delta_k}, \tag{B.50}$$

which is equation (3.17) of McFadden (1984, p. 1413). Two implications follow. Choice probabilities on a smaller or larger choice set are obtained by deleting or adding terms in the denominator. The cross elasticity of every alternative with respect to an attribute of k is the same (McFadden, 1984, p. 1414). The classic illustration is the red bus and the blue bus. A commuter chooses between a car and a red bus with equal mean utilities, so each share is $\frac{1}{2}$. Add a blue bus identical to the red one. IIA keeps the ratio of car to red bus at one, so logit predicts shares of $\frac{1}{3}$ each. Common sense predicts $\frac{1}{2}$ for the car and $\frac{1}{4}$ for each bus. IIA is a property of independent shocks across alternatives. Independent normal shocks produce similar substitution patterns, because they too contain no notion of similarity between products. The remedy is correlation across alternatives, through nests (Section B.5.7) or random coefficients (Chapter 8). IIA can be tested by comparing estimates from the full and a restricted choice set (Hausman and McFadden, 1984).

B.5.4 Expected maximum utility and consumer surplus

Proposition B.93 (Log-sum formula)**.** *In the logit model of Theorem B.91,*

$$\mathcal{W}(\delta) = \mathbb{E}\Big[\max_j (\delta_j + \epsilon_{ij}) \Big] = \ln \sum_{j=0}^{J} e^{\delta_j} + \gamma_E = \ln \Lambda + \gamma_E. \tag{B.51}$$

Proposition 6.13 proves the formula. By Proposition B.89 with $b = 1$ the maximum is $\mathrm{EV}(\ln \Lambda, 1)$, and its mean is $\ln \Lambda + \gamma_E$ by Proposition B.87.

The quantity $\ln \Lambda$ is the *inclusive value* of the choice set. The next theorem shows that the gradient of the expected maximum utility is the vector of choice probabilities in every additive random utility model. The logit is one instance.

Theorem B.94 (Williams-Daly-Zachary, Williams, 1977; Daly and Zachary, 1978; McFadden, 1981)**.** *Under Assumption B.83, the function $\mathcal{W}(\delta) = \mathbb{E}[\max_k(\delta_k + \epsilon_{ik})]$ is finite, convex and continuously differentiable, and*

$$\frac{\partial \mathcal{W}(\delta)}{\partial \delta_j} = s_j(\delta), \qquad j = 0, \ldots, J. \tag{B.52}$$

Theorem 6.7 proves finiteness, convexity and (B.52). Off the tie set, which has probability zero, a small change in δ_j does not change the maximizer. The pointwise derivative of $\max_k(\delta_k + \epsilon_k)$ is therefore the indicator that j is chosen. The difference quotients are bounded by one, and dominated convergence moves the derivative inside the expectation. The one addition is continuity of the derivative.

Proof of continuous differentiability. Let $\delta' \to \delta$. The indicator of $A_j(\delta')$ converges to the indicator of $A_j(\delta)$ at every ϵ off the boundary of $A_j(\delta)$, which is a null set. Indicators are bounded by one, so dominated convergence gives $s_j(\delta') \to s_j(\delta)$. The gradient of $\mathcal{W}$ is therefore continuous. □

The theorem is an envelope theorem: the derivative of a maximum with respect to a parameter is the derivative of the chosen term (Section B.3). Four consequences follow.

(a) (Symmetry) Where s is differentiable, $\frac{\partial s_j}{\partial \delta_k} = \frac{\partial^2 \mathcal{W}}{\partial \delta_k \partial \delta_j} = \frac{\partial s_k}{\partial \delta_j}$ in every additive random utility model.

(b) (Positive semidefiniteness) The Jacobian $\frac{\partial s}{\partial \delta^\top}$ is the Hessian of a convex function, hence positive semidefinite. In particular $\frac{\partial s_j}{\partial \delta_j} \geq 0$.

(c) (Translation) $\mathcal{W}(\delta + c\mathbf{1}) = \mathcal{W}(\delta) + c$. Differentiating in c gives $\sum_j s_j = 1$.

(d) (Roy's identity) Let $\delta_j = \alpha(y - p_j) + \tilde{\delta}_j$ for $j \geq 1$ and $\delta_0 = \alpha y$. Then $\frac{\partial \mathcal{W}}{\partial p_j} = -\alpha s_j$ and $\frac{\partial \mathcal{W}}{\partial y} = \alpha$, so $s_j = -\frac{\partial \mathcal{W}}{\partial p_j}\left[\frac{\partial \mathcal{W}}{\partial y}\right]^{-1}$, the analogue of (B.32) with $\mathcal{W}$ as the indirect utility function.

For the logit, $\frac{\partial}{\partial \delta_j} \ln \sum_k e^{\delta_k} = \frac{e^{\delta_j}}{\sum_k e^{\delta_k}} = s_j$, which checks (B.52) against (B.51).

Proposition B.95 (Logit consumer surplus, Small and Rosen, 1981)**.** *Let $u_{ij} = \alpha(y_i - p_j) + \tilde{\delta}_j + \epsilon_{ij}$ for $j \geq 1$ and $u_{i0} = \alpha y_i + \epsilon_{i0}$, with independent standard Gumbel shocks and $\alpha > 0$. Write $\delta_j = \tilde{\delta}_j - \alpha p_j$. Then the expected consumer surplus in money is*

$$CS_i = \frac{1}{\alpha} \ln\left(1 + \sum_{k=1}^{J} e^{\delta_k}\right) + C, \tag{B.53}$$

where C is a constant that cancels in comparisons. For a change from δ^0 to δ^1, the expectation of each consumer's exact compensating variation is $\frac{1}{\alpha}\left(\ln \Lambda^1 - \ln \Lambda^0\right)$, where $\Lambda^s = 1 + \sum_{k \geq 1} e^{\delta_k^s}$.

Section 6.2.4 proves the general formula (6.12), and Section 6.3.3 evaluates it for the logit. Income enters every alternative with the same coefficient, so each consumer's compensating variation is $\frac{1}{\alpha}$ times the change in her maximal utility. Taking expectations with Proposition B.93 gives the result. This CV is a gain measure, positive when the consumer is better off, which is the opposite sign convention to Definition B.72.

The utility is quasi-linear in income, so Proposition B.76 applies. No income effects arise, and the compensating and equivalent variations coincide. With market size M, the aggregate change is $\frac{M}{\alpha}(\ln \Lambda^1 - \ln \Lambda^0)$. With random coefficients, each consumer type i has its own price coefficient α_i and inclusive value $\ln \Lambda_i$, and $\Delta CS = M \int \frac{1}{\alpha_i}(\ln \Lambda_i^1 - \ln \Lambda_i^0)\, dF(\nu_i)$ (Chapter 8, Chapter 11).

Corollary B.96 (Value of a product)**.** *In the setting of Proposition B.95:*

(i) Adding a product n with mean utility δ_n raises expected surplus by

$$\Delta CS = \frac{1}{\alpha} \ln\left(1 + \frac{e^{\delta_n}}{\Lambda^0}\right) = -\frac{1}{\alpha} \ln(1 - s_n), \tag{B.54}$$

where $s_n = \frac{e^{\delta_n}}{\Lambda^0 + e^{\delta_n}}$ is the share of the product after its introduction. Removing a product with share s_n costs the same amount.

(ii) A perfect clone of an existing product j, with $\delta_n = \delta_j$, adds $\frac{1}{\alpha} \ln\left(1 + \frac{e^{\delta_j}}{\Lambda^0}\right) > 0$.

(iii) With J identical products of mean utility δ, $CS = \frac{1}{\alpha} \ln(1 + Je^{\delta}) + C$, which grows like $\frac{1}{\alpha} \ln J$ without bound.

Proof. (i) $\Lambda^1 = \Lambda^0 + e^{\delta_n}$, so $\ln \Lambda^1 - \ln \Lambda^0 = \ln\left(1 + \frac{e^{\delta_n}}{\Lambda^0}\right)$. Since $\frac{\Lambda^0}{\Lambda^1} = 1 - s_n$, the same quantity equals $-\ln(1 - s_n)$. (ii) Set $\delta_n = \delta_j$ in (i). (iii) Here $\Lambda = 1 + Je^{\delta}$ and $\ln(1 + Je^{\delta}) = \ln J + \delta + \ln(1 + \frac{e^{-\delta}}{J})$. □

The corollary is the formal content of the statement that the logit shock never exhausts the product space. Every product arrives with its own independent taste draw, so every product, even a duplicate, attracts consumers who value it highly and adds surplus. The same feature bounds logit markups below by $\frac{1}{\alpha}$ (Proposition B.97). It biases upward the estimated value of new goods and the markups in crowded markets (Chapter 6, Chapter 10). The mirror image concerns data. The model predicts a positive share for every product, so the inversion $\ln s_j - \ln s_0$ is undefined for a product with zero observed sales, and such products carry no information in the logit. If the shocks represent mistakes or psychological biases rather than tastes, the log-sum counts them as welfare. The pure characteristics model removes the shock altogether, and the nested logit shrinks the value of a clone as within-nest correlation rises (Remark B.109).

In computation, $\ln \sum_{k=0}^{J} e^{\delta_k}$ overflows when some δ_k is large. Let $c = \max\{0, \max_k \delta_k\}$, where the zero is the outside good. Then evaluate

$$\ln \sum_{k=0}^{J} e^{\delta_k} = c + \ln \sum_{k=0}^{J} e^{\delta_k - c}, \tag{B.55}$$

in which every exponent is at most zero. The same shift stabilizes the share formula.

B.5.5 Logit derivatives, Jacobians and markups

With $s_j = \frac{e^{\delta_j}}{\Lambda}$ and $\Lambda = 1 + \sum_k e^{\delta_k}$, the quotient rule gives the derivatives that Example B.25 computed. We collect them in three equivalent forms,

$$\frac{\partial s_j}{\partial \delta_k} = s_j\big(\mathbf{1}\{j = k\} - s_k\big), \qquad \frac{\partial \ln s_j}{\partial \delta_k} = \mathbf{1}\{j = k\} - s_k, \qquad \frac{\partial s}{\partial \delta^\top} = \operatorname{diag}(s) - ss^\top, \tag{B.56}$$

where $s = (s_1, \dots, s_J)^\top$ collects the inside shares. The Jacobian is symmetric, as Theorem B.94 requires. Its row sums are $\sum_{k \geq 1} \frac{\partial s_j}{\partial \delta_k} = s_j(1 - \sum_k s_k) = s_j s_0 > 0$. The derivative with respect to the outside good is $-s_j s_0$, so the full row sums to zero, as translation invariance requires (Corollary B.10). The Jacobian is invertible, and the Sherman-Morrison formula gives its inverse $\operatorname{diag}(\frac{1}{s_1}, \dots, \frac{1}{s_J}) + \frac{1}{s_0}\mathbf{1}\mathbf{1}^\top$ in (B.11). Inverting the shares themselves is easier still: $\frac{s_j}{s_0} = e^{\delta_j}$ gives $\delta_j = \ln s_j - \ln s_0$, the inversion of Berry (1994) that Chapter 7 turns into a linear instrumental variables regression.

With $\delta_j = \tilde{\delta}_j - \alpha p_j$, the chain rule gives the price derivatives $\frac{\partial s_j}{\partial p_j} = -\alpha s_j(1 - s_j)$ and $\frac{\partial s_j}{\partial p_k} = \alpha s_j s_k$. The own-price elasticity and the cross elasticities are

$$\varepsilon_j = -\frac{\partial s_j}{\partial p_j}\frac{p_j}{s_j} = \alpha p_j(1 - s_j), \qquad \varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j} = \alpha p_k s_k \quad (k \neq j). \tag{B.57}$$

The own elasticity is nearly proportional to price when shares are small, so the model predicts that expensive products face the most elastic demand. The cross elasticity with respect to p_k is the same for every j, whatever the similarity of j and k. The diversion ratio from j to k is

$$D_{jk} = -\frac{\partial s_k}{\partial p_j}\left[\frac{\partial s_j}{\partial p_j}\right]^{-1} = \frac{\alpha s_j s_k}{\alpha s_j(1 - s_j)} = \frac{s_k}{1 - s_j}, \qquad D_{j0} = \frac{s_0}{1 - s_j}. \tag{B.58}$$

Customers who leave j spread over the other alternatives in proportion to their shares, and the diversion ratios sum to one.

Proposition B.97 (Logit markups)**.** *Let firms set prices in a Bertrand-Nash equilibrium with constant marginal costs and logit demand, and write $m_j = p_j - mc_j$.*

(i) A single-product firm sets $m_j = \frac{1}{\alpha(1 - s_j)}$.

(ii) A firm f that owns the products $\mathcal{J}_f$, with combined share $S_f = \sum_{k \in \mathcal{J}_f} s_k$, sets the common markup $m_j = m_f = \frac{1}{\alpha(1 - S_f)}$ on all its products.

(iii) A single owner of all inside goods sets the common markup $\frac{1}{\alpha s_0}$.

In every case $m_j > \frac{1}{\alpha}$.

Proof. (ii) The profit of firm f is $\sum_{k \in \mathcal{J}_f} m_k s_k(p)$. For $j \in \mathcal{J}_f$, the first-order condition is

$$0 = s_j + \sum_{k \in \mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} = s_j - \alpha m_j s_j(1 - s_j) + \sum_{k \in \mathcal{J}_f, k \neq j} \alpha m_k s_k s_j = s_j\Big[1 - \alpha m_j + \alpha \sum_{k \in \mathcal{J}_f} m_k s_k\Big].$$

Dividing by $s_j > 0$ gives $m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} m_k s_k$. The right side does not depend on j, so all products of the firm carry the same markup m_f. Substituting $m_k = m_f$ gives $m_f = \frac{1}{\alpha} + S_f m_f$, hence $m_f = \frac{1}{\alpha(1 - S_f)}$. (i) is the case $\mathcal{J}_f = \{j\}$. (iii) is the case $S_f = 1 - s_0$. Each markup exceeds $\frac{1}{\alpha}$ because $S_f < 1$. □

Example B.25 reaches the same three formulas from the matrix condition $m = -(\Omega \odot \Delta^\top)^{-1} s$, by inverting each block of the logit Jacobian with the Sherman-Morrison formula.

The first-order condition of a single-product firm is also sufficient. Write $\frac{\partial \pi_j}{\partial p_j} = s_j \, g(m_j)$ with $g(m) = 1 - \alpha m(1 - s_j)$, where s_j depends on m through p_j. For $m \le 0$ we have $g > 0$. For $m > 0$, g is strictly decreasing, because both αm and $1 - s_j$ rise with p_j, and $g \to -\infty$ as $m \to \infty$. The derivative of profit therefore changes sign exactly once, from positive to negative, and the stationary point is the unique maximizer. The best response has a closed form in terms of the Lambert function.

Lemma B.98 (Lambert function, Corless et al., 1996)**.** *For every $z \ge 0$, the equation $we^w = z$ has exactly one solution $w \ge 0$, denoted $W_0(z)$. The function W_0 is strictly increasing on $[0, \infty)$, with $W_0(0) = 0$ and $W_0(e) = 1$, and for $z > 0$*

$$W_0'(z) = \frac{W_0(z)}{z\,(1 + W_0(z))}. \tag{B.59}$$

Proof. The map $g(w) = we^w$ is continuous on $[0, \infty)$ with $g(0) = 0$, $g(w) \to \infty$ and $g'(w) = (1 + w)e^w > 0$. By the intermediate value theorem and strict monotonicity, each $z \ge 0$ has exactly one preimage, and the inverse is strictly increasing. Since $1 \cdot e^1 = e$, $W_0(e) = 1$. By the inverse function theorem,

$$W_0'(z) = \frac{1}{g'(W_0(z))} = \frac{1}{(1 + W_0(z))e^{W_0(z)}} = \frac{W_0(z)}{z\,(1 + W_0(z))},$$

where the last step uses $e^{W_0(z)} = \frac{z}{W_0(z)}$ for $z > 0$. □

The principal branch extends to $z \ge -\frac{1}{e}$, but we only need $z > 0$. Standard numerical libraries evaluate it.

Proposition B.99 (Logit best response)**.** *Let firm j sell one product with logit demand, $\delta_j = \tilde{\delta}_j - \alpha p_j$, and constant marginal cost mc_j. Define the mean utility at marginal-cost pricing, $v_j = \tilde{\delta}_j - \alpha mc_j$, and the part of the logit denominator that rivals control, $\Lambda_{-j} = 1 + \sum_{l \ne j} e^{\delta_l}$. Then the unique best response to the rivals' prices is*

$$BR_j(p_{-j}) = mc_j + \frac{1}{\alpha}\left[1 + W_0\left(\frac{e^{v_j - 1}}{\Lambda_{-j}}\right)\right]. \tag{B.60}$$

At the best response, with W_0 evaluated at $z_j = \frac{e^{v_j - 1}}{\Lambda_{-j}}$,

$$s_j = \frac{W_0(z_j)}{1 + W_0(z_j)}, \qquad \frac{e^{\delta_l}}{\Lambda_{-j}} = \frac{s_l}{1 - s_j} \quad (l \ne j). \tag{B.61}$$

For a multiproduct firm f with $E_f = \sum_{k \in \mathcal{J}_f} e^{v_k}$ and $\Lambda_{-f} = 1 + \sum_{l \notin \mathcal{J}_f} e^{\delta_l}$, the best-response common markup is $m_f = \frac{1}{\alpha}\left[1 + W_0\left(\frac{E_f e^{-1}}{\Lambda_{-f}}\right)\right]$.

Proof. By Proposition B.97 and the single-crossing argument above, the best response is the unique solution of $\alpha m_j(1 - s_j) = 1$. Write $\delta_j = v_j - \alpha m_j$ and $1 - s_j = \frac{\Lambda_{-j}}{\Lambda_{-j} + e^{\delta_j}}$. The condition becomes

$$\alpha m_j \Lambda_{-j} = \Lambda_{-j} + e^{v_j - \alpha m_j} \quad \Longleftrightarrow \quad (\alpha m_j - 1)\Lambda_{-j} = e^{v_j - \alpha m_j}.$$

Let $w = \alpha m_j - 1$. Then $w\Lambda_{-j} = e^{v_j - 1 - w}$, that is,

$$we^w = \frac{e^{v_j - 1}}{\Lambda_{-j}} = z_j > 0.$$

Any solution has $w > 0$, because the right side is positive. By Lemma B.98, $w = W_0(z_j)$, and $m_j = \frac{1 + W_0(z_j)}{\alpha}$, which is (B.60). At the best response the first-order condition gives $1 - s_j = \frac{1}{\alpha m_j} = \frac{1}{1 + W_0(z_j)}$, which yields the first identity in (B.61). For the second, $\frac{\Lambda_{-j}}{\Lambda} = 1 - s_j$ with $\Lambda = \Lambda_{-j} + e^{\delta_j}$, so $\frac{e^{\delta_l}}{\Lambda_{-j}} = \frac{e^{\delta_l}}{\Lambda} \cdot \frac{\Lambda}{\Lambda_{-j}} = \frac{s_l}{1 - s_j}$. For the multiproduct firm, the common-markup condition $\alpha m_f (1 - S_f) = 1$ with $1 - S_f = \frac{\Lambda_{-f}}{\Lambda_{-f} + E_f e^{-\alpha m_f}}$ gives $(\alpha m_f - 1)\Lambda_{-f} = E_f e^{-\alpha m_f}$, and the same substitution yields $we^w = \frac{E_f e^{-1}}{\Lambda_{-f}}$. □

The best response rises with every rival price, because Λ_{-j} falls and W_0 is increasing. Prices are strategic complements. Section B.7 differentiates (B.60) with (B.59) and (B.61) to show that best-response iteration is a contraction, so the logit pricing equilibrium is unique.

Remark B.100 (Mixed logit). In the random-coefficients (mixed) logit, conditional on the consumer's taste draw ν_i the choice probabilities s_{ij} are logit, and every formula of this subsection holds consumer by consumer. Aggregate shares and derivatives are integrals, for example $\frac{\partial s_j}{\partial p_k} = \int \alpha_i s_{ij} \big(s_{ik} - \mathbf{1}\{j = k\}\big)\, \mathrm{d}F(\nu_i)$, where differentiation under the integral is justified by Proposition B.15. Aggregate cross derivatives are large when the same consumers are likely to buy both products, so substitution depends on characteristics. Markups are no longer common within a firm. McFadden and Train (2000) show that any random utility model can be approximated arbitrarily well by a mixed logit (Chapter 8).

B.5.6 Representative-consumer foundations

The logit can also be derived from a single consumer who likes variety.

Proposition B.101 (Entropy representative consumer, Anderson et al., 1988a, 1992)**.** *Let $\delta_0, \dots, \delta_J$ be given, with $\delta_j = \tilde{\delta}_j - \alpha p_j$ and $\delta_0 = 0$. The problem*

$$\max_{q_0, \dots, q_J \geq 0} \sum_{j=0}^{J} \delta_j q_j - \sum_{j=0}^{J} q_j \ln q_j \qquad \textit{subject to} \qquad \sum_{j=0}^{J} q_j = 1 \tag{B.62}$$

has the unique solution $q_j = \frac{e^{\delta_j}}{\sum_k e^{\delta_k}}$, the logit shares. Its maximized value is $\ln \sum_k e^{\delta_k}$.

Proposition 4.46 proves the result. Strict concavity of $-q \ln q$ gives a unique maximizer, its infinite slope at zero makes the maximizer interior, and the first-order conditions $\delta_j - \ln q_j - 1 - \lambda = 0$ give the logit shares.

The entropy term $-\sum_j q_j \ln q_j$ rewards spreading consumption across products, a taste for variety. The maximized value equals the log-sum of (B.51) without the constant γ_E, so the representative consumer and the population of random-utility consumers agree on welfare. In the language of convex analysis, the log-sum is the convex conjugate of negative entropy on the simplex. Weighting the entropy term by $b > 0$ gives the logit with scale b, and as $b \to 0$ the consumer buys only the product with the highest δ_j.

Remark B.102 (Logit and CES). CES expenditure shares are logit shares in log prices. With the CES price index $P^{1-\sigma_{\text{CES}}} = \sum_k a_k p_k^{1-\sigma_{\text{CES}}}$, the budget share of good j is $w_j = \frac{a_j p_j^{1-\sigma_{\text{CES}}}}{\sum_k a_k p_k^{1-\sigma_{\text{CES}}}}$ (Chapter 4). Setting $\delta_j = \ln a_j - (\sigma_{\text{CES}} - 1)\ln p_j$ in (B.47) without an outside good gives

$$s_j = \frac{e^{\ln a_j - (\sigma_{\text{CES}}-1)\ln p_j}}{\sum_k e^{\ln a_k - (\sigma_{\text{CES}}-1)\ln p_k}} = \frac{a_j p_j^{1-\sigma_{\text{CES}}}}{\sum_k a_k p_k^{1-\sigma_{\text{CES}}}} = w_j.$$

The coefficient on log price, $\sigma_{\text{CES}} - 1$, plays the role of the logit price coefficient, and the CES inherits IIA. Anderson et al. (1987) give a discrete-choice foundation. Suppose each consumer buys one variety and spends all income y on it, with conditional indirect utility $\ln y - \ln p_j + \ln \tilde{a}_j + \mu \epsilon_{ij}$ and standard Gumbel shocks scaled by $\mu > 0$. The choice probabilities are logit in $\frac{\ln \tilde{a}_j - \ln p_j}{\mu}$, and expected demand for j is the choice probability times $\frac{y}{p_j}$. This is CES demand with $\sigma_{\text{CES}} = 1 + \frac{1}{\mu}$ and weights $a_j = \tilde{a}_j^{\sigma_{\text{CES}}-1}$. The subscript keeps σ free for the nesting parameter.

B.5.7 Generalized extreme value models

The generalized extreme value (GEV) class of McFadden (1978) keeps closed-form choice probabilities while allowing the shocks to be correlated across alternatives. Its key object is a generating function.

Theorem B.103 (GEV models, McFadden, 1978)**.** *Let $H : \mathbb{R}_+^{J+1} \to \mathbb{R}_+$ satisfy three conditions:*

(G1) H is nonnegative and homogeneous of degree one.

(G2) $H(y_0, \dots, y_J) \to \infty$ as any single argument $y_j \to \infty$.

(G3) For every set of m distinct arguments, the mixed partial derivative of H with respect to them is nonnegative when m is odd and nonpositive when m is even.

Then $F(\epsilon_0, \dots, \epsilon_J) = \exp\{-H(e^{-\epsilon_0}, \dots, e^{-\epsilon_J})\}$ is a multivariate extreme value CDF. Let $u_{ij} = \delta_j + \epsilon_{ij}$ with $\epsilon_i \sim F$ and $y_j = e^{\delta_j}$. Then:

(i) $\mathbb{P}(\max_j u_{ij} \le x) = \exp\{-e^{-x} H(y)\}$, so the maximal utility is $\text{EV}(\ln H(y), 1)$. Expected maximum utility is

$$\mathcal{W}(\delta) = \ln H\left(e^{\delta_0}, \dots, e^{\delta_J}\right) + \gamma_E. \tag{B.63}$$

(ii) The choice probabilities are

$$s_j = \frac{\partial \ln H(e^{\delta_0}, \dots, e^{\delta_J})}{\partial \delta_j} = \frac{y_j H_j(y)}{H(y)}, \tag{B.64}$$

where H_j is the partial derivative of H with respect to its j-th argument.

McFadden (1984, eqs. 3.29–3.31, p. 1421) states the theorem in this form. The first claim, that (G1) to (G3) make F a valid distribution function, is due to McFadden (1978). Condition (G3) makes the mixed partial derivative of F of order $J+1$, its density, nonnegative. Condition (G2) makes each marginal CDF vanish as its argument tends to $-\infty$. Theorem 6.18 proves (i) and (ii). Part (i) follows from homogeneity, since $F(x - \delta_0, \dots, x - \delta_J) = \exp\{-H(e^{-x} y)\} = \exp\{-e^{-x} H(y)\}$. That proof derives (ii) by direct integration. Part (ii) also follows from (i) in

one line. The distribution F satisfies Assumption B.83, so Theorem B.94 applied to (B.63) gives $s_j = \frac{H_j(y)}{H(y)} \cdot \frac{\partial y_j}{\partial \delta_j} = \frac{y_j H_j(y)}{H(y)}$.

By Euler's theorem, $\sum_j y_j H_j(y) = H(y)$, so the shares in (B.64) sum to one. Part (i) explains a remark of McFadden (1984, p. 1425). The generating function can be read as a measure of social utility, because its logarithm is expected maximum utility up to a constant.

Example B.104 (Logit as a GEV model)**.** With $H(y) = \sum_j y_j$, $H_j = 1$ and (B.64) gives $s_j = \frac{y_j}{\sum_k y_k}$, the logit. The generating function $H(y) = \left(\sum_j y_j^{\frac{1}{\lambda}}\right)^{\lambda}$ with $0 < \lambda \leq 1$ (McFadden, 1984, eq. 3.32) also gives a logit. Here $H_j = \left(\sum_k y_k^{\frac{1}{\lambda}}\right)^{\lambda-1} y_j^{\frac{1}{\lambda}-1}$, so $s_j = \frac{y_j^{\frac{1}{\lambda}}}{\sum_k y_k^{\frac{1}{\lambda}}} = \frac{e^{\frac{\delta_j}{\lambda}}}{\sum_k e^{\frac{\delta_k}{\lambda}}}$, a logit with scale λ.

Proposition B.105 (Nested logit from GEV)**.** *Partition the inside goods into nests $g = 1, \ldots, G$, with the outside good alone in its own nest, and let $\sigma \in [0, 1)$. The generating function*

$$H(y) = y_0 + \sum_{g=1}^{G} \Big(\sum_{j \in g} y_j^{\frac{1}{1-\sigma}} \Big)^{1-\sigma} \tag{B.65}$$

satisfies (G1) to (G3). With $\delta_0 = 0$ and the inclusive sums $D_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma}}$, the choice probabilities are $s_j = s_{j|g}\, s_g$ for $j \in g$, where

$$s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}, \qquad s_g = \frac{D_g^{1-\sigma}}{1 + \sum_{h=1}^{G} D_h^{1-\sigma}}, \qquad s_0 = \frac{1}{1 + \sum_{h=1}^{G} D_h^{1-\sigma}}. \tag{B.66}$$

Expected maximum utility is $\mathcal{W} = \ln\left(1 + \sum_g D_g^{1-\sigma}\right) + \gamma_E$.

Lemma 7.22 verifies (G1) to (G3) for $\sigma \in [0, 1)$, including the signs of all higher mixed partial derivatives. Proposition 7.25 derives the shares from (B.64). For $j \in g$ the key product is $y_j H_j(y) = D_g^{-\sigma} e^{\frac{\delta_j}{1-\sigma}}$, and with $y_0 = 1$ the generating function is $H(y) = 1 + \sum_h D_h^{1-\sigma}$. Their ratio factors as $s_{j|g}\, s_g$. The outside share is $\frac{y_0 H_0}{H} = \frac{1}{H}$, and $\mathcal{W}$ follows from (B.63).

Berry (1994, eqs. 23–25, p. 253) writes the same shares. The nest probability s_g is a logit in the nest *inclusive values* $I_g = (1-\sigma)\ln D_g$, and the within-nest probability $s_{j|g}$ is a logit with scale $1-\sigma$. At $\sigma = 0$, $D_g^{1-\sigma} = \sum_{k \in g} e^{\delta_k}$, and the model collapses to the logit. As $\sigma \to 1$, $(1-\sigma)\ln D_g \to \max_{k \in g} \delta_k$, and $s_{j|g} \to 1$ for the product with the highest δ_j in its nest. Products in a nest become perfect substitutes, and only the best product of each nest sells. The bound $\sigma \geq 0$, equivalently $\lambda \leq 1$, is what the GEV conditions impose. McFadden (1984, pp. 1423 and 1425) calls $\lambda = 1 - \sigma$ an "independence" parameter, because it measures the independence of the shocks within a nest. On p. 1426 he refers to such parameters as inclusive value coefficients. His cross-elasticity formula for the nested model (his eq. 3.49, p. 1425) explains why the unit interval matters. For values in $(0, 1)$, cross-elasticities are largest for alternatives in the same nest and smallest across nests. Values outside the interval reverse one of these rankings. Estimates outside $(0, 1]$ may therefore indicate a misspecified tree (McFadden, 1984, pp. 1425–1426).

Remark B.106 (Three-level nesting). McFadden (1984, eqs. 3.33–3.39, pp. 1421–1422) gives a three-level generating function. In our notation, with clusters C of subclusters D and $y_i = e^{\delta_i}$,

$$H(y) = \sum_{C} a(C) \Bigg\{ \sum_{D \subseteq C} b(D, C) \Big[\sum_{i \in D} y_i^{\frac{1}{\lambda_{DC}\lambda_C}} \Big]^{\lambda_{DC}} \Bigg\}^{\lambda_C},$$

with $0 < \lambda_{DC}, \lambda_C \le 1$ and positive weights $a(C)$ and $b(D, C)$. The choice probability factors as $Q(i \mid D, C)\, Q(D \mid C)\, Q(C)$. The bottom level is a logit in $\frac{\delta_i}{\lambda_{DC}\lambda_C}$. The middle level is a logit in $\ln b(D, C) + \lambda_{DC} J(D, C)$ with inclusive value $J(D, C) = \ln \sum_{j \in D} e^{\frac{\delta_j}{\lambda_{DC}\lambda_C}}$. The top level is a logit in $\ln a(C) + \lambda_C I(C)$ with $I(C) = \ln \sum_{D' \subseteq C} b(D', C) e^{\lambda_{D'C} J(D', C)}$. When all λ's equal one the model is a logit. When λ_{DC} is near zero, the subcluster D behaves like a single alternative with the best scale value in D.

The nested logit also has a random-coefficients representation, which explains the parameter restriction and gives the correlation of utilities within a nest.

Proposition B.107 (Cardell's representation, Cardell, 1997)**.** *For every $\sigma \in [0, 1)$ there is a distribution $C(\sigma)$ with the following property: if $\zeta \sim C(\sigma)$ and ϵ is standard Gumbel and independent of ζ, then $\zeta + (1 - \sigma)\epsilon$ is standard Gumbel. Let*

$$u_{ij} = \delta_j + \zeta_{ig} + (1 - \sigma)\epsilon_{ij}, \qquad j \in g, \tag{B.67}$$

with $\zeta_{ig} \sim C(\sigma)$ independent across nests, ϵ_{ij} independent standard Gumbels, independent of the ζ's, and $u_{i0} = \epsilon_{i0}$. Then the choice probabilities are the nested logit shares (B.66). Within a nest, $\operatorname{Corr}(u_{ij}, u_{ik}) = 1 - (1 - \sigma)^2$. Across nests the correlation is zero.

The existence of $C(\sigma)$ is Cardell's result, which we take as given (Lemma 7.24). Berry (1994, eq. 22, p. 252) uses this representation. Given existence, Proposition 7.25 derives the shares nest by nest. Max-stability (Proposition B.89 with $b = 1 - \sigma$) gives the best utility in nest g as $\zeta_{ig} + (1 - \sigma) \ln D_g + (1 - \sigma)\tilde{\epsilon}_{ig}$ with $\tilde{\epsilon}_{ig}$ standard Gumbel. The within-nest winner is independent of this maximum (Proposition B.92). Cardell's property makes $\zeta_{ig} + (1 - \sigma)\tilde{\epsilon}_{ig}$ standard Gumbel, so the choice of nest is a logit in $(1 - \sigma) \ln D_g$. For the correlation, the two parts of the standard Gumbel shock $\zeta_{ig} + (1 - \sigma)\epsilon_{ij}$ are independent, so $\operatorname{Var}(\zeta_{ig}) = [1 - (1 - \sigma)^2]\frac{\pi^2}{6}$. The common component ζ_{ig} then gives (7.60).

The within-nest correlation $1 - (1 - \sigma)^2 = \sigma(2 - \sigma)$ is zero at $\sigma = 0$ and tends to one as $\sigma \to 1$. A negative σ would require a negative variance for ζ, which is the random-coefficients reading of the restriction $\sigma \ge 0$. Berry (1994, pp. 252–253) rewrites (B.67) as $u_{ij} = \delta_j + \sum_g d_{jg}\zeta_{ig} + (1 - \sigma)\epsilon_{ij}$, where d_{jg} indicates membership of nest g. The nested logit is a random-coefficients model with random coefficients on nest dummies only. Its correlation pattern depends on groupings fixed before estimation, while the full random-coefficients model lets correlation depend on continuous characteristics.

Proposition B.108 (Nested-logit inversion and derivatives)**.** *In the nested logit of Proposition B.105:*

(i) The mean utilities satisfy

$$\ln s_j - \ln s_0 = \delta_j + \sigma \ln s_{j|g}, \qquad j \in g. \tag{B.68}$$

(ii) The derivatives of log shares with respect to mean utilities are

$$\frac{\partial \ln s_j}{\partial \delta_k} = \begin{cases} \dfrac{1}{1 - \sigma} - \dfrac{\sigma}{1 - \sigma} s_{j|g} - s_j, & k = j, \\ -\dfrac{\sigma}{1 - \sigma} s_{k|g} - s_k, & k \ne j,\ k \in g, \\ -s_k, & k \notin g,\ k \ge 1, \end{cases} \tag{B.69}$$

and $\frac{\partial \ln s_j}{\partial \delta_0} = -s_0$. The inside derivatives in each row sum to s_0.

(iii) With $\delta_j = \tilde{\delta}_j - \alpha p_j$, the price derivatives are $\frac{\partial s_j}{\partial p_j} = -\alpha s_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}s_{j|g} - s_j\right]$, $\frac{\partial s_j}{\partial p_k} = \alpha s_k\left[\frac{\sigma}{1-\sigma}s_{j|g} + s_j\right]$ for $k \neq j$ in the same nest, and $\frac{\partial s_j}{\partial p_k} = \alpha s_j s_k$ for k in another nest.

Proposition 7.26 proves (i), and Section 7.5.3 derives the derivatives in (ii) and (iii), (7.61) to (7.64). Both start from $\ln s_j = \frac{\delta_j}{1-\sigma} - \sigma \ln D_g - \ln\left(1 + \sum_h D_h^{1-\sigma}\right)$. The form of the same-nest cross derivative in (iii) uses $s_j s_{k|g} = s_k s_{j|g}$. Two statements of (ii) are new.

Proof of the outside-good derivative and the row sum. Without the normalization, the last term of $\ln s_j$ is $\ln\left(e^{\delta_0} + \sum_h D_h^{1-\sigma}\right)$. Its derivative with respect to δ_0 is s_0, so $\frac{\partial \ln s_j}{\partial \delta_0} = -s_0$. For the row sum,

$$\sum_{k\geq 1} \frac{\partial \ln s_j}{\partial \delta_k} = \frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}\sum_{k\in g} s_{k|g} - \sum_{k\geq 1} s_k = \frac{1-\sigma}{1-\sigma} - (1 - s_0) = s_0. \qquad \square$$

Berry (1994, eqs. 26–27, p. 253) reaches (B.68) by a second route. Taking logs of the nest share gives $\ln D_g = \frac{\ln s_g - \ln s_0}{1-\sigma}$, and substituting into $\ln s_j - \ln s_0 = \frac{\delta_j}{1-\sigma} - \sigma \ln D_g$ yields $\delta_j = \ln s_j - \sigma \ln s_{j|g} - \ln s_0$. With $\delta_j = x_j\beta - \alpha p_j + \xi_j$ this is the linear estimating equation $\ln s_j - \ln s_0 = x_j\beta - \alpha p_j + \sigma \ln s_{j|g} + \xi_j$, in which both the price and the within-nest share are endogenous (Chapter 7).

The derivatives in (B.69) have three uses. First, the own derivative $\frac{\partial \ln s_j}{\partial \delta_j}$ can far exceed one when σ is large and $s_{j|g}$ is small. This is why the share inversion for nested models needs a dampened contraction (Section B.7). Second, the same-nest cross derivative exceeds the cross-nest one by $\frac{\sigma}{1-\sigma}s_{k|g}$, so substitution is stronger within nests. Third, the own-price elasticity and the cross elasticities are

$$\varepsilon_j = \alpha p_j\left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma}s_{j|g} - s_j\right], \qquad \varepsilon_{jk} = \alpha p_k\left[\frac{\sigma}{1-\sigma}s_{k|g} + s_k\right] (k \in g), \qquad \varepsilon_{jk} = \alpha p_k s_k\ (k \notin g),$$

and the diversion ratio between two products of the same nest is

$$D_{jk} = \frac{\sigma s_{k|g} + (1-\sigma)s_k}{1 - \sigma s_{j|g} - (1-\sigma)s_j}.$$

The cross elasticity with respect to p_k is the same for every product in the nest of k, and the same for every product outside it. Substitution is therefore proportional within each of these two groups, and the ratio of two shares in the same nest, $\frac{s_j}{s_k} = e^{\frac{\delta_j - \delta_k}{1-\sigma}}$, does not depend on any other alternative.

Remark B.109 (Clone welfare in the nested logit). Add a clone of product j to its nest g, which contains only j. Before the clone, $D_g^{1-\sigma} = e^{\delta_j}$. After it, $D_g^{1-\sigma} = \left(2e^{\frac{\delta_j}{1-\sigma}}\right)^{1-\sigma} = 2^{1-\sigma}e^{\delta_j}$. With $\Lambda^0 = 1 + \sum_h D_h^{1-\sigma}$ before the clone, the surplus gain is

$$\Delta CS = \frac{1}{\alpha}\ln\frac{\Lambda^0 + (2^{1-\sigma} - 1)e^{\delta_j}}{\Lambda^0}.$$

It equals the logit value of Corollary B.96 at $\sigma = 0$ and falls to zero as $\sigma \to 1$. Within-nest correlation disciplines the value of variety.

Table B.3: Extreme value and logit formulas

Object	Formula	Reference
Standard Gumbel	CDF $\exp(-e^{-\epsilon})$, mean $\gamma_E \approx 0.5772$, variance $\frac{\pi^2}{6}$, mode 0	Definition B.85, Proposition B.87
Simulation	$-\ln(-\ln U) \sim \mathrm{EV}(0,1)$ for U uniform	Lemma B.86
Maximum of independent $\mathrm{EV}(0,b)$	$\max_j(\delta_j + \epsilon_j) \sim \mathrm{EV}\big(b \ln \sum_j e^{\frac{\delta_j}{b}}, b\big)$	Proposition B.89
Difference of two Gumbels	logistic, CDF $\frac{1}{1+e^{-x}}$, variance $\frac{\pi^2}{3}$	Proposition B.90
Logit shares	$s_j = \frac{e^{\delta_j}}{1+\sum_{k\geq 1} e^{\delta_k}}$, IIA $\frac{s_j}{s_k} = e^{\delta_j - \delta_k}$	Theorem B.91
Chosen maximum	$\max_k u_{ik} \mid j$ chosen $\sim \mathrm{EV}(\ln \Lambda, 1)$, $\mathbb{E}[\epsilon_{ij} \mid j] = \gamma_E - \ln s_j$	Proposition B.92
Log-sum	$\mathcal{W} = \ln \Lambda + \gamma_E$, $\frac{\partial \mathcal{W}}{\partial \delta_j} = s_j$ in any additive random utility model	Proposition B.93, Theorem B.94
Consumer surplus	$CS = \frac{1}{\alpha} \ln \Lambda + C$, value of a product $-\frac{1}{\alpha}\ln(1 - s_n)$	Proposition B.95, Corollary B.96
Logit derivatives	$\frac{\partial s_j}{\partial \delta_k} = s_j(\mathbf{1}\{j = k\} - s_k)$, $D_{jk} = \frac{s_k}{1 - s_j}$	(B.56), (B.58)
Markups and best response	$m_f = \frac{1}{\alpha(1 - S_f)}$, $BR_j = mc_j + \frac{1}{\alpha}\big[1 + W_0\big(\frac{e^{v_j - 1}}{\Lambda_{-j}}\big)\big]$	Proposition B.97, Proposition B.99
GEV	$\mathcal{W} = \ln H(e^{\delta}) + \gamma_E$, $s_j = \frac{y_j H_j(y)}{H(y)}$	Theorem B.103
Nested logit	$H = y_0 + \sum_g \big(\sum_{j \in g} y_j^{\frac{1}{1-\sigma}}\big)^{1-\sigma}$, $s_j = s_{j\mid g} s_g$	Proposition B.105
Nested-logit inversion	$\ln s_j - \ln s_0 = \delta_j + \sigma \ln s_{j\mid g}$	Proposition B.108
Within-nest correlation	$\mathrm{Corr}(u_{ij}, u_{ik}) = 1 - (1 - \sigma)^2$	Proposition B.107

Notes: $\delta_0 = 0$, $\Lambda = 1 + \sum_{k\geq 1} e^{\delta_k}$, $y_j = e^{\delta_j}$, $D_g = \sum_{k \in g} e^{\frac{\delta_k}{1-\sigma}}$, $s_{j\mid g}$ is the within-nest share, m_f the common markup of firm f with combined share S_f, and W_0 the principal branch of the Lambert function.

Remark B.110 (Random-coefficients nested logit). Combining nests with random coefficients (Grigolon and Verboven, 2014) gives, for a consumer type i with mean utilities $\delta_j + \mu_{ij}$, the nest inclusive values $I_{ig} = (1 - \sigma) \ln \sum_{j \in g} e^{\frac{\delta_j + \mu_{ij}}{1-\sigma}}$ and the overall inclusive value $I_i = \ln\big(1 + \sum_g e^{I_{ig}}\big)$. The type's choice probability is the product of a within-nest and a nest probability,

$$s_{ij} = \exp\left(\frac{\delta_j + \mu_{ij} - I_{ig}}{1 - \sigma}\right) \cdot \exp\left(I_{ig} - I_i\right),$$

and aggregate shares average over types. By (B.63), the type's expected consumer surplus is $\frac{I_i}{\alpha_i}$ plus a constant. Merger simulations (Chapter 11) therefore compute

$$\Delta CS = M \int \frac{I_i^{\text{post}} - I_i^{\text{pre}}}{\alpha_i} \, \mathrm{d}F(\nu_i).$$

Table B.3 collects the formulas of this section.

B.6 Order statistics

Auction data rarely reveal every bidder's value. An ascending auction ends at the price where the second-to-last bidder drops out, which is the second-highest value. A Dutch auction

records only the winning bid. *Order statistics*, the sorted values of a sample, connect such partial observations to the distribution of values. The Gumbel distribution of Section B.5.2 arose as the limit of a sample maximum, and here we study maxima and the other order statistics in finite samples. This section collects their distribution theory and the identification results built on it. Chapter 14 uses these tools to derive equilibrium bids and revenues. Chapter 15 uses them to identify and estimate value distributions.

B.6.1 Definitions, maxima and minima

Let $X_1, \dots, X_n$ be i.i.d. random variables with continuous CDF F, density f and support $[\underline{x}, \bar{x}]$, where the endpoints may be infinite. Sorting the sample from lowest to highest gives the order statistics

$$X_{(1:n)} \le X_{(2:n)} \le \cdots \le X_{(n:n)}.$$

Thus $X_{(k:n)}$ is the k-th lowest of the n draws, $X_{(n:n)}$ is the maximum and $X_{(1:n)}$ is the minimum. We write $F_{(k:n)}$ for the CDF of $X_{(k:n)}$ and $f_{(k:n)}$ for its density. The indexing from lowest to highest follows Athey and Haile (2007, Section 2.1). Because F is continuous, two draws coincide with probability zero, so the inequalities are strict almost surely.

The maximum is at most x if and only if every draw is at most x. Independence then gives

$$F_{(n:n)}(x) = \mathbb{P}(X_1 \le x, \dots, X_n \le x) = \prod_{m=1}^{n} \mathbb{P}(X_m \le x) = F(x)^n, \tag{B.70}$$

and differentiation gives $f_{(n:n)}(x) = nF(x)^{n-1} f(x)$. The minimum exceeds x if and only if every draw exceeds x, so

$$1 - F_{(1:n)}(x) = \mathbb{P}(X_1 > x, \dots, X_n > x) = \big(1 - F(x)\big)^n. \tag{B.71}$$

Hence $F_{(1:n)}(x) = 1 - (1 - F(x))^n$ and $f_{(1:n)}(x) = n(1 - F(x))^{n-1} f(x)$.

Two special cases recur in auctions. First, bidder i faces $n - 1$ rivals, and the highest rival value $Y_1 = \max_{j \ne i} X_j$ is the maximum of $n - 1$ i.i.d. draws. By (B.70) its CDF is $F_{Y_1}(y) = F(y)^{n-1}$. If all bidders use the same strictly increasing bid function, a bidder with value v therefore wins with probability $F(v)^{n-1}$. Second, the lowest bid wins a procurement auction. Minima then play the role that maxima play in sales, and the survival function $1 - F$ replaces F. For example, a supplier with cost c undercuts $n - 1$ independent rivals with costs drawn from F_c with probability $(1 - F_c(c))^{n-1}$.

Remark B.111 (Reduction to the uniform case). Let $U_1, \dots, U_n$ be i.i.d. uniform on $[0, 1]$ and set $X_m = F^{-1}(U_m)$, so that each X_m has CDF F by Lemma B.19. The quantile function F^{-1} is nondecreasing, so it preserves the ordering of the sample. Hence $X_{(k:n)} = F^{-1}(U_{(k:n)})$. In the other direction, $F(X_m)$ is uniform and F is nondecreasing, so $F(X_{(k:n)})$ has the distribution of $U_{(k:n)}$. Every distributional statement about order statistics of a continuous parent distribution therefore reduces to a statement about uniform order statistics.

B.6.2 The k-th order statistic

For $t \in [0, 1]$ and $1 \le k \le n$ define

$$\phi_{k:n}(t) = \frac{n!}{(k-1)!\,(n-k)!} \int_0^t u^{k-1}(1-u)^{n-k}\, \mathrm{d}u. \tag{B.72}$$

This is the CDF of a beta distribution with parameters k and $n-k+1$. Chapter 14 writes Λ_n for the map $\phi_{n-1:n}$.

Proposition B.112 (Distribution of the k-th order statistic)**.** *For $k = 1, \dots, n$ and every x,*

$$F_{(k:n)}(x) = \sum_{m=k}^{n} \binom{n}{m} F(x)^m \big(1 - F(x)\big)^{n-m} = \phi_{k:n}\big(F(x)\big). \tag{B.73}$$

Proposition 14.21 proves the formula in two steps. The k-th lowest draw is at most x if and only if at least k of the n draws are. Their number is binomial with parameters n and $F(x)$, which gives the binomial sum. Its derivative in $F(x)$ telescopes to the integrand of (B.72), and both sides vanish at $F(x) = 0$. Formula (B.73) is equation (5) of Athey and Haile (2002), who cite Arnold et al. (1992). The chain rule gives the density,

$$f_{(k:n)}(x) = \phi'_{k:n}\big(F(x)\big) f(x) = \frac{n!}{(k-1)!\,(n-k)!} F(x)^{k-1} \big(1 - F(x)\big)^{n-k} f(x). \tag{B.74}$$

The density has a multinomial reading. For $X_{(k:n)}$ to fall in $[x, x + \mathrm{d}x]$, one draw must land in that interval, $k-1$ draws must fall below x and $n-k$ above. These events have probabilities $f(x)\,\mathrm{d}x$, $F(x)^{k-1}$ and $(1-F(x))^{n-k}$. The multinomial coefficient $\frac{n!}{(k-1)!\,1!\,(n-k)!}$ counts the ways of assigning the draws to the three groups. The cases $k = n$ and $k = 1$ recover the maximum and the minimum.

Example B.113 (The second-highest draw)**.** Take $k = n-1$. By Remark B.111 it suffices to consider uniform draws. The second-highest of n uniform draws is at most t when at least $n-1$ of them are at most t. Either all n are, with probability t^n, or exactly $n-1$ are, with probability $nt^{n-1}(1-t)$, where the factor n counts the choices of the single draw above t. Hence

$$\phi_{n-1:n}(t) = nt^{n-1}(1-t) + t^n.$$

The integral formula (B.72) gives the same answer:

$$\begin{aligned} \phi_{n-1:n}(t) &= n(n-1) \int_0^t u^{n-2}(1-u)\,\mathrm{d}u \\ &= n(n-1)\Big[\frac{t^{n-1}}{n-1} - \frac{t^n}{n}\Big] \\ &= nt^{n-1} - (n-1)t^n, \end{aligned}$$

which equals $nt^{n-1}(1-t) + t^n$. Differentiating the last form,

$$\phi'_{n-1:n}(t) = n(n-1)t^{n-2} - n(n-1)t^{n-1} = n(n-1)t^{n-2}(1-t) > 0 \qquad \text{for } t \in (0,1).$$

In a second-price or ascending auction with symmetric independent private values, the price is the second-highest value. Its CDF is therefore $nF(v)^{n-1}(1-F(v)) + F(v)^n$ (Chapter 14).

Proposition B.114 (Uniform order statistics)**.** *The random variable $U_{(k:n)} = F(X_{(k:n)})$ has the beta distribution with parameters k and $n-k+1$. Its mean and variance are*

$$\mathbb{E}\big[U_{(k:n)}\big] = \frac{k}{n+1}, \qquad \operatorname{Var}\big(U_{(k:n)}\big) = \frac{k(n-k+1)}{(n+1)^2(n+2)}. \tag{B.75}$$

Proof. By Remark B.111, $U_{(k:n)}$ is the k-th order statistic of n uniform draws. With $F(u) = u$ on $[0,1]$, the density (B.74) becomes $\frac{n!}{(k-1)!\,(n-k)!} u^{k-1}(1-u)^{n-k}$, the beta density with parameters k and $n-k+1$. For the moments we use the beta integral $\int_0^1 u^a (1-u)^b \,\mathrm{d}u = \frac{a!\,b!}{(a+b+1)!}$ for nonnegative integers a and b. The mean is

$$\mathbb{E}\big[U_{(k:n)}\big] = \frac{n!}{(k-1)!\,(n-k)!} \cdot \frac{k!\,(n-k)!}{(n+1)!} = \frac{k}{n+1}.$$

The second moment is

$$\mathbb{E}\big[U_{(k:n)}^2\big] = \frac{n!}{(k-1)!\,(n-k)!} \cdot \frac{(k+1)!\,(n-k)!}{(n+2)!} = \frac{k(k+1)}{(n+1)(n+2)}.$$

Subtracting the squared mean,

$$\operatorname{Var}\big(U_{(k:n)}\big) = \frac{k(k+1)}{(n+1)(n+2)} - \frac{k^2}{(n+1)^2} = \frac{k\big[(k+1)(n+1) - k(n+2)\big]}{(n+1)^2(n+2)} = \frac{k(n-k+1)}{(n+1)^2(n+2)}.$$

□

The means say that n uniform draws split $[0,1]$ into $n+1$ spacings of equal expected length $\frac{1}{n+1}$. The variances say that extremes are more precisely located than central order statistics. At $k = n$ the variance is $\frac{n}{(n+1)^2(n+2)}$, of order $\frac{1}{n^2}$. Near the median it is approximately $\frac{1}{4n}$, of order $\frac{1}{n}$.

Corollary B.115 (Expected values in auctions with uniform values)**.** *If n bidders have values drawn i.i.d. from the uniform distribution on $[0,1]$, then $\mathbb{E}[X_{(n:n)}] = \frac{n}{n+1}$ and $\mathbb{E}[X_{(n-1:n)}] = \frac{n-1}{n+1}$. The expected revenue of a second-price or ascending auction without a reserve price is $\frac{n-1}{n+1}$, and the winner's expected rent is $\frac{n}{n+1} - \frac{n-1}{n+1} = \frac{1}{n+1}$.*

By revenue equivalence the first-price auction yields the same expected revenue (Chapter 14). For a general parent distribution, Remark B.111 gives $\mathbb{E}[X_{(k:n)}] = \mathbb{E}[F^{-1}(U_{(k:n)})]$. If $X \geq 0$, the formula $\mathbb{E}[X] = \int_0^\infty (1 - F_X(x))\,\mathrm{d}x$ of Section B.1.3 and (B.73) give

$$\mathbb{E}\big[X_{(k:n)}\big] = \int_0^\infty \Big[1 - \phi_{k:n}\big(F(x)\big)\Big]\,\mathrm{d}x. \tag{B.76}$$

B.6.3 Joint and conditional distributions

The vector of all n order statistics has the joint density

$$f_{(1,\dots,n)}(x_1,\dots,x_n) = n! \prod_{m=1}^{n} f(x_m) \qquad \text{for } x_1 < x_2 < \cdots < x_n, \tag{B.77}$$

and zero elsewhere. To see this, fix one of the $n!$ orderings π of the indices. On the event $\{X_{\pi(1)} < \cdots < X_{\pi(n)}\}$, the sorted vector equals $(X_{\pi(1)},\dots,X_{\pi(n)})$, which has density $\prod_m f(x_m)$ by independence. The $n!$ events are disjoint up to ties, and each contributes the same function on the ordered region. Integrating out all coordinates except two, or applying the multinomial reading of (B.74), gives the joint density of $(X_{(j:n)}, X_{(k:n)})$ for $j < k$ and $x < y$:

$$f_{(j,k:n)}(x,y) = \frac{n!}{(j-1)!\,(k-j-1)!\,(n-k)!}\, F(x)^{j-1} f(x) \big[F(y) - F(x)\big]^{k-j-1} f(y) \big[1 - F(y)\big]^{n-k}. \tag{B.78}$$

Here $j-1$ draws fall below x, one at x, $k-j-1$ between x and y, one at y, and $n-k$ above y.

Proposition B.116 (Conditioning on the maximum)**.** *Conditional on $X_{(n:n)} = x$, the other $n-1$ draws, listed in their original index order, are i.i.d. with CDF $\frac{F(t)}{F(x)}$ on $t \le x$.*

Proof. Let A_m be the event that X_m is the largest draw, and let $\tilde{X} = (\tilde{X}_1, \dots, \tilde{X}_{n-1})$ list the other draws in index order. On A_m, the pair $(X_{(n:n)}, \tilde{X})$ equals (X_m, X_{-m}). Its joint density at (x, z) restricted to A_m is therefore

$$f(x) \prod_{l=1}^{n-1} f(z_l)\, \mathbf{1}\{z_l < x\}.$$

The events $A_1, \dots, A_n$ are disjoint up to ties and contribute the same function, so the joint density of $(X_{(n:n)}, \tilde{X})$ is $n f(x) \prod_l f(z_l) \mathbf{1}\{z_l < x\}$. Dividing by the density $nF(x)^{n-1} f(x)$ of the maximum gives the conditional density

$$f_{\tilde{X} | X_{(n:n)}}(z \mid x) = \prod_{l=1}^{n-1} \frac{f(z_l)}{F(x)}\, \mathbf{1}\{z_l < x\}.$$

This is the density of $n-1$ i.i.d. draws from F truncated above at x. □

The same argument, applied conditional on $X_{(k:n)} = x$, shows that the $n-k$ larger order statistics are distributed as the order statistics of $n-k$ i.i.d. draws from F truncated below at x. Conditional on $X_{(k:n)} = x$, they are also independent of the $k-1$ smaller order statistics. These are distributed as the order statistics of $k-1$ i.i.d. draws from F truncated above at x. The order statistics therefore form a Markov chain (Arnold et al., 1992).

Proposition B.116 delivers the expected payment in auctions. Conditional on $X_{(n:n)} = v$, the second-highest draw is the maximum of $n-1$ draws from $\frac{F}{F(v)}$, so its CDF is $\left(\frac{F(y)}{F(v)}\right)^{n-1}$ for $y \le v$. This is also the CDF of the highest rival value Y_1 conditional on $Y_1 < v$. Integrating by parts,

$$\begin{aligned} \mathbb{E}\left[X_{(n-1:n)} \mid X_{(n:n)} = v\right] = \mathbb{E}[Y_1 \mid Y_1 < v] &= \frac{1}{F(v)^{n-1}} \int_{\underline{x}}^{v} y \, \mathrm{d}\left[F(y)^{n-1}\right] \\ &= v - \frac{1}{F(v)^{n-1}} \int_{\underline{x}}^{v} F(y)^{n-1} \, \mathrm{d}y. \end{aligned}$$

With a reserve price $r \le v$, the winner of a second-price auction pays $\max\{Y_1, r\}$. The event $Y_1 \le r$ has probability $F(r)^{n-1}$ and then the payment is r. Adding this term to the integral above, the integration by parts of Example B.18 gives

$$\mathbb{E}\left[\max\{Y_1, r\} \mid Y_1 < v\right] = v - \frac{\int_r^v F(y)^{n-1} \, \mathrm{d}y}{F(v)^{n-1}}, \tag{B.79}$$

which is (B.8). The right side is the symmetric equilibrium bid of the first-price auction (Riley and Samuelson, 1981), which Example B.57 derives by the envelope theorem (Chapter 14). Each bidder bids the payment it would expect to make in a second-price auction, conditional on winning. Averaging (B.79) over the winner's value gives revenue equivalence between the two formats.

Milgrom and Weber (1982) need the analogous formula when values are not independent. Let $(X_1, \dots, X_n)$ have a joint density f that is symmetric in its last $n-1$ arguments. Let $Y_1 \ge Y_2 \ge \cdots \ge Y_{n-1}$ be $X_2, \dots, X_n$ arranged in decreasing order. Then the joint density of $(X_1, Y_1, \dots, Y_{n-1})$ is

$$(n-1)!\, f(x_1, y_1, \dots, y_{n-1})\, \mathbf{1}\{y_1 \ge y_2 \ge \cdots \ge y_{n-1}\}. \tag{B.80}$$

The proof repeats the permutation argument. Each of the $(n-1)!$ orderings of the rivals contributes f evaluated at a permutation of $(y_1, \dots, y_{n-1})$, which equals $f(x_1, y_1, \dots, y_{n-1})$ by symmetry. Milgrom and Weber (1982, eq. (4), p. 1099) state (B.80) with common value components added as further arguments of f. Under independence the formula reduces to the product form used above. Section B.9.6 uses (B.80) to show that ordering rivals' signals preserves affiliation.

B.6.4 Exchangeability and a recurrence relation

Random variables $Z_1, \dots, Z_n$ are *exchangeable* if their joint distribution is unchanged by any permutation of the indices. I.i.d. variables are exchangeable. So are variables that are i.i.d. conditional on a common factor, such as signals $S_i = V + \epsilon_i$ with a common value V and i.i.d. errors ϵ_i. Exchangeable variables share a marginal distribution, but they need not be independent. Every subset of $n-1$ of them has the same joint distribution. We write $F_{(k:n-1)}$ for the CDF of the k-th order statistic of any such subset.

Proposition B.117 (Recurrence relation)**.** *Let $Z_1, \dots, Z_n$ be exchangeable, with a joint distribution under which ties have probability zero (for example, an absolutely continuous joint distribution). Then for $k = 1, \dots, n-1$ and every z,*

$$\frac{n-k}{n} F_{(k:n)}(z) + \frac{k}{n} F_{(k+1:n)}(z) = F_{(k:n-1)}(z). \tag{B.81}$$

Lemma 15.40 proves the relation. Delete one of the n variables, chosen uniformly at random and independently of Z. By exchangeability, the k-th lowest of the remaining $n-1$ has CDF $F_{(k:n-1)}$. The rank of the deleted variable is uniform and independent of the order statistics, because ties have probability zero. The k-th lowest of the remaining variables is therefore $Z_{(k:n)}$ with probability $\frac{n-k}{n}$ and $Z_{(k+1:n)}$ with probability $\frac{k}{n}$.

Proposition B.117 is equation (8.5) of Athey and Haile (2007), who cite David (1981). Taking expectations gives their equation (8.6):

$$\frac{n-k}{n} \mathbb{E}\left[Z_{(k:n)}\right] + \frac{k}{n} \mathbb{E}\left[Z_{(k+1:n)}\right] = \mathbb{E}\left[Z_{(k:n-1)}\right]. \tag{B.82}$$

The uniform case gives a check. By (B.75) the left side is $\frac{(n-k)k+k(k+1)}{n(n+1)} = \frac{k(n+1)}{n(n+1)} = \frac{k}{n}$, which is the mean of the k-th lowest of $n-1$ uniform draws.

The relation links order statistics from samples of different sizes. In a private-value auction a bidder's value does not depend on how many rivals it faces. Suppose the number of bidders varies exogenously. Then the value order statistics recovered from auctions with n and with $n-1$ bidders must satisfy (B.81). With $k = n-1$ the relation reads $\frac{1}{n} F_{(n-1:n)} + \frac{n-1}{n} F_{(n:n)} = F_{(n-1:n-1)}$. In a common-value auction the winner's curse makes willingness to pay fall with n, which breaks the relation in a predictable direction. Athey and Haile (2002) and Athey and Haile (2007, Section 8.3) build tests of private against common values on this observation (Chapter 15).

B.6.5 Identification from order statistics

The map $\phi_{k:n}$ in (B.73) depends only on k and n. If it can be inverted, the distribution of a single order statistic reveals the parent distribution.

Proposition B.118 (Identification from one order statistic)**.** *Let $X_1, \dots, X_n$ be i.i.d. with continuous CDF F, and suppose n is known. If the distribution of $X_{(k:n)}$ is known for one k, then F is identified, and*

$$F(x) = \phi_{k:n}^{-1}\big(F_{(k:n)}(x)\big) \qquad \text{for all } x. \tag{B.83}$$

Proof. The function $\phi_{k:n}$ is continuous on $[0,1]$ with $\phi_{k:n}(0) = 0$. By the beta integral, $\phi_{k:n}(1) = \frac{n!}{(k-1)!\,(n-k)!} \cdot \frac{(k-1)!\,(n-k)!}{n!} = 1$. Its derivative $\frac{n!}{(k-1)!\,(n-k)!} t^{k-1}(1-t)^{n-k}$ is strictly positive on $(0,1)$. Hence $\phi_{k:n}$ is a strictly increasing bijection of $[0,1]$ with a continuous inverse. Applying the inverse to both sides of (B.73) gives (B.83). □

This is part (i) of Theorem 1 in Athey and Haile (2002, p. 2115). In an ascending (button) auction with symmetric independent private values, the price is the second-highest value. The distribution of prices in auctions with n bidders therefore identifies F. The same holds in a second-price sealed-bid auction, where bidding one's value is a weakly dominant strategy. With a binding reserve price r, the price is $\max\{X_{(n-1:n)}, r\}$, and F is identified only above r.

The result also yields testable restrictions. Suppose we observe two order statistics, $X_{(k:n)}$ and $X_{(k':n')}$, with $k \neq k'$ or with exogenously different numbers of bidders $n \neq n'$. Each gives a candidate for F, and the model requires

$$\phi_{k:n}^{-1}\big(F_{(k:n)}(x)\big) = \phi_{k':n'}^{-1}\big(F_{(k':n')}(x)\big) \qquad \text{for all } x.$$

This is part (ii) of the same theorem. Formula (B.73) holds only for i.i.d. draws, so the restriction can fail when values are asymmetric or strictly affiliated (Athey and Haile, 2002, fn. 20).

The inversion suggests a simple estimator. Let $w_1, \dots, w_T$ be the observed values of $X_{(k:n)}$ in T auctions with n bidders, and let $\hat{G}_T(x) = \frac{1}{T}\sum_{t=1}^{T} \mathbf{1}\{w_t \le x\}$ be their empirical CDF. The estimator is

$$\hat{F}(x) = \phi_{k:n}^{-1}\big(\hat{G}_T(x)\big), \tag{B.84}$$

computed at each x by bisection on $[0,1]$, which works because $\phi_{k:n}$ is monotone. Since $\phi_{k:n}^{-1}$ is continuous, $\hat{F}$ is consistent uniformly in x by the Glivenko-Cantelli theorem. Its pointwise sampling variance follows from the delta method (Appendix A). The empirical CDF has variance $\frac{G(1-G)}{T}$ with $G = \phi_{k:n}(F(x))$, and the inverse has derivative $\frac{1}{\phi'_{k:n}(F(x))}$. With $t = F(x) \in (0,1)$,

$$\operatorname{Var}\big(\hat{F}(x)\big) \approx \frac{\phi_{k:n}(t)\big[1 - \phi_{k:n}(t)\big]}{T\,\phi'_{k:n}(t)^2}. \tag{B.85}$$

Remark B.119 (Where the inversion loses precision). Compare (B.85) with the variance $\frac{t(1-t)}{T}$ that we would obtain from one direct draw of X per auction. The ratio of the two is

$$R_{k:n}(t) = \frac{\phi_{k:n}(t)\big[1 - \phi_{k:n}(t)\big]}{t(1-t)\,\phi'_{k:n}(t)^2}.$$

For the second-highest draw, Example B.113 gives $\phi_{n-1:n}(t) \approx n t^{n-1}$ and $\phi'_{n-1:n}(t) \approx n(n-1)t^{n-2}$ near $t = 0$. Hence

$$R_{n-1:n}(t) \approx \frac{n t^{n-1}}{t\, n^2 (n-1)^2 t^{2n-4}} = \frac{t^{2-n}}{n(n-1)^2} \qquad \text{as } t \to 0.$$

Near the top, set $t = 1 - \varepsilon$. A second-order expansion gives $1 - \phi_{n-1:n}(1-\varepsilon) \approx \frac{n(n-1)}{2}\varepsilon^2$, while $\phi'_{n-1:n}(1-\varepsilon) \approx n(n-1)\varepsilon$. Hence

$$R_{n-1:n}(1-\varepsilon) \approx \frac{\frac{n(n-1)}{2}\varepsilon^2}{\varepsilon\, n^2(n-1)^2\varepsilon^2} = \frac{1}{2n(n-1)\varepsilon} \qquad \text{as } \varepsilon \to 0.$$

The ratio explodes in the upper tail for every n, and in the lower tail for every $n \geq 3$. The price carries little information about the top of the value distribution, because the highest value never appears in the price. It also carries little information about the bottom when n is large, because the second-highest of many draws rarely falls there. With $n = 2$ the ratio tends to $\frac{1}{2}$ at the bottom. The price is then the lower of two values, which is more informative about the lower tail than a single draw.

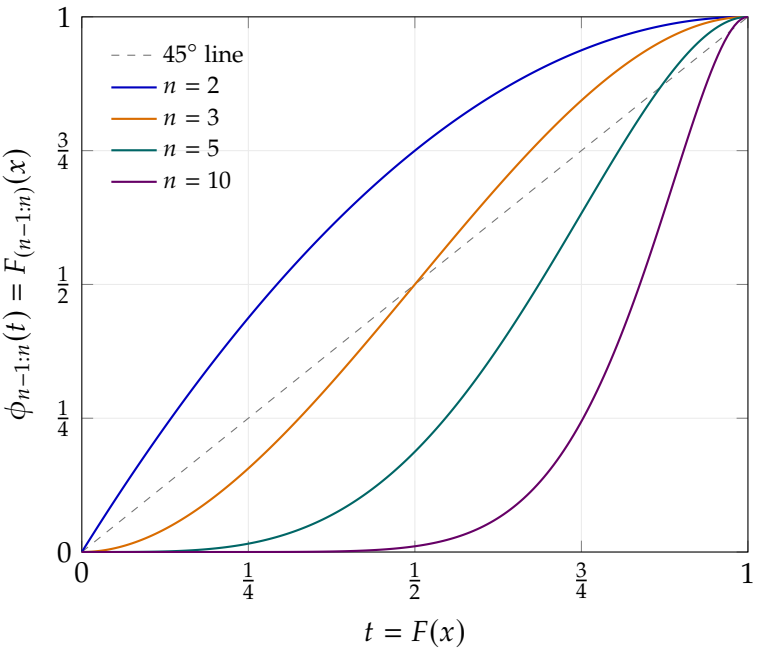

Figure B.6: The map $\phi_{n-1:n}(t) = nt^{n-1} - (n-1)t^n$ from the parent CDF to the CDF of the second-highest of n draws, for $n = 2, 3, 5, 10$. Each map is a strictly increasing bijection of $[0, 1]$, so it can be inverted (Proposition B.118). Every map is flat at $t = 1$, and for $n \geq 3$ it is also flat near $t = 0$ over a range that widens with n. Where the map is flat, small errors in the price distribution become large errors in F, so the tails of F are hard to recover from transaction prices (Remark B.119).

Example B.120 (First-price auctions with only the winning bid)**.** In a first-price auction with symmetric independent private values, equilibrium bids are i.i.d. with some CDF G and density g. A Dutch auction records only the winning bid $B_{(n:n)}$, whose CDF is G^n and whose density is $nG^{n-1}g$. Hence

$$\frac{G_{(n:n)}(b)}{g_{(n:n)}(b)} = \frac{G(b)^n}{nG(b)^{n-1}g(b)} = \frac{G(b)}{n\, g(b)}.$$

The first-order condition of a bidder delivers the inverse bid function of Guerre et al. (2000), which can be rewritten in terms of the winning-bid distribution:

$$v = b + \frac{G(b)}{(n-1)g(b)} = b + \frac{n}{n-1} \cdot \frac{G_{(n:n)}(b)}{g_{(n:n)}(b)}.$$

The value distribution is therefore identified from winning bids alone when n is known (Athey and Haile, 2007, Section 3.3.1, eq. (3.7)). Chapter 15 develops the inversion.

Without symmetry, the parent distributions differ across bidders and one order statistic cannot separate them. Observing the identity of the winner restores identification. The argument comes from the statistics of *competing risks*, where a system fails when its first component fails and we observe the failure time and which component failed (Berman, 1963). Up to a sign change, this is the same as observing the highest bid and the identity of the highest bidder (Athey and Haile, 2002, fn. 21).

Proposition B.121 (Competing risks)**.** *Let $X_1, \dots, X_n$ be independent, with continuous CDFs $F_1, \dots, F_n$ that share the support $[\underline{x}, \bar{x}]$. Suppose we observe the maximum $M = \max_i X_i$ and the identity I of the maximizer. Define $G_i^w(x) = \mathbb{P}(M \le x, I = i)$. Then each F_i is identified, and for every x in the interior of the support*

$$F_i(x) = \exp\left(- \int_x^{\bar{x}} \frac{\mathrm{d}G_i^w(t)}{\sum_{j=1}^n G_j^w(t)} \right). \tag{B.86}$$

Proof. For transparency we assume densities f_i. The general case replaces $f_i(t)\,\mathrm{d}t$ by $\mathrm{d}F_i(t)$.

Step 1. Bidder i wins with a value at most x when $X_i \le x$ and every rival draw is below X_i. Conditioning on $X_i = t$ and using independence,

$$G_i^w(x) = \mathbb{P}\big(X_i \le x,\ X_j < X_i\ \forall j \ne i\big) = \int_{\underline{x}}^{x} \prod_{j \ne i} F_j(t)\, f_i(t)\, \mathrm{d}t.$$

Step 2. Ties have probability zero, so the events $\{I = j\}$ partition the sample space. Summing over j gives the CDF of the maximum:

$$\sum_{j=1}^{n} G_j^w(x) = \mathbb{P}(M \le x) = \prod_{j=1}^{n} F_j(x) \equiv F_M(x).$$

Step 3. For t in the interior of the support, $F_i(t) > 0$. Writing the integrand of Step 1 as $\frac{F_M(t)}{F_i(t)} f_i(t)$,

$$\mathrm{d}G_i^w(t) = F_M(t)\, \frac{f_i(t)}{F_i(t)}\, \mathrm{d}t = F_M(t)\, \mathrm{d}\ln F_i(t).$$

Step 4. Divide by $F_M(t)$, which is positive on the interior because the supports coincide, and integrate from x to $\bar{x}$:

$$\int_x^{\bar{x}} \frac{\mathrm{d}G_i^w(t)}{F_M(t)} = \ln F_i(\bar{x}) - \ln F_i(x) = -\ln F_i(x).$$

Exponentiating and substituting Step 2 for F_M gives (B.86). Every term on the right is a feature of the distribution of (M, I). □

Athey and Haile (2002, Theorem 2) state this result for asymmetric independent private values. Their case (b) observes the highest bid of a second-price auction together with the winner's identity, which is Proposition B.121. Their case (a) observes the transaction price $X_{(n-1:n)}$ and the winner's identity, and identification then follows from Meilijson (1981). We

omit that more involved argument. Athey and Haile (2007, Section 3.3.1, eq. (3.8)) apply (B.86) to the winning bid and winner's identity in a first-price auction. This identifies each bidder's bid distribution, and the first-order conditions then identify the value distributions. The common support matters. If some rival's values never fall below a, bidder i never wins with a value below a, so F_i is not identified there. Theorem 2 relaxes symmetry and keeps independence. Dropping independence as well destroys point identification, a classic result for competing risks (Tsiatis, 1975). Athey and Haile (2002, Theorem 2, p. 2116) also give two routes to testing the model. In the first, participation is exogenous and each bidder faces at least two different sets of opponents. Each set identifies F_i, and the versions must agree. In the second, a second-price auction reveals both the transaction price and the highest bid, each with the winner's identity. Cases (a) and (b) then deliver two versions of F_i, which again must coincide.

Remark B.122 (Minima and procurement). In a procurement auction we observe the lowest cost $m = \min_i X_i$ and the identity of the low bidder. The mirror image of the proof uses $G_i^{\ell}(x) = \mathbb{P}(m \le x, I = i) = \int_{\underline{x}}^{x} \prod_{j \neq i} [1 - F_j(t)] \, \mathrm{d}F_i(t)$ and the survival function of the minimum, $S_m(t) = \prod_j [1 - F_j(t)] = 1 - \sum_j G_j^{\ell}(t)$. Then $\mathrm{d}G_i^{\ell}(t) = -S_m(t) \, \mathrm{d} \ln[1 - F_i(t)]$, and integrating from $\underline{x}$ to x gives

$$1 - F_i(x) = \exp\left(- \int_{\underline{x}}^{x} \frac{\mathrm{d}G_i^{\ell}(t)}{1 - \sum_{j=1}^{n} G_j^{\ell}(t)} \right).$$

The integrand is the *cause-specific hazard* of reliability theory.

Example B.123 (Two exponential suppliers)**.** Let supplier $i \in \{1, 2\}$ have cost X_i with $F_i(x) = 1 - e^{-\lambda_i x}$ on $[0, \infty)$, where the rates $\lambda_i > 0$ are local notation. The probability that supplier 1 wins at a cost at most x is

$$G_1^{\ell}(x) = \int_0^x e^{-\lambda_2 t} \lambda_1 e^{-\lambda_1 t} \, \mathrm{d}t = \frac{\lambda_1}{\lambda_1 + \lambda_2} \Big(1 - e^{-(\lambda_1 + \lambda_2) x} \Big).$$

The minimum has survival function $S_m(t) = e^{-(\lambda_1 + \lambda_2) t}$. Hence $\frac{\mathrm{d}G_1^{\ell}(t)}{S_m(t)} = \lambda_1 \, \mathrm{d}t$, and the formula of Remark B.122 returns $1 - F_1(x) = e^{-\lambda_1 x}$. The example shows where the information comes from. The winning cost is exponential with rate $\lambda_1 + \lambda_2$ whoever wins, and the frequency with which supplier 1 wins, $\frac{\lambda_1}{\lambda_1 + \lambda_2}$, splits the total rate between the two suppliers.

B.6.6 Deconvolution and Kotlarski's lemma

A related tool separates a common component from idiosyncratic ones. It is used for auctions with unobserved heterogeneity, where all bids in an auction share a component that the econometrician does not observe. We write i for the imaginary unit and $\psi_X(t) = \mathbb{E}[e^{\mathrm{i}tX}]$ for the *characteristic function* of a random variable X.

Lemma B.124 (Kotlarski)**.** *Let Y_1, Y_2, Y_3 be mutually independent with nonvanishing characteristic functions. Assume $\mathbb{E}|Y_1| < \infty$ and $\mathbb{E}|Y_3| < \infty$, and normalize $\mathbb{E}[Y_1] = 0$. Let $Q_1 = Y_1 + Y_3$ and $Q_2 = Y_2 + Y_3$, with joint characteristic function $\psi_Q(t_1, t_2) = \mathbb{E}[e^{\mathrm{i}(t_1 Q_1 + t_2 Q_2)}]$, and let ∂_1 denote the derivative with respect to the first argument. Then the distribution of (Q_1, Q_2) determines the distributions of Y_1, Y_2 and Y_3, through*

$$\psi_{Y_3}(t) = \exp\left(\int_0^t \frac{\partial_1 \psi_Q(0, u)}{\psi_Q(0, u)} \, \mathrm{d}u \right), \qquad \psi_{Y_1}(t) = \frac{\psi_Q(t, 0)}{\psi_{Y_3}(t)}, \qquad \psi_{Y_2}(t) = \frac{\psi_Q(0, t)}{\psi_{Y_3}(t)}. \tag{B.87}$$

Proof. Step 1 (factorization). Write $t_1 Q_1 + t_2 Q_2 = t_1 Y_1 + t_2 Y_2 + (t_1 + t_2) Y_3$. Independence gives

$$\psi_Q(t_1, t_2) = \psi_{Y_1}(t_1)\, \psi_{Y_2}(t_2)\, \psi_{Y_3}(t_1 + t_2).$$

Step 2 (differentiation). The moment conditions make ψ_{Y_1} and ψ_{Y_3} differentiable, with $\psi'_{Y_1}(0) = \mathrm{i}\mathbb{E}[Y_1] = 0$ and $\psi_{Y_1}(0) = 1$. Differentiating Step 1 in t_1 at $t_1 = 0$,

$$\partial_1 \psi_Q(0, u) = \psi'_{Y_1}(0) \psi_{Y_2}(u) \psi_{Y_3}(u) + \psi_{Y_2}(u) \psi'_{Y_3}(u) = \psi_{Y_2}(u) \psi'_{Y_3}(u).$$

Since $\psi_Q(0, u) = \psi_{Y_2}(u) \psi_{Y_3}(u)$ and the characteristic functions do not vanish,

$$\frac{\partial_1 \psi_Q(0, u)}{\psi_Q(0, u)} = \frac{\psi'_{Y_3}(u)}{\psi_{Y_3}(u)}.$$

Step 3 (integration). Let $\ell(t) = \int_0^t \frac{\psi'_{Y_3}(u)}{\psi_{Y_3}(u)}\, \mathrm{d}u$ and $h(t) = \psi_{Y_3}(t) e^{-\ell(t)}$. Then $h'(t) = \psi'_{Y_3}(t) e^{-\ell(t)} - \psi_{Y_3}(t) \ell'(t) e^{-\ell(t)} = 0$, and $h(0) = 1$. So $h \equiv 1$, which is the first formula in (B.87). Setting $t_2 = 0$ or $t_1 = 0$ in Step 1 gives the other two. A characteristic function determines its distribution, which completes the proof. □

The lemma is Lemma 6.1 of Athey and Haile (2007), after Kotlarski (1966) and Prakasa Rao (1992). Lemma 15.50 gives the same result in auction notation, together with identification up to location when the mean of Y_1 is unknown. The normalization is needed because adding a constant to Y_3 and subtracting it from Y_1 and Y_2 leaves (Q_1, Q_2) unchanged. In auctions with additive unobserved heterogeneity, a bidder's value is $A_{it} + V_{0t}$, where V_{0t} is common to auction t and unobserved. Equilibrium bids then take the form $B_{it} = B^0_{it} + V_{0t}$, where the homogenized bid B^0_{it} is the bid in an auction with $V_{0t} = 0$ (Athey and Haile, 2007, Section 6.1.2). Two bids from the same auction play the roles of Q_1 and Q_2, with $Y_3 = V_{0t}$. Lemma B.124 recovers the distribution of homogenized bids, and the first-order condition then recovers values. Krasnokutskaya (2011) uses the multiplicative version, which becomes additive after taking logarithms (Chapter 15).

B.7 Fixed points and the contraction mapping theorem

Many objects in industrial organization are *fixed points*, points x^* with $\Phi(x^*) = x^*$ for some map Φ. The mean utilities that rationalize observed shares solve $\delta = \delta + \ln s^{obs} - \ln s(\delta)$. Equilibrium prices solve $p = BR(p)$, where BR stacks the firms' best responses. Value functions of dynamic problems solve Bellman equations. Each case raises three questions. Does a fixed point exist? Is it unique? How do we compute it? The contraction mapping theorem answers all three at once when it applies. Brouwer's and Kakutani's theorems answer only the first, and uniqueness then needs a separate argument such as diagonal dominance. The proof of the implicit function theorem (Theorem B.27) already relied on the contraction mapping theorem, which we now prove. Throughout, Φ is the map, $\kappa \in [0, 1)$ a modulus, x^* a fixed point and $x^{(h)}$ the h-th iterate.

B.7.1 Metric spaces and contractions

Definition B.125 (Metric space)**.** A *metric space* is a set X with a function $d : X \times X \to [0, \infty)$ with three properties for all $x, y, z \in X$.

(i) $d(x, y) = 0$ if and only if $x = y$.

(ii) $d(x, y) = d(y, x)$.

(iii) $d(x, z) \le d(x, y) + d(y, z)$.

A sequence $(x^{(h)})$ is *Cauchy* if for every $\epsilon > 0$ there is H with $d(x^{(h)}, x^{(m)}) < \epsilon$ for all $h, m \ge H$. The space is *complete* if every Cauchy sequence converges to a point of X.

The leading example is $\mathbb{R}^n$ with the sup norm $\|x\|_\infty = \max_k |x_k|$ and $d(x, y) = \|x - y\|_\infty$. A sequence that is Cauchy in this metric is Cauchy coordinate by coordinate, and $\mathbb{R}$ is complete, so $(\mathbb{R}^n, \|\cdot\|_\infty)$ is complete. A closed subset of a complete space is complete, because limits of its sequences stay in the set. Boxes $[\underline{y}, \bar{y}]^J$ and orthants $(-\infty, \bar{\delta}]^J$ are therefore complete. The interval $(0, 1]$ is not complete, since the Cauchy sequence $\frac{1}{h}$ converges to $0 \notin (0, 1]$. The set of bounded real functions on a set S, with the metric $\sup_{s \in S} |g(s) - g'(s)|$, is complete. So is its subset of bounded continuous functions when S is a metric space (Stokey et al., 1989). Dynamic programming works in these function spaces.

Definition B.126 (Contraction)**.** A map $\Phi : X \to X$ is a *contraction with modulus* $\kappa \in [0, 1)$ if

$$d\big(\Phi(x), \Phi(y)\big) \le \kappa\, d(x, y) \qquad \text{for all } x, y \in X.$$

A map that satisfies the inequality with some $\kappa \ge 0$ is *Lipschitz* with constant κ. A contraction is Lipschitz and hence continuous. The uniform modulus is essential. Consider $\Phi(x) = x + \frac{1}{x}$ on $[1, \infty)$. It maps the set into $[2, \infty)$, and $\Phi'(x) = 1 - \frac{1}{x^2} \in [0, 1)$, so the mean value theorem gives $|\Phi(x) - \Phi(y)| < |x - y|$ whenever $x \ne y$. Yet $\Phi(x) = x$ would require $\frac{1}{x} = 0$, so there is no fixed point. The local modulus $\Phi'(x)$ approaches one as $x \to \infty$, and the iterates drift off to infinity. The share inversion has the same feature, which is why Berry et al. (1995) truncate the map (Theorem B.133). Completeness matters too. The map $\Phi(x) = \frac{x}{2}$ is a contraction of $(0, 1]$ into itself without a fixed point in $(0, 1]$.

B.7.2 The Banach fixed-point theorem

Theorem B.127 (Banach fixed-point theorem)**.** *Let (X, d) be a complete metric space and let $\Phi : X \to X$ be a contraction with modulus κ. Then the following hold.*

(i) Φ has exactly one fixed point x^*.

(ii) For every starting point $x^{(0)} \in X$, the iterates $x^{(h+1)} = \Phi(x^{(h)})$ converge to x^*.

(iii) $d(x^{(h)}, x^*) \le \kappa^h\, d(x^{(0)}, x^*)$ for all h.

Proof. Step 1 (successive steps shrink geometrically). For $h \ge 1$,

$$d\big(x^{(h+1)}, x^{(h)}\big) = d\big(\Phi(x^{(h)}), \Phi(x^{(h-1)})\big) \le \kappa\, d\big(x^{(h)}, x^{(h-1)}\big).$$

Applying this h times gives $d(x^{(h+1)}, x^{(h)}) \le \kappa^h d_0$, where $d_0 = d(x^{(1)}, x^{(0)})$.

Step 2 (the iterates form a Cauchy sequence). For $m > h$, the triangle inequality and Step 1 give

$$d\big(x^{(m)}, x^{(h)}\big) \le \sum_{l=h}^{m-1} d\big(x^{(l+1)}, x^{(l)}\big) \le d_0 \sum_{l=h}^{m-1} \kappa^l \le \frac{\kappa^h}{1 - \kappa}\, d_0.$$

The bound tends to zero as $h \to \infty$, so the sequence is Cauchy. By completeness it converges to some $x^* \in X$.

Step 3 (the limit is a fixed point). For every h,

$$d\big(\Phi(x^*), x^*\big) \le d\big(\Phi(x^*), \Phi(x^{(h)})\big) + d\big(x^{(h+1)}, x^*\big) \le \kappa\, d\big(x^*, x^{(h)}\big) + d\big(x^{(h+1)}, x^*\big).$$

The right side tends to zero, so $\Phi(x^*) = x^*$.

Step 4 (uniqueness). If $\Phi(y) = y$, then $d(x^*, y) = d(\Phi(x^*), \Phi(y)) \le \kappa\, d(x^*, y)$. Since $\kappa < 1$, this forces $d(x^*, y) = 0$.

Step 5 (the rate). $d(x^{(h)}, x^*) = d(\Phi(x^{(h-1)}), \Phi(x^*)) \le \kappa\, d(x^{(h-1)}, x^*)$, and induction gives (iii). □

The theorem is due to Banach (1922). Part (iii) says that the error falls at least geometrically, a property called *linear convergence*. In practice we do not know x^*, so we need bounds in terms of computable quantities.

Corollary B.128 (Error bounds)**.** *Under the conditions of Theorem B.127, for every $h \ge 1$,*

$$d\big(x^{(h)}, x^*\big) \le \frac{\kappa^h}{1-\kappa}\, d\big(x^{(1)}, x^{(0)}\big) \qquad \textit{(a priori bound)}, \tag{B.88}$$

$$d\big(x^{(h)}, x^*\big) \le \frac{\kappa}{1-\kappa}\, d\big(x^{(h)}, x^{(h-1)}\big) \qquad \textit{(a posteriori bound)}. \tag{B.89}$$

Proof. For (B.88), let $m \to \infty$ in Step 2 of the proof of Theorem B.127, using continuity of d. For (B.89), apply the triangle inequality and the contraction property:

$$\begin{aligned} d\big(x^{(h)}, x^*\big) &= d\big(\Phi(x^{(h-1)}), \Phi(x^*)\big) \le \kappa\, d\big(x^{(h-1)}, x^*\big) \\ &\le \kappa\, d\big(x^{(h-1)}, x^{(h)}\big) + \kappa\, d\big(x^{(h)}, x^*\big). \end{aligned}$$

Collecting the terms in $d(x^{(h)}, x^*)$ gives $(1-\kappa)\, d(x^{(h)}, x^*) \le \kappa\, d(x^{(h)}, x^{(h-1)})$. □

The a posteriori bound justifies the usual stopping rule, which halts when successive iterates are within a tolerance ε_{tol}. The rule controls the true error only up to the factor $\frac{\kappa}{1-\kappa}$. This factor is 1 for $\kappa = \frac{1}{2}$, 9 for $\kappa = 0.9$ and 99 for $\kappa = 0.99$, so the stopping tolerance must be tighter than the accuracy we want when κ is near one. Proposition 8.18 applies this bound to the inner loop of BLP estimation. The a priori bound tells us how many iterations suffice. The bound is below ε_{tol} when $\kappa^h d(x^{(1)}, x^{(0)}) \le \varepsilon_{tol}(1-\kappa)$. Taking logarithms and dividing by $\ln \kappa < 0$, which reverses the inequality,

$$h \ge \frac{\ln\big(\varepsilon_{tol}(1-\kappa)\big) - \ln d\big(x^{(1)}, x^{(0)}\big)}{\ln \kappa}. \tag{B.90}$$

With $d(x^{(1)}, x^{(0)}) = 1$ and $\varepsilon_{tol} = 10^{-12}$, the bound requires 41 iterations for $\kappa = \frac{1}{2}$, 285 for $\kappa = 0.9$ and 3,208 for $\kappa = 0.99$. The cost of a fixed-point computation grows roughly like $\frac{1}{1-\kappa}$.

Remark B.129 (Contractions on subsets). The theorem applies to any closed subset $C \subseteq X$ that Φ maps into itself and on which Φ contracts, since C is complete. A convenient sufficient condition uses a closed ball. Suppose Φ is Lipschitz with constant $\kappa < 1$ on $\bar{B} = \{x : d(x, x^{(0)}) \le \tau\}$ and $d(\Phi(x^{(0)}), x^{(0)}) \le (1-\kappa)\tau$. Then for $x \in \bar{B}$,

$$d\big(\Phi(x), x^{(0)}\big) \le d\big(\Phi(x), \Phi(x^{(0)})\big) + d\big(\Phi(x^{(0)}), x^{(0)}\big) \le \kappa\tau + (1-\kappa)\tau = \tau,$$

so Φ maps $\bar{B}$ into itself and has a unique fixed point there. The proof of the implicit function theorem (Theorem B.27) uses this device, and so does the truncation argument of Theorem B.133.

Remark B.130 (Local convergence and the choice of norm). Suppose $\Phi : \mathbb{R}^n \to \mathbb{R}^n$ is continuously differentiable near a fixed point x^*. If the spectral radius of the Jacobian $D\Phi(x^*)$, the largest modulus of its eigenvalues, is below one, then the iterates converge to x^* from every starting point close enough to it. The asymptotic rate equals the spectral radius. If some eigenvalue has modulus above one, x^* repels the iterates in the direction of the corresponding eigenvector, and iteration started near x^* generally fails to converge (Judd, 1998). The contraction property depends on the metric. The matrix $A = \left(\begin{smallmatrix} 0 & 2 \\ 0 & 0 \end{smallmatrix}\right)$ has spectral radius zero, and $A^2 x = 0$ for every x, yet $\|Ax\|_\infty = 2\|x\|_\infty$ for $x = (0, 1)$. The sup norm suits the applications below because row sums of Jacobians are easy to bound.

Figure B.7 shows the iteration on the real line as a *cobweb*. Each step moves vertically to the graph of Φ and then horizontally to the 45-degree line. In the left panel, $\Phi(x) = 1 + \frac{1}{2}\cos x$ has $|\Phi'(x)| = \frac{1}{2}|\sin x| \le \frac{1}{2}$, so it is a contraction of $\mathbb{R}$ with modulus $\frac{1}{2}$. Starting from $x^{(0)} = 0$, the iterates are 1.5, 1.035, 1.255, 1.155 and so on, and they converge to $x^* = 1.187151$. After ten steps the error is 3.2×10^{-4}, below the a priori bound $\frac{\kappa^{10}}{1-\kappa}\, d(x^{(1)}, x^{(0)}) = 2^{-9} \times 1.5 = 2.9 \times 10^{-3}$. The errors shrink by a factor close to $|\Phi'(x^*)| = 0.464$ per step, as Remark B.130 predicts. In the right panel, $\Phi(x) = 3 - \frac{3}{2}x$ has slope $-\frac{3}{2}$. Its fixed point is $x^* = \frac{6}{5}$, but from $x^{(0)} = 1$ the distance to x^* grows by the factor $\frac{3}{2}$ each step, from 0.2 to 0.3, 0.45, 0.675 and beyond. The negative slope makes the path spiral, and the slope above one in absolute value makes it diverge.

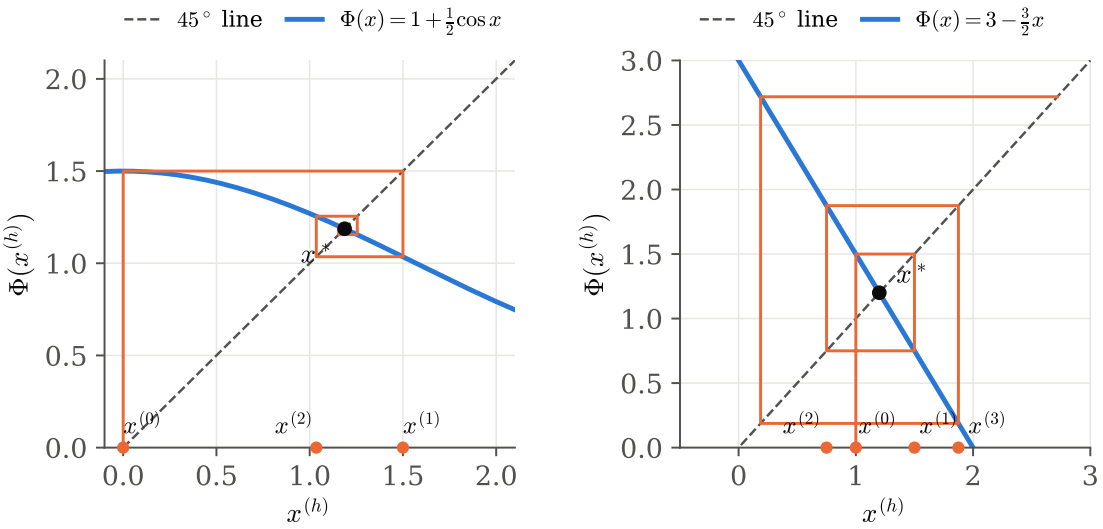

Figure B.7: Cobweb diagrams for the iteration $x^{(h+1)} = \Phi(x^{(h)})$. In the left panel, $\Phi(x) = 1 + \frac{1}{2}\cos x$ is a contraction with modulus $\frac{1}{2}$, and the path from $x^{(0)} = 0$ converges to the fixed point $x^* \approx 1.187$. In the right panel, $\Phi(x) = 3 - \frac{3}{2}x$ has slope $-\frac{3}{2}$, and the path from $x^{(0)} = 1$ spirals away from the fixed point $x^* = \frac{6}{5}$.

B.7.3 Checking the contraction property

For smooth maps on $\mathbb{R}^n$, the contraction property follows from a bound on the Jacobian.

Proposition B.131 (Jacobian row-sum criterion). *Let $X \subseteq \mathbb{R}^n$ be convex and let $\Phi : X \to \mathbb{R}^n$ be*

continuously differentiable on an open set containing X. If

$$\sup_{x \in X} \max_{j} \sum_{k=1}^{n} \left| \frac{\partial \Phi_j(x)}{\partial x_k} \right| \leq \kappa, \tag{B.91}$$

then $\|\Phi(x) - \Phi(y)\|_\infty \leq \kappa \|x - y\|_\infty$ for all $x, y \in X$. If in addition $\kappa < 1$ and Φ maps X into itself, then Φ is a contraction of X in the sup norm.

Proof. Fix $x, y \in X$ and a component j. By convexity the segment $x + \tau(y - x)$, $\tau \in [0, 1]$, lies in X. The fundamental theorem of calculus and the chain rule give

$$\Phi_j(y) - \Phi_j(x) = \int_0^1 \sum_{k=1}^{n} \frac{\partial \Phi_j}{\partial x_k}\big(x + \tau(y - x)\big)\,(y_k - x_k)\,\mathrm{d}\tau.$$

Bounding each $|y_k - x_k|$ by $\|y - x\|_\infty$,

$$|\Phi_j(y) - \Phi_j(x)| \leq \int_0^1 \sum_{k=1}^{n} \left| \frac{\partial \Phi_j}{\partial x_k}\big(x + \tau(y - x)\big) \right| \mathrm{d}\tau \, \|y - x\|_\infty \leq \kappa \|y - x\|_\infty.$$

Taking the maximum over j proves the claim. □

The constant in (B.91) is the largest induced sup norm of the Jacobian over X, by Lemma B.2. For a linear map the criterion is therefore sharp. The proof is the mean value inequality of Section B.1.3.

When all partial derivatives are nonnegative, as in the share inversion below, the absolute values in (B.91) drop out. The row sum then has a direct reading:

$$\sum_{k=1}^{n} \frac{\partial \Phi_j(x)}{\partial x_k} = \frac{\mathrm{d}}{\mathrm{d}c}\, \Phi_j(x + c\mathbf{1})\Big|_{c=0},$$

where $\mathbf{1}$ is the vector of ones. The condition says that Φ is monotone and that raising every argument by c raises each component by less than c. Blackwell's theorem is the version of this idea for maps between function spaces.

Theorem B.132 (Blackwell, 1965)**.** *Let $B(S)$ be the space of bounded real functions on a set S with the sup metric, and let $\mathcal{T} : B(S) \to B(S)$ satisfy two conditions. The first, monotonicity, requires that $g \leq g'$ pointwise implies $\mathcal{T} g \leq \mathcal{T} g'$. The second, discounting, requires that there is $\kappa \in [0, 1)$ such that $\mathcal{T}(g + c) \leq \mathcal{T} g + \kappa c$ for every g and every constant $c \geq 0$. Then $\mathcal{T}$ is a contraction with modulus κ.*

Proof. Fix $g, g' \in B(S)$ and let $c = \sup_s |g(s) - g'(s)|$. Then $g \leq g' + c$ pointwise. Monotonicity and discounting give $\mathcal{T} g \leq \mathcal{T}(g' + c) \leq \mathcal{T} g' + \kappa c$. Exchanging the roles of g and g' gives $\mathcal{T} g' \leq \mathcal{T} g + \kappa c$. Hence $|\mathcal{T} g(s) - \mathcal{T} g'(s)| \leq \kappa c$ for every s, which is the claim. □

The Bellman operator $(\mathcal{T} g)(s) = \max_a \{u(s, a) + \kappa\, \mathbb{E}[g(s') \mid s, a]\}$ of a dynamic program with discount factor κ satisfies both conditions, so value functions are unique fixed points that value iteration computes. Dynamic models lie outside this edition, but the logic is the same as in the static applications below.

Some maps of interest have row sums below one at every point but not uniformly, as in the example $x + \frac{1}{x}$. Berry et al. (1995, Appendix I) handle this case with a truncation.

Theorem B.133 (Berry et al., 1995, Appendix I)**.** *Consider $\mathbb{R}^J$ with the sup norm, and let $\Phi : \mathbb{R}^J \to \mathbb{R}^J$ satisfy three conditions. (1) Φ is continuously differentiable, with $\frac{\partial \Phi_j(y)}{\partial y_k} \geq 0$ and $\sum_{k=1}^J \frac{\partial \Phi_j(y)}{\partial y_k} < 1$ for all j, k and y. (2) Φ is bounded below: $\underline{y} \equiv \min_j \inf_y \Phi_j(y) > -\infty$. (3) There is a value $\bar{y}$ such that, whenever $y_j \geq \bar{y}$ for some j, there is some k (not necessarily equal to j) with $\Phi_k(y) < y_k$. Then Φ has a unique fixed point in $\mathbb{R}^J$. Moreover, the truncated map $\hat{\Phi}_j(y) = \min\{\Phi_j(y), \bar{y}\}$ is a contraction of $[\underline{y}, \bar{y}]^J$ with modulus below one.*

Theorem 8.15 proves the theorem in full. The idea is short. On the compact set $[\underline{y}, \bar{y}]^J$, enlarged by the segments along which the proof integrates, the continuous row sums attain a maximum $\kappa < 1$. The truncated map is therefore a contraction there, and Theorem B.127 gives a fixed point. Condition (3) keeps that fixed point away from the cap $\bar{y}$, so it is a fixed point of Φ itself. The bound $\bar{y}$ is needed because no uniform modulus exists on all of $\mathbb{R}^J$. In the logit model, for instance, the row sums of the share-inversion map equal $1 - s_0(\delta)$, which tends to one as the mean utilities grow (Section B.7.4).

B.7.4 Application: inverting market shares

Consider a market with inside goods $j = 1, \ldots, J$ and the outside good $j = 0$. In the random coefficients logit model, consumer i chooses j with probability

$$s_{ij}(\delta) = \frac{e^{\delta_j + \mu_{ij}}}{1 + \sum_{k=1}^J e^{\delta_k + \mu_{ik}}}, \qquad s_{i0}(\delta) = 1 - \sum_{k=1}^J s_{ik}(\delta),$$

and the market share is $s_j(\delta) = \int s_{ij}(\delta)\, \mathrm{d}F(\nu_i)$, where μ_{ij} depends on the consumer's tastes ν_i and the nonlinear parameters (Chapter 8). Given observed shares s^{obs} with $s_j^{obs} > 0$ and $\sum_j s_j^{obs} < 1$, estimation needs the vector δ that solves $s(\delta) = s^{obs}$. Berry et al. (1995, eq. (6.8), p. 865) compute it as the fixed point of

$$\Phi_j(\delta) = \delta_j + \ln s_j^{obs} - \ln s_j(\delta), \qquad j = 1, \ldots, J. \tag{B.92}$$

A vector δ is a fixed point of Φ exactly when $s(\delta) = s^{obs}$.

Proposition B.134 (Row sums of the BLP map)**.** *In the random coefficients logit model, for all j and all $k \neq j$,*

$$\frac{\partial \Phi_j}{\partial \delta_j} = \frac{1}{s_j} \int s_{ij}^2 \, \mathrm{d}F > 0, \qquad \frac{\partial \Phi_j}{\partial \delta_k} = \frac{1}{s_j} \int s_{ij} s_{ik} \, \mathrm{d}F > 0,$$

and the row sums are

$$\sum_{k=1}^J \frac{\partial \Phi_j}{\partial \delta_k} = 1 - \frac{1}{s_j} \int s_{ij} s_{i0} \, \mathrm{d}F \in (0, 1). \tag{B.93}$$

Proof. The individual logit derivatives are $\frac{\partial s_{ij}}{\partial \delta_k} = s_{ij}(\mathbf{1}\{j = k\} - s_{ik})$, bounded by one, so we may differentiate under the integral (Section B.1.3). Hence $\frac{\partial s_j}{\partial \delta_j} = \int s_{ij}(1 - s_{ij})\, \mathrm{d}F$ and $\frac{\partial s_j}{\partial \delta_k} = -\int s_{ij} s_{ik} \, \mathrm{d}F$ for $k \neq j$. Differentiating (B.92),

$$\frac{\partial \Phi_j}{\partial \delta_j} = 1 - \frac{1}{s_j} \int s_{ij}(1 - s_{ij}) \, \mathrm{d}F = 1 - \frac{s_j}{s_j} + \frac{1}{s_j} \int s_{ij}^2 \, \mathrm{d}F = \frac{1}{s_j} \int s_{ij}^2 \, \mathrm{d}F,$$

and $\frac{\partial \Phi_j}{\partial \delta_k} = -\frac{1}{s_j}\frac{\partial s_j}{\partial \delta_k} = \frac{1}{s_j}\int s_{ij}s_{ik}\,\mathrm{d}F$. For the row sum, consumer i's choice probabilities depend only on differences of the utilities $(\delta_0 + \mu_{i0}, \ldots, \delta_J + \mu_{iJ})$, with $\delta_0 = \mu_{i0} = 0$. By Corollary B.10, $\sum_{k=0}^{J} \frac{\partial s_{ij}}{\partial \delta_k} = 0$, and the outside derivative is $\frac{\partial s_{ij}}{\partial \delta_0} = -s_{ij}s_{i0}$. Hence $\sum_{k=1}^{J} \frac{\partial s_{ij}}{\partial \delta_k} = s_{ij}s_{i0}$. Integrating and dividing by s_j,

$$\sum_{k=1}^{J} \frac{\partial \Phi_j}{\partial \delta_k} = 1 - \frac{1}{s_j}\sum_{k=1}^{J} \frac{\partial s_j}{\partial \delta_k} = 1 - \frac{1}{s_j}\int s_{ij}s_{i0}\,\mathrm{d}F.$$

The integral is positive and smaller than $\int s_{ij}\,\mathrm{d}F = s_j$, so the row sum lies in $(0, 1)$. □

Corollary 8.16 gives the same computation, and Chapter 8 verifies the remaining conditions of Theorem B.133. The row sum has a useful reading. The weights $\frac{s_{ij}}{s_j}$ form the distribution of consumer types among the buyers of j. The row sum is therefore one minus the average probability of choosing the outside good among those buyers. The modulus is close to one when the buyers of some product rarely choose the outside good, and convergence is then slow. The plain logit model shows this in its simplest form. There $s_{ij} = s_j$, so $\frac{\partial \Phi_j}{\partial \delta_k} = s_k$ for every k, including $k = j$. The Jacobian is the rank-one matrix $\mathbf{1}s^\top$, whose only nonzero eigenvalue is $s^\top\mathbf{1} = 1 - s_0$. With $s_0 = 0.1$ the iteration gains one digit of accuracy only every 22 steps, since $\frac{\ln 10}{-\ln 0.9} \approx 21.9$, although the logit inverse $\delta_j = \ln s_j - \ln s_0$ is available in closed form.

Three practical rules follow. First, the logit inversion $\ln s_j^{obs} - \ln s_0^{obs}$ is a natural starting value, and inside an estimation routine the solution at the previous parameter value is better. Second, the stopping tolerance must be tight, by (B.89), because the inversion error propagates into the estimation objective (Proposition 8.18). Dubé et al. (2012) study how to improve the numerical performance of random coefficients demand estimation (Chapter 8). Third, the update can be written multiplicatively as $e^{\delta_j^{(h+1)}} = e^{\delta_j^{(h)}} \frac{s_j^{obs}}{s_j(\delta^{(h)})}$. Each step raises δ_j when the model underpredicts the share of j and lowers it when the model overpredicts.

Remark B.135 (Where the iteration typically moves from the logit start). For a product with a small share, the logistic function $\frac{e^u}{1+e^u}$ is convex in the relevant range of utilities. Random coefficients spread individual utilities around δ_j. By Jensen's inequality the average choice probability at a given δ then exceeds the logit probability, so the model share at the logit starting value typically exceeds the observed share. The iteration then lowers δ_j, and the recovered mean utilities typically lie below the logit start. The statement describes a tendency. It is not a theorem, because the denominators of all products move together. Chapter 8 and Appendix C report worked examples.

Berry (1994, Appendix) proved existence and uniqueness of the inverse for a broad class of discrete choice models without the contraction. His argument combines Brouwer's theorem with a diagonal dominance condition.

Proposition B.136 (Berry, 1994, Appendix)**.** *Let $s : \mathbb{R}^J \to (0,1)^J$ be the inside shares of a random utility model with $\delta_0 = 0$. Suppose s is continuously differentiable, and that for all goods $j, k \in \{0, 1, \ldots, J\}$ the share of j rises in δ_j and falls in δ_k for $k \neq j$. Suppose also that, for any values of the other inside mean utilities, finite or $-\infty$, $s_j \to 0$ as $\delta_j \to -\infty$ and $s_j \to 1$ as $\delta_j \to \infty$. Then for every s^{obs} with positive entries and $\sum_j s_j^{obs} < 1$ there is exactly one δ with $s(\delta) = s^{obs}$.*

Outline of the proof. Step 1 (the element-by-element inverse). For each j, let $r_j(\delta)$ be the value of δ_j that makes $s_j(\delta_1, \ldots, r_j, \ldots, \delta_J) = s_j^{obs}$, given the other mean utilities. It exists, is unique and is

continuous, by monotonicity and the limits. It does not depend on δ_j. The implicit function theorem (Theorem B.27) gives, for $k \neq j$,

$$\frac{\partial r_j}{\partial \delta_k} = -\left(\frac{\partial s_j}{\partial \delta_j}\right)^{-1} \frac{\partial s_j}{\partial \delta_k} > 0.$$

A vector δ solves $s(\delta) = s^{obs}$ if and only if it is a fixed point of $r = (r_1, \ldots, r_J)$.

Step 2 (a lower bound). Since r_j rises in every δ_k, it is bounded below by its limit as all other $\delta_k \to -\infty$. Let $\underline{\delta}$ be the smallest of these J limits.

Step 3 (an upper bound). For each j, let $\bar{\delta}_j$ be the value of δ_j that sets the outside share equal to $s_0^{obs} = 1 - \sum_k s_k^{obs}$ when all other inside δ_k are $-\infty$. Choose $\bar{\delta} > \max_j \bar{\delta}_j$. Suppose $\delta_j \geq \bar{\delta}$ for some j. Adding products and raising δ_j both lower the outside share, so $s_0(\delta) < s_0^{obs}$. The inside shares then sum to more than $\sum_k s_k^{obs}$, so $s_k(\delta) > s_k^{obs}$ for some k. For that k, matching the smaller observed share requires a lower utility, so $r_k(\delta) < \delta_k$.

Step 4 (existence). The truncated map $\bar{r}_j(\delta) = \min\{r_j(\delta), \bar{\delta}\}$ is continuous and maps the box $[\underline{\delta}, \bar{\delta}]^J$ into itself. Brouwer's theorem (Theorem B.146) gives a fixed point δ^*. If $\delta_j^* = \bar{\delta}$ for some j, Step 3 gives k with $\bar{r}_k(\delta^*) \leq r_k(\delta^*) < \delta_k^*$, a contradiction. So δ^* lies below the cap and is a fixed point of r.

Step 5 (uniqueness). Shares depend only on utility differences, so Corollary B.10 gives $\sum_{k=0}^{J} \frac{\partial s_j}{\partial \delta_k} = 0$. All cross derivatives are negative, including the one with respect to δ_0. Hence

$$\frac{\partial s_j}{\partial \delta_j} = \sum_{k \neq j,\ k \geq 1} \left|\frac{\partial s_j}{\partial \delta_k}\right| + \left|\frac{\partial s_j}{\partial \delta_0}\right| > \sum_{k \neq j,\ k \geq 1} \left|\frac{\partial s_j}{\partial \delta_k}\right|. \tag{B.94}$$

Dividing by $\frac{\partial s_j}{\partial \delta_j}$ shows that the row sums $\sum_k \left|\frac{\partial r_j}{\partial \delta_k}\right|$ are below one at every point. On the compact box their maximum κ is below one. The truncation is nonexpansive, so Proposition B.131 makes $\bar{r}$ a contraction of the box. Every solution lies in the box by Steps 2 and 3, so the solution is unique. □

Condition (B.94) is (A2) in Berry (1994, p. 261). It also makes the Jacobian $\frac{\partial s}{\partial \delta^\top}$ strictly diagonally dominant, hence nonsingular by Lemma B.21. Berry (1994, p. 260) notes that a strictly positive and continuous density of the consumer-level unobservables suffices for his sign conditions. On the same page he states the limit conditions for finite values of the other mean utilities. We also allow the value $-\infty$, which Steps 2 and 3 of the proof use.

Remark B.137 (Connected substitutes). Berry et al. (2013) replace Berry's sign conditions by a weaker structure. Write $s_j(\delta, p)$ for the demand system and let λ stand for either $-p$ or δ. Goods $0, 1, \ldots, J$ are *connected substitutes* in λ if two conditions hold (Berry and Haile, 2014, Definition 1, p. 1759). First, s_k is nonincreasing in λ_j for all $j > 0$ and $k \neq j$. Second, for every nonempty set $\mathcal{K} \subseteq \{1, \ldots, J\}$, some $k \in \mathcal{K}$ and some good $\ell \notin \mathcal{K}$ have s_ℓ strictly decreasing in λ_k. The first condition requires weak gross substitutes. The second requires enough strict substitution that no group of inside goods trades only among itself, where the outside good may serve as the good ℓ. Connected substitutes are combined with an *index restriction*. One observed characteristic $x_{jt}^{(1)}$ and the unobservable ξ_{jt} affect the distribution of utilities only through the scalar index $\delta_{jt} = x_{jt}^{(1)}\beta_j + \xi_{jt}$, so consumers treat them as perfect substitutes (Berry and Haile, 2014, Section 3.2, eq. (2) and Assumption 1, p. 1757). Under the index restriction and connected substitutes in both $-p$ and δ, there is at most one δ with $s(\delta, p) = s^{obs}$ for any

interior share vector. This is Lemma 1 of Berry and Haile (2014, p. 1760), who credit the proof to Berry et al. (2013). The result needs no functional form, and it allows zero cross effects, as in the vertical model where each product competes only with its neighbors (Chapter 6). It delivers injectivity. Existence must be argued separately.

Nested logit demand shows why the BLP map sometimes needs to be modified. With nests g, nesting parameter $\sigma \in [0,1)$ and within-nest shares $s_{j|g}$, the derivatives of the log shares are given by (B.69) in Proposition B.108. The own derivative $\frac{\partial \ln s_j}{\partial \delta_j} = \frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j$ can be far above one when σ is large. The diagonal partial of the BLP map, $1 - \frac{\partial \ln s_j}{\partial \delta_j}$, is then negative, and the map can fail to be a contraction.

Proposition B.138 (Dampened inversion for the nested logit)**.** *Consider the nested logit model and the dampened map*

$$\Phi^D(\delta) = \delta + (1-\sigma)\big[\ln s^{obs} - \ln s(\delta)\big]. \tag{B.95}$$

(i) For j in nest g, its partial derivatives are all nonnegative:

$$\frac{\partial \Phi_j^D}{\partial \delta_k} = \begin{cases} \sigma s_{j|g} + (1-\sigma) s_j, & k = j, \\ \sigma s_{k|g} + (1-\sigma) s_k, & k \neq j,\ k \in g, \\ (1-\sigma) s_k, & k \notin g. \end{cases}$$

(ii) Every row sums to $1-(1-\sigma)s_0(\delta) < 1$. (iii) Let $\bar{\delta}$ be the cap of Step 3 in the proof of Proposition B.136. The truncated map $\min\{\Phi_j^D(\delta), \bar{\delta}\}$ is a contraction of $(-\infty, \bar{\delta}]^J$ with modulus $\kappa = 1-(1-\sigma)s_0(\bar{\delta}\mathbf{1}) < 1$, and its unique fixed point solves $s(\delta) = s^{obs}$. (iv) If some nest contains at least two products, the undampened map (B.92) has the Jacobian eigenvalue $-\frac{\sigma}{1-\sigma}$ at every δ. Its modulus exceeds one when $\sigma > \frac{1}{2}$.

Proof. (i) Multiply (B.69) by $-(1-\sigma)$ and add the identity. For $k = j$,

$$1 - (1-\sigma)\Big[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j\Big] = 1 - 1 + \sigma s_{j|g} + (1-\sigma) s_j = \sigma s_{j|g} + (1-\sigma) s_j.$$

For $k \neq j$ in the same nest, $-(1-\sigma)\big[-\frac{\sigma}{1-\sigma} s_{k|g} - s_k\big] = \sigma s_{k|g} + (1-\sigma) s_k$. For k in another nest, $-(1-\sigma)(-s_k) = (1-\sigma)s_k$.

(ii) Summing over k, the within-nest shares of nest g add to one and the inside shares add to $1 - s_0$:

$$\sum_{k=1}^{J} \frac{\partial \Phi_j^D}{\partial \delta_k} = \sigma \sum_{k \in g} s_{k|g} + (1-\sigma) \sum_{k=1}^{J} s_k = \sigma + (1-\sigma)(1-s_0) = 1 - (1-\sigma)s_0.$$

(iii) The outside share $s_0(\delta) = \big(1 + \sum_h D_h^{1-\sigma}\big)^{-1}$, with $D_h = \sum_{k \in h} e^{\frac{\delta_k}{1-\sigma}}$, falls in every δ_k. On $C = (-\infty, \bar{\delta}]^J$ it is therefore at least $s_0(\bar{\delta}\mathbf{1}) > 0$, so the row sums are at most $\kappa < 1$ on C. The set C is convex, so Proposition B.131 makes Φ^D Lipschitz with constant κ on C. Taking the minimum with the constant $\bar{\delta}$ is nonexpansive and maps into C, so the truncated map is a contraction of the complete set C. Its fixed point δ^* is unique by Theorem B.127. The dampened map lowers δ_k exactly when $s_k(\delta) > s_k^{obs}$, as the BLP map does. The argument of Step 4 in the proof of Proposition B.136 therefore keeps δ^* below the cap, so $\Phi^D(\delta^*) = \delta^*$ and $s(\delta^*) = s^{obs}$.

(iv) Write A for the matrix with elements $\frac{\partial \ln s_j}{\partial \delta_k}$. Let nest g contain at least two products, and take a nonzero vector x supported on g with $\sum_{k\in g} s_{k|g} x_k = 0$. By (B.69),

$$(Ax)_j = \frac{x_j}{1-\sigma} - \frac{\sigma}{1-\sigma}\mathbf{1}\{j \in g\} \sum_{k\in g} s_{k|g} x_k - \sum_{k=1}^{J} s_k x_k.$$

The middle term vanishes by construction. The last term is $s_g \sum_{k\in g} s_{k|g} x_k = 0$, where s_g is the share of nest g. Hence $Ax = \frac{1}{1-\sigma} x$. The Jacobian of the undampened map is $I - A$, so x is an eigenvector with eigenvalue $1 - \frac{1}{1-\sigma} = -\frac{\sigma}{1-\sigma}$. □

The proof of (iv) also shows that the dampened Jacobian $I - (1-\sigma)A$ has eigenvalue zero along the same directions. Dampening removes the within-nest overshooting exactly. The remaining eigenvalue governs the overall level of utilities and equals the row sum in (ii) in the one-nest case. The factor $1 - \sigma$ is the scale of the within-nest logit error in the nested logit (Section B.5), and this is why it is the right step size.

Example B.139 (Divergence and dampening)**.** Take one nest with two products, $\sigma = 0.8$ and true mean utilities $\delta = (0, -0.5)$. The shares are $(0.4657, 0.0382)$ and $s_0 = 0.4961$. At the solution, the Jacobian of the undampened map has eigenvalues $1 - s_0 = 0.504$ and $-\frac{\sigma}{1-\sigma} = -4$. Started from the logit inversion, the undampened iteration diverges, with sup-norm errors 7.9, 36.6 and 163.9 after one, two and three steps. The dampened map has row sums $1 - 0.2 \times 0.4961 = 0.901$. It reaches an error below 10^{-12} after 240 iterations. The rate is slow because dampening by $1 - \sigma = 0.2$ also slows the adjustment of the overall level of utilities, whose eigenvalue rises from $1 - s_0 = 0.504$ to 0.901.

Remark B.140 (Random coefficients nested logit). With random coefficients on top of the nested logit, the same computation holds consumer by consumer. The dampened map has nonnegative partials, and its row sums are

$$\sum_{k=1}^{J} \frac{\partial \Phi_j^D}{\partial \delta_k} = 1 - \frac{1-\sigma}{s_j} \int s_{ij} s_{i0} \, \mathrm{d}F < 1,$$

using $\sum_{k\geq 1} \frac{\partial s_{ij}}{\partial \delta_k} = s_{ij} s_{i0}$, which holds in the nested logit as in the logit. Global convergence then follows from an argument like that of Theorem B.133 once the iterates are confined to a compact set. The model nests the nested logit (F degenerate) and the random coefficients logit ($\sigma = 0$), and Grigolon and Verboven (2014) compare these alternatives. Chapter 11 applies the dampened iteration in merger simulation, and Remark 8.19 discusses it in the BLP framework.

Remark B.141 (Error scale and the pure characteristics model). The same logic explains why the inversion of the pure characteristics model is not a contraction. Suppose the logit errors are multiplied by a scale $\lambda > 0$, so that

$$s_{ij} = \frac{\exp\left(\frac{\delta_j + \mu_{ij}}{\lambda}\right)}{1 + \sum_k \exp\left(\frac{\delta_k + \mu_{ik}}{\lambda}\right)}.$$

Then $\frac{\partial s_{ij}}{\partial \delta_k} = \frac{1}{\lambda} s_{ij}(\mathbf{1}\{j = k\} - s_{ik})$. The undampened map has diagonal partial $1 - \frac{1}{\lambda s_j} \int s_{ij}(1 - s_{ij}) \, \mathrm{d}F$, which turns negative as λ falls. The map $\delta + \lambda[\ln s^{obs} - \ln s(\delta)]$ restores the structure of

Proposition B.134, with row sums $1 - \frac{1}{s_j}\int s_{ij}s_{i0}\,\mathrm{d}F$. As $\lambda \to 0$ each consumer chooses one option with probability near one, so $s_{ij}s_{i0} \to 0$ and the modulus tends to one. The pure characteristics model of Berry and Pakes (2007) is the limit $\lambda = 0$. Its share function is not smooth, and the contraction is lost. Berry and Pakes (2007, proof of Theorem 1, pp. 17–18) show that the element-by-element inverse of the proof of Proposition B.136 is only a weak contraction, with modulus at most one. They could not prove that the modulus is below one, and in Monte Carlo runs it "sometimes contracts so slowly as to become useless" (p. 19). They therefore combine three methods. The BLP contraction is applied to the model with logit errors of a small scale, which corresponds to a small λ here. A *homotopy* deforms a fixed-point problem with a known solution continuously into the target problem and tracks the solution along the way. One built on the element-by-element inverse takes over when progress stalls, and Newton steps finish the computation (Berry and Pakes, 2007, Section 4.3). Ackerberg et al. (2007, p. 35) likewise note that the inversion of this model is not necessarily a contraction with modulus less than one (Chapter 6).

B.7.5 Application: computing and counting price equilibria

In a differentiated-products Bertrand game, firm f chooses the prices of its products $\mathcal{J}_f$ to maximize $\pi_f(p) = \sum_{k\in\mathcal{J}_f}(p_k - mc_k)s_k(p)$. A price vector p^* is a Nash equilibrium if and only if $p^* = BR(p^*)$, where BR stacks the best responses. Uniqueness matters for counterfactuals more than for estimation. Estimation evaluates the first-order conditions at observed prices to recover marginal costs and never solves for an equilibrium. A counterfactual, such as a merger or a tax, must solve for new prices. If several equilibria exist, the analyst must select one, for example the one reached from the status quo (Chapter 4, Chapter 11).

Single-product logit firms: a global contraction

Let demand be logit with $\delta_j = \tilde{\delta}_j - \alpha p_j$, $\alpha > 0$, and constant marginal costs. Define $v_j = \tilde{\delta}_j - \alpha mc_j$, the mean utility at marginal-cost pricing, and $\Lambda_{-j} = 1 + \sum_{l\neq j} e^{\delta_l}$, which depends only on rivals' prices. Proposition B.99 gives the best response in closed form, $BR_j(p_{-j}) = mc_j + \frac{1}{\alpha}[1 + W_0(z_j)]$ with $z_j = \frac{e^{v_j-1}}{\Lambda_{-j}}$, as in (B.60). Here W_0 is the principal branch of the Lambert function, with derivative $W_0'(z) = \frac{W_0(z)}{z(1+W_0(z))}$ (Lemma B.98).

Proposition B.142 (Best-response contraction in the logit pricing game)**.** *With single-product firms, logit demand and constant marginal costs, the best-response map is a contraction of $\mathbb{R}^J$ in the sup norm with modulus*

$$\kappa = \max_j \frac{W_0(e^{v_j-1})}{1 + W_0(e^{v_j-1})} < 1. \tag{B.96}$$

Hence the Bertrand equilibrium exists and is unique, and best-response iteration converges to it from any starting prices.

Proof. Step 1 (slopes). Let $z_j = \frac{e^{v_j-1}}{\Lambda_{-j}}$. For $l \neq j$, $\frac{\partial \Lambda_{-j}}{\partial p_l} = -\alpha e^{\delta_l}$, so $\frac{\partial z_j}{\partial p_l} = \alpha z_j \frac{e^{\delta_l}}{\Lambda_{-j}}$. The chain rule and the derivative of W_0 give

$$\frac{\partial BR_j}{\partial p_l} = \frac{1}{\alpha}\cdot\frac{W_0(z_j)}{z_j(1+W_0(z_j))}\cdot\alpha z_j\frac{e^{\delta_l}}{\Lambda_{-j}} = \frac{W_0(z_j)}{1+W_0(z_j)}\cdot\frac{e^{\delta_l}}{\Lambda_{-j}}.$$

The derivative with respect to p_j is zero.

Step 2 (shares at the best response). At $p_j = BR_j(p_{-j})$, the identities (B.61) give $s_j = \frac{W_0(z_j)}{1+W_0(z_j)}$ and $\frac{e^{\delta_l}}{\Lambda_{-j}} = \frac{s_l}{1-s_j}$, with shares evaluated at $(BR_j(p_{-j}), p_{-j})$. Substituting into Step 1,

$$\frac{\partial BR_j}{\partial p_l} = \frac{s_j s_l}{1 - s_j}, \qquad l \neq j.$$

Step 3 (row sums). The slopes are positive, and

$$\sum_{l \neq j} \frac{\partial BR_j}{\partial p_l} = \frac{s_j}{1 - s_j} \sum_{l \neq j} s_l = \frac{s_j(1 - s_j - s_0)}{1 - s_j} < s_j.$$

Step 4 (a uniform bound). Since $\Lambda_{-j} \geq 1$, we have $z_j \leq e^{v_j - 1}$. The functions W_0 and $w \mapsto \frac{w}{1+w}$ are increasing, so $s_j = \frac{W_0(z_j)}{1+W_0(z_j)} \leq \frac{W_0(e^{v_j-1})}{1+W_0(e^{v_j-1})} \leq \kappa$. The bound holds at every price vector. Proposition B.131 on the convex set $\mathbb{R}^J$ and Theorem B.127 complete the proof. □

The bound κ is the share that firm j would choose if all rivals priced out of the market. It is uniform because a firm's share at its own best response can never exceed that value.

Example B.143 (Three logit firms)**.** Let $\alpha = 1$, $\tilde{\delta} = (2, 3, 4)$ and $mc = (1, 1, 1)$, so $v = (1, 2, 3)$. The share bounds are $(0.362, 0.500, 0.609)$, so $\kappa = 0.609$. Best-response iteration from $p^{(0)} = mc$ stops after 21 iterations, when successive prices differ by less than 10^{-12}. The equilibrium prices are $(2.143, 2.372, 2.847)$, with shares $(0.125, 0.271, 0.459)$ and $s_0 = 0.145$. The markups $(1.143, 1.372, 1.847)$ equal $\frac{1}{\alpha(1-s_j)}$. At the equilibrium the row sums of the Jacobian are $(0.105, 0.217, 0.336)$, and its spectral radius is 0.233, close to the observed rate of convergence of 0.232 per step. The a priori bound (B.90) with $\kappa = 0.609$ guarantees accuracy 10^{-12} after 59 iterations, so it is conservative by a factor of three. Two hundred random starting points in $mc + [0, 20]^3$ all reach the same equilibrium.

Remark B.144 (Multiproduct logit firms). Logit first-order conditions imply that firm f sets a common markup $m_f = \frac{1}{\alpha(1-S_f)}$ on all its products, where $S_f = \sum_{k \in \mathcal{J}_f} s_k$ (Proposition B.97). With $E_f = \sum_{k \in \mathcal{J}_f} e^{v_k}$ and $\Lambda_{-f} = 1 + \sum_{l \notin \mathcal{J}_f} e^{\delta_l}$, the best-response markup is $\frac{1}{\alpha}\left[1 + W_0\left(\frac{E_f e^{-1}}{\Lambda_{-f}}\right)\right]$ (Proposition B.99). The computation of the proof gives $\frac{\partial BR_k}{\partial p_l} = \frac{S_f s_l}{1-S_f}$ for $k \in \mathcal{J}_f$ and $l \notin \mathcal{J}_f$, and zero for $l \in \mathcal{J}_f$. The row sums are $\frac{S_f(1-S_f-s_0)}{1-S_f} < S_f \leq \frac{W_0(E_f e^{-1})}{1+W_0(E_f e^{-1})}$, so the best-response map is again a global contraction. The equilibrium is unique for every ownership structure, and merger simulation by best-response iteration converges.

Remark B.145 (Uniqueness through a scalar aggregate). A second proof reduces the equilibrium to one equation in the aggregate $\Lambda = 1 + \sum_l e^{\delta_l}$. Multiproduct pricing games with logit or CES demands are *aggregative games*. Each firm's profit depends on its rivals' prices only through one scalar aggregator, and consumer surplus is a monotone function of that aggregator (Nocke and Schutz, 2018). Each firm is then summarized by a one-dimensional *type*, its contribution to consumer surplus if it priced at cost (Asker and Nocke, 2021, p. 229 and fn. 127). In the logit model the aggregator is Λ, consumer surplus is $\frac{1}{\alpha} \ln \Lambda$ up to a constant (Proposition B.95), and the type of firm f is $E_f = \sum_{k \in \mathcal{J}_f} e^{v_k}$. This is what the products of f add to Λ when they are priced at marginal cost. A merger without synergies gives the merged firm the sum of the partners' types. Asker and Nocke (2021, p. 229) report that consumer surplus then falls. It

does not fall only if synergies raise the merged type above a cutoff that exceeds this sum. In equilibrium $\alpha m_f = \frac{1}{1-S_f}$ and $S_f = \frac{E_f e^{-\alpha m_f}}{\Lambda}$. Eliminating the markup,

$$h(S_f) \equiv S_f \, e^{\frac{1}{1-S_f}} = \frac{E_f}{\Lambda}.$$

The left side is strictly increasing on $(0,1)$, since $h'(S) = e^{\frac{1}{1-S}}\left[1 + \frac{S}{(1-S)^2}\right] > 0$, with $h(0) = 0$ and $h(S) \to \infty$ as $S \to 1$. Each $\Lambda > 0$ therefore pins down a unique $S_f(\Lambda)$, strictly decreasing in Λ. Adding up requires $\Psi(\Lambda) \equiv \sum_f S_f(\Lambda) + \frac{1}{\Lambda} = 1$, because $s_0 = \frac{1}{\Lambda}$. The function Ψ is strictly decreasing, with $\Psi(1) > 1$ and $\Psi(\Lambda) \to 0$ as $\Lambda \to \infty$. So there is exactly one root Λ^*, and it determines all shares, markups and prices. In Example B.143 the root is $\Lambda^* = 6.908 = \frac{1}{s_0}$, and $\Psi(1) = 2.75$.

Existence without contraction

When best responses are not contractions, existence rests on topological fixed-point theorems.

Theorem B.146 (Brouwer)**.** *Let $K \subseteq \mathbb{R}^n$ be nonempty, compact and convex, and let $\Phi : K \to K$ be continuous. Then Φ has a fixed point.*

Theorem B.147 (Kakutani)**.** *Let $K \subseteq \mathbb{R}^n$ be nonempty, compact and convex, and let Γ be a correspondence from K to K with nonempty convex values and a closed graph. Then there is $x^* \in K$ with $x^* \in \Gamma(x^*)$.*

Both theorems are standard (Brouwer, 1912; Kakutani, 1941; Mas-Colell et al., 1995). Neither says anything about uniqueness or computation. Kakutani's theorem gives the basic existence result for pricing games.

Corollary B.148 (Existence of a pure-strategy equilibrium)**.** *Suppose each firm's price vector lies in a nonempty, compact, convex set P_f. Suppose also that each profit function π_f is continuous in all prices and quasi-concave in firm f's own prices. Then a pure-strategy Nash equilibrium exists.*

Proof. Let $\Gamma(p) = \prod_f BR_f(p_{-f})$ on $K = \prod_f P_f$. By Berge's maximum theorem, continuity of π_f and compactness of P_f make each BR_f nonempty valued with a closed graph (Mas-Colell et al., 1995). Quasi-concavity makes the set of maximizers convex, since it is an upper contour set of a quasi-concave function at its maximum value. Theorem B.147 gives $p^* \in \Gamma(p^*)$, which is an equilibrium. □

Corollary B.148 is the pricing-game case of a theorem of Debreu (1952). Tirole (1988, Section 11.6.1) states a special case of it for any normal-form game with finitely many players. Each action set is a compact convex subset of a Euclidean space, and each payoff is continuous in all actions and quasi-concave in the player's own action (Theorem 2.15). Debreu's version also lets a player's feasible actions depend on the actions of the others. Two consequences follow. First, a finite game always has an equilibrium in mixed strategies (Nash, 1950). A mixed strategy is a point of a simplex, which is compact and convex, and the expected payoff is linear, hence quasi-concave, in the player's own mixture. It is also a polynomial in all mixtures, hence continuous. Second, some games of industrial organization fall outside the theorem. Auctions, Cournot competition and location games can have payoffs that are discontinuous or not quasi-concave. Dasgupta and Maskin (1986) give existence conditions for such games, for pure strategies when payoffs are quasi-concave and for mixed strategies when they are not (Tirole, 1988, Section 11.6.1).

Remark B.149 (Equilibrium concepts used in the book). The book uses four equilibrium concepts, all developed in Tirole (1988, Sections 11.2–11.5). A *Nash equilibrium*, in pure or mixed strategies, is a profile in which each player's strategy is a best response to the strategies of the others (Definition 2.14). The static pricing and quantity games use it (Definition 4.2). A *subgame perfect equilibrium* requires Nash play in every subgame, so threats that would not be carried out are ruled out (Tirole, 1988, Section 11.3). The repeated games of collusion use it (Definition 12.3). A *Bayesian Nash equilibrium* applies to games of incomplete information. Each player's type-contingent strategy maximizes its expected payoff, given its type and the strategies of the others (Tirole, 1988, Section 11.4). Auction models use it (Definition 14.29). A *perfect Bayesian equilibrium* combines subgame perfection with Bayesian beliefs for dynamic games of incomplete information. Strategies are optimal given beliefs at every information set, and beliefs follow from the equilibrium strategies by Bayes' rule where possible (Tirole, 1988, Section 11.5). Signaling models of limit pricing, which Chapter 3 mentions in passing, rest on it. In these models entrants are unsure of an incumbent's cost. In games with finitely many actions and types, Tirole (1988, Section 11.6.1) derives the existence of the other three equilibria from the same theorem. The Bayesian case treats each type of a player as a separate player. The perfect Bayesian case takes limits of equilibria of games in which every action is played with a small positive probability.

Quasi-concavity is the substantive condition. Without it a best response can jump between two prices, and a pure-strategy equilibrium may fail to exist. Caplin and Nalebuff (1991) derive quasi-concavity of profits from conditions on the distribution of consumer tastes. They then apply Kakutani's theorem to the best-response correspondence on $\prod_f [mc_f, Y]$, where Y is an upper bound on prices (Section B.8.4, Chapter 4).

Uniqueness by diagonal dominance

The next result turns diagonal dominance of the first-order conditions into uniqueness.

Proposition B.150 (Uniqueness by dominant diagonal)**.** *Let $P \subseteq \mathbb{R}^N$ be convex and let $g : P \to \mathbb{R}^N$ be continuously differentiable with*

$$\left|\frac{\partial g_i(p)}{\partial p_i}\right| > \sum_{j \neq i} \left|\frac{\partial g_i(p)}{\partial p_j}\right| \qquad \text{for all } i \text{ and all } p \in P. \tag{B.97}$$

Then g has at most one zero in P. In particular, if $g_i = \frac{\partial \pi_i}{\partial p_i}$ and

$$\left|\frac{\partial^2 \pi_i}{\partial p_i^2}\right| > \sum_{j \neq i} \left|\frac{\partial^2 \pi_i}{\partial p_i \, \partial p_j}\right|$$

on P, there is at most one equilibrium in P at which every firm's first-order condition holds.

Proof. Suppose $g(p) = g(p') = 0$ with $p \neq p'$. Choose i with $|p_i - p'_i| = \|p - p'\|_\infty \equiv \lambda > 0$. The function $\tau \mapsto g_i(p + \tau(p' - p))$ is differentiable on $[0, 1]$, and P contains the segment. By the mean value theorem there is a point z on the segment with

$$0 = g_i(p') - g_i(p) = \sum_{j=1}^{N} \frac{\partial g_i(z)}{\partial p_j}(p'_j - p_j).$$

Isolating the own term and bounding the others by λ,

$$\left|\frac{\partial g_i(z)}{\partial p_i}\right|\lambda = \left|\sum_{j\neq i}\frac{\partial g_i(z)}{\partial p_j}(p_j'-p_j)\right| \le \sum_{j\neq i}\left|\frac{\partial g_i(z)}{\partial p_j}\right|\lambda < \left|\frac{\partial g_i(z)}{\partial p_i}\right|\lambda,$$

where the last step is (B.97). This is a contradiction. □

The argument is the nonsingularity of diagonally dominant matrices (Lemma B.21) applied along a segment. Friedman (1977) gives the condition for pricing games. Caplin and Nalebuff (1991) use it to prove uniqueness in duopoly with a log-concave taste density, in one-dimensional markets and in the logit model. The condition also yields a contraction. If firm i's best response is interior and the second-order condition is strict, the implicit function theorem gives

$$\frac{\partial BR_i}{\partial p_j} = -\left(\frac{\partial^2\pi_i}{\partial p_i^2}\right)^{-1}\frac{\partial^2\pi_i}{\partial p_i\,\partial p_j},$$

so the dominant diagonal is equivalent to row sums $\sum_{j\neq i}|\frac{\partial BR_i}{\partial p_j}| < 1$. On a compact rectangle that the best-response map sends into itself, Proposition B.131 then makes best-response iteration converge. Gale and Nikaidô (1965) prove a related global result. A continuously differentiable map on a rectangle whose Jacobian has positive principal minors everywhere is one-to-one.

The proposition applies to any function whose zeros are the equilibria, which leaves room to transform the first-order conditions. In the single-product logit game, profits are positive whenever $p_j > mc_j$, and the first-order conditions are equivalent to $g_j(p) = \frac{\partial \ln \pi_j}{\partial p_j} = \frac{1}{p_j - mc_j} - \alpha(1-s_j) = 0$. Differentiating,

$$\frac{\partial g_j}{\partial p_j} = -\frac{1}{(p_j-mc_j)^2} - \alpha^2 s_j(1-s_j), \qquad \frac{\partial g_j}{\partial p_k} = \alpha^2 s_j s_k \quad (k\neq j).$$

The off-diagonal terms sum to $\alpha^2 s_j(1-s_j-s_0) < \alpha^2 s_j(1-s_j)$, so (B.97) holds on the convex set $\{p : p_j > mc_j\ \forall j\}$. This gives a second proof of uniqueness in Proposition B.142.

B.7.6 Computing equilibria in practice

Four algorithms are in common use. They differ in what they iterate and in how much they guarantee.

Best-response iteration sets $p^{(h+1)} = BR(p^{(h)})$, solving each firm's problem given rivals' current prices. It converges whenever BR is a contraction, as in the logit game of Proposition B.142. Each step requires solving J (or F) single-firm problems, which is cheap when the best response has a closed form such as (B.60).

Markup iteration rearranges the stacked first-order conditions $s(p) + (\Omega \odot \Delta(p)^\top)(p - mc) = 0$, with ownership matrix Ω and $\Delta_{jk} = \frac{\partial s_j}{\partial p_k}$, into

$$p^{(h+1)} = mc - \left(\Omega \odot \Delta(p^{(h)})^\top\right)^{-1} s(p^{(h)}). \tag{B.98}$$

It needs no inner optimization, but it need not converge. With single-product logit firms it reads $p_j^{(h+1)} = mc_j + \frac{1}{\alpha(1-s_j(p^{(h)}))}$. Differentiating the right side with respect to p_j gives

$$\frac{1}{\alpha(1-s_j)^2}\cdot\frac{\partial s_j}{\partial p_j} = \frac{-\alpha s_j(1-s_j)}{\alpha(1-s_j)^2} = -\frac{s_j}{1-s_j}.$$

For a single-product monopolist this is the whole Jacobian. The iteration therefore oscillates and diverges locally whenever the monopoly share exceeds one half, while the best response (B.60) solves the problem in one step.

The Morrow and Skerlos iteration splits the derivative matrix of random coefficients logit demand into two parts (Morrow and Skerlos, 2011). With consumer price sensitivity α_i, the share derivatives are $\frac{\partial s_j}{\partial p_k} = \int \alpha_i s_{ij}(s_{ik} - \mathbf{1}\{j = k\})\,\mathrm{d}F$. Hence $\Delta = -\Lambda_D + \Gamma$, where $\Lambda_D = \operatorname{diag}\left(\int \alpha_i s_{ij}\,\mathrm{d}F\right)$ and $\Gamma_{jk} = \int \alpha_i s_{ij} s_{ik}\,\mathrm{d}F$ is symmetric. Since Ω has ones on its diagonal, $\Omega \odot \Delta^\top = -\Lambda_D + \Omega \odot \Gamma$. The first-order conditions become

$$p - mc = \Lambda_D(p)^{-1}\left[s(p) + (\Omega \odot \Gamma(p))(p - mc)\right], \tag{B.99}$$

which is iterated as a fixed point in p. The map is not guaranteed to be a contraction. In the simulated random coefficients markets of Section C.4 it converges in every market, in 10 to 13 iterations (Table C.15). The logit case suggests why it behaves well. There the right side of (B.99) for product j is $\frac{1}{\alpha} + s_j(p)(p_j - mc_j)$. Its derivative with respect to p_j is $s_j[1 - \alpha(p_j - mc_j)(1 - s_j)]$, which is zero at the solution by the first-order condition. Its derivative with respect to p_l is $\frac{s_j s_l}{1 - s_j}$ at the solution. Near the equilibrium the iteration therefore behaves like best-response iteration.

Newton's method solves the stacked first-order conditions $\Psi(p) = s(p) + (\Omega \odot \Delta(p)^\top)(p - mc) = 0$ by

$$p^{(h+1)} = p^{(h)} - \left[D_p \Psi(p^{(h)})\right]^{-1} \Psi(p^{(h)}).$$

Near a solution with a nonsingular Jacobian it converges quadratically, so the number of correct digits roughly doubles at each step (Judd, 1998). It needs second derivatives of demand and can fail far from the solution. A common hybrid starts with a fixed-point iteration and switches to Newton steps near the solution.

Two devices improve slow fixed-point iterations. Dampening replaces Φ by $x + \omega[\Phi(x) - x]$ with a step $\omega \in (0, 1)$. This maps each eigenvalue ς of the Jacobian to $1 - \omega(1 - \varsigma)$. A suitable step turns a large negative eigenvalue into a small one, as in Proposition B.138, at the cost of slowing directions whose eigenvalues are near one. Extrapolation methods such as SQUAREM (Varadhan and Roland, 2008) accelerate iterations whose modulus is close to one (Chapter 8). Whatever the method, a careful analyst checks uniqueness numerically by solving from many starting points, unless a result such as Proposition B.142 guarantees it.

Merger simulation is this fixed point with a new ownership matrix. One recovers marginal costs from pre-merger prices, $\widehat{mc} = p^{pre} + (\Omega^{pre} \odot \Delta(p^{pre})^\top)^{-1} s(p^{pre})$. One then replaces Ω^{pre} by Ω^{post} and solves for the new equilibrium, starting from pre-merger prices. The first iteration of (B.98) from p^{pre} is closely related to upward pricing pressure, and the converged solution is the post-merger Bertrand equilibrium (Chapter 11, Appendix C).

B.8 Log-concavity

Many results in the book need a function to be "concave enough" without being concave. A monopolist's profit must have a single peak for the first-order condition to identify the optimal price. A best-response correspondence must be convex-valued for Kakutani's theorem (Theorem B.147) to deliver a price equilibrium. A first-price auction's bid distribution must map into a well-behaved value distribution. The property that delivers all three is log-concavity, together with its generalization, ϱ-concavity. Log-concavity is weaker than concavity and

stronger than quasi-concavity. Unlike quasi-concavity, it survives multiplication, integration and the passage from a density to its distribution function. This section states the definitions, proves the preservation results the book uses, and works through the applications to pricing, existence of equilibrium and auctions.

B.8.1 Definitions and characterizations

Throughout this section $C \subseteq \mathbb{R}^k$ is a convex set and $h : C \to [0, \infty)$ is a nonnegative function. We write $x_\lambda = \lambda x + (1-\lambda)y$ for a convex combination of two points $x, y \in C$ with weight $\lambda \in [0,1]$.

Definition B.151 (Log-concavity)**.** The function h is *log-concave* if, for all $x, y \in C$ and all $\lambda \in [0,1]$,

$$h(x_\lambda) \geq h(x)^\lambda \, h(y)^{1-\lambda}. \tag{B.100}$$

It is *strictly log-concave* if the inequality is strict whenever $x \neq y$, $\lambda \in (0,1)$ and $h(x)h(y) > 0$. It is *log-convex* if $h > 0$ and the reverse inequality holds.

If $h(x) > 0$ and $h(y) > 0$, the right side of (B.100) is positive, so $h(x_\lambda) > 0$. The *support* $\{x \in C : h(x) > 0\}$ of a log-concave function is therefore convex. On the support we may take logarithms, and (B.100) becomes

$$\ln h(x_\lambda) \geq \lambda \ln h(x) + (1-\lambda) \ln h(y).$$

So h is log-concave exactly when its support is convex and $\ln h$ is concave on it. With the convention $\ln 0 = -\infty$, log-concavity says that $\ln h$ is an extended-valued concave function. Smooth functions have a convenient test.

Lemma B.152 (Derivative tests)**.** *Let h be positive and twice continuously differentiable on an open interval $I \subseteq \mathbb{R}$. The following statements are equivalent.*

(i) h is log-concave on I.

(ii) $h(x)h''(x) - h'(x)^2 \leq 0$ for all $x \in I$.

(iii) The ratio $\frac{h'(x)}{h(x)}$ is nonincreasing on I.

For a positive C^2 function on an open convex set in $\mathbb{R}^k$, log-concavity is equivalent to negative semidefiniteness of the matrix $h(x)D^2h(x) - \nabla h(x)\nabla h(x)^\top$ at every x.

Proof. Differentiate the logarithm once,

$$\frac{\mathrm{d}}{\mathrm{d}x} \ln h(x) = \frac{h'(x)}{h(x)}.$$

Differentiate once more by the quotient rule:

$$\frac{\mathrm{d}^2}{\mathrm{d}x^2} \ln h(x) = \frac{h(x)h''(x) - h'(x)^2}{h(x)^2}.$$

A C^2 function of one variable is concave if and only if its second derivative is nonpositive, which gives (ii). It is concave if and only if its first derivative is nonincreasing, which gives (iii). For k variables the Hessian of $\ln h$ is $\frac{D^2h}{h} - \frac{\nabla h \nabla h^\top}{h^2}$. It is negative semidefinite if and only if the stated matrix is, because the two differ by the positive factor h^2. $\square$

Log-concavity sits between two familiar notions. A nonnegative concave function is log-concave. Indeed, concavity and the weighted inequality between arithmetic and geometric means give

$$h(x_\lambda) \geq \lambda h(x) + (1-\lambda)h(y) \geq h(x)^\lambda h(y)^{1-\lambda}.$$

A log-concave function is quasi-concave, because $h(x)^\lambda h(y)^{1-\lambda} \geq \min\{h(x), h(y)\}$. Neither converse holds. The standard normal density is log-concave, since $\frac{\mathrm{d}^2}{\mathrm{d}x^2} \ln \phi(x) = -1$, but it is convex in its tails. The Cauchy density $h(x) = \frac{1}{\pi(1+x^2)}$ has a single peak, so it is quasi-concave. Yet

$$\frac{\mathrm{d}^2}{\mathrm{d}x^2} \ln h(x) = -\frac{2(1-x^2)}{(1+x^2)^2},$$

which is positive for $|x| > 1$, so it is not log-concave.

Caplin and Nalebuff embed these notions in a one-parameter family. For $a, b \geq 0$, $\lambda \in [0,1]$ and $\varrho \in [-\infty, \infty]$, define the *power mean*

$$\mathcal{M}_\varrho(a, b; \lambda) = \left[\lambda a^\varrho + (1-\lambda) b^\varrho\right]^{\frac{1}{\varrho}} \quad \text{for } \varrho \neq 0,$$

with the limits $\mathcal{M}_0(a, b; \lambda) = a^\lambda b^{1-\lambda}$, $\mathcal{M}_\infty(a, b; \lambda) = \max\{a, b\}$ and $\mathcal{M}_{-\infty}(a, b; \lambda) = \min\{a, b\}$.

Definition B.153 (ϱ-concavity)**.** Let $\varrho \in [-\infty, \infty]$ and let h have convex support. The function h is *ϱ-concave* if, for all $x, y \in C$ and $\lambda \in [0,1]$,

$$h(x_\lambda) \geq \mathcal{M}_\varrho\big(h(x), h(y); \lambda\big), \tag{B.101}$$

where for $\varrho < 0$ the inequality is required only when $h(x)h(y) > 0$ (Caplin and Nalebuff, 1991, Section 3).

Caplin and Nalebuff (1991) write ρ for the index. We write ϱ because ρ denotes pass-through in this book. Our section and page references to their paper follow its working-paper version, Cowles Foundation Discussion Paper 937 (1990). The cases unpack as follows. For $\varrho > 0$, raising both sides of (B.101) to the power ϱ preserves the inequality, so h is ϱ-concave exactly when h^ϱ is concave. For $\varrho < 0$, raising positive numbers to the power ϱ reverses inequalities, so h is ϱ-concave exactly when h^ϱ is convex on the support. The case $\varrho = 1$ is concavity, $\varrho = 0$ is log-concavity, and $\varrho = -\infty$ is quasi-concavity. The case $\varrho = \infty$ forces h to be constant on its support, which is the uniform density. The case $\varrho = -1$ will matter most below: h is (-1)-concave exactly when $\frac{1}{h}$ is convex where $h > 0$.

Lemma B.154 (The ϱ-concavity hierarchy)**.** *For all $a, b > 0$ and $\lambda \in [0,1]$, the power mean $\mathcal{M}_\varrho(a, b; \lambda)$ is nondecreasing in ϱ. Consequently a ϱ-concave function is ϱ'-concave for every $\varrho' < \varrho$. In particular,*

$$\textit{concave} \implies \textit{log-concave} \implies (-1)\textit{-concave} \implies \textit{quasi-concave}.$$

Proof. Fix $a, b > 0$ and $\lambda \in (0,1)$, and let $\varrho' < \varrho$. The bounds $\min\{a, b\} \leq \mathcal{M}_\varrho \leq \max\{a, b\}$ dispose of $\varrho' = -\infty$ and $\varrho = \infty$. For finite nonzero exponents, let $s = \frac{\varrho}{\varrho'}$ and $u = a^{\varrho'}$, $w = b^{\varrho'}$, so that $a^\varrho = u^s$ and $b^\varrho = w^s$. There are three sign patterns.

(a) If $0 < \varrho' < \varrho$, then $s > 1$ and $t \mapsto t^s$ is convex on $(0, \infty)$. Jensen's inequality gives $(\lambda u + (1-\lambda)w)^s \leq \lambda u^s + (1-\lambda)w^s$. Raising both sides to the positive power $\frac{1}{\varrho}$ yields $\mathcal{M}_{\varrho'} \leq \mathcal{M}_\varrho$.

(b) If $\varrho' < \varrho < 0$, then $0 < s < 1$ and $t \mapsto t^s$ is concave. Jensen's inequality reverses, $(\lambda u + (1-\lambda)w)^s \geq \lambda u^s + (1-\lambda)w^s$. Raising both sides to the negative power $\frac{1}{\varrho}$ reverses it again, so $\mathcal{M}_{\varrho'} \leq \mathcal{M}_{\varrho}$.

(c) If $\varrho' < 0 < \varrho$, then $s < 0$ and $t \mapsto t^s$ is convex on $(0, \infty)$. Jensen's inequality gives the inequality of case (a), and the positive power $\frac{1}{\varrho}$ again yields $\mathcal{M}_{\varrho'} \leq \mathcal{M}_{\varrho}$.

For the geometric mean, concavity of the logarithm gives $\ln(\lambda a^{\varrho} + (1-\lambda)b^{\varrho}) \geq \varrho[\lambda \ln a + (1-\lambda)\ln b]$. Dividing by $\varrho > 0$ gives $\ln \mathcal{M}_{\varrho} \geq \ln \mathcal{M}_0$, and dividing by $\varrho < 0$ gives $\ln \mathcal{M}_{\varrho} \leq \ln \mathcal{M}_0$. This proves monotonicity. If h is ϱ-concave and $h(x)h(y) > 0$, then $h(x_\lambda) \geq \mathcal{M}_{\varrho} \geq \mathcal{M}_{\varrho'}$, which is ϱ'-concavity at that pair. When $h(x)h(y) = 0$, the requirement is void for $\varrho' < 0$ and trivial for $\varrho' = 0$, since then $\mathcal{M}_{\varrho'} = 0$. For $\varrho' > 0$ and, say, $h(x) = 0$, the requirement reads $h(x_\lambda) \geq (1-\lambda)^{\frac{1}{\varrho'}} h(y)$. It follows from ϱ-concavity, which gives $h(x_\lambda) \geq (1-\lambda)^{\frac{1}{\varrho}} h(y)$, because $\frac{1}{\varrho} < \frac{1}{\varrho'}$ and $1 - \lambda \leq 1$. The chain is the case $\varrho \in \{1, 0, -1, -\infty\}$. □

The monotonicity of power means is a standard inequality (Hardy et al., 1952, Chapter II). The index ϱ is a measure of how concave a function is. Lower values of ϱ give weaker requirements.

B.8.2 Preservation properties

Log-concavity is useful because it is preserved by the operations that turn primitives into economic objects. Products arise when independent consumers or bidders are combined, integrals arise when demand aggregates over types, and distribution functions arise whenever probabilities of events matter.

Proposition B.155 (Algebraic preservation)**.** *Let h_1 and h_2 be log-concave on C.*

(i) The product $h_1 h_2$ is log-concave.

(ii) For any matrix A and vector b of conformable dimensions, $x \mapsto h_1(Ax + b)$ is log-concave on the convex set where it is defined.

(iii) The indicator function of a convex set is log-concave, so the restriction of h_1 to a convex subset (a truncation) is log-concave.

(iv) For $a > 0$, the power h_1^a is log-concave.

Proof. On the supports, $\ln(h_1 h_2) = \ln h_1 + \ln h_2$ is a sum of concave functions, and $\ln h_1(Ax + b)$ is a concave function of an affine map. Both are concave, and the supports are convex. For (iii), the indicator $\mathbf{1}_K$ of a convex set K satisfies (B.100): if $x, y \in K$ then $x_\lambda \in K$ and both sides equal one, and otherwise the right side is zero. Part (i) then covers truncation. For (iv), $\ln h_1^a = a \ln h_1$ is concave. □

Sums are not preserved. An equal mixture of $N(-3, 1)$ and $N(3, 1)$ has two peaks. It is not quasi-concave, so it is not log-concave, although each component is.

The next result is the one the book uses most often. It transfers log-concavity from a density to its distribution and survival functions.

Proposition B.156 (Log-concave densities have log-concave CDFs and survival functions)**.** *Let the random variable X have a density f that is positive and continuously differentiable on an open interval $(\underline{x}, \bar{x})$, possibly unbounded, and zero outside it. If f is log-concave, then the CDF F and the survival function $1 - F$ are log-concave on $(\underline{x}, \bar{x})$.*

Proof. By Lemma B.152, $\frac{f'}{f}$ is nonincreasing. Fix $x \in (\underline{x}, \bar{x})$. For every $t \in (\underline{x}, x]$ we have $\frac{f'(t)}{f(t)} \geq \frac{f'(x)}{f(x)}$, and multiplying by $f(t) > 0$ gives

$$f'(t) \geq \frac{f'(x)}{f(x)} f(t).$$

Integrate both sides over $t \in (\underline{x}, x]$. Because $\ln f$ is concave and f is integrable, f has a finite limit $f(\underline{x}^+) \geq 0$ at the lower end, so

$$f(x) - f(\underline{x}^+) \geq \frac{f'(x)}{f(x)} F(x).$$

Since $f(\underline{x}^+) \geq 0$, the left side is at most $f(x)$. Multiplying by $f(x) > 0$ gives $f(x)^2 \geq f'(x)F(x)$, that is,

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{f(x)}{F(x)}\right) = \frac{f'(x)F(x) - f(x)^2}{F(x)^2} \leq 0.$$

The ratio $\frac{f}{F}$ is the derivative of $\ln F$, so $\ln F$ has a nonincreasing derivative and is concave.

For the survival function, take $t \in [x, \bar{x})$. Now $\frac{f'(t)}{f(t)} \leq \frac{f'(x)}{f(x)}$, so $f'(t) \leq \frac{f'(x)}{f(x)} f(t)$. Integrating over $t \in [x, \bar{x})$ and using $f(\bar{x}^-) \geq 0$,

$$-f(x) \leq f(\bar{x}^-) - f(x) \leq \frac{f'(x)}{f(x)}\big(1 - F(x)\big).$$

Multiplying by $f(x) > 0$ and rearranging gives $f'(x)(1 - F(x)) + f(x)^2 \geq 0$. Hence

$$\frac{\mathrm{d}^2}{\mathrm{d}x^2} \ln\big(1 - F(x)\big) = \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{-f(x)}{1 - F(x)}\right) = -\frac{f'(x)(1 - F(x)) + f(x)^2}{(1 - F(x))^2} \leq 0. \qquad \square$$

The *hazard rate* of X is $\frac{f(x)}{1-F(x)}$, the density of X at x conditional on $X \geq x$. The *reverse hazard rate* is $\frac{f(x)}{F(x)}$, the density at x conditional on $X \leq x$. Since $\frac{f}{1-F} = -\frac{\mathrm{d}}{\mathrm{d}x} \ln(1 - F)$ and $\frac{f}{F} = \frac{\mathrm{d}}{\mathrm{d}x} \ln F$, the proposition has an immediate corollary.

Corollary B.157 (Monotone hazard rates)**.** *Under the conditions of Proposition B.156, the hazard rate $\frac{f}{1-F}$ is nondecreasing (the* increasing failure rate *property) and the reverse hazard rate $\frac{f}{F}$ is nonincreasing. More precisely, $1 - F$ is log-concave if and only if the hazard rate is nondecreasing, and F is log-concave if and only if the reverse hazard rate is nonincreasing.*

The converse of Proposition B.156 fails in both directions. The survival function $1 - F(x) = \exp(-x - x^3)$ on $[0, \infty)$ has hazard rate $1 + 3x^2$, which is increasing, so the survival function is log-concave. Its density is $f(x) = (1 + 3x^2)e^{-x-x^3}$, and

$$\frac{\mathrm{d}^2}{\mathrm{d}x^2} \ln f(x) = \frac{6 - 18x^2}{(1 + 3x^2)^2} - 6x,$$

which equals 6 at $x = 0$ and stays positive up to $x \approx 0.35$. The density is not log-concave. For the CDF, the lognormal distribution has a log-concave CDF but a density that is not log-concave (Table B.4).

When the density is not differentiable, or when X is a vector, a more powerful theorem applies.

Theorem B.158 (Prékopa). *Let $h : \mathbb{R}^m \times \mathbb{R}^k \to [0, \infty)$ be log-concave in (x, y) jointly. Then $x \mapsto \int_{\mathbb{R}^k} h(x, y)\, \mathrm{d}y$ is log-concave on $\mathbb{R}^m$ (Prékopa, 1971).*

We use the theorem without proof. Three consequences follow from it and Proposition B.155.

(a) *Marginals.* If a random vector has a log-concave density, every subvector has a log-concave marginal density. Take h to be the joint density and integrate out the other coordinates.

(b) *Convolutions.* If X and Y are independent with log-concave densities f_X and f_Y, then $X + Y$ has the density $\int f_X(x - y) f_Y(y)\, \mathrm{d}y$. The integrand is a product of log-concave functions of affine maps of (x, y), so the density of the sum is log-concave. For example, the difference of two independent Gumbel variables, which is logistic (Section B.5), has a log-concave density because both Gumbel densities are log-concave.

(c) *Distribution functions.* The CDF of a random vector is $F(x) = \int \mathbf{1}\{y \le x\} f(y)\, \mathrm{d}y$. The set $\{(x, y) : y \le x\}$ is convex, so the integrand is log-concave when f is. This proves the CDF part of Proposition B.156 in any dimension and without differentiability. For a scalar X, the convex set $\{(x, y) : y > x\}$ gives the survival part in the same way.

Theorem B.158 concerns integrals over the sections of a convex set. Caplin and Nalebuff (1991) need a version for integrals over arbitrary sets that move with a parameter, and for densities that are only ϱ-concave. For sets $A_0, A_1 \subseteq \mathbb{R}^L$ and $\lambda \in [0, 1]$, the *Minkowski average* is the set $A_\lambda = \lambda A_0 + (1 - \lambda) A_1 = \{\lambda a_0 + (1 - \lambda) a_1 : a_0 \in A_0,\ a_1 \in A_1\}$.

Theorem B.159 (Prékopa-Borell). *Let f be a probability density on $\mathbb{R}^L$ with convex support B, and let $\varrho \ge -\frac{1}{L}$. Define $\varrho^* = \frac{\varrho}{1 + L\varrho}$, with $\varrho^* = \frac{1}{L}$ when $\varrho = \infty$. If f is ϱ-concave, then for all measurable sets A_0 and A_1 that intersect B and all $\lambda \in [0, 1]$,*

$$\int_{A_\lambda} f(v)\, \mathrm{d}v \ge \left[\lambda \left(\int_{A_0} f(v)\, \mathrm{d}v \right)^{\varrho^*} + (1 - \lambda) \left(\int_{A_1} f(v)\, \mathrm{d}v \right)^{\varrho^*} \right]^{\frac{1}{\varrho^*}}. \tag{B.102}$$

The theorem is due to Prékopa (1971) for $\varrho = 0$ and to Borell (1975) in general. Das Gupta (1980) gives proofs, and we state it in the form used by Caplin and Nalebuff (1991, Section 4). The right side of (B.102) is the power mean $\mathcal{M}_{\varrho^*}$ of the two probabilities. In words, a ϱ-concave density generates a ϱ^*-concave probability measure over Minkowski averages of sets. Three cases show what the transformation does.

- A uniform density has $\varrho = \infty$ and $\varrho^* = \frac{1}{L}$. The theorem becomes the Brunn-Minkowski inequality for volumes: the L-th root of volume is concave along Minkowski averages.
- A log-concave density has $\varrho = 0$ and $\varrho^* = 0$. The probability of a Minkowski average is at least the geometric average of the two probabilities.
- As ϱ falls toward $-\frac{1}{L}$, the denominator $1 + L\varrho$ falls to zero and $\varrho^* \to -\infty$. Only quasi-concavity of the measure survives.

Since $\frac{\mathrm{d}\varrho^*}{\mathrm{d}\varrho} = \frac{1}{(1 + L\varrho)^2} > 0$, more concave densities yield more concave measures. Aggregation costs concavity, and the cost rises with the dimension L.

Table B.4 sorts common distributions. Every entry follows from the sign of the second derivative of the logarithm, given in the table notes, and we confirmed each sign numerically on a fine grid. Bagnoli and Bergstrom (2005) give a systematic treatment.

Figure B.8 shows the two faces of the table. The left panel plots log densities. The normal, logistic and Gumbel log densities are concave, while the Student t log density bends upward in

Table B.4: Log-concavity of common distributions

Distribution	Parameters	Density	CDF	Survival
Uniform	on $[a, b]$	yes	yes	yes
Normal	any	yes	yes	yes
Logistic	any	yes	yes	yes
Gumbel (type-I extreme value)	any	yes	yes	yes
Exponential	any	yes	yes	yes
Laplace	any	yes	yes	yes
Gamma	shape $a \geq 1$	yes	yes	yes
	shape $a < 1$	no	yes	no
Weibull	shape $k \geq 1$	yes	yes	yes
	shape $k < 1$	no	yes	no
Beta	$a, b \geq 1$	yes	yes	yes
Lognormal	any	no	yes	no
Pareto	any	no	yes	no
Student t	a degrees of freedom	no	no	no

Notes: "Yes" means log-concave on the support. Uniform, exponential and Laplace densities are log-linear on pieces of the support, the boundary case. The second derivative of the log density is -1 for the standard normal, $-\frac{2e^{-x}}{(1+e^{-x})^2}$ for the standard logistic and $-e^{-x}$ for the standard Gumbel. It is $-\frac{a-1}{x^2}$ for the gamma, $-\frac{k-1}{x^2} - k(k-1)x^{k-2}$ for the Weibull with unit scale, and $-\frac{a-1}{x^2} - \frac{b-1}{(1-x)^2}$ for the beta. It is $\frac{a+1}{x^2}$ for the Pareto and $-\frac{(a+1)(1-\frac{x^2}{a})}{a(1+\frac{x^2}{a})^2}$ for the Student t. For the lognormal with $\ln X \sim N(m, \varsigma^2)$ it is positive for $x > e^{m+1-\varsigma^2}$. Decreasing densities (gamma and Weibull with shape below one, Pareto) have concave, hence log-concave, CDFs. The Student t CDF behaves like $|x|^{-a}$ in the left tail, whose log is convex. The t density is ϱ-concave with $\varrho = -\frac{1}{1+a}$, because $f^{-\frac{1}{1+a}}$ is proportional to $\left(1 + \frac{x^2}{a}\right)^{\frac{1}{2}}$, a convex function (Caplin and Nalebuff, 1991, Section 3).

its tails. The right panel plots hazard rates. Log-concave densities have nondecreasing hazard rates, the exponential sits on the boundary with a constant hazard, and the lognormal and Pareto hazards eventually fall.

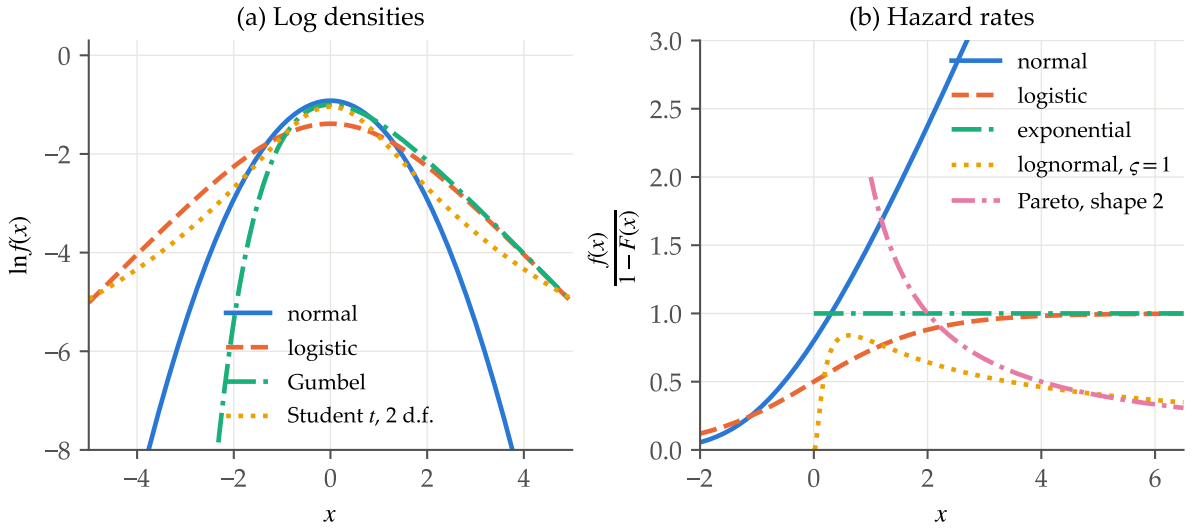

Figure B.8: Log densities and hazard rates. Panel (a): $\ln f$ for the standard normal, standard logistic and standard Gumbel densities, all concave, and for the Student t density with two degrees of freedom, which is convex in the tails. Panel (b): hazard rates $\frac{f(x)}{1-F(x)}$. The normal and logistic hazards rise, the unit exponential hazard is constant, the lognormal hazard with $\varsigma = 1$ peaks near $x = 0.62$ and then falls, and the Pareto hazard $\frac{2}{x}$ falls.

B.8.3 Pricing applications

Monopoly. Consider a single-product monopolist with constant marginal cost c and differentiable demand $Q(p)$ that is nonincreasing and positive on an interval $(c, \bar{p})$, with $\bar{p} \leq \infty$ and $Q(p) = 0$ for $p \geq \bar{p}$. Profit is $\pi(p) = (p - c)Q(p)$. Write $m(p) = -\frac{Q(p)}{Q'(p)}$ for the dollar markup that the first-order condition supports at price p, the reciprocal of the semi-elasticity $-\frac{Q'}{Q}$ (Chapter 2).

Proposition B.160 (Log-concave demand and the monopoly problem)**.** *Suppose Q is log-concave on $(c, \bar{p})$.*

(i) Profit is log-concave on $(c, \bar{p})$ and quasi-concave on $\mathbb{R}$, so the set of profit-maximizing prices is an interval.

(ii) The first-order condition $p - c = m(p)$ has at most one solution in $(c, \bar{p})$, and a solution is the global profit maximizer.

(iii) Where m is differentiable at the optimum, monopoly pass-through satisfies $\rho = \frac{1}{1-m'(p)} \in (0, 1]$.

If Q is strictly log-concave, the maximizer is unique.

Proof. (i) On $(c, \bar{p})$ profit is positive and $\ln \pi(p) = \ln(p - c) + \ln Q(p)$. Both terms are concave, so $\ln \pi$ is concave. Outside $(c, \bar{p})$ profit is nonpositive. Each upper contour set $\{p : \pi(p) \geq k\}$ with $k > 0$ is an upper contour set of the concave function $\ln \pi$, hence an interval. For $k \leq 0$ the

set contains all prices above c. It is an interval because profit is nondecreasing below c, where a higher price shrinks both the loss per unit and the number of units sold.

(ii) Since $(\ln Q)' = \frac{Q'}{Q}$ is nonincreasing, the semi-elasticity $-\frac{Q'}{Q}$ is nondecreasing and the markup $m(p)$ is nonincreasing where $Q' < 0$. The left side $p - c$ of the first-order condition is strictly increasing. The two sides can cross at most once. A solution makes $(\ln \pi)'$ vanish, and a stationary point of a concave function is a global maximizer on $(c, \bar{p})$, where all positive profits are earned.

(iii) Differentiate the identity $p(c) - c = m(p(c))$ with respect to c:

$$\rho - 1 = m'(p)\rho.$$

Solving gives $\rho = \frac{1}{1-m'(p)}$, and $m' \leq 0$ gives $0 < \rho \leq 1$. Strict log-concavity makes $\ln \pi$ strictly concave, so the maximizer is unique. □

Part (iii) is the global counterpart of Corollary B.34. That corollary states that at the monopoly price pass-through is below one if and only if $(\ln Q)'' < 0$ and above one if and only if $(\ln Q)'' > 0$. The two statements agree because $m' = -1 + \frac{QQ''}{(Q')^2}$, so $\frac{1}{1-m'} = \frac{1}{2-\frac{QQ''}{(Q')^2}}$.

The proposition has a probabilistic reading. Suppose consumers have unit demand and their willingness to pay W has CDF F_W and density f_W. Demand is $Q(p) = M[1 - F_W(p)]$ for market size M, and the markup is $m(p) = \frac{1-F_W(p)}{f_W(p)}$, the reciprocal of the hazard rate of W. Demand is log-concave exactly when the survival function of W is log-concave, that is, when W has an increasing failure rate (Corollary B.157). A log-concave density of willingness to pay suffices (Proposition B.156). The same object reappears as Myerson's virtual valuation in Section B.8.5.

Constant pass-through. Pass-through usually varies with the level of cost. Bulow and Pfleiderer (1983) identify the demand curves for which it does not. Let $P(q)$ be inverse demand with $P' < 0$ and curvature $\chi(q) = -\frac{qP''(q)}{P'(q)}$, as in (B.16). By Proposition B.33, monopoly pass-through at output q is $\rho = \frac{1}{2-\chi(q)}$, and the second-order condition is $2 - \chi > 0$.

Proposition B.161 (Constant pass-through demands)**.** *Let a monopolist with constant marginal cost face a twice continuously differentiable inverse demand with $P' < 0$ and $2 - \chi > 0$ on an interval of outputs. Pass-through is the same at every cost in an interval of costs if and only if inverse demand takes one of the two forms below on the corresponding interval of outputs.*

(a) $P(q) = a - bq^\gamma$ *with* $b\gamma > 0$ *and* $\gamma > -1$*, in which case* $\rho = \frac{1}{1+\gamma}$.

(b) $P(q) = a - b \ln q$ *with* $b > 0$*, in which case* $\rho = 1$.

Proposition 2.74 states the result in the same notation and leaves the converse as an exercise. The proof below carries it out.

Proof. Monopoly output $q^*(c)$ is continuous and strictly decreasing, because the implicit function theorem gives $\frac{dq^*}{dc} = \frac{1}{2P'+qP''} = \frac{1}{P'(2-\chi)} < 0$. Hence $\rho = \frac{1}{2-\chi(q^*(c))}$ is constant on an interval of costs if and only if χ is constant on the image interval of outputs.

It remains to solve $qP''(q) = -\chi P'(q)$ for a constant χ. Since $P' < 0$, write $-P'(q) = e^{\ell(q)}$. Then $P'' = P'\ell'$, and the equation becomes $q\ell'(q) = -\chi$. Integrating $\ell'(q) = -\frac{\chi}{q}$ gives $\ell(q) = -\chi \ln q + \ln K$ for a constant $K > 0$, so

$$P'(q) = -Kq^{-\chi}.$$

If $\chi \neq 1$, integrate once more and set $\gamma = 1 - \chi$ and $b = \frac{K}{\gamma}$:

$$P(q) = a - \frac{K}{1-\chi} q^{1-\chi} = a - b q^{\gamma},$$

with $b\gamma = K > 0$. The second-order condition $2 - \chi > 0$ is $\gamma > -1$, and $\rho = \frac{1}{2-(1-\gamma)} = \frac{1}{1+\gamma}$. If $\chi = 1$, integrating $P' = -Kq^{-1}$ gives $P(q) = a - K \ln q$, form (b) with $b = K$, and $\rho = \frac{1}{2-1} = 1$. Conversely, direct differentiation shows that form (a) has $\chi = 1 - \gamma$ and form (b) has $\chi = 1$ at every output. □

The family contains the three textbook cases of Example B.35. Linear demand is $\gamma = 1$ with $\rho = \frac{1}{2}$. Constant-elasticity demand $P = q^{-\frac{1}{\varepsilon}}$ with $\varepsilon > 1$ is $a = 0$, $b = -1$ and $\gamma = -\frac{1}{\varepsilon} \in (-1, 0)$, so $\rho = \frac{1}{1-\frac{1}{\varepsilon}} = \frac{\varepsilon}{\varepsilon-1} > 1$. Exponential demand $Q = e^{\frac{a-p}{b}}$ is form (b) with $\rho = 1$. The family also sorts demand by log-concavity. Since $\frac{QQ''}{(Q')^2} = \chi = 1 - \gamma$ (Proposition B.33), direct demand is strictly log-concave when $\gamma > 0$, log-linear in form (b), and strictly log-convex when $-1 < \gamma < 0$. The ranking of pass-through rates matches Proposition B.160.

Example B.162 (Power demand in prices)**.** Let direct demand be $Q(p) = B(\bar{p} - p)^g$ for $p < \bar{p}$, with $B, g > 0$, as in Table 2.5. Its log is $\ln B + g \ln(\bar{p} - p)$, with second derivative $-\frac{g}{(\bar{p}-p)^2} < 0$, so demand is strictly log-concave. Inverting $q = B(\bar{p} - p)^g$ gives

$$P(q) = \bar{p} - B^{-\frac{1}{g}} q^{\frac{1}{g}},$$

which is form (a) with $a = \bar{p}$, $\gamma = \frac{1}{g}$ and $b = B^{-\frac{1}{g}}$. Directly, the first-order condition $p - c = m(p)$ reads

$$p - c = \frac{\bar{p} - p}{g}.$$

Solving gives $p = \frac{\bar{p}+gc}{1+g}$, so $\rho = \frac{g}{1+g} = \frac{1}{1+\gamma}$, as Proposition B.161 predicts. Under a constant conduct parameter θ and flat marginal cost, Corollary B.37(a) gives $\rho = \frac{1}{1+\theta(1-\chi)} = \frac{1}{1+\theta\gamma} = \frac{1}{1+\frac{\theta}{g}} = \frac{g}{g+\theta}$, again independent of cost. This family appears in the sugar-refining application of Chapter 3.

Example B.163 (Logit demand is log-concave)**.** Hold rivals' prices fixed and write single-product logit demand for product j as $s_j(p_j) = \frac{e^{\tilde{\delta}_j - \alpha p_j}}{\Lambda_{-j} + e^{\tilde{\delta}_j - \alpha p_j}}$, where $\tilde{\delta}_j$ is the price-free part of mean utility and $\Lambda_{-j} = 1 + \sum_{l \neq j} e^{\delta_l}$ (Section B.5). Differentiating the log,

$$\frac{\mathrm{d} \ln s_j}{\mathrm{d} p_j} = -\alpha + \alpha s_j = -\alpha(1 - s_j),$$

and differentiating again with $\frac{\mathrm{d}s_j}{\mathrm{d}p_j} = -\alpha s_j(1 - s_j)$,

$$\frac{\mathrm{d}^2 \ln s_j}{\mathrm{d} p_j^2} = \alpha \frac{\mathrm{d}s_j}{\mathrm{d}p_j} = -\alpha^2 s_j(1 - s_j) < 0.$$

Residual demand is strictly log-concave. By Proposition B.160, each firm has a unique best response, the solution of $p_j - mc_j = \frac{1}{\alpha(1-s_j)}$ (Proposition B.99 gives it in closed form). Part (iii) of the proposition puts own pass-through with rivals' prices fixed in $(0, 1]$, and Example B.35(iv) computes it exactly as $1 - s_j$.

B.8.4 Aggregation and the existence of price equilibrium

With several differentiated products, the existence of a pure-strategy Bertrand-Nash equilibrium requires each firm's profit to be quasi-concave in its own price. Otherwise best responses can jump and Kakutani's theorem fails. Demand is an aggregate over heterogeneous consumers, so the question is which primitives make aggregate demand concave enough. Caplin and Nalebuff (1991) answer it with Theorem B.159. Section 4.4.3 proves their theorems and discusses their economic coverage. This subsection restates the argument as an application of ϱ-concavity and refers to those proofs.

Setting. There are J firms. Firm j sells one product with fixed characteristics x_j at constant marginal cost c_j, and firms set prices simultaneously. Each consumer has income $y > 0$ and buys one unit of exactly one product, consuming $z = y - p_j$ of a numeraire. Consumers differ by a type $v \in \mathbb{R}^L$ with density f and convex support B. The dimension L of the type space is local to this subsection. Caplin and Nalebuff (1991) impose two assumptions.

Assumption B.164 (A1, preferences linear in the type)**.** Utility is $U(v, x, z) = \sum_{l=1}^{L} v_l t_l(x) + g(z)t_{L+1}(x) + t_{L+2}(x)$, where $t : X \to \mathbb{R}^{L+2}$ maps characteristics into benefits, g is strictly increasing and concave, and $t_{L+1}(x) > 0$.

Assumption B.165 (A2, concavity of the type density)**.** The density f is ϱ-concave with $\varrho = -\frac{1}{L+1}$, on a convex support with positive volume.

All consumers agree on the benefits $t_l(x)$ that a product delivers and differ in the weights v_l they place on them. By Lemma B.154, every log-concave density satisfies A2. A2 also admits the multivariate Cauchy, Pareto, F and Student t distributions under restrictions on their parameters, for the Student t at least one degree of freedom (Caplin and Nalebuff, 1991, Section 3, p. 6). A1 covers characteristics models, quadratic transport costs, vertical differentiation, and logit, probit and random coefficients models with a common price coefficient. It excludes Hotelling's linear transport costs, whose demand is discontinuous.

Demand as the probability of a set. Fix rivals' prices p_{-j}. Let $\mathcal{A}_j(p_j)$ be the set of types that weakly prefer product j at price p_j to every rival,

$$\mathcal{A}_j(p_j) = \left\{ v : \Delta_k(v, p_j) \geq 0 \text{ for all } k \neq j \right\}, \qquad \Delta_k(v, p_j) = U(v, x_j, y - p_j) - U(v, x_k, y - p_k).$$

Ties occur on hyperplanes of types when products are distinct, so they have probability zero. Demand is

$$D_j(p_j) = \int_{\mathcal{A}_j(p_j)} f(v)\, \mathrm{d}v, \tag{B.103}$$

which is the demand function of Caplin and Nalebuff (1991, Section 4), written with the set of buyers instead of reservation prices. Given rivals' prices, firm j is a monopolist facing a population of reservation prices.

Lemma B.166 (Buyer sets are Minkowski-concave)**.** *Under A1, for any prices p_0, p_1 and $\lambda \in [0, 1]$, with $p_\lambda = \lambda p_0 + (1 - \lambda)p_1$,*

$$\mathcal{A}_j(p_\lambda) \supseteq \lambda \mathcal{A}_j(p_0) + (1 - \lambda)\mathcal{A}_j(p_1).$$

The proof of Theorem 4.19 establishes this inclusion. It averages the preference inequalities of types v_0 and v_1, which A1 makes linear in the type, and uses concavity of g for the price term.

Theorem B.167 (Aggregation, Caplin and Nalebuff, 1991, Section 4)**.** *Assume A1, distinct products and a ϱ-concave type density with $\varrho \geq -\frac{1}{L}$. Then each firm's demand $D_j(p_j)$ is ϱ^*-concave in its own price, with $\varrho^* = \frac{\varrho}{1+L\varrho}$, on the interval of prices where it is positive.*

This is Theorem 4.19. For prices p_0 and p_1 with positive demand, Lemma B.166, monotonicity of the integral and Theorem B.159 give

$$D_j(p_\lambda) \geq \int_{\lambda\mathcal{A}_j(p_0)+(1-\lambda)\mathcal{A}_j(p_1)} f(v)\,\mathrm{d}v \geq \mathcal{M}_{\varrho^*}\big(D_j(p_0), D_j(p_1); \lambda\big).$$

The bound is tight (Example 4.20). With types uniform on the unit simplex and reservation prices $1 - \sum_l v_l$, demand is $D(p) = (1-p)^L$, which is $\frac{1}{L}$-concave and no more.

Quasi-concave profit. The second step turns concavity of demand into quasi-concavity of profit.

Proposition B.168 (Convex reciprocal demand gives quasi-concave profit)**.** *Let marginal cost c be constant and let demand D be nonincreasing, positive on an interval $(-\infty, \bar{p})$ and zero above it. If $\frac{1}{D}$ is convex on $(-\infty, \bar{p})$, then profit $\pi(p) = (p-c)D(p)$ is quasi-concave.*

Lemma 4.15 proves the result by contradiction, following Caplin and Nalebuff (1991, p. 29). A direct argument uses upper contour sets. For $k > 0$ and prices in $(c, \bar{p})$, $\pi(p) \geq k$ holds if and only if $p - c - \frac{k}{D(p)} \geq 0$. The left side is linear minus a convex function, hence concave, so its upper contour set is an interval. For $k \leq 0$ the set contains every price above c, and profit is nondecreasing below c.

For strictly decreasing, twice differentiable demand, $\frac{1}{D}$ is convex if and only if revenue $qP(q)$ is concave in quantity (Section 4.4.2 gives the computation). Caplin and Nalebuff (1991, Section 5) note that concave revenue is equivalent to quasi-concavity of profit for every convex cost function. The condition is therefore as weak as possible when costs are unrestricted. In the language of Definition B.153, $\frac{1}{D}$ convex means that D is (-1)-concave. Theorem B.167 delivers this when $\varrho^* \geq -1$. Solving $\frac{\varrho}{1+L\varrho} = -1$ step by step,

$$\begin{aligned} \varrho &= -(1 + L\varrho), \\ \varrho(1+L) &= -1, \\ \varrho &= -\frac{1}{L+1}. \end{aligned}$$

Because ϱ^* is increasing in ϱ and $-\frac{1}{L+1} > -\frac{1}{L}$, every density that satisfies A2 yields $\varrho^* \geq -1$, hence (-1)-concave demand by Lemma B.154, hence quasi-concave profit. This is why A2 has the exponent $-\frac{1}{L+1}$. The same calculation shows why earlier work that assumed concave demand was confined to special cases. Concave demand needs $\varrho^* = 1$, which requires $\varrho = \infty$ and $L = 1$, a uniform distribution of types on a line (Caplin and Nalebuff, 1991, Section 5).

Theorem B.169 (Existence, Caplin and Nalebuff, 1991, Section 5)**.** *Under A1 and A2, for any number of firms and any products, a pure-strategy Bertrand-Nash equilibrium exists.*

Theorem 4.22 proves the theorem. With distinct products, it restricts each firm to prices in $[c_j, y]$, where profits are continuous. Quasi-concavity in own price makes each best-response set an interval, and Kakutani's theorem (Theorem B.147) gives a fixed point. Equivalent products and costs above income are handled separately.

Uniqueness and log-supermodularity. Caplin and Nalebuff (1991, Section 6) prove uniqueness under differentiability in three cases.

(a) Duopoly with a log-concave type density, in any dimension.

(b) Any number of firms in a one-dimensional market with a log-concave density, given the set of active firms.

(c) The logit model.

The tool is the dominant-diagonal condition $\left|\frac{\partial^2 \pi_j}{\partial p_j^2}\right| > \sum_{k \neq j} \left|\frac{\partial^2 \pi_j}{\partial p_j \, \partial p_k}\right|$, which allows at most one equilibrium among a given set of active firms (Friedman, 1977) (Proposition B.150). In all three cases the pricing game is also log-supermodular, a property studied in Section B.9.4.

The logit case was checked in Section B.7.5. There the log first-order conditions $\frac{\partial \ln \pi_j}{\partial p_j} = \frac{1}{p_j - c_j} - \alpha(1 - s_j) = 0$ satisfy the dominant-diagonal condition on the set of prices above cost. On the best response, the implicit function theorem turns the same derivatives into the slopes $\frac{\partial BR_j}{\partial p_k} = \frac{s_j s_k}{1 - s_j} > 0$, whose row sums are below one (Proposition B.142). Best responses slope up, so logit prices are strategic complements.

Log-supermodularity combined with uniqueness has strong consequences (Milgrom and Roberts, 1990). Caplin and Nalebuff list four.

(1) There are no other equilibria in mixed or correlated strategies.

(2) The equilibrium is globally stable under best-response dynamics, fictitious play and Bayesian learning.

(3) The game is dominance solvable.

(4) Any change that raises some firm's marginal return to price raises every firm's equilibrium price.

A cost increase for one firm, for instance, raises all prices (Example B.188).

The theorem has limits. It assumes unit demand, single-product firms and fixed products. Multiproduct logit pricing is unique by a different argument (Section B.7). A random price coefficient fits A1 only after utility is divided by it, and A2 must then hold for the distribution of the resulting ratios, which can fail (Section 4.4.3).

Random price coefficients are often lognormal in random coefficients demand models, so the lognormal deserves a check. Caplin and Nalebuff (1991, Section 3, p. 6) note that A2 survives the truncation of a density to a convex support but not other transformations. They give the lognormal as a distribution that fails A2. The failure depends on the dispersion. With $L = 1$, A2 requires $f^{-\frac{1}{2}}$ to be convex. Let $\ln v \sim N(m, \varsigma^2)$ and write $t = \ln v$. Up to a positive constant, $f(v)^{-\frac{1}{2}} = e^{g(t)}$ with

$$g(t) = \frac{t}{2} + \frac{(t - m)^2}{4\varsigma^2}.$$

Since $\frac{\mathrm{d}}{\mathrm{d}v} = \frac{1}{v}\frac{\mathrm{d}}{\mathrm{d}t}$, differentiating twice gives

$$\frac{\mathrm{d}^2}{\mathrm{d}v^2} e^{g(t)} = \frac{e^{g(t)}}{v^2}\left[g'(t)^2 - g'(t) + g''(t)\right] = \frac{e^{g(t)}}{v^2}\left[\left(g'(t) - \frac{1}{2}\right)^2 - \frac{1}{4} + \frac{1}{2\varsigma^2}\right].$$

The derivative $g'(t) = \frac{1}{2} + \frac{t - m}{2\varsigma^2}$ takes every real value, so the bracket is nonnegative everywhere exactly when $\frac{1}{2\varsigma^2} \geq \frac{1}{4}$, that is, when $\varsigma^2 \leq 2$. A one-dimensional lognormal therefore satisfies A2 for moderate dispersion and fails it for large dispersion. Its density is never log-concave (Table B.4), so here A2 is a real gain over log-concavity.

B.8.5 Auction applications

Hazard rates and reverse hazard rates are the natural objects in auction theory. The hazard rate governs the seller's trade-off between price and probability of sale. The reverse hazard rate governs a bidder's trade-off between the margin and the probability of winning. In this subsection a bidder's value has CDF F with density $f > 0$ on $[\underline{v}, \bar{v}]$, and the seller values the object at v_0.

Proposition B.170 (Myerson regularity)**.** *If the hazard rate $\frac{f}{1-F}$ is nondecreasing, the virtual valuation $\psi(v) = v - \frac{1-F(v)}{f(v)}$ is strictly increasing, so F is regular. A log-concave density suffices.*

Proof. The term $\frac{1-F}{f}$ is the reciprocal of a nondecreasing positive function, so it is nonincreasing. Then ψ is the sum of the strictly increasing function v and the nondecreasing function $-\frac{1-F}{f}$. A log-concave density has a nondecreasing hazard rate by Corollary B.157. □

Regularity makes the optimal reserve price the unique solution of $r^* - \frac{1-F(r^*)}{f(r^*)} = v_0$, because the left side is strictly increasing (Myerson, 1981). For values uniform on $[0, 1]$, $\psi(v) = v - (1 - v) = 2v - 1$ and $r^* = \frac{1+v_0}{2}$. For exponential values with rate λ, $\psi(v) = v - \frac{1}{\lambda}$ and $r^* = v_0 + \frac{1}{\lambda}$. The seller's problem with one bidder is the monopoly problem of Proposition B.160 with willingness to pay V and cost v_0. Corollary 14.47 in Chapter 14 gives the general result.

Consider a symmetric first-price auction with independent private values and N bidders. A bidder who bids b must have value $\xi(b) = b + \frac{G(b)}{(N-1)g(b)}$ (Guerre et al., 2000). Here G and g are the distribution and density of equilibrium bids. Guerre et al. (2000, Theorem 1) write I for the number of bidders. They show that an observed bid distribution is rationalized by some value distribution if and only if bids are i.i.d. and ξ is strictly increasing with a differentiable inverse. The second requirement is their condition C2.

Proposition B.171 (Log-concave bids satisfy the monotonicity condition)**.** *Let G have a positive differentiable density g on $[\underline{b}, \bar{b}]$. If G is log-concave, then $\xi(b) = b + \frac{G(b)}{(N-1)g(b)}$ is strictly increasing. More generally, ξ is strictly increasing if and only if $\frac{g}{G^N}$ is strictly decreasing.*

Proof. If G is log-concave, the reverse hazard rate $\frac{g}{G}$ is nonincreasing (Corollary B.157), so $\frac{G}{g}$ is nondecreasing. Then ξ is the sum of the strictly increasing function b and a nondecreasing function. For the general statement, differentiate ξ by the quotient rule:

$$\xi'(b) = 1 + \frac{g(b)^2 - G(b)g'(b)}{(N-1)g(b)^2} = \frac{Ng(b)^2 - G(b)g'(b)}{(N-1)g(b)^2}.$$

Differentiating $\frac{g}{G^N}$ gives

$$\frac{\mathrm{d}}{\mathrm{d}b}\left(\frac{g}{G^N}\right) = \frac{g'G^N - NG^{N-1}g^2}{G^{2N}} = -\frac{Ng^2 - Gg'}{G^{N+1}}.$$

The two derivatives have opposite signs. Hence $\xi' > 0$ exactly when $\frac{g}{G^N}$ is strictly decreasing (Guerre et al., 2000, p. 530 and footnote 6). □

Log-concavity is sufficient for condition C2 and far from necessary. A violation needs a bid density that falls steeply relative to G. Guerre et al. (2000, p. 530) give the example $G(b) = \left(\frac{b}{5-4b}\right)^{\frac{1}{5}}$

on $[0,1]$ with $N=2$, whose density has a deep U shape. Here $\frac{\mathrm{d}\ln G}{\mathrm{d}b} = \frac{1}{5}\left(\frac{1}{b} + \frac{4}{5-4b}\right) = \frac{1}{b(5-4b)}$, so

$$\xi(b) = b + b(5-4b) = 6b - 4b^2,$$

which decreases for $b > \frac{3}{4}$. No independent private values model generates these bids. The identification argument is developed in Chapter 15.

Reverse hazard rates also compare bidders. In an asymmetric auction, a strong bidder's value distribution F_s and a weak bidder's F_w are typically ranked by the reverse hazard rate. The ranking implies first-order dominance.

Proposition B.172 (Reverse hazard rate dominance implies first-order dominance)**.** *Let F_s and F_w have positive densities f_s and f_w on a common support $[\underline{v}, \bar{v}]$. If $\frac{f_s(v)}{F_s(v)} \geq \frac{f_w(v)}{F_w(v)}$ for all $v \in (\underline{v}, \bar{v})$, then $F_s(v) \leq F_w(v)$ for all v.*

Proof. Since $\frac{f}{F} = \frac{\mathrm{d}}{\mathrm{d}v}\ln F$, the hypothesis says

$$\frac{\mathrm{d}}{\mathrm{d}v}\ln\frac{F_s(v)}{F_w(v)} = \frac{f_s(v)}{F_s(v)} - \frac{f_w(v)}{F_w(v)} \geq 0,$$

so the ratio $\frac{F_s}{F_w}$ is nondecreasing on $(\underline{v}, \bar{v})$. Its limit at $\bar{v}$ is $\frac{F_s(\bar{v})}{F_w(\bar{v})} = 1$. Hence $\frac{F_s(v)}{F_w(v)} \leq 1$, that is, $F_s(v) \leq F_w(v)$, for every $v \in (\underline{v}, \bar{v})$. At the endpoints both CDFs coincide. □

Section 14.10 extends the result to supports with different upper ends. The reverse hazard rate order is the assumption under which Maskin and Riley (2000) sign equilibrium behavior in asymmetric first-price auctions. The strong bidder shades its bid more, yet its bids are stochastically higher. The weak bidder sometimes wins although its value is lower. Section B.9.5 places the order in the full chain of stochastic orders.

B.9 Supermodularity, monotone comparative statics and affiliation

The implicit function theorem signs comparative statics through derivatives and second-order conditions (Proposition B.29). Many economic problems lack the smoothness or the concavity that this route needs. Choices may be discrete, maximizers may jump, and profit functions may have several local peaks. Lattice methods sign comparative statics from a single property, complementarity between the choice and the parameter, and they extend to games and to probability. This section develops the order-theoretic tools and their uses in oligopoly pricing, the vertical model and auctions. It ends with affiliation, the form of positive dependence that auction theory uses.

B.9.1 Lattices and supermodular functions

We order $\mathbb{R}^k$ componentwise: $x \geq y$ means $x_l \geq y_l$ for every l. This is a *partial order*, since two vectors need not be comparable. The *join* $x \vee y$ and the *meet* $x \wedge y$ are the componentwise maximum and minimum,

$$(x \vee y)_l = \max\{x_l, y_l\}, \qquad (x \wedge y)_l = \min\{x_l, y_l\}.$$

Definition B.173 (Lattices)**.** A set $X \subseteq \mathbb{R}^k$ is a *lattice* (a sublattice of $\mathbb{R}^k$) if $x \vee y \in X$ and $x \wedge y \in X$ whenever $x, y \in X$. A lattice is *complete* if every nonempty subset has a supremum and an infimum in X.

The whole space $\mathbb{R}^k$ and every product of intervals are lattices. A compact product of closed intervals is a complete lattice. The set $\{x \in \mathbb{R}^2 : x_1 \leq x_2\}$ is a lattice, because the componentwise maximum and minimum of two points with $x_1 \leq x_2$ inherit the inequality. The set $\{x \in \mathbb{R}^2 : x_1 + x_2 \leq 1\}$ is convex but not a lattice: $(1,0)$ and $(0,1)$ belong to it, while their join $(1,1)$ does not. Lattices are about order, convex sets about averages, and the two notions are independent.

Definition B.174 (Supermodularity and increasing differences)**.** Let X be a lattice and A a partially ordered set of parameters.

(i) A function $g : X \to \mathbb{R}$ is *supermodular* if $g(x \vee y) + g(x \wedge y) \geq g(x) + g(y)$ for all $x, y \in X$.

(ii) A function $g : X \times A \to \mathbb{R}$ has *increasing differences* in (x, a) if, for all $x' \geq x$, the difference $g(x', a) - g(x, a)$ is nondecreasing in a. It has *strictly increasing differences* if the difference is strictly increasing in a whenever $x' > x$.

(iii) A positive function g is *log-supermodular* if $\ln g$ is supermodular.

For two variables the two notions coincide. Take $x = (x_1', x_2)$ and $y = (x_1, x_2')$ with $x_1' \geq x_1$ and $x_2' \geq x_2$. Then $x \vee y = (x_1', x_2')$ and $x \wedge y = (x_1, x_2)$, and supermodularity reads

$$g(x_1', x_2') - g(x_1, x_2') \geq g(x_1', x_2) - g(x_1, x_2),$$

which says that the gain from raising the first variable is larger when the second is larger. Supermodularity is the formal statement of complementarity. Ordered pairs impose nothing, because then $\{x \vee y, x \wedge y\} = \{x, y\}$. For smooth functions on products of intervals there is a derivative test.

Proposition B.175 (Smooth test, Topkis, 1978)**.** *Let $X = \prod_{l=1}^{k} I_l$ be a product of open intervals and let $g : X \to \mathbb{R}$ be twice continuously differentiable. Then g is supermodular if and only if $\frac{\partial^2 g}{\partial x_l \, \partial x_m} \geq 0$ for all $l \neq m$ at every point of X.*

Proof. Suppose the cross partials are nonnegative and take $x, y \in X$. Let $z = x \wedge y$, $u = x - z \geq 0$ and $w = y - z \geq 0$. A coordinate l has $u_l > 0$ only if $x_l > y_l$, and $w_l > 0$ only if $y_l > x_l$, so u and w have disjoint supports. Moreover $x = z + u$, $y = z + w$ and $x \vee y = z + u + w$. We must show

$$g(z + u + w) - g(z + w) - g(z + u) + g(z) \geq 0.$$

By the fundamental theorem of calculus along the segment from z to $z + w$,

$$g(z + u + w) - g(z + w) - g(z + u) + g(z) = \int_0^1 \sum_m w_m \left[\frac{\partial g}{\partial x_m}(z + u + tw) - \frac{\partial g}{\partial x_m}(z + tw) \right] \mathrm{d}t.$$

Applying the theorem again along the segment from $z + tw$ to $z + u + tw$,

$$g(z + u + w) - g(z + w) - g(z + u) + g(z) = \int_0^1 \int_0^1 \sum_m \sum_l w_m u_l \, \frac{\partial^2 g}{\partial x_l \, \partial x_m}(z + su + tw) \, \mathrm{d}s \, \mathrm{d}t.$$

Every term with $w_m u_l \neq 0$ has $l \neq m$ by disjointness, so it multiplies a nonnegative cross partial by a nonnegative weight. The integral is nonnegative.

Conversely, suppose g is supermodular and fix $l \neq m$, a point x, and small $\epsilon, \eta > 0$. Apply the two-variable inequality above to coordinates l and m with the others held at x:

$$g(x + \epsilon e_l + \eta e_m) - g(x + \eta e_m) - g(x + \epsilon e_l) + g(x) \geq 0,$$

where e_l is the l-th unit vector. Divide by $\epsilon\eta$ and let $\epsilon, \eta \to 0$. By the double-integral representation and continuity of the cross partial, the limit is $\frac{\partial^2 g}{\partial x_l \, \partial x_m}(x) \geq 0$. □

The proposition applies to $\ln g$ as well. A positive C^2 function is log-supermodular if and only if $\frac{\partial^2 \ln g}{\partial x_l \, \partial x_m} \geq 0$ for $l \neq m$. Products of log-supermodular functions are log-supermodular, because logs add. The same test applied to a function of (x, a) with x and a scalars shows that a C^2 function has increasing differences if and only if $\frac{\partial^2 g}{\partial x \, \partial a} \geq 0$.

B.9.2 Monotone comparative statics

To compare sets of maximizers we need an order on sets.

Definition B.176 (Strong set order)**.** For subsets S, S' of a lattice, S' is higher than S in the *strong set order*, written $S' \geq_S S$, if $x \vee x' \in S'$ and $x \wedge x' \in S$ for all $x \in S$ and $x' \in S'$.

For compact intervals of $\mathbb{R}$, $S' \geq_S S$ means that $\max S' \geq \max S$ and $\min S' \geq \min S$. For general compact subsets of $\mathbb{R}$ these inequalities are necessary but not sufficient. The sets $S = \{0, 2\}$ and $S' = \{1, 3\}$ satisfy both, yet $2 \vee 1 = 2 \notin S'$. For singletons it means $x' \geq x$.

Theorem B.177 (Topkis)**.** *Let X be a lattice, A a partially ordered set, and $g : X \times A \to \mathbb{R}$ supermodular in x for each a and with increasing differences in (x, a). Let $M(a) = \arg\max_{x \in X} g(x, a)$. If $a' \geq a$, then $M(a') \geq_S M(a)$. In particular, the largest and smallest maximizers, when they exist, are nondecreasing in a (Topkis, 1978).*

Proof. Let $a' \geq a$, $x \in M(a)$ and $x' \in M(a')$. Both $x \vee x'$ and $x \wedge x'$ lie in X. Optimality of x' at a' and of x at a gives

$$g(x', a') \geq g(x \vee x', a'), \tag{B.104}$$

$$g(x, a) \geq g(x \wedge x', a). \tag{B.105}$$

Supermodularity in x at a, rearranged, and then (B.105) give

$$g(x \vee x', a) - g(x', a) \geq g(x, a) - g(x \wedge x', a) \geq 0. \tag{B.106}$$

Since $x \vee x' \geq x'$ and $a' \geq a$, increasing differences give

$$g(x \vee x', a') - g(x', a') \geq g(x \vee x', a) - g(x', a). \tag{B.107}$$

Chaining (B.107) and (B.106), $g(x \vee x', a') \geq g(x', a')$. With (B.104) this holds with equality, so $x \vee x' \in M(a')$. The left side of (B.107) is then zero, so every term in the chain is zero. In particular $g(x, a) = g(x \wedge x', a)$, and $x \wedge x' \in M(a)$. □

With strictly increasing differences and a scalar choice, every selection from the argmax is nondecreasing. To see this, suppose $a' > a$, $x \in M(a)$, $x' \in M(a')$ and $x > x'$. Strictly increasing differences and optimality of x at a give $g(x, a') - g(x', a') > g(x, a) - g(x', a) \geq 0$, which contradicts optimality of x' at a'.

Compare the theorem with Proposition B.29. The implicit function theorem gives $\frac{\mathrm{d}x^*}{\mathrm{d}a} = -\frac{g_{xa}}{g_{xx}}$, whose sign is that of g_{xa} under a strict second-order condition. Topkis's theorem reaches the qualitative conclusion from $g_{xa} \geq 0$ alone. It needs no concavity, no differentiability in x, no interior solution and no uniqueness, and the choice set may be discrete. It is silent on magnitudes, which still require derivatives.

The conditions of Theorem B.177 are cardinal: a monotone transformation of g can destroy increasing differences without changing any argmax. Milgrom and Shannon (1994) found the ordinal conditions. A function $g : X \to \mathbb{R}$ is *quasi-supermodular* if $g(x) \geq g(x \wedge y)$ implies $g(x \vee y) \geq g(y)$, and the same holds with strict inequalities. A function $g(x, a)$ satisfies the *single crossing property* in (x, a) if, for $x' > x$ and $a' > a$, $g(x', a) \geq g(x, a)$ implies $g(x', a') \geq g(x, a')$, and $g(x', a) > g(x, a)$ implies $g(x', a') > g(x, a')$. A gain from a higher choice at a low parameter persists at a higher parameter.

Theorem B.178 (Milgrom and Shannon, 1994)**.** *Let X be a lattice and $g : X \times A \to \mathbb{R}$. The following statements are equivalent.*

(a) The set $\arg\max_{x \in S} g(x, a)$ *is nondecreasing in (a, S) in the strong set order, over all sublattices $S \subseteq X$.*

(b) The function g is quasi-supermodular in x and satisfies the single crossing property in (x, a).

Both conditions are preserved by strictly increasing transformations of g. A positive log-supermodular function satisfies them. Indeed, if $\ln g$ has increasing differences, the ratio $\frac{g(x',a)}{g(x,a)}$ is nondecreasing in a for $x' \geq x$. If it is at least one at a, it is at least one at $a' > a$, which is single crossing. This is why log-supermodularity, a cardinal condition on $\ln g$, has ordinal consequences for g.

Example B.179 (Monopoly price rises with cost for any demand)**.** Let demand $Q(p)$ be any nonincreasing function on a price set $X = [0, \bar{p}]$, and let profit be $\pi(p, c) = (p - c)Q(p)$. For $p' > p$,

$$\pi(p', c) - \pi(p, c) = p'Q(p') - pQ(p) - c\big[Q(p') - Q(p)\big].$$

The bracket is nonpositive, so the difference is nondecreasing in c. Profit has increasing differences in (p, c), and by Theorem B.177 the largest and smallest optimal prices are nondecreasing in marginal cost. If Q is strictly decreasing the differences are strictly increasing, and every selection of optimal prices is nondecreasing. No curvature, concavity, continuity or differentiability of demand is used. On prices above cost, the same conclusion follows from log-supermodularity, since $\frac{\partial^2}{\partial p\, \partial c} \ln[(p - c)Q(p)] = \frac{\partial^2}{\partial p\, \partial c} \ln(p - c) = \frac{1}{(p-c)^2} > 0$. The direction of pass-through is thus a free result, while its size, $\rho = \frac{1}{2-\chi}$, depends on demand curvature (Section B.2.3).

Example B.180 (Sorting in the vertical model)**.** In the vertical model consumer i obtains $u_{ij} = \delta_j - \nu_i p_j$ from product j, with $\nu_i > 0$ the price sensitivity and the outside good at $\delta_0 = p_0 = 0$ (Section 6.5). Index the products with positive sales by price, $0 = p_0 < p_1 < \cdots < p_J$, so that qualities rise in the same order. For $k > j$,

$$u_{ij} - u_{ik} = (\delta_j - \delta_k) + \nu_i(p_k - p_j),$$

which is strictly increasing in ν_i. This is the *single crossing property* of the vertical model. As functions of ν, the utility lines of two products cross at most once, and the cheaper product wins for the more price-sensitive consumers. In lattice terms, $u(j, \nu) = \delta_j - \nu p_j$ has strictly decreasing differences in (j, ν), so by Theorem B.177 applied with $-\nu$ as the parameter, the chosen product is nonincreasing in ν.

Single crossing also explains why a consumer need compare product j only with its two neighbors. Let $\bar{\nu}_j = \frac{\delta_j - \delta_{j-1}}{p_j - p_{j-1}}$ be the type indifferent between $j - 1$ and j, and suppose the cutoffs are strictly decreasing, $\bar{\nu}_1 > \bar{\nu}_2 > \cdots > \bar{\nu}_J > 0$, as they are when every product sells. A consumer

prefers j to $j+1$ if and only if $v_i > \bar{v}_{j+1}$, and j to $j-1$ if and only if $v_i < \bar{v}_j$. Suppose both hold. Then $v_i > \bar{v}_{j+1} > \bar{v}_{j+2}$, so she also prefers $j+1$ to $j+2$. Transitivity gives $j \succ j+2$, and induction on k gives $j \succ k$ for all $k > j$. Symmetrically, $v_i < \bar{v}_j < \bar{v}_{j-1}$ gives $j-1 \succ j-2$, hence $j \succ j-2$ and, by induction, $j \succ k$ for all $k < j$. With the conventions $\bar{v}_0 = \infty$ and $\bar{v}_{J+1} = 0$, the consumer chooses j exactly when $\bar{v}_{j+1} < v_i < \bar{v}_j$.

Example B.181 (Cournot best responses without concavity)**.** In a homogeneous-good Cournot market, firm i's profit is $\pi_i(q_i, Q_{-i}) = q_i P(q_i + Q_{-i}) - C_i(q_i)$, where Q_{-i} is rivals' total output. Example B.40 computed the slope of the best response by the implicit function theorem, under a strict second-order condition. The lattice argument needs only the cross partial,

$$\frac{\partial^2 \pi_i}{\partial q_i \, \partial Q_{-i}} = P'(Q) + q_i P''(Q).$$

If $P' + q_i P'' \le 0$ on the relevant domain, profit has decreasing differences in (q_i, Q_{-i}), which are increasing differences in $(q_i, -Q_{-i})$. By Theorem B.177, the extremal best responses are nonincreasing in rivals' output. Neither concavity of profit in q_i nor convexity of cost is needed, and the best response may be a correspondence. Section B.9.3 shows that the sign of $P' + q_i P''$ can reverse.

B.9.3 Strategic substitutes and complements

Bulow et al. (1985) sort competition by the sign of a single cross partial. Orient each firm's strategic variable so that a higher value is more aggressive: quantities, advertising, or the negative of a price.

Definition B.182 (Strategic substitutes and complements)**.** Firm B regards the products as *strategic substitutes* if a more aggressive action by firm A lowers B's marginal profit, that is, $\frac{\partial^2 \pi_B}{\partial S_B \, \partial S_A} < 0$. It regards them as *strategic complements* if the cross partial is positive (Bulow et al., 1985, p. 494).

The definition concerns marginal profit. Ordinary substitutes and complements concern the level of profit, the sign of $\frac{\partial \pi_B}{\partial S_A}$. Under strict concavity in own action, the implicit function theorem gives the slope of B's best response (reaction function) BR_B,

$$\frac{\mathrm{d}BR_B}{\mathrm{d}S_A} = -\left(\frac{\partial^2 \pi_B}{\partial S_B^2}\right)^{-1} \frac{\partial^2 \pi_B}{\partial S_B \, \partial S_A}.$$

Reaction curves therefore slope down under strategic substitutes and up under strategic complements. When prices are the strategic variables, $S = -p$ and $\frac{\partial^2 \pi_B}{\partial(-p_B)\,\partial(-p_A)} = \frac{\partial^2 \pi_B}{\partial p_B \, \partial p_A}$, so prices are strategic complements when $\frac{\partial^2 \pi_B}{\partial p_B \, \partial p_A} > 0$.

Example B.183 (Multimarket contact and the sign of the strategic effect)**.** Bulow et al. (1985, pp. 492–495) study a firm A that is a monopolist in market 1 and a duopolist with firm B in market 2. The strategic variables are S_1^A, S_2^A and S_2^B. A shock Z raises A's marginal profit in market 1, so $\pi^A = R_1^A(S_1^A) + R_2^A(S_2^A, S_2^B) - C^A(S_1^A, S_2^A) + ZS_1^A$ and $\pi^B = R_2^B(S_2^A, S_2^B) - C^B(S_2^B)$, where R_i^F is firm F's revenue in market i and C^F its cost. Shared costs make the markets interdependent. There are *joint economies* if $\frac{\partial^2 \pi^A}{\partial S_1^A \, \partial S_2^A} > 0$ and joint diseconomies if it is negative.

Write a_{11}, a_{12}, a_{22} and a_{23} for the second partials of π^A with respect to (S_1^A, S_1^A), (S_1^A, S_2^A), (S_2^A, S_2^A) and (S_2^A, S_2^B). Write b_{32} and b_{33} for the second partials of π^B with respect to (S_2^B, S_2^A) and (S_2^B, S_2^B). Totally differentiating the three first-order conditions gives their system (7),

$$\begin{pmatrix} a_{11} & a_{12} & 0 \\ a_{12} & a_{22} & a_{23} \\ 0 & b_{32} & b_{33} \end{pmatrix} \begin{pmatrix} \mathrm{d}S_1^A \\ \mathrm{d}S_2^A \\ \mathrm{d}S_2^B \end{pmatrix} = \begin{pmatrix} -\mathrm{d}Z \\ 0 \\ 0 \end{pmatrix}.$$

The zero in the first row holds because S_2^B affects π^A only through market 2. Stability requires $b_{33} < 0$, $a_{22}b_{33} > a_{23}b_{32}$ (market 2 is stable on its own) and a negative determinant. We solve from the bottom. The third row gives $\mathrm{d}S_2^B = -\frac{b_{32}}{b_{33}}\mathrm{d}S_2^A$. Substituting into the second row,

$$a_{12}\,\mathrm{d}S_1^A + k\,\mathrm{d}S_2^A = 0, \qquad k \equiv a_{22} - \frac{a_{23}b_{32}}{b_{33}} = \frac{a_{22}b_{33} - a_{23}b_{32}}{b_{33}} < 0.$$

Substituting $\mathrm{d}S_2^A = -\frac{a_{12}}{k}\mathrm{d}S_1^A$ into the first row gives $\left(a_{11} - \frac{a_{12}^2}{k}\right)\mathrm{d}S_1^A = -\mathrm{d}Z$. The determinant equals $b_{33}(a_{11}k - a_{12}^2)$, which is negative, so $a_{11}k - a_{12}^2 > 0$ and $a_{11} - \frac{a_{12}^2}{k} < 0$. Three results follow.

(1) $\frac{\mathrm{d}S_1^A}{\mathrm{d}Z} > 0$: A is more aggressive in the market whose profitability rose.

(2) $\operatorname{sign}\frac{\mathrm{d}S_2^A}{\mathrm{d}Z} = \operatorname{sign}(a_{12})$: with joint economies A also becomes more aggressive in market 2.

(3) $\operatorname{sign}\frac{\mathrm{d}S_2^B}{\mathrm{d}Z} = \operatorname{sign}(a_{12}) \cdot \operatorname{sign}(b_{32})$: B's response depends on the joint economies and on whether B regards the products as strategic substitutes or complements.

By the envelope theorem (Theorem B.46), $\frac{\mathrm{d}\pi^A}{\mathrm{d}Z} = S_1^A + \frac{\partial \pi^A}{\partial S_2^B}\frac{\mathrm{d}S_2^B}{\mathrm{d}Z}$. The second term is the *strategic effect*. With ordinary substitutes, $\frac{\partial \pi^A}{\partial S_2^B} < 0$, its sign is $-\operatorname{sign}(a_{12})\operatorname{sign}(b_{32})$. It is positive under joint economies with strategic substitutes or joint diseconomies with strategic complements, and negative in the other two cases, as in their table on p. 495. The same favorable shock can hurt a firm through its rival's response.

Example B.184 (Three oligopoly games)**.**

(a) *Cournot with linear demand.* With $P(Q) = a_0 - Q$, $P' + q_i P'' = -1 < 0$, so quantities are strategic substitutes everywhere.

(b) *Cournot with constant-elasticity demand.* Let $P(Q) = Q^{-\frac{1}{\varepsilon}}$ with $\varepsilon > 0$. Then $P'(Q) = -\frac{1}{\varepsilon}Q^{-\frac{1}{\varepsilon}-1}$ and $\frac{P''(Q)}{P'(Q)} = -\frac{1+\frac{1}{\varepsilon}}{Q} = -\frac{1+\varepsilon}{\varepsilon Q}$. With the share $s_i = \frac{q_i}{Q}$,

$$P' + q_i P'' = P'\left[1 + q_i\frac{P''}{P'}\right] = P'\left[1 - \frac{1+\varepsilon}{\varepsilon}s_i\right].$$

Since $P' < 0$, the cross partial is positive, and firm i treats quantities as strategic complements, exactly when $s_i > \frac{\varepsilon}{1+\varepsilon}$. A firm with a small share regards rival output as a strategic substitute, while a firm with a large share regards it as a complement, as Bulow et al. (1985, p. 494) note.

(c) *Logit Bertrand.* With single-product logit demand, $\ln \pi_j = \ln(p_j - mc_j) + \ln s_j(p)$ and

$$\frac{\partial \ln \pi_j}{\partial p_j} = \frac{1}{p_j - mc_j} - \alpha(1 - s_j), \qquad \frac{\partial^2 \ln \pi_j}{\partial p_j \, \partial p_k} = \alpha \frac{\partial s_j}{\partial p_k} = \alpha^2 s_j s_k > 0.$$

Log profit has increasing differences in every pair of prices, so the logit pricing game is log-supermodular everywhere, and prices are strategic complements.

Strategic complementarity among the prices of close substitutes is one reason a merger can raise the prices of non-merging rivals. The MillerCoors joint venture of June 2008 tests how far this reason goes. Soon after it was cleared, the prices of Miller Lite, Coors Light and Bud Light rose by about 8 percent. The prices of Corona Extra and Heineken showed little persistent change (Asker and Nocke, 2021, pp. 241–242). Unilateral effects could produce this pattern only with extreme strategic complementarity between Bud Light and the MillerCoors brands, together with weak substitution toward imports. Asker and Nocke (2021, p. 242) judge that combination unlikely. Miller and Weinberg (2017) estimate a random coefficients nested logit demand and add a coordination parameter to the ownership matrix of the pricing first-order conditions. Its estimate rejects unilateral Bertrand pricing, and the coordinated-effects model fits the observed price paths (Asker and Nocke, 2021, p. 242 and fn. 164). The chapter on mergers develops the case (Chapter 11).

Figure B.9 contrasts the two cases. In the Cournot game, a cost reduction for firm 1 shifts its reaction curve out, and the rival responds by producing less. In the Bertrand game with differentiated products, a cost increase for firm 1 shifts its reaction curve out, and the rival responds by raising its price too.

Panel (b) uses the linear demand example of Tirole (1988, Section 11.2). Firm i sells $q_i = 1 - bp_i + dp_j$ with $0 < d < b$, at constant unit cost c. Its profit $(p_i - c)(1 - bp_i + dp_j)$ is concave in p_i, and the first-order condition is

$$1 + dp_j + bc - 2bp_i = 0, \qquad \text{so} \qquad BR_i(p_j) = \frac{1 + bc + dp_j}{2b}.$$

The slope $\frac{d}{2b}$ is positive, so prices are strategic complements. It is below one half, so the reaction curves cross once. Setting $p_i = p_j = p$ gives $2bp = 1 + bc + dp$, and the unique equilibrium is symmetric,

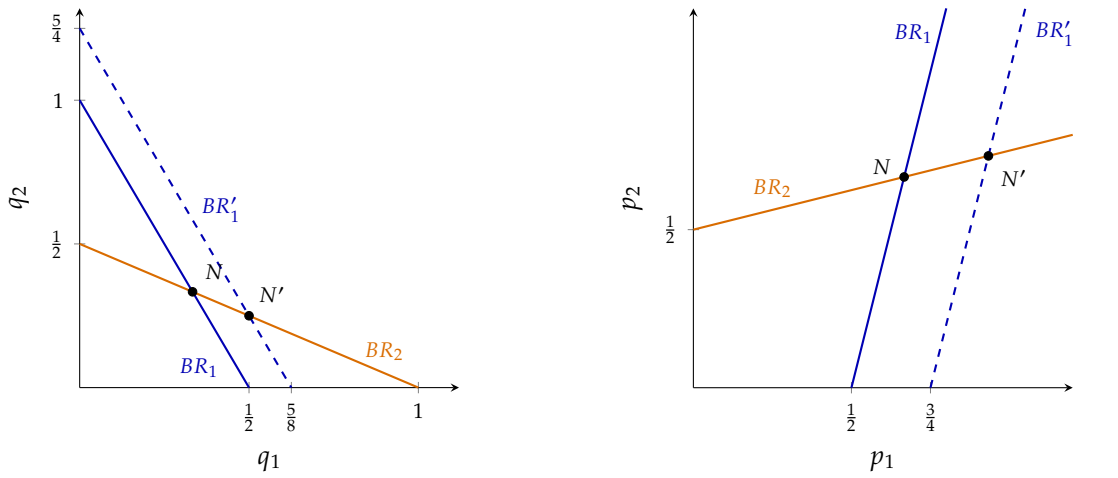
$$p = \frac{1 + bc}{2b - d}.$$

With $b = 1$, $d = \frac{1}{2}$ and $c = 0$, the best response is $\frac{1}{2} + \frac{1}{4}p_j$ and the equilibrium price is $\frac{1}{2 - \frac{1}{2}} = \frac{2}{3}$, the point N in the figure.

B.9.4 Supermodular games

Games with strategic complements have a lattice structure that delivers existence, computation and comparative statics with no concavity and no differentiability. The fixed-point theorem behind them is due to Tarski.

Theorem B.185 (Tarski)**.** *Let $\mathcal{X}$ be a complete lattice and $T : \mathcal{X} \to \mathcal{X}$ a nondecreasing map, that is, $x \le x'$ implies $T(x) \le T(x')$. Then T has a fixed point. Its largest fixed point is* $\sup\{x \in \mathcal{X} : x \le T(x)\}$*, and the set of fixed points is itself a complete lattice (Tarski, 1955).*



(a) Cournot: strategic substitutes

(b) Differentiated Bertrand: strategic complements

Figure B.9: Reaction curves under strategic substitutes and complements. Panel (a): Cournot duopoly with inverse demand $P = a_0 - Q$ and $a_0 - c = 1$, so $BR_i(q_j) = \frac{1-q_j}{2}$ and the equilibrium is $N = (\frac{1}{3}, \frac{1}{3})$. A cost reduction of $\frac{1}{4}$ for firm 1 shifts its curve to $BR_1'(q_2) = \frac{5}{8} - \frac{q_2}{2}$, and the new equilibrium is $N' = (\frac{1}{2}, \frac{1}{4})$: firm 2 contracts. Panel (b): the demand of Tirole (1988, Section 11.2) with $b = 1$ and $d = \frac{1}{2}$, $q_i = 1 - p_i + \frac{1}{2}p_j$, with zero cost, so $BR_i(p_j) = \frac{1}{2} + \frac{1}{4}p_j$ and $N = (\frac{2}{3}, \frac{2}{3})$. Raising firm 1's cost to $\frac{1}{2}$ shifts its curve to $BR_1'(p_2) = \frac{3}{4} + \frac{1}{4}p_2$, and the new equilibrium is $N' = (\frac{14}{15}, \frac{11}{15})$: both prices rise.

Proof of existence. Let $\mathcal{S} = \{x \in \mathcal{X} : x \le T(x)\}$. It is nonempty because it contains $\inf \mathcal{X}$. Let $\bar{x} = \sup \mathcal{S}$. For any $x \in \mathcal{S}$, $x \le \bar{x}$, so $x \le T(x) \le T(\bar{x})$. Thus $T(\bar{x})$ is an upper bound of $\mathcal{S}$, and $\bar{x} \le T(\bar{x})$. Applying T gives $T(\bar{x}) \le T(T(\bar{x}))$, so $T(\bar{x}) \in \mathcal{S}$ and $T(\bar{x}) \le \bar{x}$. Hence $T(\bar{x}) = \bar{x}$. Every fixed point lies in $\mathcal{S}$, so $\bar{x}$ is the largest. □

Unlike Brouwer's and Kakutani's theorems, Tarski's theorem needs no continuity and no convexity. Monotonicity does all the work.

Definition B.186 (Supermodular game)**.** A game with players $i = 1, \dots, N$, strategy sets X_i and payoffs $u_i(x_i, x_{-i})$ is *supermodular* if three conditions hold. Each X_i is a compact product of intervals in some $\mathbb{R}^{k_i}$. Each u_i is upper semicontinuous in x_i and continuous in x_{-i}. Each u_i is supermodular in x_i and has increasing differences in (x_i, x_{-i}).

Supermodularity in own strategy is automatic when each x_i is a scalar. Increasing differences in (x_i, x_{-i}) is strategic complementarity.

Theorem B.187 (Supermodular games)**.** *In a supermodular game the following hold.*

(i) The set of pure-strategy Nash equilibria is nonempty. It has a largest element $\bar{x}$ and a smallest element $\underline{x}$.

(ii) Best-response iteration from the largest strategy profile, choosing the largest best response at each step, decreases monotonically to $\bar{x}$. Iteration from the smallest profile increases to $\underline{x}$.

(iii) Suppose each $u_i(x_i, x_{-i}; a)$ has increasing differences in (x_i, a) for a parameter a. Then $\bar{x}(a)$ and $\underline{x}(a)$ are nondecreasing in a.

(iv) Every strategy that survives iterated elimination of strictly dominated strategies lies between $\underline{x}$ and $\bar{x}$. A game with a unique equilibrium is therefore dominance solvable, and adaptive dynamics converge to it.

Proof sketch. (i) By Theorem B.177, applied with x_{-i} as the parameter, player i's set of best responses has a largest element $\bar{b}_i(x_{-i})$, nondecreasing in x_{-i}. Upper semicontinuity and compactness ensure the set is nonempty and has a largest element. The map $\bar{b} = (\bar{b}_1, \dots, \bar{b}_N)$ is a nondecreasing self-map of the complete lattice $\prod_i X_i$. By Theorem B.185 it has a largest fixed point $\bar{x}$, which is an equilibrium. If x^* is any equilibrium, then $x_i^* \le \bar{b}_i(x_{-i}^*)$ for every i, so $x^* \le \bar{b}(x^*)$ and $x^* \le \bar{x}$ by the characterization in Theorem B.185. The smallest equilibrium is symmetric.

(ii) Let $x^{(0)} = \sup \prod_i X_i$ and $x^{(h+1)} = \bar{b}(x^{(h)})$. Trivially $x^{(1)} \le x^{(0)}$, and monotonicity of $\bar{b}$ gives $x^{(h+1)} \le x^{(h)}$ by induction. Similarly $\bar{x} \le x^{(0)}$ implies $\bar{x} = \bar{b}(\bar{x}) \le x^{(h)}$ for all h. The decreasing sequence converges, and continuity of payoffs makes its limit an equilibrium. The limit is at least $\bar{x}$, so it equals $\bar{x}$.

(iii) If $a' \ge a$, then $\bar{b}(x; a') \ge \bar{b}(x; a)$ for every x by Theorem B.177. Any x with $x \le \bar{b}(x; a)$ then satisfies $x \le \bar{b}(x; a')$. The set whose supremum defines the largest fixed point grows with a, so its supremum rises. Part (iv) is due to Milgrom and Roberts (1990). □

The results are due to Topkis (1979), Vives (1990) and Milgrom and Roberts (1990), and Vives (1999) develops the oligopoly applications. When payoffs are positive, the theorem applies to a game with log-supermodular payoffs after replacing u_i by $\ln u_i$, because the transformation leaves best responses unchanged.

Example B.188 (A cost increase raises all logit prices)**.** Consider the single-product logit pricing game, and fix an interval of firm 1's costs $[\underline{mc}_1, \overline{mc}_1]$ of length below $\frac{1}{\alpha}$. Every best response carries a markup $\frac{1+W_0(z_j)}{\alpha} > \frac{1}{\alpha}$ (Proposition B.99). Since $\Lambda_{-j} \ge 1$, we have $z_j \le e^{v_j - 1}$, so best responses are also bounded above, uniformly over the interval of costs. Let $\bar{p}$ be such a bound. We restrict firm 1 to $[\underline{mc}_1 + \frac{1}{\alpha}, \bar{p}]$ and each firm $j \ne 1$ to $[mc_j + \frac{1}{\alpha}, \bar{p}]$. These sets contain every best response, so the restriction leaves the equilibria unchanged. The sets do not move with mc_1. On them every price exceeds marginal cost, so profits are positive and log profits are finite. By Example B.184(c), log profits have increasing differences in every pair of prices. With firm 1's marginal cost as the parameter,

$$\frac{\partial^2 \ln \pi_1}{\partial p_1 \, \partial mc_1} = \frac{\partial}{\partial mc_1}\left[\frac{1}{p_1 - mc_1}\right] = \frac{1}{(p_1 - mc_1)^2} > 0,$$

while the log profits of the other firms do not depend on mc_1. By Theorem B.187(iii) the extremal equilibria are nondecreasing in mc_1 on the interval. Any two costs are linked by a chain of overlapping intervals of this kind, so the conclusion holds for any two costs. The equilibrium is unique (Section B.8.4), so every firm's equilibrium price is nondecreasing in firm 1's cost. This is the last property in Caplin and Nalebuff's list.

Two further applications follow the same pattern. First, a merger of two price-setting firms with substitute products adds the partner's profit to each merging firm's objective. With weight $a \in [0, 1]$ on the partner's profit, the objective $\pi_1 + a\pi_2$ has $\frac{\partial^2(\pi_1 + a\pi_2)}{\partial p_1 \, \partial a} = \frac{\partial \pi_2}{\partial p_1} = (p_2 - mc_2)\frac{\partial q_2}{\partial p_1} \ge 0$ whenever $p_2 \ge mc_2$. When the post-merger game remains supermodular, as with linear demand, all equilibrium prices rise, the merging firms' and the outsiders' alike (Deneckere and Davidson, 1985). Chapter 11 develops merger simulation. Second, with strategic complements a firm's best deviation from a collusive price profile lies above the static Nash price, because best responses slope up. The slope of best responses therefore governs the gain from deviating (Chapter 12).

B.9.5 Stochastic orders

Probability brings its own orders. Let X_A and X_B have CDFs F_A and F_B with densities f_A and f_B that are positive on a common support $(\underline{x}, \bar{x})$.

Definition B.189 (Stochastic orders)**.**

(i) X_B dominates X_A in the *first-order stochastic dominance* order, $X_B \geq_{\text{FOSD}} X_A$, if $F_B(x) \leq F_A(x)$ for all x.

(ii) $X_B \geq_{\text{hr}} X_A$ in the *hazard rate order* if $\frac{f_B(x)}{1-F_B(x)} \leq \frac{f_A(x)}{1-F_A(x)}$ for all x.

(iii) $X_B \geq_{\text{rh}} X_A$ in the *reverse hazard rate order* if $\frac{f_B(x)}{F_B(x)} \geq \frac{f_A(x)}{F_A(x)}$ for all x.

(iv) $X_B \geq_{\text{lr}} X_A$ in the *likelihood ratio order* if $\frac{f_B(x)}{f_A(x)}$ is nondecreasing in x. This is the *monotone likelihood ratio property* (MLRP).

Definition 14.73 defines the same four orders for the values of strong and weak bidders. The higher variable has the lower hazard rate, because it is less likely to stop just after any level. It has the higher reverse hazard rate, because it is more concentrated near the top of any truncation from above.

Proposition B.190 (The chain of stochastic orders)**.** *The likelihood ratio order implies both the hazard rate order and the reverse hazard rate order, and each of these implies first-order stochastic dominance:*

$$\geq_{\text{lr}} \implies \geq_{\text{hr}} \text{ and } \geq_{\text{rh}}, \qquad \geq_{\text{hr}} \implies \geq_{\text{FOSD}}, \qquad \geq_{\text{rh}} \implies \geq_{\text{FOSD}}.$$

Proof. Assume the MLRP and fix x. For every $t \leq x$, $\frac{f_B(t)}{f_A(t)} \leq \frac{f_B(x)}{f_A(x)}$, that is,

$$f_B(t) f_A(x) \leq f_A(t) f_B(x).$$

Integrating over $t \in (\underline{x}, x]$ gives $F_B(x) f_A(x) \leq F_A(x) f_B(x)$, which rearranges to $\frac{f_B(x)}{F_B(x)} \geq \frac{f_A(x)}{F_A(x)}$, the reverse hazard rate order. For $t \geq x$ the inequality reverses, $f_B(t) f_A(x) \geq f_A(t) f_B(x)$. Integrating over $t \in [x, \bar{x})$ gives $(1 - F_B(x)) f_A(x) \geq (1 - F_A(x)) f_B(x)$, which rearranges to the hazard rate order.

The reverse hazard rate order implies dominance by Proposition B.172. For the hazard rate order, use $\frac{f}{1-F} = -\frac{\mathrm{d}}{\mathrm{d}x} \ln(1 - F)$. The hypothesis says

$$\frac{\mathrm{d}}{\mathrm{d}x} \ln \frac{1 - F_B(x)}{1 - F_A(x)} = \frac{f_A(x)}{1 - F_A(x)} - \frac{f_B(x)}{1 - F_B(x)} \geq 0.$$

The ratio $\frac{1-F_B}{1-F_A}$ is nondecreasing and tends to one at $\underline{x}$. Hence it is at least one, and $F_B(x) \leq F_A(x)$. □

None of the converse implications holds in general (Shaked and Shanthikumar, 2007). First-order dominance has a useful characterization through expectations.

Proposition B.191 (Dominance and expectations)**.** $X_B \geq_{\text{FOSD}} X_A$ *if and only if* $\mathbb{E}[\varphi(X_B)] \geq \mathbb{E}[\varphi(X_A)]$ *for every nondecreasing function* φ *for which both expectations exist.*

Proof. For the "if" direction, take $\varphi(x) = \mathbf{1}\{x > t\}$. Then $\mathbb{E}[\varphi(X)] = 1 - F(t)$, so $1 - F_B(t) \geq 1 - F_A(t)$ for every t. For the "only if" direction, let $U \sim U[0,1]$ and define $\tilde{X}_A = F_A^{-1}(U)$ and $\tilde{X}_B = F_B^{-1}(U)$ with the generalized inverses $F^{-1}(u) = \inf\{x : F(x) \geq u\}$. By Lemma B.19, $\tilde{X}_A$ and $\tilde{X}_B$ have the distributions of X_A and X_B. If $F_B \leq F_A$, then $\{x : F_B(x) \geq u\} \subseteq \{x : F_A(x) \geq u\}$, so the infimum over the smaller set is larger and $\tilde{X}_B \geq \tilde{X}_A$ pointwise. Then $\varphi(\tilde{X}_B) \geq \varphi(\tilde{X}_A)$ for every realization, and taking expectations completes the proof. □

A family of conditional distributions $F(\cdot \mid z)$ is *stochastically increasing* in z if $F(\cdot \mid z') \leq F(\cdot \mid z)$ whenever $z' > z$. By Proposition B.191, $\mathbb{E}[\varphi(X) \mid Z = z]$ is then nondecreasing in z for every nondecreasing φ. Affiliation, to which we turn, is the multivariate condition that delivers such monotonicity.

B.9.6 Affiliation

Affiliation is log-supermodularity of a joint density. It is the form of positive dependence under which Milgrom and Weber (1982) develop the theory of auctions with interdependent values (Chapter 14).

Definition B.192 (Affiliation)**.** A random vector $Z = (Z_1, \ldots, Z_k)$ with joint density f is *affiliated* if, for all $z, z' \in \mathbb{R}^k$,

$$f(z \vee z')\, f(z \wedge z') \geq f(z)\, f(z') \tag{B.108}$$

(Milgrom and Weber, 1982, eq. (2), p. 1098).

The same definition appears in Athey and Haile (2007, footnote 9) and as Definition 14.11. Inequality (B.108) is also called the FKG inequality (Fortuin et al., 1971) and the MTP_2 property, multivariate total positivity of order two (Karlin and Rinott, 1980). Where $f > 0$, taking logs shows that affiliation is exactly log-supermodularity of the density. Roughly, large values of some of the variables make large values of the others more likely (Milgrom and Weber, 1982, p. 1098). Independent variables satisfy (B.108) with equality, because both sides contain the same marginal factors.

Remark B.193 (The general definition). Milgrom and Weber (1982, Appendix) define affiliation without densities. A set $A \subseteq \mathbb{R}^k$ is *increasing* if its indicator is nondecreasing, and a set S is a sublattice if $z \vee z', z \wedge z' \in S$ whenever $z, z' \in S$. The variables are *associated* if $\mathbb{P}(Z \in A \cap A') \geq \mathbb{P}(Z \in A)\mathbb{P}(Z \in A')$ for all increasing sets A and A'. They are affiliated if they are associated conditional on every sublattice S of positive probability. Their Theorem 24 shows that, for variables with a density, this is equivalent to (B.108) almost everywhere.

Proposition B.194 (Characterization, Milgrom and Weber, 1982, Theorem 1)**.**

(i) A strictly positive, twice continuously differentiable density f on a product of intervals is affiliated if and only if $\frac{\partial^2 \ln f}{\partial z_l \, \partial z_m} \geq 0$ for all $l \neq m$.

(ii) If $f = g_1 g_2$ with g_1 and g_2 nonnegative functions that satisfy (B.108), then f is affiliated.

Proposition 14.12 proves both parts. Part (i) is also Proposition B.175 applied to $\ln f$, and Milgrom and Weber (1982, p. 1098) cite Topkis (1978, p. 310) for it. Part (ii) multiplies the inequalities for g_1 and g_2, which is legitimate because all terms are nonnegative.

For two variables, affiliation is a statement about conditional densities, and it feeds directly into the chain of stochastic orders.

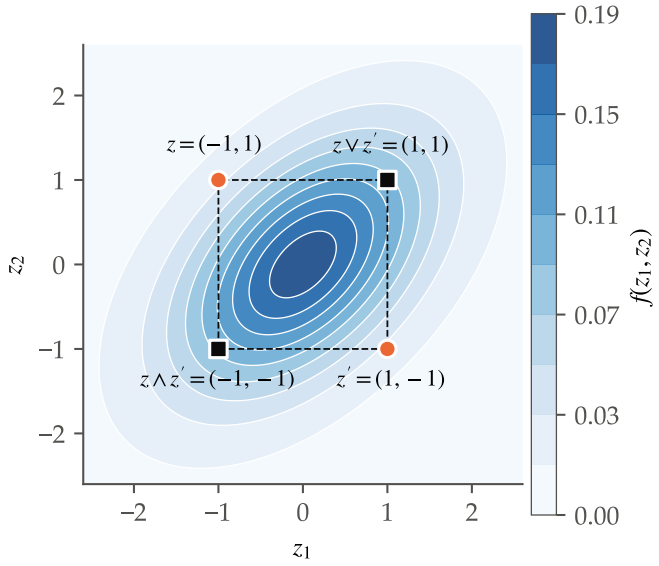


Figure B.10: The affiliation inequality for the standard bivariate normal density with correlation $\frac{1}{2}$. The unordered points $z = (-1,1)$ and $z' = (1,-1)$ (circles) have join $z \vee z' = (1,1)$ and meet $z \wedge z' = (-1,-1)$ (squares). The density is 0.09435 at the join and the meet and 0.02487 at z and z', so $f(z \vee z')f(z \wedge z') = 0.00890$ exceeds $f(z)f(z') = 0.000619$, by the factor $e^{\frac{8}{3}} \approx 14.39$.

Proposition B.195 (Affiliation, MLRP and dominance)**.** *Let (X, Z) have a strictly positive density $f(x, z)$ on a rectangle, with conditional density $f(x \mid z)$ and conditional CDF $F(x \mid z)$.*

(i) (X, Z) is affiliated if and only if $f(x \mid z)$ has the MLRP in z: for $z' > z$, $\frac{f(x|z')}{f(x|z)}$ is nondecreasing in x.

(ii) Let (X, Z) be affiliated and $z' > z$. The conditional distribution given z' dominates the one given z in the reverse hazard rate and hazard rate orders. In particular, $\mathbb{P}(X \geq x \mid Z = z)$ is nondecreasing in z.

(iii) If (X, Z) is affiliated, then $\mathbb{E}[\varphi(X) \mid Z = z]$ is nondecreasing in z for every nondecreasing φ.

Proof. (i) For $x' > x$ and $z' > z$, inequality (B.108) reads $f(x', z')f(x, z) \geq f(x, z')f(x', z)$. Dividing by the product of the marginal densities of Z at z and z' turns joint densities into conditional ones, and dividing again by $f(x' \mid z)f(x \mid z) > 0$ gives $\frac{f(x'|z')}{f(x'|z)} \geq \frac{f(x|z')}{f(x|z)}$, the MLRP. Each step reverses (Milgrom and Weber, 1982, footnote 16). Parts (ii) and (iii) follow from part (i) by Proposition B.190 and Proposition B.191, applied to $X_B \sim F(\cdot \mid z')$ and $X_A \sim F(\cdot \mid z)$. □

Part (ii) follows from the affiliation that Campo et al. (2003) assume in their asymmetric affiliated private values model, so that $\mathbb{P}(V_1 \geq v \mid V_2 = v_2)$ is nondecreasing in v_2. Chapter 14 proves the same chain in the auction notation. Milgrom and Weber derive the properties that auction theory needs from affiliation.

Proposition B.196 (Properties of affiliated variables, Milgrom and Weber, 1982, Theorems 2–5)**.** *Let $Z = (Z_1, \ldots, Z_k)$ be affiliated.*

(i) *(Order statistics.)* *Suppose the density $f(s, x_1, \dots, x_n)$ of a common component s and signals x_i is affiliated and symmetric in $(x_2, \dots, x_n)$. Let $Y_1 \geq \cdots \geq Y_{n-1}$ be the order statistics of $(X_2, \dots, X_n)$. Then $(S, X_1, Y_1, \dots, Y_{n-1})$ is affiliated.*

(ii) *(Monotone transformations.)* *If $g_1, \dots, g_k$ are all nondecreasing or all nonincreasing, then $g_1(Z_1), \dots, g_k(Z_k)$ are affiliated.*

(iii) *(Subvectors.)* *$Z_1, \dots, Z_{k-1}$ are affiliated.*

(iv) *(Conditional expectations.)* *For any nondecreasing H, the function $h(a_1, b_1; \dots; a_k, b_k) = \mathbb{E}[H(Z) \mid a_1 \leq Z_1 \leq b_1, \dots, a_k \leq Z_k \leq b_k]$ is nondecreasing in all its arguments. In particular, $\mathbb{E}[H(Z) \mid Z_1 = z_1, \dots, Z_l = z_l]$ is nondecreasing in $(z_1, \dots, z_l)$.*

Proofs and sketches. (i) The joint density of $(S, X_1, Y_1, \dots, Y_{n-1})$ is

$$(n-1)!\, f(s, x_1, y_1, \dots, y_{n-1})\, \mathbf{1}\{y_1 \geq y_2 \geq \cdots \geq y_{n-1}\}$$

(Milgrom and Weber, 1982, eq. (4), p. 1099). The set of ordered vectors is a lattice, because componentwise maxima and minima of two decreasing sequences are decreasing. Its indicator therefore satisfies (B.108). The product rule of Proposition B.194(ii) gives the result.

(ii) We prove the case of strictly increasing, differentiable g_l. By the change-of-variables formula, the density of $W = (g_1(Z_1), \dots, g_k(Z_k))$ is

$$f_W(w) = f\big(g_1^{-1}(w_1), \dots, g_k^{-1}(w_k)\big) \prod_{l=1}^{k} \frac{1}{g_l'(g_l^{-1}(w_l))}.$$

The map $w \mapsto (g_1^{-1}(w_1), \dots, g_k^{-1}(w_k))$ is increasing coordinate by coordinate, so it commutes with joins and meets. The first factor therefore satisfies (B.108). The product is a product of functions of one coordinate each, which satisfies (B.108) with equality. Proposition B.194(ii) completes the argument. If all g_l are decreasing, joins and meets swap, and (B.108) is symmetric in them.

(iii) Write $Z = (U, W)$ with $U = (Z_1, \dots, Z_{k-1})$ and $W = Z_k$, and let $f(u, w)$ be the joint density. Fix $u, u' \in \mathbb{R}^{k-1}$. We must show that the marginal $\int f(u, w)\, \mathrm{d}w$ satisfies (B.108), that is,

$$\int f(u \vee u', w)\, \mathrm{d}w \int f(u \wedge u', w)\, \mathrm{d}w \geq \int f(u, w)\, \mathrm{d}w \int f(u', w)\, \mathrm{d}w.$$

Write each product as a double integral over (w, w') and fold the region $w > w'$ onto $w < w'$. For $w < w'$ define

$$\Theta_1 = f(u \vee u', w) f(u \wedge u', w'), \qquad \Theta_2 = f(u \vee u', w') f(u \wedge u', w),$$
$$\Xi_1 = f(u, w) f(u', w'), \qquad \Xi_2 = f(u, w') f(u', w).$$

The left side is the integral of $\Theta_1 + \Theta_2$ and the right side the integral of $\Xi_1 + \Xi_2$ over $w < w'$, so it suffices to show $\Theta_1 + \Theta_2 \geq \Xi_1 + \Xi_2$ pointwise. Affiliation of f gives $\Theta_2 \geq \Xi_1$ and $\Theta_2 \geq \Xi_2$, because in both cases the join of the two arguments is $(u \vee u', w')$ and the meet is $(u \wedge u', w)$. Affiliation in u at fixed w and at fixed w' gives, after multiplying, $\Theta_1 \Theta_2 \geq \Xi_1 \Xi_2$. Now $(\Theta_2 - \Xi_1)(\Theta_2 - \Xi_2) \geq 0$ expands to

$$\Theta_2(\Xi_1 + \Xi_2) \leq \Theta_2^2 + \Xi_1 \Xi_2 \leq \Theta_2^2 + \Theta_1 \Theta_2.$$

Dividing by $\Theta_2 > 0$ gives the claim. If $\Theta_2 = 0$, then $\Xi_1 = \Xi_2 = 0$ and the claim is trivial. This is the simplest case of the composition results of Karlin and Rinott (1980).

(iv) We prove the bivariate case $k = 2$, $l = 1$. Write $\mathbb{E}[H(Z_1, Z_2) \mid Z_1 = z_1] = \mathbb{E}[H(z_1, Z_2) \mid Z_1 = z_1]$. Raising z_1 raises the integrand $H(z_1, \cdot)$ pointwise, and it shifts the conditional distribution of Z_2 up in the sense of first-order dominance (Proposition B.195). By Proposition B.191 both effects raise the conditional expectation. Milgrom and Weber (1982, Appendix) derive the general statement from the conditional covariance inequality below. □

Affiliation implies a covariance inequality that is often easier to use than the density condition.

Theorem B.197 (Association, Milgrom and Weber, 1982, Theorems 22–23)**.** *If Z is affiliated, then for every pair of nondecreasing functions g and h and every sublattice S of positive probability,*

$$\mathbb{E}[g(Z)h(Z) \mid S] \geq \mathbb{E}[g(Z) \mid S]\,\mathbb{E}[h(Z) \mid S].$$

With $S = \mathbb{R}^k$, affiliated variables are associated*: $\operatorname{Cov}(g(Z), h(Z)) \geq 0$. Moreover, $\mathbb{E}[g(Z) \mid A] \geq \mathbb{E}[g(Z)] \geq \mathbb{E}[g(Z) \mid A^c]$ for every increasing set A of positive probability.*

Proof for one variable. Let $k = 1$ and let Z' be an independent copy of Z. Because g and h are both nondecreasing, $g(Z) - g(Z')$ and $h(Z) - h(Z')$ have the same sign, so

$$0 \leq \mathbb{E}\big[(g(Z) - g(Z'))(h(Z) - h(Z'))\big] = 2\mathbb{E}[g(Z)h(Z)] - 2\mathbb{E}[g(Z)]\mathbb{E}[h(Z)].$$

This is Chebyshev's covariance inequality. For general k, the inequality for indicators of increasing sets is association, which is part of Milgrom and Weber's general definition of affiliation (Remark B.193). Their Theorem 24 shows that a density satisfying (B.108) is affiliated in that sense. The step functions $g_m(z) = \frac{1}{m}\sum_{i \geq 1} \mathbf{1}\{g(z) > \frac{i}{m}\}$ are sums of indicators of increasing sets and approximate a nonnegative nondecreasing g, which extends the inequality from indicators to functions (Milgrom and Weber, 1982, Theorems 22–23). Conditioning on a sublattice S multiplies the density by the indicator of S, which satisfies (B.108), so the conditional density is again affiliated. □

Taking g and h to be coordinate functions shows that affiliated variables are nonnegatively correlated. The converse fails badly, as the examples show.

Example B.198 (Affiliated and non-affiliated densities)**.**

(a) *Independence.* A product of marginal densities satisfies (B.108) with equality.

(b) *Normal vectors.* Let $Z \sim N(\mu, \Sigma)$. Then $\ln f(z) = \text{const} - \frac{1}{2}(z - \mu)^\top \Sigma^{-1}(z - \mu)$, and $\frac{\partial^2 \ln f}{\partial z_l \, \partial z_m} = -(\Sigma^{-1})_{lm}$. By Proposition B.194(i), Z is affiliated if and only if every off-diagonal element of the precision matrix Σ^{-1} is nonpositive. In the bivariate case with standard deviations σ_1, σ_2 and correlation ρ_{12} (written with a subscript to distinguish it from pass-through),

$$\ln f = \text{const} - \frac{1}{2(1 - \rho_{12}^2)} \left[\frac{(z_1 - \mu_1)^2}{\sigma_1^2} - \frac{2\rho_{12}(z_1 - \mu_1)(z_2 - \mu_2)}{\sigma_1 \sigma_2} + \frac{(z_2 - \mu_2)^2}{\sigma_2^2} \right],$$

so $\frac{\partial^2 \ln f}{\partial z_1 \, \partial z_2} = \frac{\rho_{12}}{(1 - \rho_{12}^2)\sigma_1 \sigma_2}$. A bivariate normal vector is affiliated if and only if $\rho_{12} \geq 0$. With three or more variables, nonnegative correlations do not suffice. The covariance matrix

with unit variances and correlations $\operatorname{Corr}(Z_1, Z_2) = \operatorname{Corr}(Z_1, Z_3) = \frac{1}{2}$ and $\operatorname{Corr}(Z_2, Z_3) = 0$ is positive definite, but its inverse has $(\Sigma^{-1})_{23} = \frac{1}{2} > 0$. Conditional on Z_1, the variables Z_2 and Z_3 are negatively related, and the vector is not affiliated.

(c) *Farlie-Gumbel-Morgenstern density.* On $[0,1]^2$ let $c(z_1, z_2) = 1 + \vartheta(1-2z_1)(1-2z_2)$ with $|\vartheta| \le 1$. It integrates to one, has uniform marginals, and $\operatorname{Cov}(Z_1, Z_2) = \frac{\vartheta}{36}$, so $\operatorname{Corr}(Z_1, Z_2) = \frac{\vartheta}{3}$. Its partial derivatives are $c_1 = -2\vartheta(1-2z_2)$, $c_2 = -2\vartheta(1-2z_1)$ and $c_{12} = 4\vartheta$. Hence

$$\frac{\partial^2 \ln c}{\partial z_1 \, \partial z_2} = \frac{c\, c_{12} - c_1 c_2}{c^2} = \frac{4\vartheta\left[1 + \vartheta(1-2z_1)(1-2z_2)\right] - 4\vartheta^2(1-2z_1)(1-2z_2)}{c^2} = \frac{4\vartheta}{c^2}.$$

The density is affiliated if and only if $\vartheta \ge 0$.

(d) *Mineral rights.* Let the common value V have density h, and let signals be $S_i = V + \epsilon_i$ with $\epsilon_1, \ldots, \epsilon_n$ i.i.d., independent of V, with a log-concave density f_ϵ. The conditional density of a signal is $f_\epsilon(s - v)$. For $v' > v$, write $t = s - v$ and $d = v' - v > 0$. Then

$$\ln \frac{f_\epsilon(s - v')}{f_\epsilon(s - v)} = \ln f_\epsilon(t - d) - \ln f_\epsilon(t),$$

which is nondecreasing in t, and hence in s, because the increments of the concave function $\ln f_\epsilon$ shrink as its argument grows. The MLRP holds. Each factor $f_\epsilon(s_i - v)$ of the joint density $h(v) \prod_{i=1}^n f_\epsilon(s_i - v)$ satisfies (B.108) in (v, s_i), and therefore on the whole vector, since joins and meets act coordinate by coordinate. By Proposition B.194(ii), $(V, S_1, \ldots, S_n)$ is affiliated (Milgrom and Weber, 1982, p. 1099). Normal, logistic and Gumbel noise all qualify (Table B.4).

Figure B.10 illustrates (B.108) for a bivariate normal density with correlation $\frac{1}{2}$. The points $z = (-1, 1)$ and $z' = (1, -1)$ are unordered, and their join $(1, 1)$ and meet $(-1, -1)$ lie along the direction of positive dependence, where the density is higher.

In auction theory these tools combine as follows. By Proposition B.196(i) and (iv), the expected value $\mathbb{E}[V_1 \mid X_1 = x, Y_1 = y]$ is nondecreasing in both arguments, which makes symmetric equilibrium bids increasing. By part (iv) with the upper bound on Y_1 lowered, $\mathbb{E}[V_1 \mid X_1 = x, Y_1 < x] \le \mathbb{E}[V_1 \mid X_1 = x]$, which is the winner's curse. Chapter 14 develops both, and Chapter 15 uses affiliation in the identification of affiliated private values.

The first-order condition of a symmetric first-price auction with affiliated private values shows where the conditional distributions enter. Let B_1 be the highest bid among bidder 1's rivals. Let $G_{B_1|b_1}$ and $g_{B_1|b_1}$ be its distribution and density conditional on bidder 1's own bid. Li et al. (2002, eq. 4, p. 175) show that the equilibrium condition is equivalent to

$$v = b + \frac{G_{B_1|b_1}(b \mid b)}{g_{B_1|b_1}(b \mid b)}.$$

Each value is therefore a known function of its bid and of the joint distribution of bids, which the data reveal (Athey and Haile, 2007, Section 3.1, eq. 3.1). Under independence the conditioning on b_1 drops out. Under affiliation it stays, because a high own bid signals high rival bids. Bids inherit affiliation from values, since the equilibrium bid function is increasing (Proposition B.196(ii)). Li et al. (2002, Proposition 1, p. 175) characterize the bid distributions that such a model can generate. A distribution qualifies if and only if it is symmetric and affiliated and the right side above is strictly increasing in b.

B.10 Bibliographic notes

Optimization, comparative statics and duality are covered in every graduate text in microeconomic theory. Mas-Colell et al. (1995) prove the Kuhn-Tucker conditions, the theorem of the maximum and the duality results of Section B.4. Simon and Blume (1994) give the matrix and calculus background. Milgrom and Segal (2002) prove the envelope theorem for arbitrary choice sets, which is the version that mechanism design and auction theory need. Samuelson (1947) introduced the correspondence principle and the Le Chatelier principle into economics. Deaton and Muellbauer (1980b) develop duality for demand analysis at book length. Their chapters on rationing, aggregation and index numbers supply the shadow prices, representative incomes and cost-of-living bounds of Section B.4.4. Hausman (1981) showed how to recover exact welfare measures from an estimated demand curve. Bulow and Pfleiderer (1983) and Weyl and Fabinger (2013) are the main references on pass-through and the curvature of demand.

The extreme value foundations of discrete choice are due to McFadden (1974, 1978, 1981), and the survey of McFadden (1984) collects them. Small and Rosen (1981) derived the log-sum measure of consumer surplus, and Williams (1977) and Daly and Zachary (1978) proved that the expected maximum utility has the choice probabilities as its gradient. Anderson et al. (1992) connect discrete choice with representative-consumer models of product differentiation. Train (2009) is the standard text on discrete choice with simulation. Cardell (1997) constructed the distribution behind the random-coefficients reading of the nested logit, and McFadden and Train (2000) showed that mixed logits approximate any random utility model.

David (1981) and Arnold et al. (1992) are the standard references on order statistics. Athey and Haile (2002, 2007) turned these results into a theory of identification for auctions, and the deconvolution lemma of Kotlarski (1966) underlies the treatment of unobserved auction heterogeneity. On fixed points, Stokey et al. (1989) treat contractions in function spaces, and Judd (1998) discusses the numerical side. Berry (1994) proved that market shares can be inverted for mean utilities, and Berry et al. (1995) supplied the contraction that computes the inverse. Berry et al. (2013) established invertibility under much weaker conditions. Berry and Pakes (2007) show how far the contraction weakens when the logit error vanishes. Chapter 11 of Tirole (1988) is a compact guide to the equilibrium concepts of the book, and its Section 11.6.1 derives their existence from the theorem of Debreu (1952). Dasgupta and Maskin (1986) treat games with discontinuous payoffs.

Log-concavity entered economics from probability theory. Prékopa (1971) and Borell (1975) proved the integration results, and Caplin and Nalebuff (1991) used them to prove the existence of price equilibrium in differentiated-products oligopoly. Bagnoli and Bergstrom (2005) classify the common distributions. Lattice methods for comparative statics begin with Topkis (1978), and Milgrom and Shannon (1994) found their ordinal form. Topkis (1979), Vives (1990) and Milgrom and Roberts (1990) developed the theory of supermodular games, and Vives (1999) applies it to oligopoly. Bulow et al. (1985) introduced strategic substitutes and complements. Nocke and Schutz (2018) develop the aggregative structure of logit and CES pricing games, and Asker and Nocke (2021, p. 229) survey its use in merger analysis. Milgrom and Weber (1982) made affiliation the central dependence concept of auction theory, and Li et al. (2002) turned it into a nonparametric estimator for first-price auctions. Karlin and Rinott (1980) study the same property under the name of multivariate total positivity, and Shaked and Shanthikumar (2007) cover the stochastic orders of Section B.9.5.

B.11 Exercises

1. *Duality with CES utility.* Let $U(q_1, q_2) = (q_1^r + q_2^r)^{\frac{1}{r}}$ with $r < 1$ and $r \neq 0$, and write $\sigma_{\text{CES}} = \frac{1}{1-r}$.

   (a) Derive the Marshallian demands and the indirect utility function. Show that $q_i = \frac{p_i^{-\sigma_{\text{CES}}} I}{P^{1-\sigma_{\text{CES}}}}$ with $P^{1-\sigma_{\text{CES}}} = p_1^{1-\sigma_{\text{CES}}} + p_2^{1-\sigma_{\text{CES}}}$.

   (b) Derive the expenditure function $e(p, u) = uP$. Verify Shephard's lemma, Roy's identity and the symmetry of the Slutsky matrix.

   (c) Show that the elasticity of $\frac{h_1}{h_2}$ with respect to $\frac{p_2}{p_1}$ equals σ_{CES}.

   (d) Use Proposition B.74 to show that the compensating variation of removing good 2 is finite when $\sigma_{\text{CES}} > 1$ and infinite when $\sigma_{\text{CES}} < 1$. Interpret the difference.

   (e) Ration good 1 at z units. Derive the restricted expenditure function $e^*(p, u, z)$ and the shadow price $p_1^*(p_2, u, z)$, and verify $\frac{\partial e^*}{\partial z} = p_1 - p_1^*$ (Remark B.75). With two goods the ration fixes q_2, so $S_{22}^* = 0$. Use $Sp = 0$ to check that $S_{22} - \frac{S_{21}^2}{S_{11}} = 0$, as Remark B.52 requires.

2. *Exact welfare from log-linear demand.* Let the demand for good 1 be $q_1 = \exp(c_0 + c_1 p_1 + c_2 I)$ with $c_1 < 0$ and $c_2 > 0$, holding the other prices fixed.

   (a) Write the differential equation (B.35) for this demand and solve it by separation of variables. Use the constant of integration as the utility index.

   (b) Derive the indirect utility function and check that Roy's identity returns q_1.

   (c) Derive the compensating variation of a price increase from p_1^0 to p_1^1. Show that it tends to the change in Marshallian consumer surplus as $c_2 \to 0$.

   (d) Show that the Hicksian demand is positive at every finite price, so the virtual price is infinite. Is the value of the good still finite? Compare with the linear demand of Example B.71.

   (e) For a rise in p_1 alone, show that the bounds (B.40) follow from the fact that compensated demand slopes down. Compute both bounds and both exact measures for $c_0 = 1$, $c_1 = -1$, $c_2 = 0.01$, $I = 100$ and a price rise from 1 to 2.

3. *Pass-through and conduct.* Consider the supply relation (B.18).

   (a) Derive (B.19) step by step, with ε_S defined relative to marginal cost including the tax.

   (b) Show that a pass-through rate of one is consistent with three worlds: price taking with flat marginal cost, monopoly with exponential demand, and monopoly with log-convex demand and rising marginal cost.

   (c) Let $P(Q) = a - bQ$ and $mc(Q) = c + dQ$ with $b, d > 0$. Show that $\rho = \frac{1}{1+\theta+\frac{d}{b}}$, first from the proposition and then by solving the model directly.

   (d) Explain what these results imply for tests of market power that regress prices on taxes.

4. *Cournot comparative statics.* Let N symmetric firms with constant marginal cost c face inverse demand $P(Q)$, and treat N as a continuous variable.

   (a) Write the symmetric equilibrium condition $P(Nq) + qP'(Nq) = c$. Use the implicit function theorem to derive $\frac{\mathrm{d}q}{\mathrm{d}N}$ and $\frac{\mathrm{d}Q}{\mathrm{d}N}$.

(b) State conditions on P' and P'' under which $\frac{\mathrm{d}Q}{\mathrm{d}N} > 0$ and $\frac{\mathrm{d}q}{\mathrm{d}N} < 0$. Relate the second inequality, business stealing, to the sign of $P' + qP''$.

(c) Use the envelope theorem to derive $\frac{\mathrm{d}\pi}{\mathrm{d}N}$ and show that it is negative under the conditions of part (b).

(d) Verify all three derivatives for linear demand $P(Q) = A - Q$.

5. *Extreme value algebra.* Let $\epsilon_{i0}, \dots, \epsilon_{iJ}$ be independent standard Gumbel shocks and $u_{ij} = \delta_j + \epsilon_{ij}$.

(a) Prove max-stability for $\mathrm{EV}(0, b)$ shocks and use it to derive the logit shares with scale b.

(b) Show that the expected maximal utility conditional on choosing j is the same for every j. Derive $\mathbb{E}[\epsilon_{ij} \mid j \text{ chosen}] = \gamma_E - \ln s_j$.

(c) In a nested logit with one nest of m identical products of mean utility δ and an outside good, compute expected consumer surplus as a function of m and σ. Show that it grows like $\frac{1-\sigma}{\alpha} \ln m$ for large m, and explain the role of σ.

(d) Derive the within-nest correlation $1 - (1 - \sigma)^2$ from Cardell's representation.

6. *Order statistics and competing risks.*

(a) Let n values be drawn independently from $F(x) = x^a$ on $[0, 1]$ with $a > 0$. Derive the CDF and the mean of the second-highest value. Check your answer against Corollary B.115 at $a = 1$.

(b) Prove the recurrence relation (B.81) for $k = n - 1$ directly from (B.73), for i.i.d. draws.

(c) Two independent bidders have values with $F_i(x) = x^{a_i}$ on $[0, 1]$, $i = 1, 2$. Compute $G_1^w(x) = \mathbb{P}(M \le x, I = 1)$ and the CDF of the maximum M. Verify that (B.86) recovers F_1.

(d) In part (c), show that the winning value and the identity of the winner are independent. Explain why the frequency of wins then carries all the information that separates the two distributions.

7. *Contractions and equilibrium computation.*

(a) In the plain logit, show that the Jacobian of the share-inversion map (B.92) is $\mathbf{1}s^\top$. Compute the number of iterations needed per digit of accuracy when $s_0 = 0.05$ and when $s_0 = 0.5$.

(b) Take a nested logit with one nest of two products. Show that the undampened map has a Jacobian eigenvalue $-\frac{\sigma}{1-\sigma}$, and that the dampened map (B.95) sends this eigenvalue to zero.

(c) A single-product logit monopolist has $\alpha = 1$ and $v = \tilde{\delta} - \alpha mc = 3$. Use Proposition B.99 to compute its share. Show that the markup iteration (B.98) diverges locally while best-response iteration converges in one step.

(d) Use (B.90) to bound the number of iterations that reach a tolerance of 10^{-8} from an initial step of 10, for $\kappa = 0.9$ and $\kappa = 0.99$.

8. *Log-concavity, supermodularity and affiliation.*

(a) Show that the standard logistic density is log-concave. Deduce that its hazard rate is nondecreasing and that values with this distribution satisfy Myerson's regularity condition.

(b) Show that the single-product logit pricing game is log-supermodular. Use Theorem B.187 to show that an increase in one firm's marginal cost does not lower any equilibrium price. Then use the closed-form best response (B.60) to show that every price strictly rises.

(c) Verify that the Farlie-Gumbel-Morgenstern density of Example B.198 is affiliated if and only if $\vartheta \geq 0$. Show directly that affiliation implies the monotone likelihood ratio property for this density.

(d) Prove that the likelihood ratio order implies first-order stochastic dominance. Give an example of two distributions ranked by first-order dominance but not by the likelihood ratio.

Appendix C

Worked Problems

This appendix works through eight problems with complete solutions. They apply the tools of the book to concrete markets: the Cournot and conduct models of Chapters 2 and 3, the pricing theory of Chapter 4, and the demand models of Chapters 6 to 8. Following a derivation and carrying one out are different skills. A model becomes a working tool only once we have computed its equilibrium, estimated it on data and checked the answer. Most of the problems use simulated data. We then know the truth, so we can see exactly what each estimator recovers and where it fails.

The problems fall into four groups. Sections C.1 and C.2 treat a homogeneous good. The first works out what Cournot competition, collusion and free entry imply for the relation between concentration and margins, and what that relation can say about mergers. The second asks what the pass-through of a tax reveals about conduct, and it re-estimates the cigarette tax regressions of Sumner (1981). Sections C.3 and C.4 compute price equilibria with differentiated products. The first does so for logit demand, proves that the equilibrium is unique, and evaluates a merger and a tax. The second simulates 100 markets from a random coefficients logit with multi-product pricing. Sections C.5 to C.7 estimate the vertical model, the logit and the random coefficients logit on these simulated data. They compare the elasticities, markups, recovered costs and merger predictions of the three models with the truth. Section C.8 closes with real data, the product file of the replication package of Grieco et al. (2024). It asks what simple demand models say about the decline of markups in the U.S. automobile market, and it compares their answer with the full model of that paper. Table C.1 lists the problems with the tools and chapters each one draws on.

Every problem has the same format. A short paragraph motivates it. A statement gives the data and the parameters and poses parts (a), (b) and so on. The solution answers every part in order, with propositions and proofs for the results it relies on. Theory proved in a chapter is restated in one line with a cross-reference and then used. Computational notes describe the algorithms as numbered steps. Readers gain most by attempting each part before reading its solution. The numerical parts need a scientific programming language with linear algebra, a root finder and a random number generator. Every number computed in the solutions was produced by a Python script in `figures/appC/src`, and numbers quoted from papers are cited to their tables or pages. The scripts read the supplied data files in `figures/appC/data`, or the replication package used in Section C.8. They draw all simulated consumers, bootstrap samples and Monte Carlo samples with fixed seeds. Readers who draw their own random numbers will obtain slightly different values.

Three conventions need care across the problems. First, δ is the discount factor in Section C.1

Table C.1: The eight worked problems

Problem	Topic	Main tools	Builds on
C.1	Cournot competition, collusion and entry, concentration and margins, mergers	Nash and subgame-perfect equilibrium, repeated games, OLS limits, Monte Carlo	Chapters 1, 2, 11
C.2	Tax pass-through and conduct in cigarettes	Comparative statics, two-way fixed effects, clustered inference, power, ad valorem taxes	Chapters 2, 3
C.3	Logit Bertrand pricing with single- and multi-product firms, a merger and a tax	Lambert W function, aggregative uniqueness proof, contraction mapping, upward pricing pressure	Chapters 4, 7, 11
C.4	Simulating a random coefficients logit market	Simulated shares, Morrow-Skerlos fixed point, sampling and simulation error	Chapter 8
C.5	Estimating the vertical model	Share inversion, normalization, clustered OLS, implied costs	Chapter 6
C.6	Estimating logit demand and recovering costs	Berry inversion, 2SLS, instrument strength, market bootstrap, joint GMM, omitted-heterogeneity bias	Chapters 7, 8
C.7	Random coefficients estimation, a comparison of three models and a merger	BLP contraction, 2SLS, elasticity matrices, diversion, merger simulation	Chapters 8, 11
C.8	Markups over time in U.S. automobiles	Nested logit, weak instruments with two endogenous regressors, second-choice data, decompositions	Chapters 1, 7

Notes: Problems C.4 to C.7 share one simulated data set and are best read in order. The other problems can be read on their own.

and mean utility in the other problems. Second, in Sections C.1 and C.2 the symbol ε is the market elasticity written as a positive number, as in the notation list. From Section C.3 on, we report elasticity matrices with entries $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$. Own elasticities are then negative, and the positive own elasticity of the notation list is $-\varepsilon_{jj}$. Third, Φ always denotes the logit denominator, while Λ_t and Γ_t are the matrices of the Morrow-Skerlos fixed point of Section C.4. Symbols used in a single problem are defined where they first appear.

C.1 Cournot competition, entry, collusion and the concentration-margin relation

Cross-industry studies in the structure-conduct-performance tradition relate profitability to concentration. Bain (1951) compared profit rates across industries, and later work regressed price-cost margins on concentration (Schmalensee, 1989). This problem works out what four canonical models of a homogeneous-good industry imply for that relation, and what the relation can and cannot say about mergers. The four models are Cournot competition and perfect collusion, each with a fixed number of firms and with free entry. Two extensions add firms with different costs and mergers. A computational part simulates a cross-section of industries and compares the merger predictions of the regression with the true equilibrium effects. The theory behind the problem is developed in Sections 2.4, 2.5 and 2.10, and the

cross-industry regression is studied in Section 1.4.4.

C.1.1 Statement

A homogeneous good has linear inverse demand $P(Q) = a - bQ$, where Q is total output, $a > c > 0$ and $b > 0$. Every active firm pays a fixed cost $F > 0$ per period and produces at constant marginal cost c. The Lerner index is $L = \frac{P-c}{P}$, the Herfindahl index is $HHI = \sum_i s_i^2$ with market shares $s_i = \frac{q_i}{Q}$, and $\varepsilon = -\frac{\mathrm{d}Q}{\mathrm{d}P}\frac{P}{Q}$ is the market elasticity of demand, written as a positive number. Two constants recur. The *market-size index* is $x \equiv \frac{a-c}{\sqrt{bF}}$, and the *profit scale* is $k \equiv \frac{(a-c)^2}{b}$.

(a) There are N firms that choose outputs simultaneously. Describe the game and the equilibrium concept. Show that the equilibrium is unique and symmetric. Compute the price, outputs, profits, L and HHI, and verify that $L = \frac{HHI}{\varepsilon}$.

(b) Firms first decide whether to enter and then play the game of part (a). Treating the number of firms as continuous, find the free-entry number of firms and the resulting price, outputs, L and HHI.

(c) Repeat parts (a) and (b) when the active firms collude perfectly, charging the monopoly price and splitting output equally. Show that collusion is not a Nash equilibrium of the one-shot game. Find the discount factor above which grim-trigger strategies sustain collusion in the infinitely repeated game.

(d) Describe the relation between HHI and L in the four cases.

(e) An economist posits $\mathbb{E}[L] = \beta_0 + \beta_1 HHI$ and estimates it on a cross-section of industries. Does the specification make sense under each model? Are the estimates consistent, and for what? Are they useful for predicting the effect of a merger?

(f) Let firm i have its own constant marginal cost c_i, with every firm active. Show that $L_i = \frac{s_i}{\varepsilon}$ and $\sum_i s_i L_i = \frac{HHI}{\varepsilon}$. Show that a mean-preserving spread of costs that keeps every firm active raises HHI and the share-weighted Lerner index, leaves the price unchanged and raises welfare.

(g) Evaluate every object of parts (a) to (c) for $a = 10$, $c = 2$, $b = 1$ and $F = 1$, including consumer surplus, total welfare and the welfare-maximizing number of firms.

(h) In the symmetric Cournot model, study the profitability of a merger of two firms and of k_M firms. Compare the change in HHI computed from pre-merger shares with the equilibrium change. Find the marginal cost of the merged firm below which the merger does not raise the price.

(i) (Computational.) Simulate a cross-section of Cournot industries, estimate the regression of part (e), and compare the merger effects it predicts with the true equilibrium effects.

C.1.2 Solution

Part (a). The game has players $i = 1, \dots, N$. Each player chooses an output $q_i \geq 0$, all players move simultaneously, and all primitives are common knowledge. Firm i's payoff is

$$\pi_i(q_i, q_{-i}) = \big(a - bQ - c\big)q_i - F, \qquad Q = q_i + Q_{-i}, \quad Q_{-i} = \sum_{j \neq i} q_j. \tag{C.1}$$

A *Nash equilibrium* is a profile $q^* = (q_1^*, \dots, q_N^*)$ such that q_i^* maximizes $\pi_i(q_i, q_{-i}^*)$ for every i. The fixed cost lowers the profit of an active firm but does not affect its output choice.

Profit is strictly concave in the firm's own output, since

$$\frac{\partial \pi_i}{\partial q_i} = a - c - bQ_{-i} - 2bq_i, \qquad \frac{\partial^2 \pi_i}{\partial q_i^2} = -2b < 0.$$

The unique best response to rivals' total output Q_{-i} is therefore

$$BR_i(Q_{-i}) = \max\left\{0, \frac{a - c - bQ_{-i}}{2b}\right\}. \tag{C.2}$$

Proposition C.1 (Linear Cournot equilibrium)**.** *With $a > c$, the Cournot game has a unique Nash equilibrium. It is symmetric, every firm is active, and*

$$q = \frac{a - c}{b(N+1)}, \qquad Q = \frac{N(a-c)}{b(N+1)}, \qquad P = \frac{a + Nc}{N+1}. \tag{C.3}$$

Proof. We proceed in three steps. First, total output is positive in any equilibrium. If $Q = 0$, every firm faces $Q_{-i} = 0$, and (C.2) gives $BR_i(0) = \frac{a-c}{2b} > 0$, a contradiction. Second, every firm is active. An active firm l satisfies the first-order condition $a - c - bQ - bq_l = 0$, so

$$bq_l = a - c - bQ.$$

Since $q_l > 0$, this gives $a - c - bQ > 0$. A firm i with $q_i = 0$ would need $\frac{\partial \pi_i}{\partial q_i}\big|_{q_i=0} = a - c - bQ \le 0$, which contradicts the previous inequality. Third, every firm satisfies $bq_i = a - c - bQ$, so all outputs are equal. Summing over the N firms gives

$$\begin{aligned} bQ &= N(a-c) - NbQ, \\ Q &= \frac{N(a-c)}{b(N+1)}. \end{aligned}$$

Total output is unique, so each output $q = \frac{Q}{N}$ is unique. The price is $P = a - bQ = \frac{a(N+1) - N(a-c)}{N+1} = \frac{a+Nc}{N+1}$. □

The remaining objects follow by substitution. The margin and the profit are

$$P - c = \frac{a + Nc - (N+1)c}{N+1} = \frac{a-c}{N+1} = bq, \tag{C.4}$$

$$\pi = (P - c)q - F = \frac{a-c}{N+1} \cdot \frac{a-c}{b(N+1)} - F = \frac{k}{(N+1)^2} - F. \tag{C.5}$$

The Lerner index divides the margin by the price, and every firm has share $\frac{1}{N}$:

$$L = \frac{a-c}{N+1} \cdot \frac{N+1}{a+Nc} = \frac{a-c}{a+Nc}, \qquad HHI = N \cdot \frac{1}{N^2} = \frac{1}{N}. \tag{C.6}$$

With linear demand $-\frac{\mathrm{d}Q}{\mathrm{d}P} = \frac{1}{b}$, so the elasticity at the equilibrium is

$$\varepsilon = \frac{P}{bQ} = \frac{a+Nc}{N+1} \cdot \frac{N+1}{N(a-c)} = \frac{a+Nc}{N(a-c)}.$$

The check is direct: $\frac{HHI}{\varepsilon} = \frac{1}{N} \cdot \frac{N(a-c)}{a+Nc} = \frac{a-c}{a+Nc} = L$. The relation holds for any demand curve. Firm i's first-order condition $P + q_i P'(Q) = c$ gives $\frac{P-c}{P} = -\frac{q_i P'}{P} = \frac{q_i}{Q} \cdot \frac{1}{\varepsilon}$, and symmetry sets $\frac{q_i}{Q} = \frac{1}{N} = HHI$ (Section 2.4.4).

Part (b). Entry adds a first stage. In stage 1, a large pool of identical potential entrants decide simultaneously whether to enter and pay F. In stage 2, the N entrants observe N and play the Cournot game of part (a). The solution concept is *subgame-perfect equilibrium*. Proposition C.1 fixes play in every stage-2 subgame, so an entrant earns $\pi(N) = \frac{k}{(N+1)^2} - F$, which is strictly decreasing in N. In equilibrium no entrant regrets entering and no outsider wants to enter, so the number of firms N^e satisfies $\pi(N^e) \geq 0 \geq \pi(N^e + 1)$. Treating N as continuous gives the zero-profit condition $\pi(N^e) = 0$:

$$\begin{aligned} (N^e + 1)^2 &= \frac{(a-c)^2}{bF} = x^2, \\ N^e &= x - 1 = \frac{a-c}{\sqrt{bF}} - 1. \end{aligned} \tag{C.7}$$

The free-entry outcomes follow from (C.3) and (C.4) with $\frac{a-c}{N^e+1} = \sqrt{bF}$:

$$\begin{aligned} P^e &= c + \frac{a-c}{N^e+1} = c + \sqrt{bF}, \qquad q^e = \frac{a-c}{b(N^e+1)} = \frac{\sqrt{bF}}{b} = \sqrt{\frac{F}{b}}, \\ Q^e &= \frac{a-P^e}{b} = \frac{a-c-\sqrt{bF}}{b}, \\ L^e &= \frac{P^e-c}{P^e} = \frac{\sqrt{bF}}{c+\sqrt{bF}}, \qquad HHI^e = \frac{1}{N^e} = \frac{1}{x-1} = \frac{\sqrt{bF}}{a-c-\sqrt{bF}}. \end{aligned} \tag{C.8}$$

Each entrant earns $(P^e - c)q^e - F = \sqrt{bF}\sqrt{\frac{F}{b}} - F = 0$. The formulas require $N^e \geq 1$, that is, $x \geq 2$, or equivalently $0 < F \leq \frac{(a-c)^2}{4b}$. The Cournot rule survives entry. The elasticity at P^e is $\varepsilon^e = \frac{P^e}{bQ^e} = \frac{c+\sqrt{bF}}{a-c-\sqrt{bF}}$, and $\frac{HHI^e}{\varepsilon^e} = L^e$. Under free entry the dollar margin $\sqrt{bF}$ is fixed by technology and the slope of demand. A larger intercept a brings more firms and leaves the margin unchanged. With the integer constraint, N^e is the integer part of $x - 1$ (Section 2.5.3).

Part (c). Under perfect collusion with N firms fixed, the firms choose total output to maximize joint profit

$$\Pi(Q) = (a - bQ - c)Q - NF, \qquad \Pi''(Q) = -2b < 0.$$

The first-order condition $a - c - 2bQ = 0$ gives the monopoly outcome

$$Q^m = \frac{a-c}{2b}, \qquad P^m = a - bQ^m = \frac{a+c}{2}, \qquad P^m - c = \frac{a-c}{2}. \tag{C.9}$$

Each firm produces $q = \frac{Q^m}{N} = \frac{a-c}{2bN}$ and earns $\pi = \frac{a-c}{2} \cdot \frac{a-c}{2bN} - F = \frac{k}{4N} - F$. The Lerner index is $L = \frac{a-c}{a+c}$ for every N, and $HHI = \frac{1}{N}$. The elasticity at the monopoly price is $\varepsilon(P^m) = \frac{P^m}{bQ^m} = \frac{a+c}{a-c}$, so $L = \frac{1}{\varepsilon(P^m)}$, the monopoly inverse-elasticity rule. Price, total output and the margin do not depend on N. Profit per firm and HHI fall as N rises.

Collusion is not a Nash equilibrium of the one-shot game when $N \geq 2$. Suppose every rival produces $\frac{Q^m}{N}$. At $q_i = \frac{Q^m}{N}$ the marginal profit of firm i is

$$\frac{\partial \pi_i}{\partial q_i} = a - c - bQ^m - b\frac{Q^m}{N} = \frac{a-c}{2} - \frac{a-c}{2N} = \frac{(N-1)(a-c)}{2N} > 0.$$

Each firm gains by expanding, because it bears only its own share of the price reduction that its extra output causes.

Collusion can be sustained in the infinitely repeated game. In periods $t = 0, 1, 2, \ldots$ the N firms play the stage game of part (a). Outputs are observed at the end of each period. In this problem $\delta \in (0, 1)$ denotes the discount factor, as in Chapter 12 (in the demand chapters δ is mean utility). Firm i maximizes $\sum_{t \geq 0} \delta^t \pi_{it}$. Under *grim-trigger* strategies (Friedman, 1971), each firm produces $\frac{Q^m}{N}$ in period 0 and in every period that follows no deviation. After any deviation every firm produces the Cournot output $\frac{a-c}{b(N+1)}$ forever.

Proposition C.2 (Threshold discount factor for Cournot collusion)**.** *Grim-trigger strategies form a subgame-perfect equilibrium that sustains the monopoly outcome if and only if*

$$\delta \geq \delta^*(N) \equiv \frac{(N+1)^2}{N^2 + 6N + 1}. \tag{C.10}$$

The threshold satisfies $\delta^*(2) = \frac{9}{17}$*, is strictly increasing in* N *for* $N > 1$*, and tends to one as* $N \to \infty$*.*

Proof. The fixed cost enters every period's payoff equally, so it cancels from every incentive constraint. What remains is Proposition 12.18, which gives the threshold, its monotonicity and its limit. At $N = 2$ the threshold is $\frac{9}{4+12+1} = \frac{9}{17}$. □

Figure C.1 plots the threshold together with the Bertrand benchmark. In the Bertrand supergame a deviator undercuts slightly and takes the whole monopoly profit π^m, after which profits are zero. The condition $\frac{\pi^m}{N(1-\delta)} \geq \pi^m$ gives $\delta \geq 1 - \frac{1}{N}$ (Proposition 12.14). Tirole (1988, Section 6.3.2.1) uses this threshold to formalize the old claim that concentration facilitates tacit collusion. The two thresholds cross between $N = 2$ and $N = 3$. Cournot collusion is harder to sustain for $N = 2$ ($\frac{9}{17} = 0.529$ against 0.5) and easier for every $N \geq 3$ ($\frac{4}{7} = 0.571$ against 0.667 at $N = 3$). For large N, $1 - \delta^*(N) = \frac{4N}{N^2+6N+1}$ is close to $\frac{4}{N}$, four times the Bertrand slack $\frac{1}{N}$. Cournot reversion is a mild punishment, but the one-shot gain from deviating is also small, because the deviator expands only to its best response.

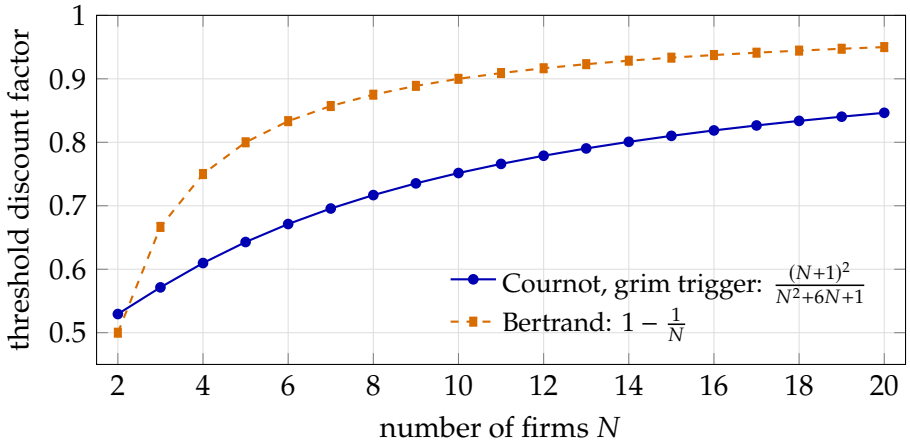

Figure C.1: Lowest discount factor at which grim-trigger strategies sustain the monopoly outcome among N symmetric firms, for Cournot and Bertrand stage games with linear demand and constant marginal cost. The Cournot threshold does not depend on a, b, c or F.

Remark C.3. Grim trigger is not the harshest credible punishment. Abreu (1986) studies stick-and-carrot punishments, in which firms produce more than the Cournot output for one period and then return to collusion. These punish deviators more severely and sustain the monopoly outcome at lower discount factors than (C.10). Chapter 12 develops optimal punishments.

With free entry, collusive play in stage 2 yields per-firm profit $\pi(N) = \frac{k}{4N} - F$. The free-entry condition $\pi(N^m) = 0$, with N continuous, gives

$$N^m = \frac{(a-c)^2}{4bF} = \frac{x^2}{4}. \tag{C.11}$$

Price and total output stay at the monopoly values, so entry only changes how Q^m is divided:

$$q^m = \frac{Q^m}{N^m} = \frac{a-c}{2b} \cdot \frac{4bF}{(a-c)^2} = \frac{2F}{a-c}, \qquad L = \frac{a-c}{a+c}, \qquad HHI^m = \frac{1}{N^m} = \frac{4bF}{(a-c)^2}.$$

Total fixed costs equal the monopoly profit, $N^m F = \frac{(a-c)^2}{4b} = (P^m - c)Q^m$, so entry dissipates the whole rent. Consumers gain nothing, because the price stays at P^m. Collusion attracts more entrants than Cournot competition:

$$N^m - N^e = \frac{x^2}{4} - x + 1 = \left(\frac{x}{2} - 1\right)^2 \geq 0, \tag{C.12}$$

with equality only at $x = 2$, where both equal one. The higher collusive margin draws firms in until profit is again zero. The collusive outcome with N^m firms is an equilibrium of the repeated game only if $\delta \geq \delta^*(N^m)$. Lower fixed costs raise N^m and push the threshold toward one, so free entry also makes collusion harder to enforce.

Part (d). Table C.2 collects the four regimes (the closed forms are also in Table 2.1). Under Cournot conduct with N fixed, substitute $N = \frac{1}{HHI}$ in the elasticity of part (a):

$$\varepsilon = \frac{aHHI + c}{a-c}, \qquad L = \frac{HHI}{\varepsilon} = \frac{(a-c)HHI}{aHHI + c}. \tag{C.13}$$

The derivatives

$$\frac{\mathrm{d}L}{\mathrm{d}HHI} = \frac{(a-c)(aHHI + c) - (a-c)HHIa}{(aHHI + c)^2} = \frac{c(a-c)}{(aHHI + c)^2} > 0,$$
$$\frac{\mathrm{d}^2L}{\mathrm{d}HHI^2} = -\frac{2ac(a-c)}{(aHHI + c)^3} < 0$$

show an increasing and concave curve. It runs from $L = 0$ at $HHI = 0$ to the monopoly value $\frac{a-c}{a+c}$ at $HHI = 1$. When N is set outside the model, the curve is the causal effect of concentration on margins in an industry with given (a, c).

With free entry, Cournot industries stay on the curve (C.13), but HHI^e and L^e are now both outcomes of (a, b, c, F). Write $r = \sqrt{bF}$, so that $HHI^e = \frac{r}{a-c-r}$ and $L^e = \frac{r}{c+r}$. Each primitive moves the pair differently. A higher F or b raises r and with it both HHI^e and L^e, so the industry moves up along the curve. A higher a lowers HHI^e and leaves L^e unchanged. A higher c raises HHI^e and lowers L^e. Across industries, the sign of the association between HHI and L therefore depends on which primitive varies.

Table C.2: Concentration and margins in the linear homogeneous-good industry under four regimes

Regime	N	P	q	L	HHI	Relation of L to HHI
Cournot, fixed N	N	$\frac{a+Nc}{N+1}$	$\frac{a-c}{b(N+1)}$	$\frac{a-c}{a+Nc}$	$\frac{1}{N}$	increasing, concave, causal
Cournot, free entry	$x-1$	$c+\sqrt{bF}$	$\sqrt{\frac{F}{b}}$	$\frac{\sqrt{bF}}{c+\sqrt{bF}}$	$\frac{\sqrt{bF}}{a-c-\sqrt{bF}}$	same curve, both endogenous
Collusion, fixed N	N	$\frac{a+c}{2}$	$\frac{a-c}{2bN}$	$\frac{a-c}{a+c}$	$\frac{1}{N}$	flat
Collusion, free entry	$\frac{x^2}{4}$	$\frac{a+c}{2}$	$\frac{2F}{a-c}$	$\frac{a-c}{a+c}$	$\frac{4bF}{(a-c)^2}$	opposite directions when a or c vary

Notes: Inverse demand $P = a - bQ$, marginal cost c, fixed cost F, and $x = \frac{a-c}{\sqrt{bF}}$. Free-entry columns treat N as continuous and require $x \geq 2$. Under Cournot conduct $L = \frac{HHI}{\varepsilon}$, and under collusion $L = \frac{1}{\varepsilon}$, with ε evaluated at the equilibrium price.

Under collusion with N fixed, $L = \frac{a-c}{a+c}$ for every N, so the relation is flat. With free entry, L still depends only on (a, c), while $HHI^m = \frac{4bF}{(a-c)^2}$. Variation in F or b moves HHI^m alone. A higher a raises L and lowers HHI^m, and a higher c does the reverse, so variation in a or c moves the two indices in opposite directions.

Differences in conduct weaken, and can reverse, the positive Cournot relation. Compare a Cournot industry and a collusive industry with the same primitives. With N fixed both have $HHI = \frac{1}{N}$, and the collusive industry has the higher margin, since $\frac{a-c}{a+c} > \frac{a-c}{a+Nc}$ for $N > 1$. With free entry, collusion again raises the margin, because $P^e = c + \sqrt{bF} \leq \frac{a+c}{2} = P^m$ whenever $x \geq 2$. By (C.12) the collusive industry is also less concentrated. A cross-section that mixes the two pairs high margins with low concentration. This pulls the slope of L on HHI below the Cournot curve and can make it negative. Figure 2.6 draws the four cases for $a = 10$ and $c = 2$.

Part (e). The specification $\mathbb{E}[L] = \beta_0 + \beta_1 HHI$ fits the four models to different degrees.

- Cournot, fixed N. The model implies $L = \frac{HHI}{\varepsilon}$, so $\beta_0 = 0$ and margins rise with HHI. The relation is linear with $\beta_1 = \frac{1}{\varepsilon}$ only if ε is the same in every industry. With linear demand, $\varepsilon = \frac{aHHI+c}{a-c}$ rises with HHI by (C.13), so the true relation is concave and the linear form is an approximation.
- Cournot, free entry. Industries still lie on $L = \frac{HHI}{\varepsilon}$, so the specification remains an approximation. Differences in HHI now reflect differences in (a, b, c, F).
- Collusion, fixed N. The margin does not depend on HHI, so the specification holds only in the degenerate form $\beta_1 = 0$.
- Collusion, free entry. A nonzero slope can arise from joint variation of the primitives, and it has no causal meaning.

Cross-industry OLS converges to $\frac{\text{Cov}(L,HHI)}{\text{Var}(HHI)}$ (Proposition 1.24). This limit summarizes the joint distribution of outcomes. It equals a structural parameter such as $\frac{1}{\varepsilon}$ only under special conditions, and four problems separate the two. First, concentration is endogenous, because the same primitives determine HHI and L, and part (d) shows that even the sign of the association

depends on which primitive varies. Second, industries differ in elasticity and conduct, so $\hat{\beta}_1$ averages over different models. If $L_k = \frac{HHI_k}{\varepsilon_k}$ with ε_k independent of HHI_k, the slope converges to $\mathbb{E}[\frac{1}{\varepsilon_k}]$, and otherwise it does not. Third, accounting margins differ from economic margins. Measured price-cost margins omit the cost of capital, and capital intensity is correlated with fixed costs and hence with HHI. Fourth, HHI is measured with error and depends on the market definition, which attenuates the slope.

Even a positive and precisely estimated $\hat{\beta}_1$ need not mean that concentration raises margins. Part (f) shows that when firms differ in costs, efficient firms are large, so concentration and the average margin rise together while welfare also rises. This is the efficiency critique of Demsetz (1973).

The regression is a weak tool for merger prediction. The economist would compute $\widehat{\Delta L} = \hat{\beta}_1 \, \Delta HHI$ with $\Delta HHI = 2 s_i s_j$ from the merging firms' pre-merger shares. The prediction inherits every bias of $\hat{\beta}_1$. The share-based ΔHHI also misstates the equilibrium change in concentration (part (h)), and the prediction ignores entry, coordinated effects and cost savings. Part (i) measures the size of these errors in simulated data.

Part (f). Let firm i have constant marginal cost c_i and suppose all N firms are active. The first-order condition of firm i is $a - bQ - bq_i - c_i = 0$, that is,

$$bq_i = P - c_i. \tag{C.14}$$

Summing over firms gives $bQ = Na - \sum_j c_j - NbQ$, so

$$Q = \frac{Na - \sum_j c_j}{b(N+1)}, \qquad P = a - bQ = \frac{a + \sum_j c_j}{N+1}, \qquad q_i = \frac{a + \sum_j c_j - (N+1)c_i}{b(N+1)}. \tag{C.15}$$

All firms are active if and only if $c_i < P$ for every i. Dividing (C.14) by P,

$$L_i = \frac{P - c_i}{P} = \frac{bq_i}{P} = \frac{q_i}{Q} \cdot \frac{bQ}{P} = \frac{s_i}{\varepsilon}, \qquad \sum_i s_i L_i = \frac{1}{\varepsilon} \sum_i s_i^2 = \frac{HHI}{\varepsilon}.$$

The share-weighted Lerner index equals the Herfindahl index divided by the market elasticity (Cowling and Waterson, 1976). The same steps apply to any demand curve, because the first-order condition $P + q_i P' = c_i$ gives $L_i = \frac{s_i}{\varepsilon}$ directly. The ratio of industry variable profit to revenue is the same object,

$$\frac{\sum_i (P - c_i) q_i}{PQ} = \sum_i \frac{q_i}{Q} \cdot \frac{P - c_i}{P} = \sum_i s_i L_i = \frac{HHI}{\varepsilon},$$

which is Exercise 5.6 of Tirole (1988, Section 5.5).

A *mean-preserving spread* of costs is a change from (c_i) to (c_i') with $\sum_i c_i' = \sum_i c_i$ and $\sum_i (c_i' - \bar{c})^2 > \sum_i (c_i - \bar{c})^2$, where $\bar{c}$ is the mean cost. We write $\mathrm{Var}(c) = \frac{1}{N} \sum_i (c_i - \bar{c})^2$ for the cross-firm variance.

Proposition C.4 (Cost dispersion, concentration and welfare)**.** *In the linear Cournot model with all firms active, a mean-preserving spread of marginal costs that keeps every firm active leaves Q, P, ε and consumer surplus unchanged. It raises HHI and the share-weighted Lerner index, and it raises total welfare by $\frac{N \Delta \mathrm{Var}(c)}{b}$, where $\Delta \mathrm{Var}(c)$ is the increase in the cost variance.*

Proof. We use four steps. First, by (C.15) total output and the price depend on costs only through $\sum_j c_j$, which the spread holds fixed. Hence Q, P, the elasticity $\varepsilon = \frac{P}{bQ}$ and consumer surplus $\frac{bQ^2}{2}$ are unchanged. Second, by (C.14) outputs are $q_i = \frac{P - c_i}{b}$, and their mean is $\bar{q} = \frac{Q}{N}$, so

$$q_i - \bar{q} = -\frac{c_i - \bar{c}}{b}, \qquad \operatorname{Var}(q) = \frac{\operatorname{Var}(c)}{b^2}.$$

Third, the Herfindahl index is

$$HHI = \frac{\sum_i q_i^2}{Q^2} = \frac{N\left[\operatorname{Var}(q) + \bar{q}^2\right]}{Q^2} = \frac{1}{N} + \frac{N \operatorname{Var}(c)}{b^2 Q^2},$$

which rises with $\operatorname{Var}(c)$ because Q is fixed. Since ε is fixed, $\sum_i s_i L_i = \frac{HHI}{\varepsilon}$ rises too. Fourth, total variable cost is

$$\sum_i c_i q_i = \frac{1}{b}\sum_i c_i (P - c_i) = \frac{1}{b}\left[PN\bar{c} - N\left(\operatorname{Var}(c) + \bar{c}^2\right)\right] = \frac{N\bar{c}(P - \bar{c})}{b} - \frac{N \operatorname{Var}(c)}{b}.$$

With P and $\bar{c}$ fixed, it falls by $\frac{N \Delta \operatorname{Var}(c)}{b}$. Welfare equals consumer surplus plus revenue PQ minus variable and fixed costs, and only variable cost changes, so welfare rises by the same amount. □

The proposition gives the Demsetz critique a precise form. Across otherwise identical industries, those with more dispersed costs are more concentrated and have higher average margins. They also produce the same output at lower cost. A regression of margins on concentration across such industries finds a positive slope, and a policy of deconcentration would lower welfare. Tirole (1988, Section 5.5, Exercise 5.7) poses the two-firm case. With demand $Q = 1 - P$ and costs satisfying $c_1 + c_2 = 2c$, a spread of costs raises both concentration and industry profit.

The fourth step has a general version that needs neither linear demand nor fixed total output. Total surplus is $W = \int_0^Q P(z)\,\mathrm{d}z - \sum_i c_i q_i - NF$. Holding the cost functions fixed, a small change $\mathrm{d}q$ in outputs changes it by

$$\mathrm{d}W = P\,\mathrm{d}Q - \sum_i c_i\,\mathrm{d}q_i = \sum_i (P - c_i)\,\mathrm{d}q_i.$$

This is the output term of Farrell and Shapiro (1988, eq. 3, p. 7), the working-paper version of Farrell and Shapiro (1990). Its page numbers differ from those of the published article, and its equation numbers may differ too. It models a merger as a transfer of capital between firms. In a Cournot equilibrium with constant marginal costs, the first-order condition gives $P - c_i = |P'| q_i$. Differentiating $\sum_i q_i^2 = HHI\,Q^2$ gives $\sum_i q_i\,\mathrm{d}q_i = HHI\,Q\,\mathrm{d}Q + \frac{Q^2}{2}\,\mathrm{d}HHI$. Substituting,

$$\mathrm{d}W = |P'| \sum_i q_i\,\mathrm{d}q_i = |P'|\left[HHI\,Q\,\mathrm{d}Q + \frac{Q^2}{2}\,\mathrm{d}HHI\right]. \tag{C.16}$$

This is their decomposition, written with X for output and H for the Herfindahl index (p. 17). With total output fixed, a small reallocation that raises the Herfindahl index raises welfare. It moves production toward the largest firms, which have the lowest marginal costs. Even when output falls, welfare rises if the Herfindahl index rises by enough (p. 17).

The same identity bounds the welfare effect of any small change in outputs. By the Cauchy-Schwarz inequality, $\sum_i q_i \, \mathrm{d}q_i \le \|q\| \, \|\mathrm{d}q\|$, and $\|q\| = Q\sqrt{HHI}$. Hence

$$\mathrm{d}W \le |P'| \, Q\sqrt{HHI} \, \|\mathrm{d}q\|,$$

with equality when $\mathrm{d}q$ is proportional to q. Among changes of a given Euclidean size, the largest welfare gain is proportional to the square root of the Herfindahl index. This is the bound of Dansby and Willig (1979), posed as Exercise 5.8 of Tirole (1988, Section 5.5). The Herfindahl index thus also measures how much a small reallocation of output can raise welfare.

Part (g). With $a = 10$, $c = 2$, $b = 1$ and $F = 1$ we have $a - c = 8$, $k = 64$ and $x = 8$. Table C.3 reports every object for $N = 3$ under both conducts and for the two free-entry equilibria. The Cournot rows follow from (C.3) to (C.6). For example, with $N = 3$ the price is $\frac{10+6}{4} = 4$ and each firm produces $\frac{8}{4} = 2$. Free entry gives $N^e = 8 - 1 = 7$ and $P^e = 2 + 1 = 3$. Collusion gives $Q^m = 4$ and $P^m = 6$, and free entry under collusion gives $N^m = \frac{64}{4} = 16$. The difference $N^m - N^e = 9$ equals $(\frac{8}{2} - 1)^2$, as (C.12) requires.

Table C.3: The four regimes for $a = 10$, $c = 2$, $b = 1$ and $F = 1$

	Cournot		Collusion	
	$N = 3$	Free entry	$N = 3$	Free entry
Number of firms N	3	7	3	16
Price P	4	3	6	6
Total output Q	6	7	4	4
Output per firm q	2	1	$\frac{4}{3}$	$\frac{1}{4}$
Profit per firm π (net of F)	3	0	$\frac{13}{3}$	0
Lerner index L	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{2}{3}$	$\frac{2}{3}$
Herfindahl index HHI	$\frac{1}{3}$	$\frac{1}{7}$	$\frac{1}{3}$	$\frac{1}{16}$
Elasticity ε at P	$\frac{2}{3}$	$\frac{3}{7}$	$\frac{3}{2}$	$\frac{3}{2}$
$\frac{HHI}{\varepsilon}$	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{2}{9}$	$\frac{1}{24}$
$\frac{1}{\varepsilon}$	$\frac{3}{2}$	$\frac{7}{3}$	$\frac{2}{3}$	$\frac{2}{3}$
Consumer surplus $\frac{bQ^2}{2}$	18	24.5	8	8
Total profit (net of fixed costs)	9	0	13	0
Total welfare W	27	24.5	21	8
Threshold $\delta^*(N)$ for collusion	$\frac{4}{7} = 0.571$	$\frac{16}{23} = 0.696$	$\frac{4}{7} = 0.571$	$\frac{289}{353} = 0.819$

Notes: Free-entry columns use the continuous free-entry conditions (C.7) and (C.11). Welfare is consumer surplus plus profits net of fixed costs. Under Cournot conduct $L = \frac{HHI}{\varepsilon}$, and under collusion $L = \frac{1}{\varepsilon}$. The last row is $\delta^*(N)$ from (C.10) evaluated at the number of firms in each column.

Welfare under Cournot conduct has a convenient closed form. Consumer surplus is $\frac{bQ^2}{2} = \frac{(a-c)^2 N^2}{2b(N+1)^2}$ and gross profits are $\frac{N(a-c)^2}{b(N+1)^2}$, so

$$W(N) = \frac{(a-c)^2}{2b} \cdot \frac{N^2 + 2N}{(N+1)^2} - NF = \frac{(a-c)^2}{2b}\left[1 - \frac{1}{(N+1)^2}\right] - NF. \tag{C.17}$$

The first term is the maximal gross surplus $\frac{(a-c)^2}{2b} = 32$ less the deadweight loss $\frac{(a-c)^2}{2b(N+1)^2}$. A planner who chooses N but cannot control post-entry conduct sets

$$W'(N) = \frac{(a-c)^2}{b(N+1)^3} - F = 0 \quad \Longrightarrow \quad (N^o + 1)^3 = \frac{(a-c)^2}{bF} = 64 \quad \Longrightarrow \quad N^o = 3.$$

So the Cournot column with $N = 3$ is also the second-best optimum, with $W(3) = 32 \cdot \frac{15}{16} - 3 = 27$. Free entry yields $W(7) = 32 \cdot \frac{63}{64} - 7 = 24.5$. The comparison $N^e + 1 = 8 = (N^o + 1)^{\frac{3}{2}}$ illustrates excess entry (Proposition 2.40, Mankiw and Whinston, 1986). The welfare loss of 2.5 is 7.8 percent of the maximal gross surplus. Collusion with three firms yields $W = 8 + 16 - 3 = 21$, and collusion with free entry yields $W = 8$, since entry dissipates the whole monopoly profit of 16. For reference, a single firm pricing at marginal cost with its fixed cost covered would reach $32 - 1 = 31$.

Part (f) can be checked in the same market. Replace the common cost 2 by costs $(1, 2, 3)$, which keeps $\bar{c} = 2$ and raises $\mathrm{Var}(c)$ from 0 to $\frac{2}{3}$. The price stays at $\frac{10+6}{4} = 4$ and outputs become $(3, 2, 1)$. The Herfindahl index rises from $\frac{1}{3}$ to $\frac{9+4+1}{36} = \frac{7}{18}$, and the share-weighted Lerner index rises from $\frac{1}{2}$ to $\frac{7}{18} \cdot \frac{3}{2} = \frac{7}{12}$. Variable cost falls from 12 to $3 + 4 + 3 = 10$, a saving of $\frac{N\,\mathrm{Var}(c)}{b} = 3 \cdot \frac{2}{3} = 2$, and welfare rises from 27 to 29.

Part (h). A merger without cost savings turns two of N symmetric firms into one firm with the same marginal cost. The merged firm is then one of $N - 1$ symmetric Cournot competitors.

Proposition C.5 (Mergers in symmetric linear Cournot)**.** *Consider the model of part (a) with $N \geq 2$ firms.*

(i) A merger of two firms without cost savings leads to the $(N-1)$-firm equilibrium. If both fixed costs remain, it is profitable for the merging firms if and only if $N \leq 1 + \sqrt{2}$, that is, if and only if $N = 2$. If the merger saves one fixed cost, it is profitable if and only if $\frac{k}{N^2} - \frac{2k}{(N+1)^2} + F \geq 0$.

(ii) A merger of k_M firms, $2 \leq k_M \leq N$, without cost savings is profitable for the merging firms, with all fixed costs kept, if and only if $(N+1)^2 \geq k_M(N - k_M + 2)^2$.

(iii) The share-based change in concentration of a two-firm merger is $2s_i s_j = \frac{2}{N^2}$, and the equilibrium change is $\frac{1}{N-1} - \frac{1}{N} = \frac{1}{N(N-1)}$. The share-based formula overstates the equilibrium change if and only if $N > 2$. The equilibrium changes in price and margin are

$$\Delta P = \frac{a - c}{N(N+1)}, \qquad \Delta L = \frac{c(a-c)}{\big(a + (N-1)c\big)(a + Nc)}. \tag{C.18}$$

(iv) Let the merged firm have marginal cost c_M, and suppose all firms remain active. The merger does not raise the price if and only if

$$c_M \leq c - \frac{a - c}{N + 1} = 2c - P^0, \tag{C.19}$$

where P^0 is the pre-merger price. Equivalently, the merged firm's margin must be at least the sum of the two pre-merger margins, $P^0 - c_M \geq 2(P^0 - c)$.

Proof. (i) After the merger there are $N - 1$ firms with marginal cost c, so Proposition C.1 applies with $N - 1$ firms. The merged firm earns $\frac{k}{N^2} - F$ if one fixed cost is saved and $\frac{k}{N^2} - 2F$ if both remain. The two firms earned $2\big[\frac{k}{(N+1)^2} - F\big]$ before. With both fixed costs kept, the merger is profitable if and only if

$$\frac{k}{N^2} \geq \frac{2k}{(N+1)^2} \iff (N+1)^2 \geq 2N^2 \iff N + 1 \geq \sqrt{2}\,N \iff N \leq \frac{1}{\sqrt{2} - 1} = 1 + \sqrt{2}.$$

Saving one fixed cost adds F to the gain, which gives the second condition. (ii) After the merger there are $N - k_M + 1$ firms, so the merged firm earns $\frac{k}{(N - k_M + 2)^2}$ gross of fixed costs. The

k_M insiders earned $\frac{k_M k}{(N+1)^2}$ before. Cross-multiplying the comparison gives the condition. (iii) Before the merger every share is $\frac{1}{N}$, so $2s_is_j = \frac{2}{N^2}$. In equilibrium the index moves from $\frac{1}{N}$ to $\frac{1}{N-1}$, and $\frac{1}{N-1} - \frac{1}{N} = \frac{1}{N(N-1)}$. The ratio of the two changes is $\frac{2}{N^2} \cdot N(N-1) = \frac{2(N-1)}{N}$, which exceeds one if and only if $N > 2$. By (C.4), $P - c = \frac{a-c}{N+1}$, so $\Delta P = \frac{a-c}{N} - \frac{a-c}{N+1} = \frac{a-c}{N(N+1)}$. By (C.6),

$$\Delta L = \frac{a-c}{a+(N-1)c} - \frac{a-c}{a+Nc} = \frac{(a-c)\big[(a+Nc)-(a+(N-1)c)\big]}{\big(a+(N-1)c\big)(a+Nc)} = \frac{c(a-c)}{\big(a+(N-1)c\big)(a+Nc)}.$$

(iv) After the merger there are $N-1$ firms, $N-2$ with cost c and one with cost c_M. By (C.15) with $N-1$ firms, the post-merger price is $P^1 = \frac{a+(N-2)c+c_M}{N}$. Then

$$\begin{aligned} P^1 \le P^0 &\iff \frac{a+(N-2)c+c_M}{N} \le \frac{a+Nc}{N+1} \\ &\iff c_M \le \frac{N(a+Nc)}{N+1} - a - (N-2)c = \frac{(N+2)c-a}{N+1} = c - \frac{a-c}{N+1}. \end{aligned}$$

The last expression equals $2c - P^0$ because $P^0 - c = \frac{a-c}{N+1}$. □

Part (i) is the merger paradox of Salant et al. (1983). Outsiders respond to the merged firm's contraction by expanding, because quantities are strategic substitutes, and the expansion erodes the insiders' gain. Part (ii) shows how large a merger must be to pay. With $N = 10$, a merger of $k_M = 8$ firms fails, since $121 < 8 \cdot 4^2 = 128$, while a merger of $k_M = 9$ firms succeeds, since $121 > 9 \cdot 3^2 = 81$. A profitable merger must include at least 80 percent of the firms (Proposition 11.4 and Figure 11.6). Part (iv) is the linear case of the synergy condition proved in general in Proposition 11.12, following Farrell and Shapiro (1990). Asker and Nocke (2021, eq. 6, pp. 228–229) state it for a set $\mathcal{M}$ of merging firms with cost functions C_i, pre-merger outputs q_i and merged cost function C_M. The merger does not lower aggregate output, and so does not lower consumer surplus, if

$$P(Q) - C_M'\Big(\sum_{i\in\mathcal{M}} q_i\Big) \ge \sum_{i\in\mathcal{M}} \big[P(Q) - C_i'(q_i)\big].$$

It does not raise consumer surplus if the inequality is reversed. With two merging firms of marginal cost c, the condition is $P^0 - c_M \ge 2(P^0 - c)$, the second form of (C.19). The required saving is the full pre-merger margin, $c - c_M \ge P^0 - c$, so a merger that only rationalizes production always raises the price (Figure 11.7). The working paper states the price result for small transfers of capital (Farrell and Shapiro, 1988, Proposition 2, p. 13). A transfer from firm 2 to firm 1 raises the price if and only if capital has a smaller direct effect on output at firm 1 than at firm 2.

The numerical market of part (g) makes these magnitudes concrete. A merger of two of three firms raises the price from 4 to $\frac{14}{3} = 4.67$ and the Lerner index from $\frac{1}{2}$ to $\frac{4}{7}$, so $\Delta L = \frac{1}{14} = 0.071$. The share-based change in concentration is $\frac{2}{9} = 0.222$ (2,222 points), against an equilibrium change of $\frac{1}{6} = 0.167$ (1,667 points). Consumer surplus falls from 18 to $\frac{128}{9} = 14.2$. The merged firm earns $\frac{64}{9} - 2 = 5.11$ with both fixed costs, less than the 6 the two firms earned before. If the merger saves one fixed cost, it earns $\frac{64}{9} - 1 = 6.11$ and the merger becomes profitable. The outsider gains most, from 3 to 6.11. For the price not to rise, the merged firm's marginal cost must fall to $2c - P^0 = 4 - 4 = 0$, which eliminates marginal cost entirely.

Remark C.6. At the price-neutral cost $c_M = 2c - P^0$, the share-based change in concentration is exact. Total output is unchanged, so each outsider's first-order condition $bq_j = P - c$ leaves its output unchanged, and the merged firm produces the sum of the two pre-merger outputs. In the numerical market with $c_M = 0$, the price stays at 4, the merged firm produces 4 and the outsider 2. The index rises from $\frac{1}{3}$ to $\frac{4}{9} + \frac{1}{9} = \frac{5}{9}$, exactly $\frac{2}{9}$. The share-based formula thus describes the merger whose cost savings exactly offset its market power. Such a merger raises welfare, by the cost saving $c\,(q_i + q_j) = 2 \cdot 4 = 8$ in this example.

Three further channels break the link between ΔHHI and ΔL. With free entry, a merger that removes a firm leaves room for a new entrant, and in the long run N returns to N^e and the price to P^e. In the numerical market, a merger of two of the seven free-entry firms raises each remaining firm's gross profit to $\frac{64}{49} = 1.31$, which exceeds $F = 1$ and invites entry. When the continuous free-entry condition holds before and after, entry restores aggregate output, so the merger leaves consumer surplus unchanged (Asker and Nocke, 2021, Section 3.3.3, pp. 231–232). With the integer constraint this neutrality fails. They report the result of Spector (2003) that, in the Cournot model, a merger without synergies that is profitable once entry is taken into account still harms consumers. Under collusion the firms already charge P^m, so a merger has no direct price effect. It lowers the number of firms and with it the threshold $\delta^*(N)$, from $\frac{4}{7}$ to $\frac{9}{17}$ when three firms become two, so it can make collusion easier to sustain. With differentiated products the price effect runs through the diversion between the merging products (Section C.3).

Part (i). We simulate 1,000 industries. The primitives are drawn independently as $a \sim U[8, 12]$, $c \sim U[1, 4]$, $b \sim U[0.5, 2]$ and $\ln F \sim U[\ln 0.1, \ln 10]$, and kept if $x \geq 2$. The number of firms is drawn as $N \sim U\{1, \ldots, 20\}$ independently of the primitives, and every industry is in the Cournot equilibrium of part (a). This is design (1) of the Monte Carlo experiment in Section 1.4.4, with the same random numbers. OLS of L on a constant and HHI gives

$$\widehat{L} = \underset{(0.004)}{0.178} + \underset{(0.022)}{0.546}\, HHI, \qquad R^2 = 0.520, \tag{C.20}$$

with HC1 standard errors, as in column (1) of Table 1.3. These are heteroskedasticity-robust with the small-sample factor $\frac{n}{n-2}$ (step 3 of Section C.1.3).

For each of the 954 industries with $N \geq 2$ we consider a merger of two firms without cost savings. The equilibrium effect is ΔL in (C.18). The regression predicts $\widehat{\Delta L} = \hat{\beta}_1 \Delta HHI$, and we use two versions of ΔHHI: the share-based $\frac{2}{N^2}$ and the equilibrium change $\frac{1}{N(N-1)}$. A third prediction serves as a benchmark that no cross-industry regression can deliver. It multiplies the equilibrium ΔHHI by the local slope of the industry's own Cournot curve, $\frac{c(a-c)}{(aHHI+c)^2}$. Table C.4 and Figure C.2 report the results.

Three findings stand out. First, the regression gets the direction of the error wrong in a systematic way. For concentrated industries ($N \leq 4$) it overstates the effect of a merger by a factor of about two. For unconcentrated industries ($N \geq 11$) it understates the effect, and with the equilibrium ΔHHI the prediction is less than a third of the truth. The reason is concavity. The OLS slope 0.546 is a variance-weighted average of chord slopes, and most of the variation in HHI comes from concentrated industries, where the Cournot curve is flat. The local slope averages 1.452 across the 1,000 industries, and it is largest where HHI is small.

Second, the share-based formula appears to do better than the equilibrium change in concentration. Overall, its prediction errs by more than 50 percent in 33 percent of industries, against 71 percent for the equilibrium version. This is an accident of offsetting errors. The

Table C.4: Merger effects predicted by the cross-industry regression and equilibrium merger effects

Panel A. Means

		ΔHHI (points)			Predicted ΔL		
N	Industries	$2s_is_j$	Equilibrium	ΔL	$2s_is_j$	Equilibrium	Local slope
All ($N \geq 2$)	954	644	514	0.0248	0.0352	0.0281	0.0305
2 to 4	162	2,748	2,423	0.0695	0.1500	0.1323	0.0991
5 to 10	311	401	237	0.0250	0.0219	0.0130	0.0268

Panel B. Accuracy

	Share with error above 50%			Correlation with ΔL		
N	$2s_is_j$	Equilibrium	Local slope	$2s_is_j$	Equilibrium	Local slope
All ($N \geq 2$)	0.332	0.710	0.055	0.927	0.882	0.981
2 to 4	0.673	0.352	0.321	0.938	0.929	0.978
5 to 10	0.026	0.524	0.000	0.839	0.837	0.999
11 to 20	0.416	0.950	0.000	0.681	0.681	1.000

Notes: 1,000 simulated Cournot industries, of which 954 have $N \geq 2$ firms before the merger. Panel A reports group means. Predictions multiply $\hat{\beta}_1 = 0.546$ from (C.20) by the share-based change $\frac{2}{N^2}$ or by the equilibrium change $\frac{1}{N(N-1)}$. The local-slope benchmark multiplies the equilibrium change by $\frac{c(a-c)}{(aHHI+c)^2}$, the slope of the industry's own Cournot curve. "Error above 50 percent" means $|\widehat{\Delta L} - \Delta L| > 0.5\,\Delta L$. Source: `figures/appC/src/cournot_merger_mc.py`.

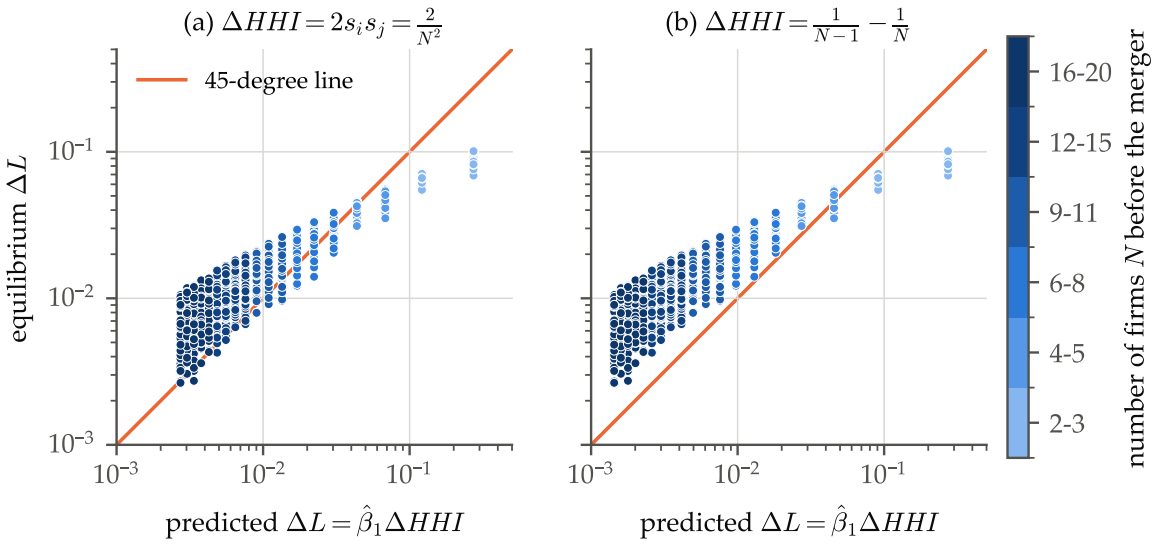

Figure C.2: Equilibrium against predicted changes in the Lerner index after a merger of two firms in 954 simulated Cournot industries, on logarithmic axes. Predictions multiply the cross-industry slope $\hat{\beta}_1 = 0.546$ by the share-based change in concentration (panel a) or by the equilibrium change (panel b). Colours group industries by the number of firms before the merger. Points above the orange line are mergers whose effect the regression understates.

share-based formula overstates the change in concentration by the factor $\frac{2(N-1)}{N}$, close to two in unconcentrated industries, and this offsets part of the slope's understatement there. A correct input combined with a wrong slope produces a worse prediction.

Third, the error comes from the common slope, and the linear approximation does little harm. The local-slope benchmark misses by more than 50 percent in only 5.5 percent of industries, all of them concentrated. Its remaining error comes from concavity, since the tangent at the pre-merger point is steeper than the chord to the post-merger point, so it overpredicts in every industry. The high correlations in Panel B reflect the fact that predicted and actual effects both fall with N. They say little about accuracy, since every prediction uses the same slope for all industries.

C.1.3 Computational notes

The script `figures/appC/src/cournot_merger_mc.py` implements part (i) in the following steps.

1. Draw $(a, c, b, \ln F)$ in batches from the stated uniform distributions with a fixed seed. Keep draws with $x \geq 2$ until 1,000 industries are accepted, then draw N for each industry.
2. Compute $L = \frac{a-c}{a+Nc}$ and $HHI = \frac{1}{N}$.
3. Run OLS of L on $(1, HHI)$. Compute HC1 standard errors as the square roots of the diagonal of $\frac{n}{n-2}(X^\top X)^{-1}\big(\sum_k \hat{e}_k^2 x_k x_k^\top\big)(X^\top X)^{-1}$ (Appendix A).
4. For industries with $N \geq 2$, compute ΔL from (C.18) and the three predictions, then summarize by groups of N.

C.2 What tax pass-through reveals about conduct

The first problem showed that the cross-section of margins and concentration cannot reveal conduct. This problem turns to a source of variation inside one industry, a shock to cost. Excise taxes are a part of marginal cost that the econometrician observes without any cost data. Sumner (1981) used this fact to test for monopoly pricing in the US cigarette industry. He found that cigarette prices rose by more than state excise taxes, and he concluded that the industry was neither competitive nor an effective cartel. This problem derives what a pass-through rate can and cannot reveal about conduct. It checks the numbers in Sumner's main table and re-estimates his regression on a reconstructed panel. It then adds clustered inference with a power calculation, a test of constant pass-through, ad valorem taxes, and a way to recover marginal cost from two kinds of taxes. Section 3.2 treats the paper as a case study, and Section 2.8 develops the theory of pass-through. Here we work through every step on the data.

C.2.1 Statement

A homogeneous good has twice differentiable inverse demand $P(Q)$ with $P'(Q) < 0$. The *curvature* of inverse demand is $\chi \equiv -\frac{QP''(Q)}{P'(Q)}$, and the market elasticity is $\varepsilon = -\frac{P}{QP'(Q)} > 0$. Sellers pay a specific tax t per unit and have marginal cost c, constant unless stated otherwise. Industry conduct is a constant $\theta \in [0, 1]$, and the equilibrium satisfies the supply relation

$$P(Q) + \theta Q P'(Q) = c + t. \tag{C.21}$$

Competition is $\theta = 0$, monopoly is $\theta = 1$, and symmetric Cournot with N firms is $\theta = \frac{1}{N}$ (Corollary 3.3). *Pass-through* is $\rho \equiv \frac{\mathrm{d}P}{\mathrm{d}t}$, the change in the equilibrium price per unit of tax.

The data form a balanced state-year panel reconstructed from the historical volume of *The Tax Burden on Tobacco* (1983, Table 13). It covers 47 states and the District of Columbia annually from 1954 to 1978, a total of 1,200 observations. Alaska, Hawaii and New Hampshire are excluded. For state s and year y, p_{sy} is the weighted-average retail price per pack and t_{sy} is the combined state and federal excise tax, both in nominal cents. Both are recorded on November 1 of each year. Municipal taxes are excluded, and the federal tax is 8 cents per pack throughout. The national consumer price index CPI_y (CPI-U, 1982–84 average equal to 100) deflates prices to $P_{sy} = \frac{100\,p_{sy}}{CPI_y}$ and taxes to $T_{sy} = \frac{100\,t_{sy}}{CPI_y}$. Table C.5 summarizes the panel.

Table C.5: The state-year cigarette panel, 1954–1978

Variable	Mean	S.d.	Min	Max	Mean 1954	Mean 1978
Retail price p_{sy} (cents per pack)	34.04	10.51	18.20	66.50	22.45	56.55
Excise tax t_{sy} (cents per pack)	15.73	4.66	8.00	29.00	11.10	20.63
Real price P_{sy} (1982–84 cents)	90.67	9.65	64.32	126.67	83.47	86.74
Real tax T_{sy} (1982–84 cents)	42.73	8.92	15.34	71.60	41.28	31.64
Tax share $\frac{t_{sy}}{p_{sy}}$	0.467	0.060	0.229	0.584	0.492	0.361

Notes: 1,200 state-years (47 states and the District of Columbia). The tax is the state excise tax plus the federal tax of 8 cents. The CPI-U is 26.9 in 1954 and 65.2 in 1978. The median state tax rises from 3 cents in 1954 to 12 cents in 1978, as Sumner (1981, n. 8) reports, and the mean tax share is close to his 48.7 and 35.5 percent. Of the 1,152 year-to-year transitions within states, 191 involve a tax change, 6 of them decreases, and the mean change is 2.39 cents. The real tax falls over the sample, as Sumner notes. Source: `figures/appC/src/sumner_passthrough.py`.

(a) Derive the pass-through rate from (C.21), first with constant marginal cost and then with marginal cost $c(Q)$ rising in output. What does $\rho > 1$ imply?

(b) Show that one pass-through rate identifies only the composite $\kappa \equiv \theta(\chi - 1)$. Work out the linear, log, constant-elasticity and symmetric Cournot cases.

(c) Sumner writes the price of firm j as $P_j = \frac{\eta_j}{\eta_j + 1} M_j$, where $\eta_j < 0$ is the elasticity of the firm's demand and $M_j = X_j\phi + E_j + t$ its marginal cost. He estimates $p_{sy} = X_{sy}\psi + \Theta t_{sy} + U_{sy}$. Derive this aggregate equation and the elasticity implied by Θ, and check the elasticities he reports.

(d) Estimate $p_{sy} = \mu_s + \tau_y + \rho\, t_{sy} + e_{sy}$ with conventional and state-clustered standard errors. Test $\rho = 1$ and assess the power of the test.

(e) Re-estimate the regression in real terms. Explain why deflating changes the estimate even though the regression contains year effects.

(f) Let pass-through vary with the real tax and test whether it does.

(g) Describe the set of pairs (χ, θ) consistent with the estimate.

(h) Derive a bound on θ from the levels of prices and taxes that does not depend on curvature, and evaluate it.

(i) Show how changes in the mix of brands affect the pass-through of an average price.

(j) Derive the pass-through of an ad valorem tax at rate τ on the consumer price.

(k) What additional data would identify θ?

C.2.2 Solution

Part (a). We write equilibrium output as a function $Q(t)$ of the tax and differentiate the supply relation. The general result allows marginal cost $c(Q)$ to rise with output.

Proposition C.7 (Pass-through of a specific tax)**.** *Replace c by a differentiable marginal cost $c(Q)$ with $c'(Q) \geq 0$ in (C.21). Suppose the equilibrium is interior and stable, in the sense that $D \equiv (1+\theta)P' + \theta Q P'' - c' < 0$. Then*

$$\rho = \frac{1}{1 + \theta(1-\chi) + \frac{c'(Q)}{|P'(Q)|}}, \tag{C.22}$$

and the denominator is positive. With constant marginal cost,

$$\rho = \frac{1}{1 + \theta(1-\chi)}. \tag{C.23}$$

Proof. This is the first form of Proposition 3.8, with c in place of MC and D in place of J. Steps 1 to 3 of the proof of Proposition 2.76 derive it by differentiating the supply relation with respect to t. Setting $c' = 0$ gives (C.23). □

Proposition 3.8 also gives the elasticity form of Weyl and Fabinger (2013). Three consequences follow. First, competition with constant marginal cost ($\theta = 0$, $c' = 0$) gives $\rho = 1$ for every demand curve, because price equals marginal cost. Second, competition with rising marginal cost gives $\rho = \frac{1}{1+\frac{c'}{|P'|}} < 1$. Sellers bear part of the tax, because their marginal cost falls as output contracts. Third, for any conduct a steeper marginal cost curve lowers ρ. Hence $\rho \leq 1$ under competition whatever the shapes of demand and cost. An estimate significantly above one rejects competition without any assumption on curvature, which is the robust half of Sumner's test.

The denominator of (C.23) has a simple reading. Perceived marginal revenue is $P + \theta Q P'$, and its slope relative to the slope of demand is

$$\frac{(1+\theta)P' + \theta Q P''}{P'} = 1 + \theta(1-\chi).$$

A tax raises effective cost by t, and output falls until perceived marginal revenue has risen by t. The price rises by more than the tax when perceived marginal revenue is flatter than demand, that is, when $\theta > 0$ and $\chi > 1$.

Part (b). With constant marginal cost, (C.23) rearranges to

$$\frac{1}{\rho} = 1 + \theta(1-\chi) \qquad \Longleftrightarrow \qquad \kappa \equiv \theta(\chi - 1) = 1 - \frac{1}{\rho}. \tag{C.24}$$

The data enter only through ρ, and ρ depends on conduct and curvature only through κ. Every pair on the hyperbola $\theta(\chi - 1) = \kappa$ generates the same pass-through. If $\rho > 1$, then $\kappa > 0$, and any $\theta > 0$ fits the data with curvature $\chi = 1 + \frac{\kappa}{\theta}$. Pass-through alone can therefore reject competition but never monopoly (Proposition 3.10).

Four special cases show how curvature disciplines the reading, and Table C.6 collects them. For *linear demand* $P = a - bQ$, $P'' = 0$, so $\chi = 0$ and $\rho = \frac{1}{1+\theta} \leq 1$. For *log demand* $P = a_0 - b_0 \ln Q$ with $b_0 > 0$, the derivatives are $P' = -\frac{b_0}{Q}$ and $P'' = \frac{b_0}{Q^2}$. Hence

$$\chi = -\frac{Q \cdot \frac{b_0}{Q^2}}{-\frac{b_0}{Q}} = 1, \qquad \rho = 1 \text{ for every } \theta.$$

The supply relation becomes $P - \theta b_0 = c + t$, a constant dollar markup. For *constant-elasticity demand* $P = AQ^{-\frac{1}{\varepsilon}}$,

$$P' = -\frac{1}{\varepsilon} AQ^{-\frac{1}{\varepsilon}-1}, \qquad P'' = \frac{1}{\varepsilon}\left(1 + \frac{1}{\varepsilon}\right) AQ^{-\frac{1}{\varepsilon}-2}, \qquad \chi = -\frac{QP''}{P'} = 1 + \frac{1}{\varepsilon}.$$

Then $1 + \theta(1 - \chi) = 1 - \frac{\theta}{\varepsilon}$, so that

$$\rho = \frac{\varepsilon}{\varepsilon - \theta}, \qquad \kappa = \frac{\theta}{\varepsilon}, \qquad \theta = \varepsilon\kappa. \tag{C.25}$$

For *symmetric Cournot* with N firms and any demand, $\theta = \frac{1}{N}$ gives $\rho = \frac{1}{1+\frac{1-\chi}{N}} = \frac{N}{N+1-\chi}$, and a given κ requires $\chi = 1 + N\kappa$.

Table C.6: Curvature, pass-through and the reading of an estimate above one

Demand and conduct	Inverse demand	χ	ρ	Reading of $\hat{\rho} = 1.075$
Linear, conduct θ	$a - bQ$	0	$\frac{1}{1+\theta}$	impossible, since $\rho \leq 1$
Log, conduct θ	$a_0 - b_0 \ln Q$	1	1	impossible, since $\rho = 1$
Constant elasticity, conduct θ	$AQ^{-\frac{1}{\varepsilon}}$	$1 + \frac{1}{\varepsilon}$	$\frac{\varepsilon}{\varepsilon-\theta}$	$\theta = 0.069\,\varepsilon$
Any, symmetric Cournot	$P(Q)$, $\theta = \frac{1}{N}$	χ	$\frac{N}{N+1-\chi}$	$\chi = 1 + 0.069N$
Any, monopoly	$P(Q)$, $\theta = 1$	χ	$\frac{1}{2-\chi}$	$\chi = 1.069$

Notes: Constant marginal cost. The last column uses $\hat{\kappa} = 1 - \frac{1}{\hat{\rho}} = 0.069$ from specification M0 in part (d). Linear and constant-elasticity demand belong to the power family $P = a_0 - b_0 Q^{\gamma}$, whose curvature $\chi = 1 - \gamma$ is constant, and log demand is its limit as $\gamma \to 0$ (Example 2.73).

The monopoly row connects to Bulow and Pfleiderer (1983). A monopolist with constant marginal cost passes through less than one if and only if direct demand is log-concave (Corollary 2.71). An estimate above one, read as monopoly, therefore requires log-convex demand at the observed prices. Constant elasticity is one such demand curve, and it is the one Sumner assumes.

Part (c). Sumner (1981, p. 1011) starts from the markup rule of firm j,

$$P_j = \frac{\eta_j}{\eta_j + 1} M_j \equiv \Theta_j M_j \qquad \text{(his eq. 1)}, \tag{C.26}$$

where $\eta_j < 0$ is the elasticity of the demand curve facing firm j (his sign convention). The marginal cost of firm j is M_j. Under monopoly η_j is the market elasticity. Under perfect competition $\eta_j = -\infty$ and the price-cost ratio Θ_j equals one. Marginal cost is

$$M_j = X_j\phi + E_j + t \qquad \text{(his eq. 2)}, \tag{C.27}$$

with observed cost factors X_j, unobserved factors E_j and the tax t, which is common to all firms. Sumner writes β, ϵ_j, R and θ where we write ϕ, E_j, t and Θ, and we rename them to avoid clashes with the book's notation.

Only state-average prices are observed, so Sumner aggregates (p. 1012). Let S_j be firm j's market share, and define the share-weighted averages $P = \sum_j S_j P_j$, $M = \sum_j S_j M_j$ and $\Theta = \sum_j S_j \Theta_j$. Writing each firm's terms as deviations from the averages,

$$\begin{aligned} P = \sum_j S_j \Theta_j M_j &= \sum_j S_j \big[\Theta + (\Theta_j - \Theta)\big]\big[M + (M_j - M)\big] \\ &= \Theta M + \Theta \sum_j S_j (M_j - M) + M \sum_j S_j (\Theta_j - \Theta) + \sum_j S_j (\Theta_j - \Theta)(M_j - M) \\ &= \Theta M + \sum_j S_j (\Theta_j - \Theta)(M_j - M). \end{aligned}$$

The two middle sums vanish because the shares sum to one and Θ and M are share-weighted means. The last line is his eq. 3. The remaining sum is the share-weighted covariance of price-cost ratios and marginal costs. Sumner drops it under any of three conditions. Elasticities vary little across firms, marginal costs vary little, or the two are nearly unrelated. He supports the approximation with two facts: retail prices vary little across brands within a market, and all brands are made in one region with a standard technology. He also writes $\Theta = \frac{\eta}{\eta+1}$ for the share-weighted elasticity $\eta = \sum_j S_j \eta_j$. This step is exact only when all firms face the same elasticity, because the map from η_j to Θ_j is nonlinear.

Dropping the covariance and substituting (C.27) gives $P = \Theta(X\phi + E + t)$. In panel form,

$$p_{sy} = X_{sy}\psi + \Theta\, t_{sy} + U_{sy}, \qquad \psi = \Theta\phi, \quad U_{sy} = \Theta E_{sy} \qquad \text{(his eq. 4)}. \tag{C.28}$$

The tax coefficient is the price-cost ratio. Competition implies $\Theta = 1$, and any market power implies $\Theta > 1$. To recover the firm-level elasticity, we invert $\Theta = \frac{\eta}{\eta+1}$:

$$\begin{aligned} \Theta(\eta + 1) &= \eta, \\ \eta(\Theta - 1) &= -\Theta, \\ \eta &= \frac{\Theta}{1 - \Theta}. \end{aligned}$$

Equivalently, the Lerner index of the firms is $\frac{P-M}{P} = 1 - \frac{1}{\Theta} = -\frac{1}{\eta}$.

Table C.7 reproduces Sumner's Table 1 (p. 1017) and adds the implied quantities. The printed elasticities equal $\frac{1}{1-\Theta}$ to the reported precision. Since $\frac{1}{1-\Theta} = \frac{\Theta}{1-\Theta} + 1 = \eta + 1$, each printed value is one unit smaller in absolute value than the exact inversion. The printed figure inverts the markup over cost, $\frac{P-M}{M} = \Theta - 1 = -\frac{1}{\eta+1}$, in place of the Lerner index. The two inversions agree to first order in $\Theta - 1$, and the gap of 3 to 7 percent leaves Sumner's conclusions unchanged. His conclusion uses the same approximation. With $\Theta = 1.05$, a 1 percent price increase lowers a firm's sales by 20 percent (p. 1019), where the exact inversion gives 21 percent.

Sumner reports two further checks. First, he lets the price-cost ratio vary with the price, $\Theta(P) = \gamma_S P^{1-\lambda_S}$, where γ_S and λ_S are his γ and λ (n. 7). The markup rule $P = \Theta(P)M$ then gives

$$P = \gamma_S P^{1-\lambda_S} M \qquad \Longrightarrow \qquad P^{\lambda_S} = \gamma_S M \qquad \Longrightarrow \qquad P = (\gamma_S M)^{\frac{1}{\lambda_S}}.$$

Table C.7: Sumner's estimates of the tax coefficient and what they imply

	Sumner (1981), Table 1			Implied by $\hat{\Theta}$				Replication
Row	$\hat{\Theta}$	S.e.	η printed	t for $\Theta = 1$	$\frac{1}{1-\hat{\Theta}}$	$\frac{\hat{\Theta}}{1-\hat{\Theta}}$	$1 - \frac{1}{\hat{\Theta}}$	$\hat{\Theta}$ (s.e.)
(1) Dummies, OLS	1.074	0.013	−13.5	5.7	−13.5	−14.5	0.069	1.075 (0.013)
(2) CPI, OLS	1.029	0.011	−34.5	2.6	−34.5	−35.5	0.028	1.029 (0.011)
(3) CPI, VC	1.069	0.013	−14.5	5.3	−14.5	−15.5	0.065	1.069 (0.013)

Notes: Dependent variable: retail price per pack in cents, 1,200 state-years. Row (1) includes a dummy for each year (1978 excluded) and each state (Wyoming excluded). Rows (2) and (3) include the national consumer price index and no dummies. VC is a variance-components GLS estimator with random state and year effects (Fuller and Battese, 1974). Sumner reports R^2 of about 0.99 with dummies and about 0.95 without. "η printed" is his implied price elasticity, with his negative sign. The next four columns are computed from his printed $\hat{\Theta}$, and $1 - \frac{1}{\hat{\Theta}}$ is the implied Lerner index. The replication uses the reconstructed panel with conventional standard errors, as in the paper, and gives R^2 of 0.994 for row (1) and 0.985 for row (2).

Substituting (C.27) and adding an additive or a multiplicative error gives his eqs. 4′ and 4″, which he estimates by nonlinear least squares. The value $\lambda_S = 1$ restores a constant ratio $\Theta = \gamma_S$. The estimates are $\hat{\lambda}_S = 0.972$ (0.027) and 0.981 (0.026), with $\hat{\gamma}_S = 1.029$ and 1.062 (n. 9). The t-statistics for $\lambda_S = 1$ are 1.04 and 0.73, so constancy is not rejected. Second, the pooled equation estimated year by year gives estimates in the range of Table 1 with no trend. A squared tax term added to the yearly equations is insignificant in most years.

Sumner reads the results in two steps (pp. 1016–1017). Estimates significantly above one reject atomistic competition. The implied firm elasticities are 13.5 to 34.5 in absolute value. They are far above estimates of the industry elasticity, which are "generally between −0.3 and −0.8." His own estimate is about −0.40 (n. 10). A cartel would face the industry elasticity, so he rejects an effective cartel. He adds that with $\Theta = 1.05$ and prices 5 percent above marginal cost, market power raises the average price by about 3 cents per pack (p. 1019).

The conduct model of part (b) gives Sumner's ratio a structural meaning. With constant-elasticity demand and flat cost, the Lerner form of (C.21) is $\frac{P-c-t}{P} = \frac{\theta}{\varepsilon}$, so

$$P = \frac{\varepsilon}{\varepsilon - \theta}(c + t), \qquad \Theta = \frac{\varepsilon}{\varepsilon - \theta} = \rho, \qquad \eta = \frac{\Theta}{1 - \Theta} = -\frac{\varepsilon}{\theta}.$$

Sumner's firm elasticity is the market elasticity divided by conduct, and his Lerner index $1 - \frac{1}{\Theta}$ equals $\frac{\theta}{\varepsilon} = \kappa$. Without constant elasticity, Θ is the pass-through ρ but no longer the price-cost ratio, and the two must be kept apart.

Part (d). We call Sumner's row (1) specification M0:

$$p_{sy} = \mu_s + \tau_y + \rho\, t_{sy} + e_{sy}. \tag{C.29}$$

The state effects μ_s absorb stable differences in non-tax costs and demand. The year effects τ_y absorb national movements in costs and in the price level. Under (C.28) they absorb $\Theta X_{sy}\phi$ when non-tax cost is additive in a state and a year component. Identification requires that tax changes within a state, relative to other states in the same year, be unrelated to shocks to cost and demand. Formally, $\mathbb{E}[e_{sy} \mid t_{s1}, \ldots, t_{sY}] = 0$ for every state, after conditioning on the fixed effects (Section 3.2.2).

By the Frisch-Waugh-Lovell theorem, OLS with both sets of dummies equals the regression of p_{sy} on the two-way demeaned tax. In a balanced panel the demeaned tax is

$$\tilde{t}_{sy} = t_{sy} - \bar{t}_{s\cdot} - \bar{t}_{\cdot y} + \bar{t}_{\cdot\cdot},$$

where $\bar{t}_{s\cdot}$, $\bar{t}_{\cdot y}$ and $\bar{t}_{\cdot\cdot}$ are the state means, the year means and the grand mean. Then

$$\hat{\rho} = \frac{\sum_{s,y} \tilde{t}_{sy} p_{sy}}{\sum_{s,y} \tilde{t}_{sy}^2}, \qquad \hat{\rho} - \rho = \frac{\sum_{s,y} \tilde{t}_{sy} e_{sy}}{\sum_{s,y} \tilde{t}_{sy}^2}. \tag{C.30}$$

The conventional variance estimator assumes independent errors with a common variance,

$$\hat{V}_{\text{conv}} = \frac{s^2}{\sum_{s,y} \tilde{t}_{sy}^2}, \qquad s^2 = \frac{1}{N-K} \sum_{s,y} \hat{e}_{sy}^2,$$

with $N = 1{,}200$ and $K = 73$ coefficients (the tax, 48 state effects and 24 year effects). The cluster-robust estimator allows any correlation among the errors of one state:

$$\hat{V}_{\text{cl}} = \frac{G}{G-1} \cdot \frac{N-1}{N-K} \cdot \frac{\sum_s \left(\sum_y \tilde{t}_{sy} \hat{e}_{sy} \right)^2}{\left(\sum_{s,y} \tilde{t}_{sy}^2 \right)^2}, \tag{C.31}$$

with $G = 48$ clusters. Inference uses the t distribution with $G - 1 = 47$ degrees of freedom, whose 97.5 percent quantile is 2.012 (Appendix A).

Table C.8 reports the estimates. M0 gives $\hat{\rho} = 1.0746$ with a conventional standard error of 0.0132, which reproduces Sumner's 1.074 (0.013). The t-statistic for $\rho = 1$ is 5.64. The clustered standard error is 0.0340, 2.57 times the conventional one. The t-statistic falls to 2.19, with $p = 0.033$ and a 95 percent interval of $[1.006, 1.143]$. The rejection of competition survives clustering, but by a much thinner margin. Our replications of Sumner's rows (2) and (3) give 1.029 (0.011) and 1.069 (0.013), equal to his estimates.

Clustering matters because both the errors and the regressor are persistent within states. The pooled first-order autocorrelation of the M0 residuals within states is $r_e = 0.64$, and that of the demeaned tax is $r_x = 0.85$. Taxes change rarely. Of the 1,152 year-to-year transitions within states, 191 involve a tax change, and only 6 of those are decreases. A standard approximation shows the size of the problem. Suppose that, within a state, the errors are AR(1) with coefficient r_e and the sample autocorrelation of $\tilde{t}$ at lag k is close to r_x^k. Then

$$\operatorname{Var}\left(\sum_y \tilde{t}_{sy} e_{sy} \right) = \sigma_e^2 \sum_{y,y'} \tilde{t}_{sy} \tilde{t}_{sy'} r_e^{|y-y'|} \approx \sigma_e^2 \sum_y \tilde{t}_{sy}^2 \left(1 + 2 \sum_{k \geq 1} r_x^k r_e^k \right) = \sigma_e^2 \sum_y \tilde{t}_{sy}^2 \cdot \frac{1 + r_x r_e}{1 - r_x r_e}.$$

The conventional formula omits the last factor. Its square root is $\sqrt{\frac{1+r_x r_e}{1-r_x r_e}} = 1.83$, with $r_x r_e = 0.848 \times 0.638 = 0.541$. The cluster-robust ratio of 2.57 is larger, because the approximation imposes a common geometric decay that the data need not follow. Both numbers say that Sumner's standard error is too small by a factor of about two or more (Bertrand et al., 2004).

The power of the clustered test is modest. A two-sided 5 percent test has 80 percent power against deviations from one of at least $(t_{0.975,47} + t_{0.80,47}) \times 0.034 = (2.012 + 0.849) \times 0.034 = 0.097$. With the conventional standard error the threshold would be 0.038. The estimated deviation of 0.075 lies below the clustered threshold. If the true pass-through were 1.075, a test on a new

Table C.8: Pass-through regressions on the reconstructed panel

Specification	Estimate	S.e.	95% interval	p for $\rho = 1$
Panel A. Nominal cents				
M0: state and year effects, conventional s.e.	1.075	0.013	[1.049, 1.101]	< 0.001
M0: state and year effects, clustered s.e.	1.075	0.034	[1.006, 1.143]	0.033
National CPI, OLS, conventional s.e.	1.029	0.011	[1.008, 1.050]	0.007
National CPI, variance components	1.069	0.013	[1.044, 1.093]	< 0.001
Panel B. Real cents, state and year effects, clustered s.e.				
M1	1.107	0.026	[1.055, 1.158]	< 0.001
Nominal, CPI-scaled state effects, unweighted	1.102	0.026	[1.050, 1.155]	< 0.001
Panel C. Pass-through varying with the real tax (M2), clustered s.e.				
$\rho(T)$ at the 10th percentile, $T = 29.9$	1.097	0.039	[1.018, 1.176]	0.017
$\rho(T)$ at the median, $T = 43.8$	1.106	0.025	[1.055, 1.157]	< 0.001
$\rho(T)$ at the 90th percentile, $T = 53.5$	1.113	0.034	[1.044, 1.181]	0.002
$\rho(p_{90}) - \rho(p_{10})$	0.016	0.053	[−0.090, 0.122]	
Panel D. Composite identified by pass-through (clustered M0)				
$\hat{\kappa} = 1 - \frac{1}{\hat{\rho}}$	0.069		[0.006, 0.125]	

Notes: 1,200 state-years. Clustered standard errors allow correlation within states (48 clusters), and their intervals and p-values use the t distribution with 47 degrees of freedom. Conventional intervals use $N - K$ degrees of freedom, and the variance-components row uses the normal distribution. In M2 the test of $b_2 = 0$ has $p = 0.76$. The interval for κ maps the endpoints of the clustered interval for ρ. The CPI-scaled row differs from M1 only in its weights (Lemma C.8). Source: `figures/appC/src/sumner_passthrough.py`.

sample of the same size would reject competition with probability 0.57. The rejection in our sample is evidence against competition, but a replication could easily have failed to reject.

Part (e). Specification M1 replaces nominal by real cents:

$$P_{sy} = \mu_s + \tau_y + \rho\, T_{sy} + e_{sy}. \tag{C.32}$$

It gives $\hat{\rho} = 1.107$ with a clustered standard error of 0.026, a 95 percent interval of $[1.055, 1.158]$ and $p < 0.001$ for $\rho = 1$. The estimate is 0.032 higher than in M0. Year effects absorb any common change in the price level, so the difference needs an explanation.

Lemma C.8 (Deflating a two-way fixed-effects regression)**.** *OLS estimation of* (C.32) *gives the same $\hat{\rho}$ as weighted least squares estimation of the nominal equation*

$$p_{sy} = \mu_s \frac{CPI_y}{100} + \tau'_y + \rho\, t_{sy} + u_{sy}$$

with weights $\left(\frac{100}{CPI_y}\right)^2$, where τ'_y are unrestricted year effects.

Proof. Multiply (C.32) by $\frac{CPI_y}{100}$. Since $P_{sy}\frac{CPI_y}{100} = p_{sy}$ and $T_{sy}\frac{CPI_y}{100} = t_{sy}$,

$$p_{sy} = \mu_s \frac{CPI_y}{100} + \tau_y \frac{CPI_y}{100} + \rho\, t_{sy} + e_{sy}\frac{CPI_y}{100}.$$

The second term varies only by year, so it is an unrestricted year effect τ'_y. The error is $u_{sy} = e_{sy}\frac{CPI_y}{100}$. OLS on (C.32) minimizes $\sum_{s,y} e_{sy}^2 = \sum_{s,y}\left(\frac{100}{CPI_y}\right)^2 u_{sy}^2$, which is the weighted least squares criterion for the nominal equation. □

Deflating therefore changes two things. First, the state effects become proportional to the price level. In nominal terms the state differences in price net of tax grow with inflation, and this is a state-by-year interaction that year effects cannot absorb. Second, observations from low-price years receive more weight. The CPI rises from 26.9 to 65.2 over the sample, so a 1954 observation has 5.9 times the weight of a 1978 observation. The script separates the two channels. OLS on the nominal equation with CPI-scaled state effects and no weights gives 1.102 (0.026), and adding the weights gives 1.107, identical to M1. Most of the change from 1.075 thus comes from the specification of the state effects. If non-tax costs and margins in each state are fixed in real terms, M1 is the more natural specification. Both specifications reject $\rho = 1$ at the 5 percent level.

Part (f). Specification M2 adds a quadratic in the real tax:

$$P_{sy} = \mu_s + \tau_y + b_1(T_{sy} - \bar{T}) + b_2(T_{sy} - \bar{T})^2 + e_{sy}, \tag{C.33}$$

where $\bar{T} = 42.73$ is the sample mean of the real tax. Pass-through at tax level T is the derivative

$$\rho(T) = \frac{\partial P}{\partial T} = b_1 + 2b_2(T - \bar{T}).$$

It is linear in (b_1, b_2) with gradient $(1, 2(T - \bar{T}))$. Its variance is therefore

$$\operatorname{Var}\left(\hat{\rho}(T)\right) = V_{11} + 4(T - \bar{T})V_{12} + 4(T - \bar{T})^2 V_{22},$$

where V is the clustered covariance matrix of $(\hat{b}_1, \hat{b}_2)$. The formula is exact here, and the delta method gives the same expression (Appendix A).

The estimates are $\hat{b}_1 = 1.105$ (0.025) and $\hat{b}_2 = 0.00034$ (0.00112), and the test of $b_2 = 0$ gives $p = 0.76$. Panel C of Table C.8 evaluates $\hat{\rho}(T)$ at three points of the tax distribution. It is 1.097 (0.039) at the 10th percentile, 1.106 (0.025) at the median and 1.113 (0.034) at the 90th percentile. The difference between the 90th and the 10th percentiles is $2\hat{b}_2(T_{90} - T_{10}) = 0.016$, with standard error 0.053 and 95 percent interval $[-0.090, 0.122]$. Figure C.3 plots $\hat{\rho}(T)$ with its confidence band.

The data show no sign that pass-through varies with the tax, but the test has little power. With 80 percent power, a 5 percent test would detect a difference between the two percentiles of $2.861 \times 0.053 = 0.151$ or more. This threshold exceeds the estimated excess of pass-through over one in both M0 (0.075) and M1 (0.107). The band in Figure C.3 also widens at the extremes, where few state-years lie.

The quadratic also speaks to smuggling. Sumner argues that bootlegging would make the price a concave function of the tax (n. 6). Bulk sales for shipment out of state lower measured prices in very low-tax states, and illegal competition lowers them in very high-tax states. Concavity means $b_2 < 0$. Our estimate is positive and insignificant, in line with his finding that squared tax terms are insignificant in most years.

A flat $\rho(T)$ would be weak evidence for constant-elasticity demand even with a precise estimate. Every member of the power family in Table C.6 has constant curvature, so with constant conduct its pass-through is the same at every tax level. The test asks only whether $\kappa = \theta(\chi - 1)$ is stable over the observed range. Sumner's estimates of λ_S near one make the same point within his family, because $\lambda_S = 1$ makes the price linear in the tax.

Part (g). By (C.24), M0 identifies $\hat{\kappa} = 1 - \frac{1}{1.0746} = 0.069$. The map from ρ to κ is increasing, so the clustered interval for ρ maps into the interval $[0.006, 0.125]$ for κ. Every pair (χ, θ) on the hyperbola $\theta(\chi - 1) = 0.069$ fits the estimate equally well, and Figure 3.2 draws this set with its band. Three points on it illustrate the range.

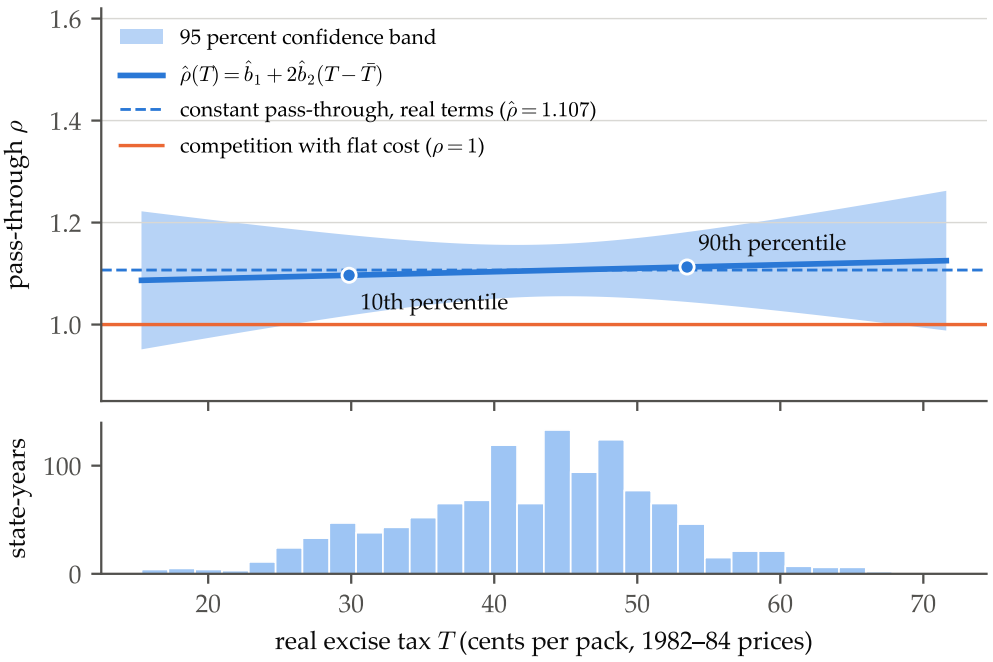

Figure C.3: Estimated pass-through as a function of the real excise tax, from specification M2, with a 95 percent state-clustered confidence band. The dashed line is the constant pass-through of M1, and the orange line is the competitive benchmark $\rho = 1$. The markers show the 10th and 90th percentiles of the real tax. The lower panel shows the distribution of the real tax over the 1,200 state-years.

- Monopoly ($\theta = 1$) fits with $\chi = 1.069$, a demand curve slightly more convex than log demand.
- Symmetric Cournot with six firms ($\theta = \frac{1}{6}$) fits with $\chi = 1 + 6 \times 0.069 = 1.42$.
- Constant elasticity with an industry elasticity of 0.4 has $\chi = 3.5$. Then (C.25) gives $\theta = 0.4 \times 0.069 = 0.028$, with interval $[0.002, 0.050]$. Elasticities of 0.3 and 0.8, the ends of the range Sumner quotes, give $\theta = 0.021$ and 0.056.

Under constant elasticity with $\varepsilon = 0.4$, conduct of 0.028 matches symmetric Cournot with about 36 firms. The industry is close to competitive under that reading. The data alone cannot choose among the three points, and Sumner's rejection of collusion rests on the constant-elasticity assumption combined with outside estimates of the elasticity. Even a precise $\hat{\theta}$ would measure market power only under the static model behind (C.21). Corts (1999) shows, analytically and by simulation, that the estimated conduct parameter can badly mismeasure market power when firms sustain tacit collusion in a repeated game (abstract and Section 1). The estimate need not even be positively correlated with the true elasticity-adjusted margin.

Part (h). The level of prices and taxes gives a bound that needs no assumption on curvature. With constant marginal cost $c \geq 0$, divide (C.21) by P and use $-\frac{QP'}{P} = \frac{1}{\varepsilon}$:

$$\frac{P - c - t}{P} = \frac{\theta}{\varepsilon} \qquad \Longrightarrow \qquad \theta = \varepsilon\left(1 - \frac{t}{P} - \frac{c}{P}\right) \leq \varepsilon\left(1 - \frac{t}{P}\right).$$

This is (3.9). The tax takes a large share of the cigarette price, so the bound is tight. With $\varepsilon = 0.4$ it gives $\theta \leq 0.4 \times (1 - 0.467) = 0.213$ at the mean tax share and $\theta \leq 0.308$ at the lowest share in

the sample (0.229). If θ and ε are the same in every state-year, the highest share (0.584) gives the tightest bound, $\theta \leq 0.166$. Industry elasticities of 0.3 and 0.8 give bounds of 0.160 and 0.426 at the mean share. Every one of these bounds rules out monopoly whatever the curvature. Equivalently, monopoly at the mean tax share requires an elasticity of at least $\frac{1}{1-0.467} = 1.88$ at the observed price, and at the lowest share at least 1.30.

Under Sumner's constant-elasticity reading, in which $1 - \frac{1}{\rho}$ is the Lerner index (part (c)), the point estimate also converts into cents. The value $1 - \frac{1}{\hat{\rho}} = 0.069$ applied to the mean price of 34.0 cents gives a margin of price over marginal cost plus tax of 2.4 cents per pack. At the 1978 mean price of 56.6 cents it gives 3.9 cents. Sumner's figure of about 3 cents uses $\Theta = 1.05$, and at the 1978 mean price this ratio implies a margin of $56.6 \times \left(1 - \frac{1}{1.05}\right) = 2.7$ cents.

Part (i). Sumner's dependent variable is an average over brands. Suppose the measured price is $\bar{p} = \sum_j w_j p_j$ with quantity weights w_j. Differentiating with respect to the tax,

$$\frac{\mathrm{d}\bar{p}}{\mathrm{d}t} = \sum_j w_j \frac{\mathrm{d}p_j}{\mathrm{d}t} + \sum_j p_j \frac{\mathrm{d}w_j}{\mathrm{d}t}. \tag{C.34}$$

The first term is the average of product-level pass-through, the object that conduct governs. The second is a composition effect (Remark 2.82). A specific tax adds the same amount to every price, which is a larger percentage of a cheap brand's price. Premium brands become relatively cheaper, consumers trade up, and the composition term is positive. The regression then overstates product-level pass-through and leans toward rejecting competition.

A back-of-the-envelope calculation shows how large the composition effect would have to be. Suppose packs come in an economy and a premium tier whose prices differ by Δ cents. Suppose also that each price rises one for one with the tax, as under competition with flat cost. The composition term is then $\Delta \frac{\mathrm{d}w_H}{\mathrm{d}t}$, where w_H is the premium share. Matching $\hat{\rho} = 1.075$ requires $\frac{\mathrm{d}w_H}{\mathrm{d}t} = \frac{0.075}{\Delta}$ per cent of tax. With a hypothetical gap of $\Delta = 5$ cents, a 10-cent tax increase would have to raise the premium share by 15 percentage points. Two features of the data make shifts of this size unlikely. The Tobacco Tax Council's price uses fixed national weights for the type of cigarette (regular, king, 100 mm) and the type of sale (carton, single pack, machine). Shifts across these categories therefore do not move it (Sumner, 1981, p. 1016). Sumner also reports that retail prices vary little across brands within a market (pp. 1012–1013), so Δ is small.

A related critique is the quality response of Barzel (1976). A per-unit tax lowers the relative price of quality, so higher taxes should raise the quality sold per pack, and with it the price per pack. Sumner replies that the price data hold the obvious quality dimensions fixed and that centralized manufacturing leaves little room for quality differences across states (p. 1018). He adds that a Barzel effect would bias the estimate upward, which strengthens the case against an effective cartel. Barzel notes that an ad valorem tax would not have this effect, and New Hampshire taxed cigarettes ad valorem until 1975. Sumner finds that New Hampshire's residuals from yearly regressions are as negative after 1975 as before, which speaks against the quality explanation (n. 11).

Section C.3 computes (C.34) in a simulated logit market. There the composition term is 0.0002 with single-product firms and −0.0005 with multi-product firms (Table C.13). Product-level pass-through is below one, because logit demand is log-concave in a product's own price (Proposition C.16). A logit market cannot produce Sumner's estimate through either term.

Part (j). An ad valorem tax at rate τ takes the fraction τ of the consumer price, and sellers

receive $(1-\tau)P$ per unit. In this part τ denotes the tax rate. The year effects τ_y carry a subscript and play no role.

Proposition C.9 (Pass-through of an ad valorem tax)**.** *Let sellers receive $(1-\tau)P$ per unit, with $\tau \in [0,1)$, and let marginal cost c be constant. Write $v \equiv \frac{1}{1-\tau}$, and let ρ be the specific-tax pass-through (C.23) at the same equilibrium.*

(i) The supply relation is $P + \theta Q P' = cv$, and $\frac{\mathrm{d}P}{\mathrm{d}v} = c\rho$.

(ii) The elasticity of the price with respect to v is

$$\varrho \equiv \frac{\mathrm{d}\ln P}{\mathrm{d}\ln v} = \rho\Big(1 - \frac{\theta}{\varepsilon}\Big). \tag{C.35}$$

(iii) $\varrho = 1$ under competition for every demand curve, and under constant-elasticity demand for every conduct. For $\theta > 0$, $\varrho > 1$ if and only if $\chi > 1 + \frac{1}{\varepsilon}$.

Proof. (i) Perceived marginal revenue per unit sold is $(1-\tau)(P + \theta Q P')$. Setting it equal to c and dividing by $1-\tau$ gives the supply relation. It has the form of (C.21), with effective marginal cost $m \equiv cv$ in place of $c + t$. The derivation in the proof of Proposition 2.76 applies to any shift in effective cost, so $\frac{\mathrm{d}P}{\mathrm{d}m} = \rho$. Since $\frac{\mathrm{d}m}{\mathrm{d}v} = c$, the chain rule gives $\frac{\mathrm{d}P}{\mathrm{d}v} = c\rho$.

(ii) Multiplying by $\frac{v}{P}$ gives $\varrho = \rho\frac{cv}{P}$. The Lerner form of the supply relation is $\frac{P-cv}{P} = \frac{\theta}{\varepsilon}$, so $\frac{cv}{P} = 1 - \frac{\theta}{\varepsilon}$.

(iii) Under competition $\theta = 0$ and $\rho = 1$, so $\varrho = 1$. Under constant elasticity $\rho = \frac{\varepsilon}{\varepsilon-\theta}$ by (C.25), and

$$\varrho = \frac{\varepsilon}{\varepsilon - \theta} \cdot \frac{\varepsilon - \theta}{\varepsilon} = 1.$$

In general, (C.23) gives $\varrho = \frac{1-\frac{\theta}{\varepsilon}}{1+\theta(1-\chi)}$ with a positive denominator. Hence

$$\varrho > 1 \iff 1 - \frac{\theta}{\varepsilon} > 1 + \theta(1-\chi) \iff \theta(\chi - 1) > \frac{\theta}{\varepsilon} \iff \chi > 1 + \frac{1}{\varepsilon},$$

where the last step divides by $\theta > 0$. □

The proposition reverses the roles of the two taxes. Sumner compares ρ with the competitive benchmark of one. For an ad valorem tax the natural benchmark is proportional pass-through, $\varrho = 1$. Under constant elasticity that benchmark holds whatever the conduct, because the price is the fixed multiple $\frac{\varepsilon}{\varepsilon-\theta}$ of effective cost. An ad valorem experiment then carries no information about conduct, while a specific-tax experiment does. With log demand the situation reverses. A specific tax gives $\rho = 1$ for every θ, while $\varrho = 1 - \frac{\theta}{\varepsilon}$ reveals the Lerner index. Which tax is informative thus depends on curvature, which reinforces part (b). For revenue-equivalent small taxes, Remark 2.81 shows that the ad valorem tax raises the price less whenever $\theta > 0$.

Sumner's data contain some ad valorem variation. State sales taxes on cigarettes ranged from 0 to 6 percent. Sumner ignores them, arguing that their effect is small because their ratio to $|\eta|$ is small (Sumner, 1981, n. 4). The reconstructed panel does not record them.

Part (k). Five kinds of additional data would move from the composite κ to conduct itself.

1. *Quantities and a demand rotator.* With quantities, demand can be estimated, and a variable that changes the slope of demand at a given price separates conduct from the level and slope of marginal cost (Bresnahan, 1982; Lau, 1982). Bresnahan (1989, Section 3.1, pp. 1032–1034) restates the argument. If the slope of inverse demand does not depend on

the demand shifters, the term $\theta Q P'$ is perfectly collinear with Q in the supply relation. Then θ cannot be separated from the slope of marginal cost. Lau's sufficient condition for identification is that the demand shifters cannot be separated from Q in inverse demand, which needs at least two shifters (fn. 22 credits both papers). A market-wide cost shifter such as a tax moves the equilibrium along one demand curve and cannot do this (Section 3.5).

2. *Demand curvature.* Demand estimated over a wide range of prices gives $\hat{\chi}$, and then $\theta = \frac{\hat{\kappa}}{\hat{\chi}-1}$. The precision of $\hat{\theta}$ depends on how far $\hat{\chi}$ is from one.
3. *Brand-level prices.* They remove the composition term of (C.34) and measure product-level pass-through directly.
4. *Firm-specific cost shifters.* They trace out each firm's residual demand, whose slope measures the firm's markup (Section 3.4). Direct measures of marginal cost work as in sugar refining (Section 3.7).
5. *A second kind of tax.* Variation in an ad valorem tax alongside the specific tax reveals marginal cost, as the next result shows.

Proposition C.10 (Two taxes reveal marginal cost)**.** *Let sellers pay a specific tax t and an ad valorem tax τ on the consumer price, so that they receive $(1-\tau)P - t$ per unit. Let marginal cost $c(Q)$ be differentiable with $c' \geq 0$, let conduct θ be constant, and suppose the equilibrium is stable. With $v = \frac{1}{1-\tau}$,*

$$c(Q) + t = v\,\frac{\partial P}{\partial v}\Big(\frac{\partial P}{\partial t}\Big)^{-1}. \tag{C.36}$$

The Lerner index $\frac{P - v(c+t)}{P} = \frac{\theta}{\varepsilon}$ is therefore identified from the two pass-through rates and the observed P, t and τ, whatever the curvature of demand and the slope of marginal cost.

Proof. Perceived marginal revenue net of the ad valorem tax equals marginal cost plus the specific tax: $(1-\tau)(P + \theta Q P') = c(Q) + t$. Multiply by v and move every term to the left. Along the demand curve, output is a function $Q(P)$ of the price, so the equilibrium price solves

$$\mathcal{F}(P; t, v) \equiv P + \theta Q(P) P'\big(Q(P)\big) - v\big[c\big(Q(P)\big) + t\big] = 0.$$

Stability makes $\mathcal{F}_P = \frac{D_\tau}{P'}$ positive, where $D_\tau = (1+\theta)P' + \theta Q P'' - v c' < 0$. By the implicit function theorem,

$$\frac{\partial P}{\partial t} = -\frac{\mathcal{F}_t}{\mathcal{F}_P} = \frac{v}{\mathcal{F}_P}, \qquad \frac{\partial P}{\partial v} = -\frac{\mathcal{F}_v}{\mathcal{F}_P} = \frac{c(Q)+t}{\mathcal{F}_P}.$$

Dividing the second by the first, $\mathcal{F}_P$ cancels and leaves $\frac{c(Q)+t}{v}$. Multiplying by v gives (C.36). The Lerner form of the supply relation then gives $\frac{\theta}{\varepsilon}$. □

The intuition is that both taxes shift effective marginal cost $v(c+t)$, but by different amounts. A cent of specific tax raises it by v cents, while a unit increase in v raises it by $c + t$. Both shifts pass through to the price at the same rate, whatever that rate is, so their ratio reveals the level of $c + t$. The argument needs both taxes to vary independently, conduct that does not depend on the tax mix, and a correct model of who remits each tax. With the Lerner index in hand, an outside estimate of ε gives θ, and, if marginal cost is flat, $\hat{\kappa}$ then gives $\chi = 1 + \frac{\hat{\kappa}}{\theta}$. In Sumner's setting, state sales taxes would supply the ad valorem variation.

The exercise leaves three lessons. A market-wide cost shifter delivers a test of competition that is robust to the shapes of demand and cost, although clustering shows it to be fragile

here. The same shifter identifies conduct only jointly with curvature, so Sumner's rejection of collusion rests on outside information about demand. Bounds from the levels of prices and taxes, or a second kind of tax, say more about market power than the pass-through rate alone.

C.2.3 Computational notes

The script `figures/appC/src/sumner_passthrough.py` produces every number in this section with numpy and scipy, in the following steps.

1. Read the panel, check that it is balanced (48 states by 25 years), and form the real price and tax by dividing by $\frac{CPI_y}{100}$.
2. For M0 and M1, regress the price on the tax, 48 state dummies and 24 year dummies. Compute the conventional variance and the cluster-robust variance (C.31) from the full regression. By the argument behind (C.30), the tax block of the full sandwich equals the expression in (C.31).
3. For Sumner's row (2), regress the price on a constant, the tax and the national CPI. For row (3), estimate a two-way random-effects model by feasible GLS. Estimate the idiosyncratic variance σ_e^2 from the two-way within regression, and the state and year variances σ_μ^2 and σ_τ^2 from the regressions of state means and year means. Transform every variable as $v_{sy}^* = v_{sy} - \lambda_1 \bar{v}_{s\cdot} - \lambda_2 \bar{v}_{\cdot y} + \lambda_3 \bar{v}_{\cdot\cdot}$, with $\lambda_1 = 1 - \sqrt{\frac{\sigma_e^2}{\sigma_e^2 + Y\sigma_\mu^2}}$, $\lambda_2 = 1 - \sqrt{\frac{\sigma_e^2}{\sigma_e^2 + S\sigma_\tau^2}}$ and $\lambda_3 = \lambda_1 + \lambda_2 - 1 + \sqrt{\frac{\sigma_e^2}{\sigma_e^2 + Y\sigma_\mu^2 + S\sigma_\tau^2}}$, then run OLS. The estimates are $\hat{\sigma}_e^2 = 0.74$, $\hat{\sigma}_\mu^2 = 0.55$ and $\hat{\sigma}_\tau^2 = 0.47$.
4. For the decomposition of part (e), regress the nominal price on the tax, the state dummies multiplied by $\frac{CPI_y}{100}$ and the year dummies, first by OLS and then with weights $\left(\frac{100}{CPI_y}\right)^2$. Check that the weighted estimate equals M1 to machine precision.
5. For M2, center the real tax at its mean, add its square, and evaluate $\hat{\rho}(T)$ and its standard error at the 10th, 50th and 90th percentiles of T_{sy}.
6. Compute $\hat{\kappa}$, the points on the identified set, the Lerner bounds, the residual autocorrelations, and the power calculations from the stored estimates, and draw Figure C.3.

An optional check with `statsmodels` reproduces the M0 coefficient and both standard errors to 10^{-9}.

C.3 Bertrand pricing with logit demand: single- and multi-product firms

The first two problems treated a homogeneous good, where one price clears the market and conduct is summarized by a single parameter. From here on products are differentiated, firms set prices, and substitution between products governs market power. The logit model is the simplest demand system for differentiated products in which Bertrand-Nash prices have closed forms. This problem uses it to compute price equilibria, to show how joint ownership of several products raises prices, and to prove that the equilibrium is unique. Two further parts evaluate a merger and a common unit tax. The market is the 25-product market of Example 4.8, and the

theory is that of Chapter 4. We restate each result we use and prove the ones that Chapter 4 leaves open.

C.3.1 Statement

A single market has a unit mass of consumers, 25 inside products and an outside good. Consumer i obtains utility $u_{ij} = \delta_j + \epsilon_{ij}$ from product j and $u_{i0} = \epsilon_{i0}$ from the outside good, where the ϵ_{ij} are independent type-I extreme value shocks. The mean utility of product j is

$$\delta_j = x_j\beta - \alpha p_j + \xi_j, \qquad x_j = (1, x_{2j}, x_{3j}), \tag{C.37}$$

where x_{2j} is a continuous characteristic, x_{3j} is a binary characteristic and ξ_j is quality that the econometrician does not observe. Marginal cost is constant and equal to

$$mc_j = x_j\gamma + \omega_j. \tag{C.38}$$

The parameters are $\beta = (0.1, 0.25, 0.1)$, $\alpha = 2$ and $\gamma = (0.2, 0.25, 0.3)$. Table C.9 lists the characteristics, the shocks and the implied marginal costs. The continuous characteristic has mean 1.79, standard deviation 1.02 and range −0.006 to 4.18. Eleven products have $x_{3j} = 1$. The quality shocks have mean 0.195 and standard deviation 1.00. The cost shocks have mean −0.013 and standard deviation 0.045, and marginal costs range from 0.164 to 1.236. Five owners, labeled 0 to 4, hold 3, 3, 6, 6 and 7 products. Product labels 0 to 24 are names. The symbol s_0 always denotes the share of the outside good.

Firms know all characteristics, shocks and parameters, so the game has complete information. They set prices simultaneously.

Table C.9: Product characteristics, shocks and marginal costs in the 25-product logit market

j	owner	x_{2j}	x_{3j}	ξ_j	ω_j	mc_j	j	owner	x_{2j}	x_{3j}	ξ_j	ω_j	mc_j

Notes: Every product also has the constant characteristic $x_{1j} = 1$. Marginal cost is $mc_j = x_j\gamma + \omega_j$ with $\gamma = (0.2, 0.25, 0.3)$. Owners 0 to 4 hold products $\{5, 21, 23\}$, $\{10, 11, 24\}$, $\{0, 3, 4, 6, 8, 16\}$, $\{2, 13, 14, 15, 17, 19\}$ and $\{1, 7, 9, 12, 18, 20, 22\}$. Values rounded to three decimals.

(a) Suppose that every product is sold by a separate firm. Derive the market shares, the profits and the derivatives of the shares with respect to prices. State the own- and cross-price elasticities.

(b) Derive the best-response price of product j to the prices of the other products. Show that it is the unique maximizer of the firm's profit.

(c) Define a Nash equilibrium of the pricing game.

(d) Describe three algorithms that compute the equilibrium. Implement one of them and report prices, markups, shares, profits and consumer surplus.

(e) Now each owner in Table C.9 sets the prices of all its products jointly. Repeat parts (a) to (d), compare the two equilibria and explain the differences.

(f) Is each equilibrium unique? Prove your answer and verify it numerically.

(g) Owners 3 and 4 merge. Compute the post-merger equilibrium. Compare the price changes with the upward pricing pressure that the merger creates at pre-merger prices.

(h) A unit tax t is added to the marginal cost of every product. Derive the pass-through of a cost increase to the prices of one firm, holding rivals' prices fixed. Derive the equilibrium pass-through of the common tax, compute it for $t = 0.1$, and compute the pass-through of the share-weighted average price.

C.3.2 Solution

Part (a). Write $a_j = x_j\beta + \xi_j$ for the part of mean utility that does not depend on price, so that $\delta_j = a_j - \alpha p_j$. The mean utility of the outside good is normalized to zero. Let

$$\Phi = 1 + \sum_{l=0}^{24} e^{\delta_l} \tag{C.39}$$

be the logit denominator, where the 1 is the outside good's contribution e^0. The extreme value shocks give the logit choice probabilities (Chapter 6). With a unit mass of consumers, shares equal quantities:

$$s_j(p) = \frac{e^{\delta_j}}{\Phi}, \qquad s_0(p) = \frac{1}{\Phi}. \tag{C.40}$$

A firm f that owns the set of products $\mathcal{J}_f$ earns

$$\pi_f(p) = \sum_{k \in \mathcal{J}_f} (p_k - mc_k)\, s_k(p). \tag{C.41}$$

With single-product firms, $\mathcal{J}_f = \{j\}$ and $\pi_j(p) = (p_j - mc_j)s_j(p)$.

A change in p_j moves the numerator of s_j and the denominator Φ at the same rate, $\frac{\partial e^{\delta_j}}{\partial p_j} = \frac{\partial \Phi}{\partial p_j} = -\alpha e^{\delta_j}$. The quotient rule gives

$$\frac{\partial s_j}{\partial p_j} = \frac{-\alpha e^{\delta_j}\Phi + \alpha e^{\delta_j} e^{\delta_j}}{\Phi^2} = -\alpha s_j + \alpha s_j^2 = -\alpha s_j(1 - s_j).$$

For $k \neq j$, including the outside good, only the denominator of s_k depends on p_j, so

$$\frac{\partial s_k}{\partial p_j} = -\frac{e^{\delta_k}}{\Phi^2}\frac{\partial \Phi}{\partial p_j} = \frac{\alpha e^{\delta_k} e^{\delta_j}}{\Phi^2} = \alpha s_j s_k.$$

These are the derivatives in (4.8). Let Δ be the 25×25 matrix with $\Delta_{jk} = \frac{\partial s_j}{\partial p_k}$. Then

$$\Delta = \alpha\big(ss^\top - \operatorname{diag}(s)\big), \tag{C.42}$$

which is symmetric. We write elasticities as $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, so own elasticities are negative. The positive own elasticity of the notation list is $-\varepsilon_{jj}$. Then

$$\varepsilon_{jj} = -\alpha p_j(1 - s_j), \qquad \varepsilon_{jk} = \alpha p_k s_k \quad (k \neq j). \tag{C.43}$$

The cross elasticity with respect to p_k is the same for every $j \neq k$. This is the independence of irrelevant alternatives (Chapter 7). Own elasticities are roughly proportional to price, because shares are small.

Part (b). Firm j chooses p_j to maximize π_j given the rival prices p_{-j}. Let $m_j = p_j - mc_j$ denote the markup. By part (a),

$$\frac{\partial \pi_j}{\partial p_j} = s_j + m_j \frac{\partial s_j}{\partial p_j} = s_j\big[1 - \alpha m_j(1 - s_j)\big]. \tag{C.44}$$

Since $s_j > 0$, the first-order condition is

$$m_j = \frac{1}{\alpha(1 - s_j)}. \tag{C.45}$$

The condition is implicit, because s_j depends on p_j. To solve it, separate the part of Φ that firm j controls. Let $v_j = a_j - \alpha\, mc_j$ be the mean utility of product j when it is priced at marginal cost, so that $\delta_j = v_j - \alpha m_j$. Let $\Phi_{-j} = 1 + \sum_{l \neq j} e^{\delta_l}$, which depends only on rival prices. Then $\Phi = \Phi_{-j} + e^{\delta_j}$ and $1 - s_j = \frac{\Phi_{-j}}{\Phi_{-j} + e^{\delta_j}}$. Substitute this into (C.45) and multiply both sides by $\Phi_{-j} + e^{\delta_j}$:

$$\begin{aligned} \alpha m_j \Phi_{-j} &= \Phi_{-j} + e^{v_j - \alpha m_j}, \\ (\alpha m_j - 1)\Phi_{-j} &= e^{v_j - \alpha m_j}. \end{aligned}$$

Multiply both sides by $\frac{e^{\alpha m_j - 1}}{\Phi_{-j}}$:

$$(\alpha m_j - 1)\, e^{\alpha m_j - 1} = \frac{e^{v_j - 1}}{\Phi_{-j}}. \tag{C.46}$$

The left side has the form we^w with $w = \alpha m_j - 1$. The next lemma inverts it.

Lemma C.11 (Lambert W function)**.** *For every $z > 0$ the equation $we^w = z$ has exactly one real solution, denoted $W(z)$, and $W(z) > 0$. The function W is differentiable and strictly increasing on $(0, \infty)$, with*

$$W'(z) = \frac{W(z)}{z\,\big(1 + W(z)\big)}. \tag{C.47}$$

The ratio $\frac{W(z)}{1+W(z)}$ is strictly increasing in z and lies in $(0, 1)$.

Proof. Let $g(w) = we^w$. If $w \leq 0$, then $g(w) \leq 0 < z$, so no solution is negative or zero. On $(0, \infty)$, $g'(w) = (1 + w)e^w > 0$, $g(0) = 0$ and $g(w) \to \infty$. By continuity and strict monotonicity, $g(w) = z$ has exactly one solution, and it is positive. The inverse function theorem gives $W'(z) = \frac{1}{g'(W(z))} = \frac{1}{(1+W)e^W}$. Since $e^W = \frac{z}{W}$, this equals (C.47), which is positive. Finally $\frac{W}{1+W} = 1 - \frac{1}{1+W}$ rises with W, and W rises with z. □

The function W is the principal branch of the Lambert W function (Corless et al., 1996). Applying Lemma C.11 with $z = \frac{e^{v_j - 1}}{\Phi_{-j}} > 0$ to (C.46) gives the best response

$$BR_j(p_{-j}) = mc_j + \frac{1}{\alpha}\left[1 + W\left(\frac{e^{v_j - 1}}{\Phi_{-j}}\right)\right]. \tag{C.48}$$

This is (4.9). Three properties follow at once. The best-response markup exceeds $\frac{1}{\alpha}$, because $W > 0$. It rises with v_j, the product's quality net of cost. It rises with every rival price, because a higher p_l lowers Φ_{-j} and W is increasing. Prices are strategic complements.

The stationary point is the unique global maximizer. Write (C.44) as $s_j\, G(m_j)$ with $G(m) = 1 - \alpha m\,(1 - s_j)$, where s_j is evaluated at $p_j = mc_j + m$. If $m \le 0$, then $G(m) \ge 1$ and profit rises with the price. If $m > 0$, both αm and $1 - s_j$ are positive and strictly increasing in m, because s_j falls as p_j rises. So G is strictly decreasing on $(0, \infty)$, and $G(m) \to -\infty$ because $1 - s_j \to 1$. Hence G has exactly one zero. Profit rises below it and falls above it, and (C.48) is the unique maximizer of π_j.

Part (c). The players are the 25 firms. Firm j chooses $p_j \in \mathbb{R}$ and receives $\pi_j(p_j, p_{-j})$. A *Nash equilibrium* is a price vector p^* such that

$$\pi_j(p_j^*, p_{-j}^*) \ge \pi_j(p_j, p_{-j}^*) \qquad \text{for every } p_j \in \mathbb{R} \text{ and every } j.$$

Equivalently, $p^* = BR(p^*)$, where $BR(p) = \big(BR_0(p_{-0}), \dots, BR_{24}(p_{-24})\big)$ is the best-response map. By part (b), each best response is unique and solves the first-order condition, so p^* is an equilibrium if and only if

$$s_j(p^*) + (p_j^* - mc_j)\frac{\partial s_j}{\partial p_j}(p^*) = 0, \qquad j = 0, \dots, 24. \tag{C.49}$$

Complete information matters here. Each best response depends on Φ_{-j}, which requires every rival's price and mean utility.

Part (d). Three algorithms are standard.

1. *Best-response iteration.* Start from $p^{(0)} = mc + \frac{1}{\alpha}$, the markup that (C.45) gives when shares are negligible. Set $p^{(n+1)} = BR(p^{(n)})$ with (C.48), and stop when $\|p^{(n+1)} - p^{(n)}\|_\infty < 10^{-12}$. Part (f) shows that the iteration converges from any starting point.
2. *Markup iteration.* Iterate on the first-order condition itself, $p^{(n+1)} = mc + \frac{1}{\alpha(1 - s(p^{(n)}))}$, element by element. The method needs no special function, but nothing guarantees its convergence in general.
3. *Newton-type root finding.* Solve the 25 equations (C.49) with a quasi-Newton method. We use the hybrid Powell method with tolerance 10^{-14}, started at $mc + \frac{1}{\alpha}$.

Best-response iteration converges in 10 iterations, markup iteration in 14, and the root finder uses 39 function evaluations. The three solutions agree to within 1.2×10^{-14}, and the largest first-order residual is 1.5×10^{-15}.

The columns marked S in Table C.10 report the equilibrium. Markups range from 0.502 to 0.566. They lie close to the floor $\frac{1}{\alpha} = 0.5$, because every share is small, and they rise with the share, as (C.45) requires. Products 20 and 5, with shares of 11.66 and 11.37 percent, carry the largest markups, 0.566 and 0.564. The outside good takes 13.67 percent of the market, so $\Phi^* = \frac{1}{s_0} = 7.314$. Total profit is 0.4616, and the share-weighted mean price is 1.2599.

Consumer surplus follows from the log-sum formula of Section 6.3.3 (Small and Rosen, 1981). The expected maximum utility is $\mathbb{E}[\max_j u_{ij}] = \ln \Phi + \gamma_E$, where $\gamma_E \approx 0.5772$ is Euler's constant. Dividing by the marginal utility of money α converts utility into money. Consumer surplus per consumer is therefore $\frac{1}{\alpha} \ln \Phi$ up to an additive constant, which equals 0.9949 here. Only differences in consumer surplus across scenarios have meaning.

Part (e). Firm f now chooses all prices in $\mathcal{J}_f$ to maximize (C.41). For $j \in \mathcal{J}_f$, the derivatives of part (a) give

$$\begin{aligned} \frac{\partial \pi_f}{\partial p_j} &= s_j + \sum_{k \in \mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} \\ &= s_j - \alpha m_j s_j (1 - s_j) + \sum_{k \in \mathcal{J}_f, k \neq j} \alpha m_k s_j s_k \\ &= s_j \Big[1 - \alpha m_j + \alpha \sum_{k \in \mathcal{J}_f} m_k s_k \Big]. \end{aligned}$$

Setting the derivative to zero and dividing by $\alpha s_j > 0$ gives

$$m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k \qquad \text{for every } j \in \mathcal{J}_f. \tag{C.50}$$

Proposition C.12 (Common markup)**.** *At any price vector at which firm f's first-order conditions hold, all products of f carry the same markup*

$$m_f = \frac{1}{\alpha (1 - S_f)}, \qquad S_f = \sum_{k \in \mathcal{J}_f} s_k. \tag{C.51}$$

This is Proposition 4.7. It follows from (C.50), whose right side does not depend on j. The firm prices as a single-product firm whose share is its combined share. Quality and cost differences among its products move their prices one for one with cost and affect markups only through S_f. Dividing (C.50) by $1 - s_j$ gives a second reading,

$$m_j = \frac{1}{\alpha (1 - s_j)} + \sum_{k \in \mathcal{J}_f, k \neq j} D_{jk} m_k, \qquad D_{jk} = -\frac{\partial s_k}{\partial p_j} \Big(\frac{\partial s_j}{\partial p_j} \Big)^{-1} = \frac{s_k}{1 - s_j}. \tag{C.52}$$

The markup of product j equals its single-product markup plus the margin earned on the sales that a price increase diverts to the firm's other products. D_{jk} is the logit *diversion ratio* from j to k, the fraction of the sales lost by j that go to k.

The multi-product best response follows the steps of part (b). Let $E_f = \sum_{k \in \mathcal{J}_f} e^{v_k}$ and $\Phi_{-f} = 1 + \sum_{l \notin \mathcal{J}_f} e^{\delta_l}$, which depends only on rivals' prices. At a common markup m, firm f's products contribute $\sum_{k \in \mathcal{J}_f} e^{v_k - \alpha m} = E_f e^{-\alpha m}$ to Φ, so

$$S_f = \frac{E_f e^{-\alpha m}}{\Phi_{-f} + E_f e^{-\alpha m}}, \qquad 1 - S_f = \frac{\Phi_{-f}}{\Phi_{-f} + E_f e^{-\alpha m}}.$$

Substitute $1 - S_f$ into $\alpha m (1 - S_f) = 1$ and clear the denominator:

$$\begin{aligned} \alpha m \, \Phi_{-f} &= \Phi_{-f} + E_f e^{-\alpha m}, \\ (\alpha m - 1) \Phi_{-f} &= E_f e^{-\alpha m}, \\ (\alpha m - 1) e^{\alpha m - 1} &= \frac{E_f e^{-1}}{\Phi_{-f}}, \end{aligned}$$

where the last line multiplies by $\frac{e^{\alpha m-1}}{\Phi_{-f}}$. Lemma C.11 gives

$$m_f^{BR} = \frac{1}{\alpha}\Big[1 + W\Big(\frac{E_f e^{-1}}{\Phi_{-f}}\Big)\Big], \qquad BR_k(p_{-\mathcal{J}_f}) = mc_k + m_f^{BR} \quad (k \in \mathcal{J}_f). \tag{C.53}$$

With one product, $E_f = e^{v_j}$ and (C.53) reduces to (C.48). Chapter 4 states this formula, (4.10), and proves its global optimality in Steps 1 and 2 of the proof of Theorem 4.25. The next proposition gives a second proof, by a change of variables from prices to shares under which profit is concave.

Proposition C.13 (Profit is concave in shares)**.** *Fix the rivals' prices, and hence Φ_{-f}.*

(i) The map from firm f's prices $(p_k)_{k\in\mathcal{J}_f}$ to its shares $(s_k)_{k\in\mathcal{J}_f}$ is a smooth bijection onto $\{s > 0 : S_f < 1\}$, with smooth inverse

$$\delta_k = \ln s_k + \ln \Phi_{-f} - \ln(1 - S_f). \tag{C.54}$$

(ii) As a function of its shares, firm f's profit is

$$\pi_f = \frac{1}{\alpha}\sum_{k\in\mathcal{J}_f} s_k\big[v_k - \ln\Phi_{-f} - \ln s_k\big] + \frac{1}{\alpha} S_f \ln(1 - S_f), \tag{C.55}$$

which is strictly concave.

(iii) Profit has a unique maximizer over f's prices. It is the unique solution of f's first-order conditions and is given by (C.53).

Proof. (i) Given prices, shares follow from (C.40). Conversely, take shares with $s_k > 0$ and $S_f < 1$. Because $\Phi = \Phi_{-f} + \sum_{k\in\mathcal{J}_f} e^{\delta_k} = \Phi_{-f} + S_f\Phi$, the denominator must equal $\Phi = \frac{\Phi_{-f}}{1-S_f}$. Then $e^{\delta_k} = s_k\Phi$ gives (C.54), and $p_k = \frac{a_k-\delta_k}{\alpha}$. Both maps are smooth, and they are inverse to each other.

(ii) The markup is $m_k = p_k - mc_k = \frac{a_k-\delta_k}{\alpha} - mc_k = \frac{v_k-\delta_k}{\alpha}$. Substituting (C.54),

$$\alpha m_k = v_k - \ln s_k - \ln\Phi_{-f} + \ln(1 - S_f).$$

Multiplying by $\frac{s_k}{\alpha}$ and summing over $k \in \mathcal{J}_f$ gives (C.55). In the first sum, each term is linear in s_k except $-s_k \ln s_k$, whose second derivative is $-\frac{1}{s_k} < 0$. In the second term, $\varphi(S) = S\ln(1-S)$ has

$$\varphi'(S) = \ln(1 - S) - \frac{S}{1-S}, \qquad \varphi''(S) = -\frac{1}{1-S} - \frac{1}{(1-S)^2} < 0,$$

and S_f is linear in the shares. A sum of strictly concave functions of separate shares and a concave function of their sum is strictly concave.

(iii) The partial derivative of (C.55) is

$$\frac{\partial\pi_f}{\partial s_k} = \frac{1}{\alpha}\big[v_k - \ln\Phi_{-f} - \ln s_k - 1 + \varphi'(S_f)\big].$$

It tends to $+\infty$ as $s_k \to 0$ with S_f bounded away from one, and profit tends to $-\infty$ as $S_f \to 1$. A maximizer therefore exists and is interior, and strict concavity makes it the only stationary point. By (i), stationary points in prices and in shares coincide, because the change of variables has an invertible Jacobian. By Proposition C.12 and the derivation above, the only stationary point in prices is (C.53). □

Stacking the first-order conditions of all firms gives one system for any ownership structure. Let Ω be the ownership matrix, with $\Omega_{jk} = 1$ when j and k have the same owner and zero otherwise. The condition for p_j is $s_j + \sum_k \Omega_{jk} \frac{\partial s_k}{\partial p_j} m_k = 0$. Since $\frac{\partial s_k}{\partial p_j} = \Delta_{kj}$, in matrix form

$$s + (\Omega \odot \Delta^\top)(p - mc) = 0, \tag{C.56}$$

with $\odot$ the element-wise product. Single-product firms correspond to $\Omega = I$. Only Ω changes between the two games, so a program written for (C.56) handles both.

All three algorithms of part (d) carry over. Best-response iteration now uses (C.53). Markup iteration uses $p_k^{(n+1)} = mc_k + \frac{1}{\alpha(1 - S_f(p^{(n)}))}$. Best-response iteration converges in 15 iterations, markup iteration in 30, and the root finder uses 41 function evaluations. The solutions agree to within 1.4×10^{-13}, and the largest first-order residual is 1.5×10^{-14}.

Table C.10: Equilibrium by product: single-product firms (S), five multi-product owners (M), and after the merger of owners 3 and 4 (G)

			Price			Markup		Share (%)		
j	owner	mc_j	p_j^S	p_j^M	p_j^G	m_j^S	m_j^M	s_j^S	s_j^M	s_j^G

Notes: Market size is one. Under M every product of an owner carries the owner's markup $\frac{1}{\alpha(1-S_f)}$. After the merger (G), the 13 products of the merged firm carry the common markup 0.821. Firm-level outcomes under S and M are in Table 4.2. Computed with `figures/appC/src/logit_bertrand.py`.

Table C.10 compares the equilibria product by product, and Table C.11 compares market outcomes. Joint ownership raises every price, by amounts from 0.015 (product 11, owner 1) to 0.167 (product 7, owner 4). Each owner's markup becomes $\frac{1}{\alpha(1-S_f)}$. It is 0.670 for owner 4, whose products have a combined share of 25.4 percent, against a share-weighted mean of 0.541 under single-product pricing. Owner 1's combined share is 4.7 percent, and its markup rises

Table C.11: Market outcomes and computational diagnostics in the 25-product logit market

	Single-product (S)	Multi-product (M)	After merger (G)
Outside share s_0	0.1367	0.1601	0.1869
Logit denominator $\Phi^* = \frac{1}{s_0}$	7.314	6.246	5.352
Consumer surplus $\frac{1}{\alpha}\ln\Phi^*$	0.9949	0.9159	0.8387
Total profit	0.4616	0.5261	0.5767
Total surplus	1.4565	1.4421	1.4154
Share-weighted mean price	1.2599	1.3553	1.4465
Range of markups	0.502 to 0.566	0.524 to 0.670	0.529 to 0.821
Best-response iterations	10	15	16
Markup iterations	14	30	85
Largest first-order residual	1.5×10^{-15}	1.5×10^{-14}	2.5×10^{-14}
Global contraction bound η	0.358	0.474	0.545
Exact global modulus	0.135	0.212	0.272
Local modulus $\max_f \frac{S_f(1-S_f-s_0)}{1-S_f}$	0.099	0.199	0.271
Sign changes of $\Psi - 1$ on the grid	1	1	1

Notes: Consumer surplus is per consumer and defined up to an additive constant. Iterations start at $mc + \frac{1}{\alpha}$ and stop when the sup-norm price change is below 10^{-12}. The exact global modulus is the supremum over $\Phi_{-f} \geq 1$ of the largest row sum of the best-response Jacobian. Computed with `figures/appC/src/logit_bertrand.py`.

only from 0.508 to 0.524. Total profit rises by 14.0 percent to 0.5261. Consumer surplus falls from 0.9949 to 0.9159, and the outside share rises from 13.67 to 16.01 percent. Total surplus, consumer surplus plus profit, falls from 1.4565 to 1.4421. Table 4.2 reports shares, markups and profits by owner, and Figure 4.2 plots the markups.

The prices differ because a multi-product firm internalizes *cannibalization*. A single-product firm that raises its price loses every customer who switches away. A multi-product firm keeps the customers who switch to its own products. By (C.52), the fraction of product j's lost sales that the firm recaptures is $\sum_{k \in \mathcal{J}_f, k \neq j} D_{jk} = \frac{S_f - s_j}{1 - s_j}$. It ranges from 0.161 to 0.250 for owner 4's products and from 0.026 to 0.037 for owner 1's. The incentive to raise prices grows with recapture. Prices are strategic complements, so the higher prices of the large owners lead every rival to raise its prices too. Large owners lose share. Owner 4's combined share falls from 28.00 to 25.36 percent, while owner 1's rises from 4.12 to 4.67 percent. Every owner nevertheless earns more, because competition softens for all of them.

Part (f). Both equilibria are unique, and so is the equilibrium under any other ownership structure.

Proposition C.14 (Uniqueness)**.** *With logit demand and constant marginal costs, the pricing game has exactly one Nash equilibrium for any partition of the products among firms.*

This is Theorem 4.25. Steps 3 and 4 of its proof reduce the equilibrium to one equation in the scalar aggregate Φ, and we use that equation again below. By Proposition C.12, $\alpha m_f = \frac{1}{1-S_f}$, and the combined share is $S_f = \frac{E_f}{\Phi} e^{-\alpha m_f}$. Together they give

$$h(S_f) \equiv S_f \, e^{\frac{1}{1-S_f}} = \frac{E_f}{\Phi}. \tag{C.57}$$

Since h rises strictly from zero to infinity on $(0, 1)$, (C.57) defines a share $S_f(\Phi)$ that falls strictly

in Φ. Adding up the shares, with $s_0 = \frac{1}{\Phi}$, gives

$$\Psi(\Phi) \equiv \sum_f S_f(\Phi) + \frac{1}{\Phi} = 1. \tag{C.58}$$

The function Ψ is strictly decreasing, exceeds one at $\Phi = 1$ and tends to zero, so it has exactly one root Φ^*. The root fixes every firm's share, markup and prices.

For single-product firms, Caplin and Nalebuff (1991) derive uniqueness in the logit model by differentiating the profit function. Their proofs rest on a *dominant diagonal* condition, $\left|\frac{\partial^2 \pi_j}{\partial p_j^2}\right| > \sum_{k \neq j} \left|\frac{\partial^2 \pi_j}{\partial p_j \partial p_k}\right|$ among active firms (Friedman, 1977) (Proposition B.150). We cite their 1990 discussion-paper version (Cowles Foundation Discussion Paper 937), where this argument is on p. 16. They also note that their uniqueness cases are log-supermodular games (p. 16), which Section B.9.4 treats. Such games have no other equilibria in mixed or correlated strategies, and best-response dynamics converge globally (Milgrom and Roberts, 1990). Their other uniqueness results cover duopoly with a log-concave density of tastes and one-dimensional markets with a given set of active firms (Propositions 6 and 7, p. 17). They credit Anderson and de Palma (1988) with first noting uniqueness in the logit duopoly (p. 17). Berry et al. (1995, fn. 12) note that the existence theorems of Caplin and Nalebuff (1991) do not easily generalize to multi-product firms. They assume that an equilibrium exists and check numerically that their estimates are consistent with one. Konovalov and Sándor (2010) prove uniqueness for multi-product logit firms, and Nocke and Schutz (2018) develop the aggregative approach behind (C.58).

A second proof shows that best-response iteration converges from any starting point.

Proposition C.15 (Best responses form a contraction)**.** *Let $\eta = \max_f \frac{W(E_f e^{-1})}{1+W(E_f e^{-1})}$, which is below one. For all price vectors p and p',*

$$\|BR(p) - BR(p')\|_\infty \leq \eta \, \|p - p'\|_\infty.$$

Hence the equilibrium is unique, and best-response iteration converges to it geometrically from any start.

Proof. Fix firm f and write $z_f = \frac{E_f e^{-1}}{\Phi_{-f}}$, so that $BR_k = mc_k + \frac{1}{\alpha}[1 + W(z_f)]$ for $k \in \mathcal{J}_f$. Own prices do not enter Φ_{-f}, so $\frac{\partial BR_k}{\partial p_l} = 0$ for $l \in \mathcal{J}_f$. For a rival product $l \notin \mathcal{J}_f$,

$$\frac{\partial \Phi_{-f}}{\partial p_l} = -\alpha e^{\delta_l}, \qquad \frac{\partial z_f}{\partial p_l} = -\frac{z_f}{\Phi_{-f}} \frac{\partial \Phi_{-f}}{\partial p_l} = \frac{\alpha z_f e^{\delta_l}}{\Phi_{-f}}.$$

The chain rule and (C.47) give

$$\frac{\partial BR_k}{\partial p_l} = \frac{1}{\alpha} W'(z_f) \frac{\partial z_f}{\partial p_l} = \frac{1}{\alpha} \cdot \frac{W(z_f)}{z_f(1 + W(z_f))} \cdot \frac{\alpha z_f e^{\delta_l}}{\Phi_{-f}} = \frac{W(z_f)}{1 + W(z_f)} \cdot \frac{e^{\delta_l}}{\Phi_{-f}}.$$

Both factors are shares evaluated at firm f's best response to $p_{-\mathcal{J}_f}$. There $1 + W(z_f) = \alpha m_f = \frac{1}{1-S_f}$, so $\frac{W(z_f)}{1+W(z_f)} = S_f$. Also $\Phi = \frac{\Phi_{-f}}{1-S_f}$, so $\frac{e^{\delta_l}}{\Phi_{-f}} = \frac{s_l}{1-S_f}$. Hence

$$\frac{\partial BR_k}{\partial p_l} = \frac{S_f s_l}{1 - S_f} > 0, \qquad \sum_{l \notin \mathcal{J}_f} \frac{\partial BR_k}{\partial p_l} = \frac{S_f(1 - S_f - s_0)}{1 - S_f} < S_f. \tag{C.59}$$

Since $\Phi_{-f} \geq 1$, $z_f \leq E_f e^{-1}$, and since $\frac{W}{1+W}$ is increasing (Lemma C.11), $S_f \leq \frac{W(E_f e^{-1})}{1+W(E_f e^{-1})} \leq \eta$. Every row of the Jacobian of BR is non-negative and sums to less than η, at every price vector. For each k, the mean value theorem gives a point $\tilde{p}$ on the segment between p and p' with

$$|BR_k(p) - BR_k(p')| = \left| \sum_l \frac{\partial BR_k}{\partial p_l}(\tilde{p})\,(p_l - p'_l) \right| \leq \eta \, \|p - p'\|_\infty .$$

Taking the maximum over k proves the inequality. The contraction mapping theorem (Appendix B) gives a unique fixed point and geometric convergence from any starting point. □

For single-product firms, (C.59) becomes $\frac{\partial BR_j}{\partial p_k} = \frac{s_j s_k}{1-s_j}$, the slope in Proposition 4.24. The modulus η is a valid but loose bound. Since $s_0 = \frac{1-S_f}{\Phi_{-f}}$ at firm f's best response, the row sum in (C.59) equals $\frac{W(z_f)}{1+W(z_f)}\left(1 - \frac{1}{\Phi_{-f}}\right)$. As rivals' prices rise without bound, $\Phi_{-f} \to 1$ and the row sum tends to zero. As they fall without bound, $z_f \to 0$ and the first factor tends to zero. The supremum of the row sum over $\Phi_{-f} \geq 1$ is the exact global modulus, 0.135 under S and 0.212 under M. The relevant local modulus is the largest row sum at the equilibrium, $\max_f \frac{S_f(1-S_f-s_0)}{1-S_f}$.

We check uniqueness numerically in three ways. First, we evaluate $\Psi(\Phi) - 1$ on 2,000 points spaced evenly in logarithms over $[1, 10^4]$. It changes sign exactly once in each game (Figure C.4). The roots are $\Phi^* = 7.314$ under S and $\Phi^* = 6.246$ under M, and each equals $\frac{1}{s_0}$ at the computed equilibrium. Second, we run best-response iteration from 500 random starting vectors $p^{(0)} = mc + U[0,5]^{25}$, and from $p^{(0)} = mc$ and $p^{(0)} = mc + 20$. All 502 runs reach the same prices, with largest deviations of 5.5×10^{-14} (S) and 2.6×10^{-13} (M), in at most 11 and 16 iterations. Third, we compute the contraction moduli. The global bound is $\eta = 0.358$ under S and 0.474 under M. The local moduli are 0.099 and 0.199, which explains the fast convergence. A finite-difference Jacobian of BR at the equilibrium matches (C.59) to within 1.7×10^{-10}.

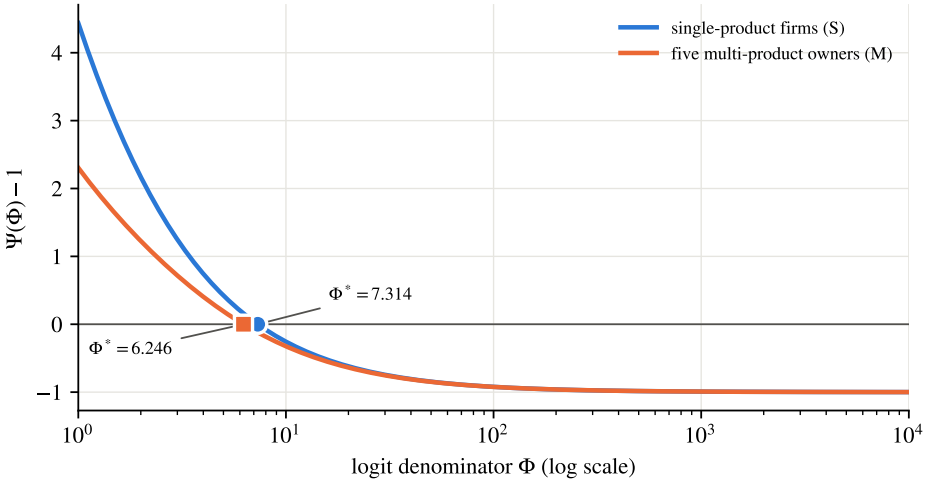

Figure C.4: The aggregate equation (C.58). Each curve plots $\Psi(\Phi) - 1$, where $\Psi(\Phi) = \sum_f S_f(\Phi) + \frac{1}{\Phi}$ and $S_f(\Phi)$ solves $S_f e^{\frac{1}{1-S_f}} = \frac{E_f}{\Phi}$. The curves are strictly decreasing and cross zero once, at $\Phi^* = \frac{1}{s_0}$. At $\Phi = 1$ they equal 4.44 (S) and 2.31 (M). Computed with `figures/appC/src/logit_bertrand.py`.

Part (g). After the merger, owners 3 and 4 form one firm with 13 products, and the other owners are unchanged. Only Ω changes. Example 4.36 introduces this merger and computes the cost reductions that would offset it. Here we compare the equilibrium effects with first-round pricing pressure. By Proposition C.14 the post-merger equilibrium is unique, so the starting point of the iteration does not matter. Best-response iteration converges in 16 iterations, and the column G of Table C.10 reports the result.

By Proposition C.12, the merged firm charges one markup on all 13 products, $m_M = \frac{1}{\alpha(1-S_M)} = 0.821$, where $S_M = 39.12$ percent is its post-merger combined share. Before the merger the markups were 0.636 (owner 3) and 0.670 (owner 4). Every product of owner 3 therefore rises in price by 0.185, and every product of owner 4 by 0.151. The mean increase over the 13 products is 0.167. Rivals respond with smaller increases: 0.018 for owner 0, 0.013 for owner 2 and 0.004 for owner 1. Figure C.5 plots the change for every product. Firm-level shares, markups and profits before and after the merger are in Table 4.4.

The merged firm loses share, from 46.76 to 39.12 percent, and every rival gains. The outside share rises from 16.01 to 18.69 percent, and consumer surplus falls by 0.0773, from 0.9159 to 0.8387. Total profit rises from 0.5261 to 0.5767. The merger is profitable for its parties, whose joint profit rises by 5.0 percent, from 0.3061 to 0.3213. The rivals gain more in percentage terms: 15.9 percent for owner 0, 16.7 percent for owner 1 and 16.3 percent for owner 2. Total surplus falls from 1.4421 to 1.4154.

The fall in consumer surplus is an instance of a general result for multi-product logit pricing. A single number summarizes each firm, its *type*, which is its contribution to consumer surplus if it priced at marginal cost. In our notation the type of firm f is E_f. A merger without cost savings gives the merged firm the type $E_3 + E_4$, the sum of the partners' types. Asker and Nocke (2021, Section 3.3.1, p. 229) report the following result of Nocke and Schutz (2019). Consumer surplus does not fall if and only if the merged type is above a cutoff, which exceeds the sum of the partners' types. A merger that only combines ownership, like this one, therefore always harms consumers. The aggregative structure behind the result is that of Proposition C.14 (Nocke and Schutz, 2018).

Upward pricing pressure (UPP) measures the merger's incentive to raise prices at pre-merger prices (Section 11.4.3). Farrell and Shapiro (2010) define the first-round tax on product 1 of a merger between two single-product firms as $t_1 = D_{12}(P_2 - C_2)$, the diversion ratio times the partner's margin (working-paper version, p. 9). When the partner owns several products, the tax sums over them, $t_j = \sum_k D_{jk} m_k$ (Equation (11.56)). For product j of owner 3, the partner is owner 4, whose seven products share the pre-merger markup m_4. With logit diversion,

$$UPP_j = \sum_{k \in \mathcal{J}_4} \frac{s_k}{1 - s_j} m_4 = \frac{S_4}{1 - s_j} m_4. \tag{C.60}$$

The *gross upward pricing pressure index* (GUPPI) divides by the product's price, $GUPPI_j = \frac{UPP_j}{p_j}$ (Equation (11.50)). For owner 3's products, UPP ranges from 0.172 to 0.187 and GUPPI from 0.116 to 0.162. For owner 4's products, UPP ranges from 0.137 to 0.153 and GUPPI from 0.078 to 0.132 (Table C.12). The UPP values bracket the equilibrium increases of 0.185 and 0.151 closely. Asker and Nocke (2021, Section 3.3.2, pp. 230–231) present UPP as the simple alternative to full merger simulation. Simulation estimates demand, recovers marginal costs from an assumption on conduct and solves for the post-merger equilibrium. Demand and costs are known here, so this part carries out the last step exactly.

Three facts explain why the first-round measure predicts so well here. First, a multi-product firm's internal tax is a firm-level object. Compare the merged firm's first-order condition for

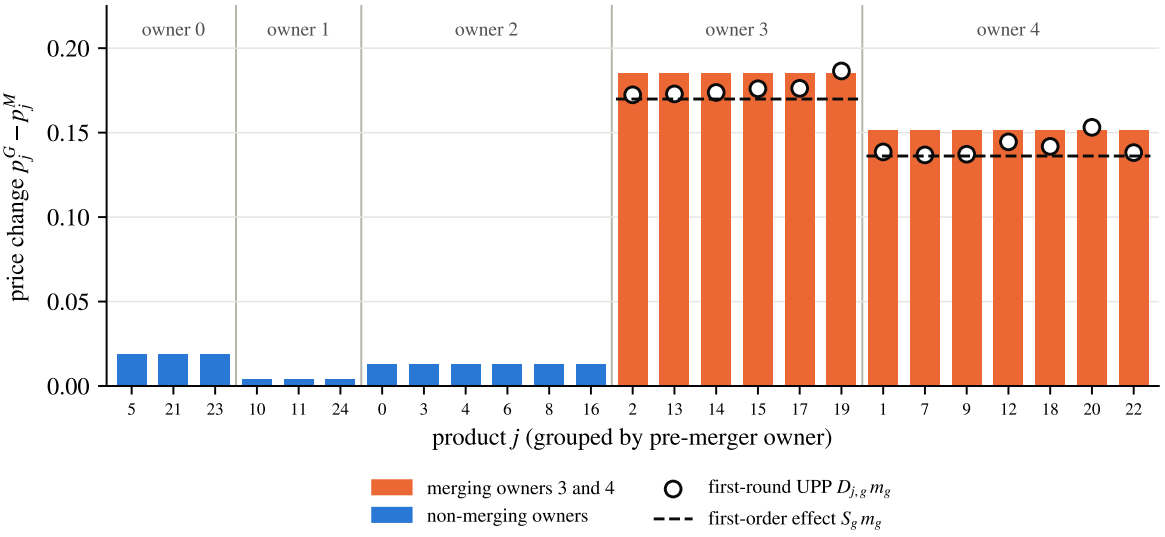

Figure C.5: Price changes caused by the merger of owners 3 and 4, by product. Bars show the change from the pre-merger equilibrium (M) to the post-merger equilibrium (G). Hollow circles show each merging product's first-round upward pricing pressure $D_{j,g}m_g$, and dashed lines show the first-order effect $S_g m_g$ of the firm-level tax. Computed with `figures/appC/src/logit_bertrand.py`.

Table C.12: Pricing pressure and price changes of the merging products

	Owner 3 (partner $g = 4$)	Owner 4 (partner $g = 3$)
Product diversion to partner $\frac{S_g}{1-s_j}$	0.257 to 0.278	0.215 to 0.241
Product-level UPP $\frac{S_g}{1-s_j}m_g$	0.172 to 0.187	0.137 to 0.153
GUPPI $\frac{1}{p_j}\frac{S_g}{1-s_j}m_g$	0.116 to 0.162	0.078 to 0.132
Firm-level tax $t_f = \frac{S_g m_g}{1-S_f}$	0.216	0.182
First-order effect $(1 - S_f)t_f = S_g m_g$	0.170	0.136
One round with taxes t_f, re-equilibrated	0.184	0.152
Equilibrium price change $m_M - m_f$	0.185	0.151

Notes: Shares and markups are those of the pre-merger equilibrium M, f is the merging owner and g its partner. Ranges are across the owner's products. Firm-level shares, markups and profits before and after the merger are in Table 4.4. Computed with `figures/appC/src/logit_bertrand.py`.

$j \in \mathcal{J}_3$ with owner 3's condition when each of its products bears a cost increase t_j. By (C.50) they coincide when

$$t_j - \sum_{k \in \mathcal{J}_3} s_k t_k = \sum_{k \in \mathcal{J}_4} s_k m_k \qquad \text{for all } j \in \mathcal{J}_3.$$

With a uniform tax and owner 4's common markup, the solution is $t_3 = \frac{S_4 m_4}{1-S_3}$. In general, $t_f = \frac{S_g m_g}{1-S_f}$ for merging firm f with partner g. This exceeds the product-level UPP (C.60), because a joint price increase on all of f's products diverts a larger fraction of sales to the partner. The firm-level taxes are 0.216 for owner 3 and 0.182 for owner 4.

Second, part (h) shows that a firm passes through a fraction $1 - S_f$ of a uniform cost increase when rivals' prices are fixed. The first-order price effect is therefore $(1 - S_f)t_f = S_g m_g$, which equals 0.170 for owner 3 and 0.136 for owner 4. Rivals' responses add the rest. Imposing the taxes t_f on owners 3 and 4 and letting all five owners re-equilibrate gives increases of 0.184 and 0.152, within 0.001 of the merger. Recomputing the taxes at the new prices and repeating, as Farrell and Shapiro propose, converges to the post-merger equilibrium in nine rounds. The taxes barely move (owner 3's rises from 0.216 to 0.217), because logit diversion changes little.

Third, an exact decomposition shows the size of the remaining gap. Subtract owner f's pre-merger condition $m_f = \frac{1}{\alpha} + S_f m_f$ from the merged firm's condition $m_M = \frac{1}{\alpha} + (S'_f + S'_g)m_M$, where primes denote post-merger shares of the former product sets:

$$m_M - m_f = S'_g\, m_M + \big(S'_f\, m_M - S_f\, m_f\big). \tag{C.61}$$

For owner 3 the two terms are 0.180 and 0.006, and for owner 4 they are 0.142 and 0.010. The first term exceeds $S_g m_g$ because the merged markup rises by more (23 and 29 percent) than the partner's share falls (14 and 19 percent). Product-level UPP exceeds $S_g m_g$ by the factor $\frac{1}{1-s_j}$, between 1.005 and 1.125. The equilibrium change exceeds $S_g m_g$ by 9 and 11 percent. The closeness of product-level UPP to the equilibrium change thus reflects two separate corrections of similar size. Imposing the product-level UPP values as taxes, product by product, would understate the firm's internal tax. Re-equilibrating with them gives increases of only 0.149 and 0.117.

Part (h). Let all marginal costs rise by a unit tax t, so $mc_k(t) = mc_k + t$. Then $v_k(t) = v_k - \alpha t$ and $E_f(t) = E_f e^{-\alpha t}$ for every firm.

Proposition C.16 (Logit pass-through)**.** *Let demand be logit with constant marginal costs.*

(i) Holding rivals' prices fixed, a uniform increase dc in the marginal costs of firm f's products raises each of its prices by $(1 - S_f)\, dc$. With one product, the pass-through is $1 - s_j$.

(ii) In equilibrium, a common unit tax on all products has pass-through, at $t = 0$,

$$\rho_f = \frac{dp_k}{dt} = 1 - \frac{S_f\, s_0}{\big[(1-S_f)^2 + S_f\big]\,(s_0 + \bar{w})} \quad (k \in \mathcal{J}_f), \qquad \bar{w} = \sum_g \frac{S_g(1-S_g)^2}{(1-S_g)^2 + S_g}. \tag{C.62}$$

With two or more firms, $1 - S_f < \rho_f < 1$.

Proof. (i) This is Proposition 4.38(iii), and part (i) of that proposition is the single-product case.

(ii) The equilibrium satisfies (C.57) for every firm and the adding-up condition (C.58). Since $\ln h(S) = \ln S + \frac{1}{1-S}$, differentiating (C.57) in logarithms gives

$$\left[\frac{1}{S_f} + \frac{1}{(1-S_f)^2}\right] dS_f = d\ln E_f - d\ln\Phi = -\alpha\, dt - d\ln\Phi.$$

Write $w_f = \frac{S_f(1-S_f)^2}{(1-S_f)^2+S_f}$, the inverse of the bracket, so that $dS_f = w_f(-\alpha\,dt - d\ln\Phi)$. Adding up gives $\sum_f dS_f = -d\frac{1}{\Phi} = s_0\,d\ln\Phi$. Summing the previous equation over firms,

$$\bar{w}\,(-\alpha\,dt - d\ln\Phi) = s_0\,d\ln\Phi \quad\Longrightarrow\quad d\ln\Phi = -\frac{\alpha\bar{w}}{s_0+\bar{w}}\,dt.$$

Substituting back, $-\alpha\,dt - d\ln\Phi = -\frac{\alpha s_0}{s_0+\bar{w}}\,dt$, so $dS_f = -\frac{\alpha w_f s_0}{s_0+\bar{w}}\,dt$. Differentiating (C.51) then gives

$$dm_f = \frac{dS_f}{\alpha(1-S_f)^2} = -\frac{S_f\,s_0}{\left[(1-S_f)^2+S_f\right](s_0+\bar{w})}\,dt,$$

and $dp_k = dt + dm_f$ gives (C.62). Since $s_0 > 0$, $\rho_f < 1$. For the lower bound, write $A_f = (1-S_f)^2 + S_f$, so that $1 - A_f = S_f(1-S_f)$. Then $\rho_f > 1 - S_f$ holds if and only if $s_0 < A_f(s_0+\bar{w})$, that is, if and only if $S_f(1-S_f)\,s_0 < A_f\bar{w}$. Since $\bar{w} \geq w_f$, the right side is at least $A_f w_f = S_f(1-S_f)^2$. This exceeds $S_f(1-S_f)s_0$ because $1 - S_f > s_0$ when another firm has a positive share. □

For a single product, part (i) is also the logit case of Lemma 11.31. Part (ii) gives in closed form, for any ownership structure, the common-tax pass-through that Corollary 4.39 expresses through a matrix inverse for single-product firms. Two special cases help to read it. Without an outside good ($s_0 \to 0$), a common cost increase is passed through fully, because relative prices are all that matter. With a single firm, $\bar{w} = w_f$ and $s_0 = 1 - S_f$, and (C.62) reduces to $\rho_f = 1 - S_f$, the partial pass-through, because no rival responds. With several firms, the common tax lowers every E_f, which by itself cuts f's markup as in part (i). It also raises rivals' prices, which lowers Φ_{-f} and offsets part of the fall in $z_f = \frac{E_f e^{-1}}{\Phi_{-f}}$. Equilibrium pass-through therefore lies between the partial rate and one.

We compute the equilibrium at $t = 0.1$ by best-response iteration and divide each price change by t. Table C.13 reports the results. Under S, product pass-through ranges from 0.980 to 0.999, with mean 0.994. It is lower for products with larger shares, and its correlation with the share is −1.000. Under M it ranges from 0.934 (owner 4) to 0.990 (owner 1), with mean 0.954. The closed form (C.62) at $t = 0$ gives almost the same values, and it matches a numerical derivative to within 5×10^{-8}. Partial pass-through $1 - S_f$ is much lower, down to 0.746 for owner 4. Rivals' responses account for most of the difference.

The share-weighted mean price $\bar{p} = \sum_j w_j p_j$, with $w_j = \frac{s_j}{1-s_0}$, changes by

$$\frac{d\bar{p}}{dt} = \sum_j w_j \frac{dp_j}{dt} + \sum_j p_j \frac{dw_j}{dt}.$$

The first term is the average product pass-through. The second is a composition term, which is positive when consumers shift toward expensive products. The mean-price pass-through is 0.9895 under S and 0.9492 under M, and the composition terms are only 0.0002 and −0.0005. A common unit tax shifts all logit prices by similar amounts, so substitution among inside goods hardly changes the mix.

These results bear on the cigarette tax study of Section C.2. With logit demand and constant marginal costs, a common tax is passed through less than one for one by every firm, whatever the ownership structure, and composition effects are negligible. Logit demand is log-concave in own price, which is why pass-through stays below one. A pass-through rate above one, as Sumner (1981) estimates, needs a feature that this model lacks. Candidates are demand that

Table C.13: Pass-through of a common unit tax $t = 0.1$

	Single-product firms (S)	Multi-product owners (M)
Panel A. Market summary		
Product pass-through at $t = 0.1$: range (mean)	0.980 to 0.999 (0.994)	0.934 to 0.990 (0.954)
Closed form (C.62) at $t = 0$: range	0.981 to 0.999	0.937 to 0.990
Partial pass-through $1 - S_f$: range	0.883 to 0.996	0.746 to 0.953
Pass-through of the share-weighted mean price	0.9895	0.9492
with weights held at pre-tax shares	0.9893	0.9497
composition term	0.0002	−0.0005
Outside share, before and after	0.1367, 0.1618	0.1601, 0.1873
Consumer surplus, before and after	0.9949, 0.9107	0.9159, 0.8374
Total profit, before and after	0.4616, 0.4474	0.5261, 0.5051

Panel B. Owners under M Owner	0	1	2	3	4
Combined share S_f (%)	18.87	4.67	13.68	21.40	25.36
Partial pass-through $1 - S_f$	0.811	0.953	0.863	0.786	0.746
Equilibrium pass-through, closed form at $t = 0$	0.955	0.990	0.969	0.949	0.937
Equilibrium pass-through at $t = 0.1$	0.953	0.990	0.967	0.946	0.934

Notes: Pass-through at $t = 0.1$ is $\frac{p(0.1)-p(0)}{0.1}$. The composition term is the difference between the pass-through of the share-weighted mean price and the same object with weights fixed at pre-tax shares. Computed with `figures/appC/src/logit_bertrand.py`.

is more convex than the logit, composition effects much larger than those found here, or a different form of conduct.

C.3.3 Computational notes

A single script produces every number in this section. It is `logit_bertrand.py` in the folder `figures/appC/src`, and it reads the data file `logit_market.csv` from the folder `figures/appC/data`.

1. Compute $a_j = x_j\beta + \xi_j$, mc_j and $v_j = a_j - \alpha\, mc_j$. An owner vector assigns products to firms. Under S it is $(0, 1, \ldots, 24)$. After the merger, owner 4 is relabeled 3.
2. For each firm compute $E_f = \sum_{k\in\mathcal{J}_f} e^{v_k}$ once. At each iteration compute $\Phi_{-f} = \Phi - \sum_{k\in\mathcal{J}_f} e^{\delta_k}$, the markup (C.53) with the principal branch of W, and the new prices.
3. Stop when the sup-norm change in prices is below 10^{-12}. Verify (C.56), the common markups (C.51) and agreement with markup iteration and a root finder.
4. For uniqueness, solve (C.57) for $S_f(\Phi)$ in logarithms, $\ln S_f + \frac{1}{1-S_f} = \ln \frac{E_f}{\Phi}$, with a bracketing root finder, and evaluate Ψ on the grid.
5. For the merger and the tax, re-solve with the new owner vector or with $mc + t$.

The best-response step takes five lines in Python with NumPy and SciPy:

```
def best_response(p, owner, mc):
    e = np.exp(a - alpha * p)                              # e^{delta_j}
    E = np.bincount(owner, weights=np.exp(a - alpha * mc))  # E_f
    phi_minus = 1 + e.sum() - np.bincount(owner, weights=e)  # Phi_{-f}
```

```
    m = (1 + lambertw(E * np.exp(-1) / phi_minus).real) / alpha
    return mc + m[owner]
```

C.4 Simulating a market with random coefficients demand

The previous problem computed prices from a known demand system. Empirical work runs in the opposite direction, from observed prices and shares back to demand and cost. To judge an estimator we need data whose true model we know. This problem builds such data, and the next three problems use it. We simulate 100 markets from a random coefficients logit model with multi-product Bertrand pricing, solve for equilibrium prices, and draw the choices of about ten thousand consumers per market. Sections C.5 to C.7 estimate the vertical, logit and random coefficients models on the resulting data. Section 8.10 uses the same design to illustrate the estimation of the random coefficients model step by step.

C.4.1 Statement

Think of the market for yogurt in 100 metropolitan areas, which we treat as independent markets $t = 0, \dots, 99$. Ten products exist in total, $j = 1, \dots, 10$. Each market offers between 4 and 9 of them, 6.54 on average, so there are 654 product-market observations. A product has three characteristics, $x_{jt} = (1, x_{jt}^{sug}, x_{jt}^{org})$: a constant, its sugar content and an indicator of organic production. Its marginal cost also depends on a cost shifter w_{jt}, the price of milk used in production. Characteristics, the cost shifter and the owner are fixed by product, so $x_{jt} = x_j$ and $w_{jt} = w_j$ in every market that offers j (Table C.14). Four firms own the products: firm A owns $\{5, 8\}$, firm B owns $\{1, 4, 6, 7\}$, firm C owns $\{2, 3, 10\}$ and firm D owns $\{9\}$. Across markets only the set of products offered $\mathcal{J}_t$, the unobservables (ξ_{jt}, ω_{jt}) and the market size M_t vary. Their values are supplied in the file `yogurt_markets.csv` in the folder `figures/appC/data`. Market sizes range from 9,756 to 10,223, with mean 9,998.7.

Consumer i in market t has utility

$$u_{ijt} = \delta_{jt} + \tilde{x}_{jt}\Sigma\nu_i + \epsilon_{ijt}, \qquad \delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \qquad u_{i0t} = \epsilon_{i0t}, \tag{C.63}$$

where $\tilde{x}_{jt} = (x_{jt}, p_{jt})$ contains the characteristics and the price, $\nu_i \sim N(0, I_4)$, and the ϵ_{ijt} are independent type-I extreme value shocks. The parameters are $\beta = (-1, 0.2, 0.15)$, $\alpha = 3$ and $\Sigma = \text{diag}(\Sigma_{11}, \Sigma_{22}, \Sigma_{33}, \Sigma_{pp}) = \text{diag}(0.5, 0.2, 0.3, 0.5)$. Marginal cost is

$$mc_{jt} = x_{jt}\gamma_1 + \gamma_2 w_{jt} + \omega_{jt}, \qquad \gamma_1 = (0.2, 0.25, 0.3), \quad \gamma_2 = 0.5. \tag{C.64}$$

The demand and cost shocks are drawn independently of each other and of the characteristics. Their sample standard deviations are 0.50 for ξ_{jt} and 0.050 for ω_{jt}, and their sample correlation is 0.004. Firms know all characteristics, shocks and parameters. Each firm evaluates expected demand by averaging over $n_s = 100$ consumer types drawn once for each market.

(a) Interpret the random coefficients. How likely is a consumer to like higher prices?

(b) Write the expected-share function that the firms use, with $n_s = 100$ fixed draws per market, and explain how to evaluate it without numerical overflow.

(c) Derive the first-order conditions of multi-product Bertrand pricing and an algorithm that solves them. Solve every market and check the solutions.

Table C.14: Products in the simulated markets

Product j	1	2	3	4	5	6	7	8	9	10
Firm	B	C	C	B	A	B	B	A	D	C
Sugar content x_j^{sug}	1.349	1.300	0.929	1.315	1.182	0.636	1.130	1.204	1.128	0.879
Organic x_j^{org}	0	1	0	1	0	0	0	0	1	0
Price of milk w_j	0.534	0.367	0.426	0.547	0.346	0.529	0.588	0.334	0.527	0.442
Markets offering j	77	58	73	65	52	66	66	68	65	64
Mean price	1.189	1.403	1.025	1.504	1.048	1.008	1.164	1.039	1.427	1.012
Mean markup	0.390	0.395	0.381	0.402	0.378	0.384	0.390	0.376	0.378	0.382
Mean realized share	0.015	0.010	0.024	0.009	0.023	0.024	0.019	0.027	0.011	0.024

Notes: The first four rows are the design. The last three rows are equilibrium outcomes, averaged over the markets that offer the product. In the data file the owner codes of firms A, B, C and D are 0, 1, 2 and 4. Computed with `figures/appC/src/appC_simulate.py`.

(d) Simulate the realized shares of M_t consumers per market and compare them with the expected shares.

(e) Report the equilibrium of market 0.

(f) Show that, when individual choice probabilities are small, the markup of product j is close to the inverse of the average price sensitivity of its buyers. Evaluate the approximation in market 0.

(g) Derive the sampling error of a realized share and of its logarithm, and evaluate it in market 0.

C.4.2 Solution

Part (a). Because Σ is diagonal, the consumer-specific term in (C.63) is

$$\tilde{x}_{jt}\Sigma\nu_i = 0.5\,\nu_{i1} + 0.2\,\nu_{i2}x_{jt}^{sug} + 0.3\,\nu_{i3}x_{jt}^{org} + 0.5\,\nu_{i4}p_{jt}.$$

Consumer i therefore has her own coefficients

$$\beta_{i1} = -1 + 0.5\,\nu_{i1}, \quad \beta_{i2} = 0.2 + 0.2\,\nu_{i2}, \quad \beta_{i3} = 0.15 + 0.3\,\nu_{i3}, \quad -\alpha_i \text{ with } \alpha_i = 3 - 0.5\,\nu_{i4}. \tag{C.65}$$

The random constant β_{i1} shifts the utility of every inside good relative to the outside good. Consumers who like yogurt are more likely to buy some yogurt. Inside goods therefore substitute more with one another than with the outside good, as in a nested logit with one nest of inside goods. The coefficients on sugar and on organic production are positive on average, but 15.9 percent of consumers dislike sugar ($\nu_{i2} < -1$) and 30.9 percent dislike organic production ($\nu_{i3} < -0.5$). The price sensitivity α_i is normal with mean 3 and standard deviation 0.5. A consumer likes higher prices only if $\alpha_i \le 0$, that is, if $\nu_{i4} \ge 6$. This has probability $\mathbb{P}(\nu_{i4} \ge 6) = 9.9 \times 10^{-10}$. Among the 10,000 consumer types the firms use, α_i ranges from 1.17 to 4.79.

Conditional on ν_i, the extreme value shocks give logit choice probabilities. With $V_{ijt} = \delta_{jt} + \tilde{x}_{jt}\Sigma\nu_i$,

$$s_{ijt} = \frac{e^{V_{ijt}}}{1 + \sum_{k \in \mathcal{J}_t} e^{V_{ikt}}}, \qquad s_{jt} = \int_{\mathbb{R}^4} s_{ijt}(\nu)\,\phi_4(\nu)\,\mathrm{d}\nu, \tag{C.66}$$

where $s_{ijt}(\nu)$ is the choice probability of a consumer with taste vector ν and ϕ_4 is the four-dimensional standard normal density. The integral breaks the independence of irrelevant alternatives. A rise in p_{kt} moves consumers who were likely to buy k, and these consumers are most likely to buy products similar to k (Proposition 8.4). Cross elasticities therefore vary across products, unlike (C.43).

Part (b). For each market we draw $n_s = 100$ vectors $\nu_{it} \sim N(0, I_4)$ once and keep them fixed. They are the consumer types whose average demand the firms compute. The expected share of product j is the simulator of Nevo (2000a, eq. 11, p. 532),

$$s_{jt}(p_t) = \frac{1}{n_s}\sum_{i=1}^{n_s} s_{ijt}(p_t), \qquad s_{ijt}(p_t) = \frac{e^{V_{ijt}}}{1 + \sum_{k\in\mathcal{J}_t} e^{V_{ikt}}}. \tag{C.67}$$

Prices enter twice, through δ_{jt} and through the last element of $\tilde{x}_{jt}$, so the function must rebuild $\tilde{x}_{jt}$ whenever prices change.

Exponentials overflow when utilities are large. For draw i, let $c_i = \max\{0, \max_k V_{ikt}\}$, where the 0 is the outside good's utility. Multiplying the numerator and the denominator of s_{ijt} by e^{-c_i} gives

$$s_{ijt} = \frac{e^{V_{ijt}-c_i}}{e^{-c_i} + \sum_{k\in\mathcal{J}_t} e^{V_{ikt}-c_i}}.$$

The value is unchanged. Every exponent is now at most zero, so nothing overflows, and the largest term in the denominator equals one, so the denominator cannot underflow to zero.

The draws stay fixed for two reasons. With fixed draws, $s_t(p_t)$ is a smooth deterministic function of prices, so the first-order conditions of part (c) define a well-posed system. With fresh draws at each evaluation, the system would change from one iteration to the next, and no solver could converge. In this design the 100 draws also define what firms believe about demand. Part (d) shows that these beliefs differ from population demand by simulation error.

Part (c). Firm f owns the products $\mathcal{J}_{ft} \subseteq \mathcal{J}_t$ and earns $\pi_{ft} = M_t \sum_{k\in\mathcal{J}_{ft}}(p_{kt} - mc_{kt})s_{kt}(p_t)$. Market size multiplies profit, so it drops out of the first-order conditions

$$s_{jt} + \sum_{k\in\mathcal{J}_{ft}} (p_{kt} - mc_{kt})\frac{\partial s_{kt}}{\partial p_{jt}} = 0, \qquad j \in \mathcal{J}_{ft}. \tag{C.68}$$

These are equations (3.3) of Berry et al. (1995, p. 853). For draw i, price enters V_{ijt} with coefficient $\frac{\partial V_{ijt}}{\partial p_{jt}} = -\alpha + 0.5\,\nu_{i4} = -\alpha_i$. The quotient rule of Section C.3, applied draw by draw, gives $\frac{\partial s_{ijt}}{\partial p_{kt}} = \alpha_i s_{ijt}(s_{ikt} - \mathbf{1}\{j = k\})$. Averaging over draws,

$$\Delta_{jk,t} = \frac{\partial s_{jt}}{\partial p_{kt}} = \frac{1}{n_s}\sum_{i=1}^{n_s} \alpha_i s_{ijt}\big(s_{ikt} - \mathbf{1}\{j = k\}\big). \tag{C.69}$$

With Ω_t the ownership matrix of market t, the conditions stack as in (C.56): $s_t + (\Omega_t \odot \Delta_t^\top)(p_t - mc_t) = 0$. Solving for the markups gives $p_t - mc_t = -(\Omega_t \odot \Delta_t^\top)^{-1}s_t$, which is equation (3.5) of Berry et al. (1995, p. 854) with their matrix equal to $-(\Omega_t \odot \Delta_t^\top)$.

Proposition C.17 (Morrow-Skerlos fixed point)**.** *Let Λ_t be the diagonal matrix with $\Lambda_{jj,t} = \frac{1}{n_s}\sum_i \alpha_i s_{ijt}$, and let Γ_t be the matrix with $\Gamma_{jk,t} = \frac{1}{n_s}\sum_i \alpha_i s_{ijt}s_{ikt}$. If every $\alpha_i > 0$, the first-order conditions hold at p_t if and only if*

$$p_t - mc_t = \zeta_t(p_t) \equiv \Lambda_t^{-1}\big[s_t + (\Omega_t \odot \Gamma_t)(p_t - mc_t)\big], \tag{C.70}$$

where Λ_t, Γ_t and s_t are evaluated at p_t.

Proof. By (C.69), $\Delta_t = -\Lambda_t + \Gamma_t$, and Γ_t is symmetric. Since Ω_t is symmetric with a unit diagonal, $\Omega_t \odot \Lambda_t = \Lambda_t$, and

$$(\Omega_t \odot \Delta_t)^\top = -\Lambda_t + \Omega_t \odot \Gamma_t.$$

The first-order conditions therefore read $s_t - \Lambda_t(p_t - mc_t) + (\Omega_t \odot \Gamma_t)(p_t - mc_t) = 0$. Every diagonal entry of Λ_t is positive because $\alpha_i > 0$ and $s_{ijt} > 0$. Moving the Λ_t term to the left and multiplying by Λ_t^{-1} gives (C.70). Each step is reversible. □

This is Proposition 8.38, due to Morrow and Skerlos (2011). In the plain logit, $\alpha_i = \alpha$ gives $\Lambda_{jj} = \alpha s_j$ and $\Gamma_{jk} = \alpha s_j s_k$, and (C.70) becomes $m_j = \frac{1}{\alpha} + \sum_{k \in \mathcal{J}_f} s_k m_k$, the multi-product condition (C.50). Here every α_i exceeds 1.17, so the proposition applies. We solve each market as follows.

1. Start at $p_t^{(0)} = mc_t$.
2. Given $p_t^{(n)}$, compute s_{ijt} for the 100 draws, then s_t, Λ_t and Γ_t.
3. Set $p_t^{(n+1)} = mc_t + \zeta_t(p_t^{(n)})$.
4. Stop when $\|p_t^{(n+1)} - p_t^{(n)}\|_\infty < 10^{-12}$. Otherwise return to step 2.
5. Verify the first-order conditions (C.68) at the solution.

Nothing guarantees that $p \mapsto mc + \zeta(p)$ is a contraction, so convergence must be checked market by market.

Table C.15 reports the diagnostics. The iteration converges in every market, in 10 to 13 iterations (11.05 on average). The largest first-order residual across markets is 8.6×10^{-15}. A hybrid Powell root finder on (C.68), started at marginal cost, reaches the same prices to within 1.0×10^{-13}. We then restart from 20 random price vectors per market, with each price drawn uniformly on $[0, 4]$. All 2,000 runs of the iteration return the original prices, to within 2.1×10^{-13}, so no market shows a second equilibrium.

The root finder is less reliable from the random starts. Applied to the residual of (C.68), it solves only 13 of the 2,000 problems. Every term of that residual tends to zero as prices rise without bound. The root finder can therefore stop at very high prices, where the residual is small and no equilibrium is near. Applied to the residual $\zeta_t(p) - (p - mc_t)$, which is measured in price units, it solves 1,817 of the 2,000 problems, and every solution it finds is the original one.

Equilibrium prices range from 0.881 to 1.609, with mean 1.180. Markups range from 0.348 to 0.451, with mean 0.386, and the Lerner index averages 0.334. Markups are close to the inverse of the mean price coefficient, $\frac{1}{3} = 0.333$, for a reason that part (f) makes precise.

Part (d). At the equilibrium prices we simulate the choices of M_t consumers in each market. Each consumer receives a fresh draw $\nu_i \sim N(0, I_4)$ and $|\mathcal{J}_t| + 1$ fresh extreme value shocks, one for each product and one for the outside good. She chooses the alternative with the highest utility u_{ijt}. The *realized share* of product j is the fraction of consumers who choose it,

$$\hat{s}_{jt} = \frac{q_{jt}}{M_t}, \qquad q_{jt} = \sum_{i=1}^{M_t} \mathbf{1}\Big\{ j = \arg\max_{k \in \mathcal{J}_t \cup \{0\}} u_{ikt} \Big\}. \tag{C.71}$$

Table C.15: Simulated markets: equilibrium computation and realized shares

Panel A. Equilibrium prices	
Morrow-Skerlos iterations per market, range (mean)	10 to 13 (11.05)
Largest first-order residual	8.6×10^{-15}
Largest price difference, iteration versus root finder	1.0×10^{-13}
Random restarts solved by the iteration, largest deviation	2,000 of 2,000, 2.1×10^{-13}
Random restarts solved by a root finder on (C.68)	13 of 2,000
Random restarts solved by a root finder on $\zeta_t(p) - (p - mc_t)$	1,817 of 2,000
Markets with a second equilibrium	0
Prices: range (mean)	0.881 to 1.609 (1.180)
Markups: range (mean)	0.348 to 0.451 (0.386)
Lerner index: range (mean)	0.234 to 0.448 (0.334)
Panel B. Realized shares	
Simulated consumers	999,870
Products with zero realized share	0
Smallest realized share (buyers)	0.0019 (19)
Mean and largest absolute gap, realized minus expected share	0.0014, 0.0100
Correlation of realized and expected shares	0.986
Outside share: mean (range across markets)	0.879 (0.788 to 0.948)
Mean squared standardized gap: realized minus population share	1.07
Mean squared standardized gap: expected minus population share	0.84
Mean squared standardized gap: realized minus expected share	1.88

Notes: 654 product-market observations in 100 markets. Random restarts draw each starting price from $U[0, 4]$, 20 per market. A run counts as solved when the largest markup residual is below 10^{-10}. Standardized gaps divide by the sampling standard deviation $\sqrt{\frac{s(1-s)}{M_t}}$, where s is the population share computed with 100,000 draws. Computed with `figures/appC/src/appC_simulate.py`.

Realized shares, prices, characteristics, the cost shifter and ownership are the data that Sections C.5 to C.7 use. The unobservables, the marginal costs and the expected shares are kept only to evaluate the estimators.

In total we simulate 999,870 consumers. No product has a zero realized share, and the smallest realized share is 0.0019, or 19 buyers. The mean absolute difference between realized and expected shares is 0.0014, the largest is 0.0100, and their correlation is 0.986. The outside good is large. Its realized share averages 0.879 across markets and ranges from 0.788 to 0.948.

Three share concepts are at work. The expected share s_{jt} averages over the firms' 100 draws. The *population share* s_{jt}^{∞} integrates over the whole normal distribution, and we approximate it with 100,000 draws per market. The realized share $\hat{s}_{jt}$ is a sample proportion among M_t consumers drawn from the population. The gap between realized and expected shares therefore has two parts,

$$\hat{s}_{jt} - s_{jt} = \left(\hat{s}_{jt} - s_{jt}^{\infty}\right) + \left(s_{jt}^{\infty} - s_{jt}\right),$$

sampling error from the finite number of consumers and *simulation error* from the finite number of firm draws. Part (g) shows that the sampling error has standard deviation close to $\sqrt{\frac{s(1-s)}{M_t}}$. Dividing each part by this standard deviation and averaging the squares over the 654 observations gives 1.07 for the sampling part, close to the value of one that the binomial formula predicts. It gives 0.84 for the simulation part, and 1.88 for the total. With $n_s = 100$, the firms' simulation error is about as large as the sampling error of ten thousand consumers. The median relative simulation error $|\frac{s_{jt}}{s_{jt}^{\infty}} - 1|$ is 4.7 percent, and the largest is 29 percent.

Part (e). Table C.16 reports market 0, which offers products 2, 3, 4, 6, 8, 9 and 10 and has

M_0 = 9,880 consumers. Markups lie between 0.375 and 0.400. The Lerner index ranges from 0.260 for product 9, the most expensive product, to 0.408 for product 10, the cheapest. The outside good's expected share is 0.8463 and its realized share is 0.8549. Realized and expected shares are close. The largest relative gaps are −20 percent for product 9 and −11 percent for product 10. In market 0 the firms' 100 draws overstate demand for every inside product. The expected shares exceed the population shares by 4 to 10 percent, and the population outside share is 0.8555.

Table C.16: Equilibrium in market 0 and the anatomy of its markups

					Share					
Product	Firm	mc_j	p_j	m_j	Expected	Realized	Population	Buyers q_j	$\frac{1}{\bar{\alpha}_j}$	Γ term
2	C	0.9204	1.3200	0.3995	0.0048	0.0052	0.0044	51	0.3669	0.0326

Notes: M_0 = 9,880. Expected shares average over the firms' 100 draws, population shares over 100,000 draws, and realized shares are fractions of the M_0 simulated consumers. $\bar{\alpha}_j$ is the mean price sensitivity of product j's buyers among the firms' draws, and the Γ term is the second term of (C.72), so $m_j = \frac{1}{\bar{\alpha}_j} + \Gamma$ term. Computed with `figures/appC/src/appC_simulate.py`.

Part (f). Rewrite (C.70) product by product. Dividing the j-th row by Λ_{jj} gives the exact decomposition

$$m_j = \frac{s_j}{\Lambda_{jj}} + \frac{1}{\Lambda_{jj}} \sum_{k \in \mathcal{J}_f} \Gamma_{jk} m_k. \tag{C.72}$$

Proposition C.18 (Markups and the price sensitivity of buyers)**.** *Suppose every $\alpha_i > 0$. Let $\bar{\alpha}_j = \frac{\Lambda_{jj}}{s_j}$.*

(i) $\bar{\alpha}_j$ is the mean price sensitivity of product j's buyers,

$$\bar{\alpha}_j = \frac{\sum_i \alpha_i s_{ij}}{\sum_i s_{ij}} = \mathbb{E}\big[\alpha_i \mid i \text{ buys } j\big], \tag{C.73}$$

where the expectation is over the n_s consumer types and their extreme value shocks.

(ii) The markup satisfies

$$\left| m_j - \frac{1}{\bar{\alpha}_j} \right| \le \Big(\max_{k \in \mathcal{J}_f} |m_k| \Big) \sum_{k \in \mathcal{J}_f} \max_i s_{ik}. \tag{C.74}$$

Hence m_j approaches $\frac{1}{\bar{\alpha}_j}$ as the individual choice probabilities of firm f's products tend to zero.

Proof. (i) Each type is equally likely, with probability $\frac{1}{n_s}$, and type i buys j with probability s_{ij}. By Bayes' rule, the probability that a buyer of j is of type i is $\frac{s_{ij}}{\sum_{i'} s_{i'j}}$. Averaging α_i with these weights gives (C.73), and the factor $\frac{1}{n_s}$ cancels from $\frac{\Lambda_{jj}}{s_j}$.

(ii) By (C.72), $m_j - \frac{1}{\bar{\alpha}_j} = \sum_{k \in \mathcal{J}_f} \frac{\Gamma_{jk}}{\Lambda_{jj}} m_k$. Each ratio is a weighted average of s_{ik} over types, with non-negative weights $\alpha_i s_{ij}$:

$$\frac{\Gamma_{jk}}{\Lambda_{jj}} = \frac{\sum_i \alpha_i s_{ij}\, s_{ik}}{\sum_i \alpha_i s_{ij}} \leq \max_i s_{ik}.$$

The triangle inequality gives (C.74). □

The markup is thus the inverse of the buyers' mean price sensitivity, corrected by a term of the order of the firm's individual choice probabilities. This is the discrete-choice form of the inverse semi-elasticity rule (Equation (8.84)). In the plain logit, $\bar{\alpha}_j = \alpha$ for every product, which is why all markups in Section C.3 lie near $\frac{1}{\alpha}$. With random coefficients, buyers select themselves. Consumers with high α_i buy the outside good more often, so the buyers of any inside product are less price sensitive than the population.

Table C.16 evaluates the decomposition in market 0. The mean of α_i over the firms' 100 draws is 3.028, and the mean among consumers who choose the outside good is 3.075. The buyers' mean sensitivity $\bar{\alpha}_j$ ranges from 2.690 (product 9) to 2.810 (product 10). Its inverse lies between 0.356 and 0.372 and accounts for 91 to 99 percent of each markup. The expensive organic products 9 and 4 attract the least price-sensitive buyers, with $\bar{\alpha}_j$ of 2.690 and 2.701. The Γ term accounts for the rest, between 1.4 and 8.6 percent of the markup. It has two parts. The diagonal part restores the factor $1 - s_{ij}$ in each type's own-price derivative and is largest for product 8 (0.034), the product with the largest share. The off-diagonal part is the value of sales recaptured by the firm's other products and is largest for firm C's product 2 (0.029). Firm D sells one product, so product 9 has no recapture. Product 2 carries the highest markup in the market, 0.3995, although its buyers are more price sensitive than those of products 4 and 9. Firm C's recapture of 0.029 lifts it to the top. Net of the recapture terms, product 2's markup is 0.370, the fifth highest of the seven.

Part (g). Given prices, the M_t consumers choose independently, and each chooses j with probability s_{jt}^{∞}. Hence q_{jt} is binomial with parameters M_t and s_{jt}^{∞}. Writing s for s_{jt}^{∞},

$$\mathbb{E}[\hat{s}_{jt}] = s, \qquad \operatorname{Var}(\hat{s}_{jt}) = \frac{s(1-s)}{M_t}. \tag{C.75}$$

The inversions in Sections C.5 to C.7 use logarithms of shares. A first-order Taylor expansion, $\ln \hat{s}_{jt} \approx \ln s + \frac{\hat{s}_{jt} - s}{s}$, gives the delta-method variance (Appendix A),

$$\operatorname{Var}(\ln \hat{s}_{jt}) \approx \frac{1-s}{M_t s} = \frac{1-s}{\mathbb{E}[q_{jt}]}. \tag{C.76}$$

The standard error of a log share is about one over the square root of the number of buyers. A second-order expansion gives the bias $\mathbb{E}[\ln \hat{s}_{jt}] - \ln s \approx -\frac{\operatorname{Var}(\hat{s}_{jt})}{2s^2} = -\frac{1-s}{2M_t s}$, the sampling analogue of the simulation bias in Proposition 8.13. The logit inversion of Chapter 7 uses the difference $\ln \hat{s}_{jt} - \ln \hat{s}_{0t}$. Since $\operatorname{Cov}(\hat{s}_{jt}, \hat{s}_{0t}) = -\frac{s_{jt} s_{0t}}{M_t}$, the delta method gives $\operatorname{Cov}(\ln \hat{s}_{jt}, \ln \hat{s}_{0t}) \approx -\frac{1}{M_t}$, and

$$\operatorname{Var}\left(\ln \frac{\hat{s}_{jt}}{\hat{s}_{0t}}\right) \approx \frac{1-s_{jt}}{M_t s_{jt}} + \frac{1-s_{0t}}{M_t s_{0t}} + \frac{2}{M_t} = \frac{1}{M_t s_{jt}} + \frac{1}{M_t s_{0t}}. \tag{C.77}$$

The variance is the sum of the inverse expected counts of the two alternatives.

In market 0, product 2 has 51 buyers and product 8 has 553. We evaluate (C.76) at the realized shares. The standard error of the log share is 0.140 for product 2, 0.132 for product 9 and 0.089 for product 4. It is 0.070 for products 6 and 10, 0.063 for product 3 and 0.041 for product 8. Across all 654 observations the standard error ranges from 0.032 to 0.229, with median 0.080, and 162 observations have fewer than 100 buyers. These errors are small relative to the standard deviation of ξ_{jt}, which is 0.50. They enter the dependent variable of every inversion in Sections C.5 to C.7. To first order they have mean zero and are independent of the instruments, so they add noise without biasing linear instrumental variable estimators. The second-order bias is largest for the smallest products, about -0.010 for product 2.

C.4.3 Computational notes

A single script produces the data and every number in this section. It is `appC_simulate.py` in the folder `figures/appC/src`, and it reads the data file `yogurt_markets.csv` from the folder `figures/appC/data`. The file holds characteristics, the cost shifter, owners, (ξ_{jt}, ω_{jt}) and M_t. The script runs in about two minutes.

1. Sort observations by market and product. Compute mc_{jt} from (C.64).
2. Draw the firms' consumer types in one call, an array of shape $100 \times 100 \times 4$ with seed 2026, markets in increasing order. Save it as `figures/appC/data/firm_draws.npz`.
3. In each market, solve (C.70) from $p = mc$, check it with the root finder, and restart from 20 random price vectors (seed 2028).
4. Simulate M_t consumers at the equilibrium prices (seed 2027) and record the counts q_{jt}. Compute population shares with 100,000 draws per market (seed 2029).
5. Write `figures/appC/data/simulated_market.csv`, with one row per product and market. Its columns are the market and product identifiers, owner, characteristics, milk price, market size, price, expected and realized shares and the number of buyers. They also hold the true marginal cost, ξ_{jt}, ω_{jt} and δ_{jt}.

The core of the iteration takes two lines once s_t, Λ_t and Γ_t are computed:

```
s, lam, gam = share_moments(p)          # s_t, diag(Lambda_t), Gamma_t
p_new = mc + (s + (own * gam.T) @ (p - mc)) / lam
```

Here `own` is Ω_t and `lam` holds the diagonal of Λ_t.

C.5 Estimating the vertical model on simulated data

The vertical model of product differentiation lets consumers differ along a single dimension, their sensitivity to price. Every consumer ranks the products by quality in the same way, and products compete only with their neighbours on the price ladder. These restrictions make the model easy to invert and to estimate. They also determine its elasticities and markups almost entirely. This problem is the first of three that estimate demand on the simulated market of Section C.4, which was generated by a random coefficients logit. Here we estimate the vertical model. Since we know the truth, we can see exactly what the single taste dimension does to substitution patterns, markups and recovered costs. The theory behind the model is in Section 6.5. Here we work through estimation in full.

C.5.1 Statement

The data are the 654 product-market observations of the simulated market of Section C.4. There are $T = 100$ independent markets, and market t offers J_t of ten products, between 4 and 9. For each observation the econometrician sees the price p_{jt}, the realized share $s_{jt} = \frac{q_{jt}}{M_t}$ and the market size M_t. The realized share is the $\hat{s}_{jt}$ of (C.71), written without the hat in this problem and the next. The econometrician also sees the characteristics $x_{jt} = (1, x_{jt}^{sug}, x_{jt}^{org})$ (a constant, sugar content and an organic indicator), the price of milk w_{jt} and the owner of the product. Characteristics, milk prices and owners are fixed by product (Table C.14). The outside share $s_{0t} = 1 - \sum_j s_{jt}$ lies between 0.788 and 0.948 across markets. The econometrician does not know how the data were generated and maintains the following assumptions.

Assumption C.19. (i) Markets are independent of one another.

(ii) The characteristics x_{jt} and the cost shifter w_{jt} are fixed (exogenous).

(iii) The demand unobservable ξ_{jt} and the cost unobservable ω_{jt} are independent of each other and of (x_{jt}, w_{jt}).

(iv) Marginal cost is $mc_{jt} = x_{jt}\gamma_1 + \gamma_2 w_{jt} + \omega_{jt}$.

Consumer i in market t obtains utility

$$u_{ijt} = \delta_{jt}^v - \nu_i p_{jt}, \qquad \delta_{jt}^v = x_{jt}\beta^v + \xi_{jt}, \tag{C.78}$$

from product j and $u_{i0t} = 0$ from the outside good, whose quality and price are normalized to zero. Here δ_{jt}^v is the *quality* of product j in market t. The taste $\nu_i \geq 0$ is drawn from a continuous and strictly increasing distribution function F on $[0, \infty)$ with $F(0) = 0$ and density f. There is no idiosyncratic taste shock.

(a) Derive δ_{jt}^v as a function of the prices and shares in market t, the market size M_t and the inverse F^{-1}.

(b) Let $F(\nu) = 1 - e^{-\lambda\nu}$. Write an estimable equation for the qualities. Is λ identified? Give the economic intuition. Normalize $\lambda = 1$, estimate β^v with standard errors and discuss the fit.

(c) Keep $\lambda = 1$. Derive the marginal cost equation under (i) marginal-cost pricing and (ii) multi-product Bertrand-Nash pricing. Estimate (γ_1, γ_2) under each conduct assumption, and explain why demand and supply can be estimated separately without loss of efficiency.

(d) Compute the matrix of own- and cross-price elasticities in market 0, including the outside good.

(e) Explain the size of these elasticities with the price ladder of market 0.

(f) When is the vertical model a good description of demand?

C.5.2 Solution

Remark C.20 (Interpretation of ν_i). A higher ν_i lowers the utility of every product in proportion to its price, so ν_i is a *price sensitivity*, a marginal utility of income. Dividing (C.78) by $\nu_i > 0$

gives the money-metric form $\frac{1}{\nu_i}\delta^v_{jt} - p_{jt}$, which ranks products in the same way. This is the form $u_{ij} = \psi_j \nu_i - p_j$ of Berry (1994, eq. 15, p. 250) and the form $U = vx + Y - P$ of Bresnahan (1987, eq. 1, p. 460). In those papers the random variable multiplies quality, so it is a taste for quality. In our notation the taste for quality is $\frac{1}{\nu_i}$, the willingness to pay for one unit of quality.

Part (a). Fix a market and drop the subscript t. Write (k) for the product with the k-th lowest price, so that $p_{(1)} < p_{(2)} < \cdots < p_{(J)}$, and give the outside good the position (0) with $\delta^v_{(0)} = p_{(0)} = 0$. For $k = 1, \ldots, J$ define the *cutoff*

$$\bar{\nu}_{(k)} = \frac{\delta^v_{(k)} - \delta^v_{(k-1)}}{p_{(k)} - p_{(k-1)}}, \tag{C.79}$$

set $\bar{\nu}_{(J+1)} = 0$, and define the upper-tail cumulative share $\bar{S}_{(k)} = \sum_{l \geq k} s_{(l)}$. Thus $\bar{S}_{(1)} = 1 - s_0$ is the inside share and $\bar{S}_{(J)} = s_{(J)}$.

Proposition C.21 (Inversion of the vertical model)**.** *Suppose that every product has a positive share and that prices are distinct. Then qualities increase with price, the cutoffs satisfy $\bar{\nu}_{(1)} > \bar{\nu}_{(2)} > \cdots > \bar{\nu}_{(J)} > 0$, and*

$$s_{(k)} = F(\bar{\nu}_{(k)}) - F(\bar{\nu}_{(k+1)}), \quad k = 1, \ldots, J, \qquad s_0 = 1 - F(\bar{\nu}_{(1)}). \tag{C.80}$$

The qualities are the unique solution of

$$\delta^v_{(k)} = \sum_{m=1}^{k} \big(p_{(m)} - p_{(m-1)}\big) F^{-1}\big(\bar{S}_{(m)}\big), \qquad \bar{S}_{(m)} = \sum_{l \geq m} \frac{q_{(l)}}{M}. \tag{C.81}$$

Conversely, every vector of positive shares with $\sum_j s_j < 1$ is generated by exactly one quality vector.

The proposition collects three results of Section 6.5, with $\bar{S}_{(k)}$ the cumulative share (6.47) written along the price ladder. A product with a positive share lies on the quality-price frontier, which gives the ordering of qualities and cutoffs (Proposition 6.26). Proposition 6.29 then gives (C.80), and Proposition 6.31 gives (C.81) with existence and uniqueness.

Market size enters only through the shares, which divide sales by M_t, including the consumers who buy nothing. Since markets are independent, the inversion is carried out market by market. Proposition C.21 is the vertical analogue of the inversion of Berry (1994). Berry orders products by quality, writes his cutoffs as $\Delta_j = \frac{p_j - p_{j-1}}{\psi_j - \psi_{j-1}}$ and solves recursively from the top product, with $\Delta_N = F^{-1}(1 - s_N)$ and $\psi_j = \psi_{j-1} + \frac{p_j - p_{j-1}}{\Delta_j}$ (eqs. 17–20, p. 251). His cutoffs are the reciprocals of ours because his random variable is the taste for quality (Remark C.20), and the two recursions produce the same qualities.

Part (b). The exponential distribution has $F^{-1}(u) = -\frac{1}{\lambda}\ln(1-u)$, and $1 - \bar{S}_{(m)t} = s_{0t} + \sum_{l<m} s_{(l)t}$ is the share of consumers who buy the outside good or a product cheaper than (m). Substituting into (C.81) gives

$$\delta^v_{(k)t} = -\frac{1}{\lambda} \sum_{m=1}^{k} \big(p_{(m)t} - p_{(m-1)t}\big) \ln\big(1 - \bar{S}_{(m)t}\big).$$

For the product j that occupies position (k) in market t, define the observable

$$y_{jt} = -\sum_{m=1}^{k} \big(p_{(m)t} - p_{(m-1)t}\big) \ln\big(1 - \bar{S}_{(m)t}\big). \tag{C.82}$$

Multiplying the expression for $\delta^v_{(k)t}$ by λ and substituting $\delta^v_{jt} = x_{jt}\beta^v + \xi_{jt}$ gives the estimable equation

$$y_{jt} = x_{jt}\left(\lambda\beta^v\right) + \lambda\xi_{jt}. \tag{C.83}$$

Proposition C.22 (Scale non-identification)**.** *Under exponential tastes, the shares depend on (λ, β^v, ξ) only through $\lambda\delta^v$. For any $c > 0$ the parameters (λ, β^v, ξ) and $(\frac{\lambda}{c}, c\beta^v, c\xi)$ generate the same shares in every market, so λ is not identified and the data identify at most $\lambda\beta^v$.*

Proof. By (C.80), $s_{(k)} = e^{-\lambda\bar{\nu}_{(k+1)}} - e^{-\lambda\bar{\nu}_{(k)}}$ and $s_0 = e^{-\lambda\bar{\nu}_{(1)}}$. From (C.79),

$$\lambda\bar{\nu}_{(k)} = \frac{\lambda\delta^v_{(k)} - \lambda\delta^v_{(k-1)}}{p_{(k)} - p_{(k-1)}},$$

so every share is a function of prices and of the vector $\lambda\delta^v$. Replacing (λ, δ^v) by $(\frac{\lambda}{c}, c\delta^v)$ leaves $\lambda\delta^v$ unchanged, and $c\delta^v = x(c\beta^v) + c\xi$. □

The economic reason is that choices are invariant to a common rescaling of quality and of price sensitivity. A consumer of type $c\nu$ facing qualities $c\delta^v_j$ compares $c(\delta^v_j - \nu p_j)$ across products and makes the same choice as a consumer of type ν facing δ^v_j. Rescaling the type by c turns the exponential rate λ into $\frac{\lambda}{c}$, because $\mathbb{P}(c\nu \le a) = 1 - e^{-\frac{\lambda}{c}a}$. Choices reveal how much quality consumers buy at each price. They measure quality in units of willingness to pay and cannot measure it in absolute units. The same argument applies to any scale family $F(\nu) = G(\lambda\nu)$. We normalize $\lambda = 1$, which sets the mean price sensitivity $\mathbb{E}[\nu_i] = \frac{1}{\lambda}$ to one. Berry (1994, p. 251) makes the same normalization when he assumes that his taste for quality has mean one. The estimated coefficients are then $\lambda\beta^v$.

With $\lambda = 1$, β^v is identified by the moment condition $\mathbb{E}[x_{jt}^\top \xi_{jt}] = 0$, which follows from Assumption C.19(ii) and (iii), together with full rank of $\mathbb{E}[x_{jt}^\top x_{jt}]$. Then $\beta^v = \mathbb{E}[x_{jt}^\top x_{jt}]^{-1}\mathbb{E}[x_{jt}^\top y_{jt}]$, and OLS of y_{jt} on x_{jt} is consistent. Price is not a regressor. It enters only the construction of y_{jt}, and the inversion is exact, so the correlation between price and ξ_{jt} that pricing creates does not bias the regression. The distribution F plays the role that the price coefficient plays in the logit, and with λ normalized nothing in it is left to estimate. The only error in y_{jt} beyond ξ_{jt} comes from sampling error in the realized shares (Section C.4).

We cluster standard errors by market. With X_t and $\hat{e}_t$ the regressors and residuals of market t, G markets, N observations and K regressors, the variance estimate is

$$\hat{V} = c\,(X^\top X)^{-1}\Big(\sum_{t=1}^{G} X_t^\top \hat{e}_t \hat{e}_t^\top X_t\Big)(X^\top X)^{-1}, \qquad c = \frac{G}{G-1}\,\frac{N-1}{N-K}, \tag{C.84}$$

with $G = 100$, $N = 654$ and $K = 3$. Clustering is needed because the constructed qualities in a market are mechanically dependent. By (C.82), $y_{(k)t} = y_{(k-1)t} - (p_{(k)t} - p_{(k-1)t})\ln(1 - \bar{S}_{(k)t})$, so sampling error in one realized share propagates to the qualities of every more expensive product in the market. Table C.17 reports the estimates.

Quality rises with sugar content and with the organic indicator, the signs of the true taste coefficients. The magnitudes are in units of mean willingness to pay and cannot be compared with utility coefficients. The second column confirms Proposition C.22. With $\lambda = 2$ every coefficient and standard error is halved, while the R^2 is unchanged. Part (c) shows that every implied marginal cost is unchanged as well.

Table C.17: Vertical model, demand side: OLS of y_{jt} on x_{jt}

	$\lambda = 1$	$\lambda = 2$
Constant	0.1280	0.0640
	(0.0058)	(0.0029)
Sugar content	0.0124	0.0062
	(0.0047)	(0.0024)
Organic	0.0077	0.0039
	(0.0022)	(0.0011)
R^2	0.015	0.015
Observations	654	654

Notes: Standard errors clustered by market (100 clusters) in parentheses. The coefficients estimate $\lambda\beta^v$ divided by λ, so the column for $\lambda = 2$ is the first column halved. Computed with `figures/appC/src/appC_vertical_logit.py`.

The fit is poor, with $R^2 = 0.015$, and the vertical structure explains why. Every cutoff satisfies $\bar{v}_{(k)t} = -\ln(1 - \bar{S}_{(k)t}) \leq -\ln s_{0t}$, and the largest cutoff in the data is $-\ln(0.788) = 0.238$. The quality of the cheapest product is $p_{(1)t}\bar{v}_{(1)t}$, and each later increment $(p_{(m)t} - p_{(m-1)t})\bar{v}_{(m)t}$ is a price gap times a small number. The recovered qualities are therefore nearly equal within a market. Their within-market range averages 0.017, while y_{jt} has mean 0.144 and standard deviation 0.042 across all observations. Most of the variation in y_{jt} is across markets, through the inside share and the price of the cheapest product. Product characteristics, which are fixed by product, cannot explain it. Table C.18 shows the inversion step by step for market 0, where qualities run only from 0.148 to 0.173.

Table C.18: The vertical model in market 0, products ordered by price

Rank	Product	$p_{(k)}$	Gap $p_{(k)} - p_{(k-1)}$	$s_{(k)}$	$\bar{S}_{(k)}$	$\bar{v}_{(k)}$	$y_{(k)}$	$\varepsilon_{(k)(k)}$	Nash markup	Gap bound	True markup
1	10	0.9429	0.9429	0.0201	0.1451	0.1568	0.1479	−103.7	0.0091	0.0097	0.3845
2	6	0.9993	0.0564	0.0203	0.1250	0.1335	0.1554	−358.4	0.0028	0.0039	0.3755
3	3	1.0182	0.0189	0.0252	0.1047	0.1105	0.1575	−240.0	0.0042	0.0048	0.3874
4	8	1.1246	0.1064	0.0560	0.0795	0.0828	0.1663	−16.8	0.0670	0.0781	0.3955
5	2	1.3200	0.1953	0.0052	0.0235	0.0238	0.1709	−77.0	0.0172	0.0283	0.3995
6	4	1.4196	0.0997	0.0126	0.0183	0.0185	0.1728	−42.2	0.0336	0.0657	0.3910
7	9	1.4497	0.0301	0.0058	0.0058	0.0058	0.1730	−48.0	0.0302	0.0302	0.3768

Notes: $\lambda = 1$. The outside share is $s_0 = 0.8549$, so $\bar{S}_{(1)} = 0.1451$ and $\bar{v}_{(1)} = -\ln(0.8549)$. The quality is $y_{(k)} = y_{(k-1)} + (p_{(k)} - p_{(k-1)})\bar{v}_{(k)}$. The own elasticity $\varepsilon_{(k)(k)}$ is from part (d), the Nash markup from part (c), and the gap bound is the right side of (C.89). True markups are those of the simulated equilibrium (Table C.16). Computed with `figures/appC/src/appC_vertical_logit.py`.

Part (c). (i) Under marginal-cost pricing, $p_{jt} = mc_{jt}$, and the supply equation is

$$p_{jt} = x_{jt}\gamma_1 + \gamma_2 w_{jt} + \omega_{jt}. \tag{C.85}$$

(ii) Under multi-product Bertrand-Nash pricing, market size scales profit and drops out of the first-order conditions, which stack as in (C.56) of Section C.3, market by market as in (C.68). Here Δ_t holds the share derivatives $\frac{\partial s_{jt}}{\partial p_{kt}}$ of the vertical model and Ω_t is the ownership matrix of market t. Solving the stacked conditions for marginal cost gives

$$s_t + (\Omega_t \odot \Delta_t^\top)(p_t - mc_t) = 0 \quad \Longrightarrow \quad p_{jt} + \left[(\Omega_t \odot \Delta_t^\top)^{-1} s_t\right]_j = x_{jt}\gamma_1 + \gamma_2 w_{jt} + \omega_{jt}. \tag{C.86}$$

The left side is the implied marginal cost. To compute it we need the share derivatives of the vertical model. For $k = 1, \dots, J$ define

$$g_{(k)} = \frac{f(\bar{v}_{(k)})\,\bar{v}_{(k)}}{p_{(k)} - p_{(k-1)}} > 0, \qquad g_{(J+1)} = 0. \tag{C.87}$$

Proposition C.23 (Tridiagonal Jacobian)**.** *Holding qualities fixed, the share derivatives of the vertical model are*

$$\frac{\partial s_{(k)}}{\partial p_{(k)}} = -g_{(k)} - g_{(k+1)}, \qquad \frac{\partial s_{(k-1)}}{\partial p_{(k)}} = g_{(k)}, \qquad \frac{\partial s_{(k+1)}}{\partial p_{(k)}} = g_{(k+1)},$$

where position (0) *is the outside good, and every other derivative is zero. The inside Jacobian is tridiagonal and symmetric along the price ladder, the outside good responds only to* $p_{(1)}$*, and each column of the Jacobian, including the outside good, sums to zero.*

This is Proposition 6.35 written along the price ladder, with $g_{(k)}$ the number g_j of (6.54). The symmetry has a simple reading. Both cross derivatives measure the density of consumers at the shared cutoff $\bar{v}_{(k)}$, scaled by the price gap that defines it.

Corollary C.24 (Markups without parameters)**.** *With exponential tastes, for every* λ*,*

$$g_{(k)} = \frac{(1 - \bar{S}_{(k)})\left[-\ln(1 - \bar{S}_{(k)})\right]}{p_{(k)} - p_{(k-1)}}.$$

The Jacobian Δ_t*, the Nash markups and the implied marginal costs are functions of observed prices and shares only, and they do not depend on* λ*.*

Proof. From part (b), $\bar{v}_{(k)} = -\frac{1}{\lambda}\ln(1 - \bar{S}_{(k)})$ and $f(\bar{v}_{(k)}) = \lambda e^{-\lambda \bar{v}_{(k)}} = \lambda(1 - \bar{S}_{(k)})$. Their product is $(1 - \bar{S}_{(k)})\left[-\ln(1 - \bar{S}_{(k)})\right]$, in which λ cancels. □

The invariance to λ is a consistency check, since an unidentified parameter must not affect predictions that the data pin down. The script confirms that the implied marginal costs with $\lambda = 2$ equal those with $\lambda = 1$ exactly. It also checks every analytic derivative of Proposition C.23 against a complex-step derivative of the share function, $\frac{\Im s(p + \mathrm{i}he_k)}{h}$ with $h = 10^{-20}$. The largest discrepancy across all markets is 3.1×10^{-11}, relative to derivatives as large as 216.

The two sides can be estimated separately without loss of efficiency. No demand parameter enters the implied marginal costs (Corollary C.24), and no cost parameter enters the demand equation. The demand block (C.83) has three moments for three parameters, and the supply block has four moments for four parameters. A GMM estimator that stacks the two blocks sets every moment to zero, whatever its weighting matrix, so it reproduces the two OLS estimates exactly. The independence of ξ_{jt} and ω_{jt} is not even needed for this argument.

In both conduct cases (γ_1, γ_2) is identified by $\mathbb{E}[\omega_{jt} \mid x_{jt}, w_{jt}] = 0$ (Assumption C.19(iii)) and full rank of (x_{jt}, w_{jt}). The milk price takes ten values that are not a linear function of the constant, sugar content and the organic indicator. Economically, once the markup is removed, price differences across products with different characteristics reveal cost differences, and the conduct assumption tells us how large the markup is. With λ fixed the dependent variables contain no estimated parameter, so clustered OLS standard errors need no correction for a generated regressand. With single-product firms the Nash version reduces to the vertical supply equation of Berry (1994, eq. 32, p. 255). Berry notes that OLS of price minus markup on the cost shifters then suffices. Further instruments are needed only when the density f depends on unknown parameters. Table C.19 reports the estimates.

Table C.19: Vertical model, supply side: OLS of marginal cost on (x_{jt}, w_{jt})

	Marginal-cost pricing	Multi-product Nash	True
Constant	0.550 (0.016)	0.674 (0.024)	0.20
Sugar content	0.260 (0.010)	0.194 (0.014)	0.25
Organic	0.309 (0.005)	0.271 (0.009)	0.30
Price of milk	0.543 (0.022)	0.356 (0.031)	0.50
Mean implied markup	0	0.048	0.386
R^2	0.922	0.790	
Observations	654	654	

Notes: Standard errors clustered by market in parentheses. Under marginal-cost pricing the dependent variable is p_{jt}. Under Nash pricing it is the implied marginal cost $p_{jt} + [(\Omega_t \odot \Delta_t^\top)^{-1} s_t]_j$ with $\lambda = 1$. The true markup is the mean of $p_{jt} - mc_{jt}$ in the simulated equilibrium. Computed with `figures/appC/src/appC_vertical_logit.py`.

A useful identity organizes the results. Write m_{jt}^{true} for the true markup and m_{jt}^{model} for the markup that a conduct assumption implies. The implied marginal cost is $mc_{jt} + m_{jt}^{\text{true}} - m_{jt}^{\text{model}}$, so the OLS estimate decomposes as

$$\hat{\gamma} - \gamma = (W^\top W)^{-1} W^\top \omega + (W^\top W)^{-1} W^\top \left(m^{\text{true}} - m^{\text{model}} \right), \tag{C.88}$$

where W stacks (x_{jt}, w_{jt}) and $\hat{\gamma} = (\hat{\gamma}_1, \hat{\gamma}_2)$. The first term is sampling error. In these data it is below 0.005 for every coefficient. The second term is the misspecification of the markup.

Under marginal-cost pricing $m^{\text{model}} = 0$, and the second term projects the true markups on the cost shifters. The true markups are nearly constant across products, from 0.348 to 0.451. Their projection loads 0.350 on the constant and only 0.013, 0.005 and 0.042 on sugar, organic and milk. The intercept therefore absorbs the mean markup, and the slopes stay close to the truth.

Under Nash pricing the vertical model implies a mean markup of only 0.048 and a median of 0.020, against a true mean of 0.386. The markups range from 4.3×10^{-5} to 0.515. The markup error loads 0.474 on the constant and -0.145 on the milk price, so the milk coefficient falls to 0.356. None of the implied marginal costs is negative. The implied markups have correlation 0.27 with the true markups. The implied marginal costs have correlation 0.920 with the true costs, which is lower than the correlation of 0.997 between price itself and true cost. Subtracting the vertical markups therefore makes price a worse proxy for cost. The small markups follow from the structure of the model, as the next result shows.

Proposition C.25 (Markups are bounded by price gaps)**.** *Consider a single-product firm selling (k). Its Nash markup is $m_{(k)} = \frac{s_{(k)}}{g_{(k)} + g_{(k+1)}}$, and*

$$m_{(k)} \leq \frac{s_{(k)}}{\max\{g_{(k)}, g_{(k+1)}\}}. \tag{C.89}$$

With exponential tastes, $m_{(k)} \leq \frac{p_{(k)} - p_{(k-1)}}{1 - \bar{s}_{(k)}}$. For $k < J$, also $m_{(k)} \leq (p_{(k+1)} - p_{(k)}) \frac{s_{(k)}}{(1 - \bar{s}_{(k+1)})\left[-\ln(1 - \bar{s}_{(k+1)})\right]}$.

Proof. With one product, (C.86) reduces to $s_{(k)} + m_{(k)} \frac{\partial s_{(k)}}{\partial p_{(k)}} = 0$. By Proposition C.23, $m_{(k)} = \frac{s_{(k)}}{g_{(k)} + g_{(k+1)}}$. Both g terms are nonnegative, so the denominator is at least the larger of them, which

gives (C.89). For the first exponential bound, use $m_{(k)} \le \frac{s_{(k)}}{g_{(k)}}$ and Corollary C.24,

$$m_{(k)} \le \frac{s_{(k)}\big(p_{(k)} - p_{(k-1)}\big)}{(1-\bar{S}_{(k)})\left[-\ln(1-\bar{S}_{(k)})\right]} \le \frac{s_{(k)}\big(p_{(k)} - p_{(k-1)}\big)}{(1-\bar{S}_{(k)})\,\bar{S}_{(k)}} \le \frac{p_{(k)} - p_{(k-1)}}{1-\bar{S}_{(k)}}.$$

The second inequality uses $-\ln(1-u) \ge u$ for $u \in [0,1)$, and the third uses $s_{(k)} \le \bar{S}_{(k)}$. The second exponential bound is $m_{(k)} \le \frac{s_{(k)}}{g_{(k+1)}}$ written out with Corollary C.24. □

In words, a product with a close neighbour on the price ladder cannot carry a markup much larger than the gap to that neighbour. In the data the median gap between adjacent prices is 0.057, 58 of the 554 adjacent gaps are below 0.01, and 8 are below 0.001. The smallest is 0.0004. The markups the model infers are correspondingly small.

Ownership matters in the vertical model only through price neighbours. Because Δ_t is tridiagonal along the ladder, $\Omega_t \odot \Delta_t^{\top}$ is diagonal unless two adjacent products share an owner. A firm internalizes cannibalization only between its own neighbouring products. In the data 125 of the 554 adjacent pairs share an owner, and 83 of the 100 markets contain at least one such pair. For 64 percent of the observations the Nash markup equals the single-product markup. Market 0 contains no adjacent pair with a common owner, so there every Nash markup equals the single-product markup and satisfies (C.89). Table C.18 shows how tight the bound is.

Part (d). The elasticity of the share of product j with respect to the price of product k is $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, and for the outside good $\varepsilon_{0k} = \frac{\partial s_0}{\partial p_k}\frac{p_k}{s_0}$. Own elasticities are negative in this convention, so the positive own elasticity used elsewhere in the book is $-\varepsilon_{jj}$. By Proposition C.23, for an inside product in position (k),

$$\varepsilon_{(k)(k)} = -\frac{p_{(k)}\big(g_{(k)} + g_{(k+1)}\big)}{s_{(k)}}, \qquad \varepsilon_{(k)(k-1)} = \frac{p_{(k-1)}\,g_{(k)}}{s_{(k)}}, \qquad \varepsilon_{(k)(k+1)} = \frac{p_{(k+1)}\,g_{(k+1)}}{s_{(k)}}, \tag{C.90}$$

where the middle formula applies for $k \ge 2$ and the last for $k < J$. The outside good responds only to the cheapest price, with $\varepsilon_{0(1)} = \frac{p_{(1)}\,g_{(1)}}{s_0}$. All other entries are zero. Table C.20 reports the matrix for market 0 at the observed prices and realized shares. With $\lambda = 1$ it requires no estimated parameter.

Table C.20: Vertical model: price elasticities in market 0

	Price of product						
Share of	2	3	4	6	8	9	10
Product 2	−76.95	0.00	50.09	0.00	25.88	0.00	0.00
Product 3	0.00	−240.00	0.00	207.13	31.96	0.00	0.00
Product 4	19.16	0.00	−42.21	0.00	0.00	22.07	0.00
Product 6	0.00	261.46	0.00	−358.41	0.00	0.00	96.07
Product 8	2.80	13.03	0.00	0.00	−16.78	0.00	0.00
Product 9	0.00	0.00	47.01	0.00	0.00	−48.00	0.00
Product 10	0.00	0.00	0.00	102.83	0.00	0.00	−103.69
Outside good	0.00	0.00	0.00	0.00	0.00	0.00	0.16

Notes: Entry (j,k) is $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, evaluated at observed prices and realized shares with $\lambda = 1$. The price ladder from cheapest to most expensive is 10, 6, 3, 8, 2, 4, 9. Computed with `figures/appC/src/appC_vertical_logit.py`.

Each row has at most two nonzero cross elasticities, one for each neighbour on the ladder. The outside good responds only to the price of the cheapest product, 10, with elasticity 0.157. The own elasticities range from −16.8 to −358.4. In the true random coefficients model they range from −2.57 to −3.85 (Section C.7). Across all 654 observations the vertical own elasticity has mean −433 and median −108. It is never smaller in magnitude than 3.6 and reaches −23,075 for a product whose neighbour sells at almost the same price.

Part (e). Figure C.6 places the products of market 0 on their price ladder. By (C.90), the own elasticity of (k) is proportional to $g_{(k)} + g_{(k+1)}$, and each g is inversely proportional to a price gap. A product squeezed between two close neighbours therefore has an enormous elasticity. Product 6 sits 0.056 above product 10 and 0.019 below product 3. Its own elasticity is −358.4, and product 3 follows with −240.0. Product 8 has gaps of 0.106 and 0.195 to its neighbours and the largest share in the market. Its own elasticity, −16.8, is the smallest in magnitude. When two products have nearly the same price, the only consumers who separate them are those whose price sensitivity lies near the cutoff between them. A small price change moves all of those consumers, so the two products are close to perfect substitutes. In the true model consumers differ in four dimensions plus an idiosyncratic shock, and substitution is spread across all products and the outside good.

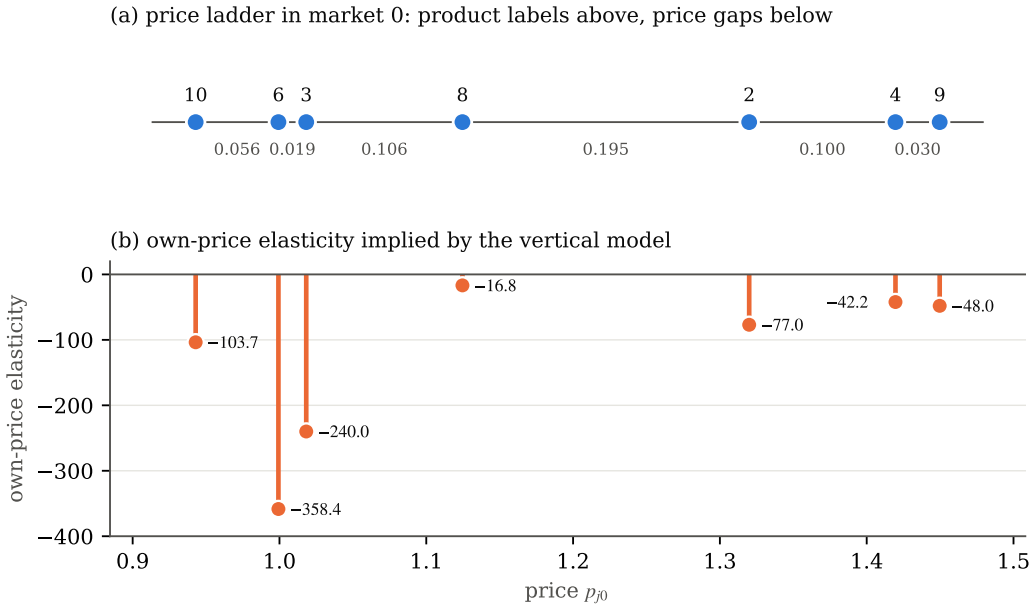

Figure C.6: The price ladder in market 0. Panel (a) shows the seven prices with the gaps between neighbours. Panel (b) shows the own-price elasticity ε_{jj} that the vertical model implies for each product. The products with the closest neighbours, 6 and 3, have the largest elasticities.

The ladder also governs substitution to the outside good. In the vertical model only the cheapest product loses customers to the outside good when its price rises. The diversion ratio from product k to the outside good is

$$D_{k0} = -\frac{\partial s_0}{\partial p_k}\left(\frac{\partial s_k}{\partial p_k}\right)^{-1},$$

the fraction of the sales that k loses which go to the outside good. For product 10 it is 0.064. Every other product diverts nothing to the outside good. The logit of Section C.6 puts these

diversion ratios between 0.86 and 0.91, much closer to the true model, in which most consumers who leave a product stop buying yogurt (Section C.7).

Part (f). The vertical model is appropriate when products differ mainly along one quality dimension that all consumers value in the same direction. Consumers should differ mainly in income or in their marginal utility of money. Then the price ladder is a quality ladder, and neighbours on it are the natural substitutes. Bresnahan (1987) uses this structure for the 1955 automobile price war. His consumers have utility $U = vx + Y - P$ from a car of quality x and price P, with v uniform on $[0, V_{\max}]$ with density d (eq. 1, p. 460, and p. 461). Bresnahan writes δ for this density. The demand for a car between neighbours h and j is linear in prices,

$$q_i = d\left[\frac{P_j - P_i}{x_j - x_i} - \frac{P_i - P_h}{x_i - x_h}\right]$$

(eq. 5, p. 462). He notes that the quality difference $x_i - x_h$ measures how close two products are as substitutes, and that they become perfect substitutes as x_i approaches x_h (p. 462). The same feature produces the large elasticities of Table C.20. Bresnahan also shows that demand in this model is continuous and concave across the point where a neighbour is priced out, so a price equilibrium always exists (footnote 6, p. 462). Because only neighbours compete, collusive and Nash pricing imply very different markups, which gives his conduct test its power (Section 6.6). The fact to explain is that 1955 production was 45 percent above that of the two surrounding years, while quality-adjusted prices were lower (p. 457). In nonnested Cox tests the collusive solution is sustained in 1954 and 1956, and the competitive (Nash) solution in 1955 (abstract, p. 457).

Our simulated market violates the premises. Tastes vary along four dimensions, the products crowd into a narrow price range, and the outside good takes more than three quarters of every market. The vertical model can explain why consumers split across products with similar prices only by placing those products almost on top of one another in quality. It then reads every small price gap as intense competition. Its elasticities are wrong by one to two orders of magnitude, its markups are close to zero, and its implied costs absorb the error. The data offer two warning signs even without knowledge of the truth. Qualities explain almost none of their own variation ($R^2 = 0.015$), and the implied Nash markups are far below what any plausible cost information would allow. A model with an idiosyncratic shock, such as the logit of Section C.6, avoids the zero cross elasticities by construction.

C.5.3 Computational notes

The computations take a few seconds in total.

1. In each market, sort products by price and form $\bar{S}_{(k)t}$ as reversed cumulative sums of the sorted realized shares.
2. Compute y_{jt} by (C.82) with `log1p` for $\ln(1 - \bar{S})$, and run OLS of y on x with the clustered variance (C.84).
3. Compute $g_{(k)t}$ from Corollary C.24, fill the tridiagonal Δ_t, form Ω_t from the owners and solve $(\Omega_t \odot \Delta_t^{\top})\, a = s_t$ for the markups $-a$.
4. Check the derivatives with a complex step, and check that the shares implied by the recovered qualities reproduce the data (largest error 1.9×10^{-14}).

The inversion takes a few lines of code.

```
def vertical_delta(p, s, lam):
    order = np.argsort(p)                          # price ladder
    tail = np.cumsum(s[order][::-1])[::-1]         # bar S_(k)
    steps = np.diff(p[order], prepend=0.0)         # p_(k) - p_(k-1)
    delta = np.empty_like(p)
    delta[order] = np.cumsum(steps * -np.log1p(-tail) / lam)
    return delta
```

C.6 Estimating logit demand and recovering costs

The logit model becomes a linear regression once shares are inverted, so all the tools of linear instrumental variables apply. In this problem we estimate it on the simulated market, study the strength of the usual instruments, recover marginal costs with correct standard errors, and estimate demand and supply jointly. Since the data come from a random coefficients model, the logit is misspecified. We close by deriving the bias that omitted taste heterogeneity creates in the logit price coefficient and by measuring it exactly. The general theory of logit estimation is in Chapter 7.

C.6.1 Statement

Use the data and Assumption C.19 of Section C.5. Demand is now logit:

$$u_{ijt} = \delta^l_{jt} + \epsilon_{ijt}, \qquad \delta^l_{jt} = x_{jt}\beta^l - \alpha^l p_{jt} + \xi_{jt}, \tag{C.91}$$

with ϵ_{ijt} independent type-I extreme value and $u_{i0t} = \epsilon_{i0t}$. Firms set prices in a multi-product Bertrand-Nash equilibrium.

(a) Estimate (β^l, α^l). Give the identification argument, justify the instruments, assess their strength and report standard errors.

(b) Compute the elasticity matrix for market 0 and discuss it.

(c) Derive the marginal cost equation under the assumed conduct, compute mc_{jt} and estimate (γ_1, γ_2) with standard errors that account for the estimation of α^l.

(d) Explain how to estimate demand and supply jointly, and when joint estimation matters. Carry it out.

(e) The true model has a random coefficient on price. Show why the logit price coefficient is then biased toward zero even with valid instruments, and measure the bias.

C.6.2 Solution

Part (a). With logit demand the inside and outside shares are

$$s_{jt} = \frac{e^{\delta^l_{jt}}}{1 + \sum_k e^{\delta^l_{kt}}}, \qquad s_{0t} = \frac{1}{1 + \sum_k e^{\delta^l_{kt}}}.$$

Dividing the first by the second gives $\frac{s_{jt}}{s_{0t}} = e^{\delta^l_{jt}}$, and taking logs gives the inversion of Berry (1994, eq. 14, p. 250),

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta^l - \alpha^l p_{jt} + \xi_{jt}. \tag{C.92}$$

The left side is computed from realized shares, with $s_{0t} = 1 - \sum_j s_{jt}$. Equation (C.92) is linear in the parameters, with the unobserved quality ξ_{jt} as its error (Equation (7.16)).

Price is endogenous. Firms observe ξ_{jt} when they set prices. A product with higher unobserved quality has a larger share, and logit markups rise with the firm's share (part (c)), so $\mathrm{Cov}(p_{jt}, \xi_{jt}) > 0$. Let $\tilde{p}_{jt}$ be the residual from projecting price on x_{jt}. The OLS estimate of the price coefficient then converges to $-\alpha^l + \frac{\mathrm{Cov}(\tilde{p}_{jt}, \xi_{jt})}{\mathrm{Var}(\tilde{p}_{jt})}$, so OLS biases α^l toward zero (Proposition 7.14). We need excluded instruments that move price and are uncorrelated with ξ_{jt}.

We use seven excluded instruments.

1. The price of milk w_{jt}. It shifts marginal cost and therefore price, it is excluded from utility, and it is independent of ξ_{jt} by Assumption C.19(iii).

2. Characteristics of the other products in the market. For each characteristic k of product j owned by firm f, Berry et al. (1995, eq. 5.8, p. 861) use the sums $\sum_{r \neq j, r \in \mathcal{J}_f} x_{rk}$ and $\sum_{r \notin \mathcal{J}_f} x_{rk}$. We form these sums for sugar content and the organic indicator. Because one characteristic is the constant, the numbers of the firm's other products and of rival products, n_{jt}^{own} and n_{jt}^{riv}, are instruments too. This gives six instruments.

Berry (1994, p. 249) explains why the second group is valid. Rival characteristics are excluded from u_{ijt}, and they are correlated with prices through the markups in the first-order conditions. Their validity requires that characteristics and the set of products offered in each market be independent of ξ_{jt}, which we add to Assumption C.19. In this design characteristics are fixed by product, so the six instruments vary only through which products a market offers and who owns them. The number of the firm's other products runs from 0 to 3 (mean 1.37), and the number of rival products from 1 to 8 (mean 4.55).

The parameters $\theta^l = (\beta^l, \alpha^l)$ are identified by the moment conditions

$$\mathbb{E}\big[z_{jt}^\top \xi_{jt}\big] = 0, \qquad z_{jt} = \big(x_{jt}, w_{jt}, \text{six competition instruments}\big), \tag{C.93}$$

together with the rank condition that $\mathbb{E}[z_{jt}^\top (x_{jt}, p_{jt})]$ has full column rank four. Economically, variation in price that comes from costs and from competition, and is unrelated to unobserved quality, traces out how shares respond to price. We estimate by *two-stage least squares* (2SLS). With Y the stacked left side of (C.92), $X = (x, p)$ and Z the instrument matrix, the estimator is

$$\hat{\theta}^l_{2SLS} = (\hat{X}^\top \hat{X})^{-1} \hat{X}^\top Y, \qquad \hat{X} = Z(Z^\top Z)^{-1} Z^\top X.$$

Its clustered variance is (C.84) with X_t replaced by $\hat{X}_t$. The residuals in the middle factor are the 2SLS residuals $\hat{e}_t = Y_t - X_t \hat{\theta}^l$, computed with the actual regressors (Appendix A).

Table C.21 reports the first stage. Instrument strength comes almost entirely from the milk price, whose coefficient is 0.497 with standard error 0.026, close to the true cost coefficient of 0.5. The cluster-robust Wald statistic for the seven excluded instruments, divided by seven, is 92.5. With one endogenous regressor this is the cluster-robust first-stage F statistic of Kleibergen and Paap (2006). The homoskedastic F is 74.1 and the partial R^2 is 0.446. The milk price alone gives $F = 591.4$. The six competition instruments are jointly weak, with $F = 2.32$ and $p = 0.039$ given the milk price.

The competition instruments are weak for two reasons. First, logit markups barely respond to competition in this market. The markup of firm f is $\frac{1}{\alpha^l (1 - s_{ft})}$ (part (c)), and the largest combined share of a firm is only 0.112, so the implied markups run from 0.379 to 0.426. Changes

Table C.21: First stage: OLS of p_{jt} on the exogenous variables

	Coefficient	Standard error
Constant	0.5778	(0.0188)
Sugar content	0.2575	(0.0113)
Organic	0.3138	(0.0064)
Price of milk w_{jt}	0.4972	(0.0256)
Sugar, firm's other products	0.0023	(0.0106)
Sugar, rival products	−0.0042	(0.0077)
Organic, firm's other products	−0.0015	(0.0068)
Organic, rival products	−0.0009	(0.0040)
Number of firm's other products	0.0038	(0.0116)
Number of rival products	0.0020	(0.0084)
R^2	0.923	
F, seven excluded instruments (cluster-robust)	92.5	
F, seven excluded instruments (homoskedastic)	74.1	
F, six competition instruments (cluster-robust)	2.32	
F, milk price only (cluster-robust)	591.4	

Notes: 654 observations. Standard errors clustered by market. The milk-price-only statistic comes from the regression of price on (x_{jt}, w_{jt}). Computed with `figures/appC/src/appC_vertical_logit.py`.

in the set of competitors cannot move prices much. Second, the instruments are nearly collinear. Sugar content varies only from 0.64 to 1.35, so each sum of sugar is close to a multiple of the corresponding count. The correlations are 0.978 for the firm's own products and 0.988 for rivals. The variance inflation factors of the two sugar sums and the two counts are 40.1, 57.8, 36.1 and 52.2. A variance inflation factor is $\frac{1}{1-R_k^2}$, the factor by which collinearity with the other regressors inflates the variance of coefficient k. Berry et al. (1995, p. 861) report the same problem, finding the matrix of these linear terms "nearly not of full rank."

Table C.22 reports the estimates. As expected, OLS gives a smaller price coefficient, 2.330, than 2SLS, 2.641. Hansen's test of the six overidentifying restrictions (Hansen, 1982) uses the two-step GMM estimator with a market-clustered weighting matrix. It does not reject, with $J = 8.82$ and $p = 0.18$. The two-step GMM estimate of the price coefficient is 2.872. With the milk price as the only excluded instrument, 2SLS gives 2.677 (0.415), so the competition instruments change little.

Consistency of 2SLS here rests on one more condition. Characteristics and milk prices are fixed by product, so the identifying variation in w_{jt} comes from its ten values across products. If ξ_{jt} contained a persistent product component, it could correlate with the product-level instruments. An F test of product dummies on the 2SLS residuals, beyond the product-level regressors, gives $F(6, 644) = 1.18$ with $p = 0.32$. With only ten products the test has little power, so it cannot rule such a component out. In this design the unobservables are drawn independently across markets, so the condition holds by construction.

The 2SLS price coefficient, 2.641, lies below the true mean of 3, but only 0.87 standard errors below. The characteristic coefficients are close to the truth and imprecise, because sugar and organic status take only ten distinct combinations. Part (e) shows that the shortfall in $\hat{\alpha}^l$ is a systematic bias of the logit and is unrelated to sampling error.

Part (b). The logit share derivatives of Section C.3, part (a), hold with α^l in place of α

Table C.22: Logit demand estimates

	OLS	2SLS	2SLS, milk price only	True
Constant	−1.443	−1.184	−1.154	−1.00
	(0.226)	(0.329)	(0.334)	
Sugar content	0.119	0.190	0.198	0.20
	(0.122)	(0.158)	(0.156)	
Organic	0.051	0.153	0.165	0.15
	(0.097)	(0.141)	(0.142)	
Price coefficient α^l	2.330	2.641	2.677	3.00
	(0.252)	(0.412)	(0.415)	
First-stage F (cluster-robust)		92.5	591.4	
Hansen J (p-value)		8.82 (0.18)		
R^2	0.396	0.395	0.395	
Observations	654	654	654	

Notes: Dependent variable $\ln s_{jt} - \ln s_{0t}$. Standard errors clustered by market in parentheses. The table reports α^l, minus the coefficient on price. The true values are the mean parameters of the random coefficients model of Section C.4. Computed with `figures/appC/src/appC_vertical_logit.py`.

(Proposition 7.6). They give the elasticities (C.43) together with the outside-good row,

$$\varepsilon_{jj} = -\alpha^l p_j (1 - s_j), \qquad \varepsilon_{jk} = \alpha^l p_k s_k \quad (k \neq j), \qquad \varepsilon_{0k} = \alpha^l p_k s_k. \tag{C.94}$$

Table C.23 evaluates them at $\hat{\alpha}^l = 2.641$ and the observed prices and realized shares of market 0.

Table C.23: Logit model: price elasticities in market 0

	Price of product						
Share of	2	3	4	6	8	9	10
Product 2	−3.47	0.07	0.05	0.05	0.17	0.02	0.05
Product 3	0.02	−2.62	0.05	0.05	0.17	0.02	0.05
Product 4	0.02	0.07	−3.70	0.05	0.17	0.02	0.05
Product 6	0.02	0.07	0.05	−2.59	0.17	0.02	0.05
Product 8	0.02	0.07	0.05	0.05	−2.80	0.02	0.05
Product 9	0.02	0.07	0.05	0.05	0.17	−3.81	0.05
Product 10	0.02	0.07	0.05	0.05	0.17	0.02	−2.44
Outside good	0.02	0.07	0.05	0.05	0.17	0.02	0.05

Notes: Entry (j, k) is ε_{jk} from (C.94) with $\hat{\alpha}^l = 2.641$ (2SLS), evaluated at observed prices and realized shares. Computed with `figures/appC/src/appC_vertical_logit.py`.

The own elasticities run from −2.44 to −3.81, so every product faces elastic demand. Across all 654 observations they lie between −2.21 and −4.24, with mean −3.06. They are close to the true values, −2.57 to −3.85 in market 0, but slightly smaller in magnitude, because $\hat{\alpha}^l$ is below 3. Since shares are small, $\varepsilon_{jj} \approx -\alpha^l p_j$, so the model makes the most expensive products the most elastic by construction. Products 9 and 4, the two most expensive, have the largest own elasticities.

Every off-diagonal entry in a column is the same, and it equals the outside-good entry. This is the independence of irrelevant alternatives. A rise in p_k raises the shares of all other products

and of the outside good in the same proportion, whatever their characteristics. Diversion from product k to the outside good is $D_{k0} = \frac{\alpha^l s_0 s_k}{\alpha^l s_k(1-s_k)} = \frac{s_0}{1-s_k}$, between 0.86 and 0.91 in market 0. In the true model a price rise for an organic product diverts more customers to the other organic products and to expensive products (Section C.7). The logit cannot produce this pattern.

Part (c). With logit demand the first-order conditions (C.86) reduce to the common-markup rule of Proposition C.12, derived in Section C.3, part (e) (see also Proposition 7.17). Every product of firm f in market t carries the markup $m_{ft} = \frac{1}{\alpha^l(1-S_{ft})}$, where $S_{ft} = \sum_{k\in\mathcal{J}_{ft}} s_{kt}$ is the firm's combined share. The marginal cost equation is

$$mc_{jt} = p_{jt} - \frac{1}{\alpha^l(1-S_{ft})} = x_{jt}\gamma_1 + \gamma_2 w_{jt} + \omega_{jt}. \tag{C.95}$$

This is (C.86) with the logit Jacobian. The script confirms that the closed form and the matrix formula agree to 2.2×10^{-16}. We compute mc_{jt} with $\hat\alpha^l = 2.641$ and the realized shares. The implied markups run from 0.379 to 0.426 with mean 0.396, against a true mean of 0.386. Their correlation with the true markups is 0.55, against 0.27 for the vertical Nash markups. No implied marginal cost is negative. Identification of (γ_1, γ_2) follows as in Section C.5, from $\mathbb{E}[\omega_{jt} \mid x_{jt}, w_{jt}] = 0$ and full rank. We estimate it by OLS of mc_{jt} on (x_{jt}, w_{jt}).

The dependent variable now contains the estimate $\hat\alpha^l$. Clustered OLS standard errors treat mc_{jt} as data and so ignore this uncertainty. We correct them in two ways.

The first is a *market bootstrap*. Each of 5,000 replications draws 100 markets with replacement, re-estimates (β^l, α^l) by 2SLS, recomputes every implied marginal cost with the new α^l, and re-runs the supply regression. The bootstrap standard error is the standard deviation of the replicated estimates. Resampling whole markets preserves dependence within markets and is valid because markets are independent. With 5,000 replications the Monte Carlo error of each bootstrap standard error of the cost coefficients is below 0.0011.

The second treats the two steps as one GMM estimator with stacked moments (Newey, 1984; Murphy and Topel, 1985). Write $k_{jt} = \frac{1}{1-S_{ft}}$, so that $mc_{jt}(\alpha) = p_{jt} - \frac{k_{jt}}{\alpha}$, and let W be the regressor matrix of (C.88), with rows $W_{jt} = (x_{jt}, w_{jt})$. The supply estimate solves $\sum_t \sum_j W_{jt}^\top \big(p_{jt} - \frac{k_{jt}}{\hat\alpha^l} - W_{jt}\hat\gamma\big) = 0$. A first-order expansion around the probability limits gives

$$\begin{aligned} \hat\gamma - \gamma &\approx (W^\top W)^{-1}\Big[\sum_t\sum_j W_{jt}^\top \omega_{jt} + \frac{W^\top k}{(\alpha^l)^2}\big(\hat\alpha^l - \alpha^l\big)\Big], \\ \hat\alpha^l - \alpha^l &\approx -\iota_p^\top (\hat X^\top \hat X)^{-1} \sum_t\sum_j \hat X_{jt}^\top \xi_{jt}, \end{aligned} \tag{C.96}$$

where ι_p selects the price coefficient. Each observation thus contributes an influence term to $\hat\gamma$. Summing these terms within markets and taking the clustered outer product gives a sandwich variance that includes the estimation error in α^l. The coefficient $(W^\top W)^{-1}\frac{W^\top k}{(\alpha^l)^2}$ measures how the cost estimates move with α^l. For the constant it is 0.148, close to the mean markup divided by α^l. With s.e.$(\hat\alpha^l) = 0.412$, this alone gives a standard error of about $0.148\times0.412 = 0.061$ for the intercept. Table C.24 reports the estimates.

The estimates are close to the true values. Uncertainty about α^l moves all markups together, since each is near $\frac{1}{\alpha^l}$ when shares are small. It therefore loads almost entirely on the intercept, whose standard error rises from 0.016 to 0.065 (stacked) or 0.072 (bootstrap), while the slope standard errors barely change. The two corrections agree closely. The decomposition (C.88)

Table C.24: Logit model, supply side: OLS of the implied marginal cost on (x_{jt}, w_{jt})

	Estimate	Clustered s.e.	Stacked s.e.	Bootstrap s.e.	Bootstrap 95% interval	True
Constant	0.160	0.016	0.065	0.072	$[-0.022, 0.257]$	0.20
Sugar content	0.258	0.010	0.010	0.010	$[0.239, 0.278]$	0.25
Organic	0.315	0.005	0.006	0.006	$[0.304, 0.327]$	0.30
Price of milk	0.532	0.023	0.023	0.023	$[0.487, 0.576]$	0.50

Notes: The implied marginal cost is (C.95) with $\hat{\alpha}^l = 2.641$, and $R^2 = 0.923$. The clustered standard errors treat mc_{jt} as data. The stacked standard errors use the influence functions in (C.96), clustered by market. The bootstrap resamples markets 5,000 times and re-estimates α^l in each replication. The interval is the percentile interval. Computed with `figures/appC/src/appC_vertical_logit.py`.

locates the remaining errors. The logit markup error loads -0.040 on the constant, 0.011 on sugar, 0.011 on organic and 0.030 on the milk price. True markups are higher for organic products (0.392 against 0.383), because their buyers are less price sensitive. Logit markups are slightly lower for them (0.392 against 0.397), because organic producers have smaller combined shares. The logit therefore understates the organic markup premium (-0.005 against $+0.008$ in the truth), so it overstates the organic cost premium. The bootstrap interval for the organic coefficient just excludes 0.30. Compared with the vertical model under Nash pricing (Table C.19), the logit recovers costs far more accurately because its markups are close to the true ones.

Part (d). Joint estimation stacks the demand and supply moments and estimates $\theta = (\beta^l, \alpha^l, \gamma_1, \gamma_2)$ by GMM. For a candidate θ, the residuals are

$$\xi_{jt}(\theta) = \ln s_{jt} - \ln s_{0t} - x_{jt}\beta^l + \alpha^l p_{jt}, \qquad \omega_{jt}(\theta) = p_{jt} - \frac{1}{\alpha^l(1 - S_{ft})} - x_{jt}\gamma_1 - \gamma_2 w_{jt}. \quad \text{(C.97)}$$

With demand instruments z^d_{jt} and supply instruments z^s_{jt}, the sample moments and the estimator are

$$\bar{g}(\theta) = \frac{1}{N}\sum_t \sum_j \begin{pmatrix} z^{d\top}_{jt}\,\xi_{jt}(\theta) \\ z^{s\top}_{jt}\,\omega_{jt}(\theta) \end{pmatrix}, \qquad \hat{\theta} = \arg\min_\theta \bar{g}(\theta)^\top \mathcal{W}\, \bar{g}(\theta). \quad \text{(C.98)}$$

The first step uses the block-diagonal weight $\mathcal{W}_1 = \operatorname{diag}\big((\frac{1}{N}Z^{d\top}Z^d)^{-1}, (\frac{1}{N}Z^{s\top}Z^s)^{-1}\big)$. The second step uses the inverse of the market-clustered covariance of the moments at the first-step estimate, $\mathcal{W}_2 = \hat{S}^{-1}$, which is efficient. Given α^l, both residuals are linear in $(\beta^l, \gamma_1, \gamma_2)$, so we concentrate these out by weighted least squares and search over α^l alone. The GMM sandwich then gives standard errors that account for the estimation of α^l in the markups (Section 8.7.2).

Proposition C.26 (A just-identified supply block adds nothing)**.** *Let $z^s_{jt} = (x_{jt}, w_{jt})$, so that the supply block has as many moments as cost parameters. Then the joint GMM estimate of (β^l, α^l) with weight $\mathcal{W}$ equals the GMM estimate from the demand moments alone with weight $\mathcal{W}_{dd} - \mathcal{W}_{ds}\mathcal{W}_{ss}^{-1}\mathcal{W}_{sd}$. With the block-diagonal $\mathcal{W}_1$ this is 2SLS. With the efficient $\mathcal{W}_2 = \hat{S}^{-1}$ it is two-step efficient GMM on the demand moments with weight $\hat{S}^{-1}_{dd}$.*

Proof. Partition $\bar{g} = (\bar{g}_d, \bar{g}_s)$. For fixed (β^l, α^l), $\bar{g}_s = b_s(\alpha^l) - \frac{1}{N}W^\top W\gamma$, and $\frac{1}{N}W^\top W$ is square and invertible. Choosing γ is therefore the same as choosing the value v of $\bar{g}_s$ freely. Minimizing

the quadratic form over v,

$$\min_{v} \begin{pmatrix} \bar{g}_d \\ v \end{pmatrix}^\top \begin{pmatrix} \mathcal{W}_{dd} & \mathcal{W}_{ds} \\ \mathcal{W}_{sd} & \mathcal{W}_{ss} \end{pmatrix} \begin{pmatrix} \bar{g}_d \\ v \end{pmatrix} = \bar{g}_d^\top \left(\mathcal{W}_{dd} - \mathcal{W}_{ds} \mathcal{W}_{ss}^{-1} \mathcal{W}_{sd} \right) \bar{g}_d,$$

attained at $v = -\mathcal{W}_{ss}^{-1} \mathcal{W}_{sd} \bar{g}_d$. The concentrated objective involves only the demand moments. For block-diagonal $\mathcal{W}$ the bracket is $\mathcal{W}_{dd}$. For $\mathcal{W} = \hat{S}^{-1}$, the formula for the inverse of a partitioned matrix gives $\mathcal{W}_{dd} - \mathcal{W}_{ds} \mathcal{W}_{ss}^{-1} \mathcal{W}_{sd} = \hat{S}_{dd}^{-1}$. □

This is a special case of a general separability result for GMM (Ahn and Schmidt, 1995). The supply side carries information about demand only when it has more moments than cost parameters. Under Assumption C.19(iii), ω_{jt} is also independent of the characteristics of other products, so the six competition instruments are valid supply instruments. Berry (1994, p. 255) proposes the characteristics of other firms as cost-side instruments for the same reason. Berry et al. (1995, pp. 861–862) interact their cost error with the three terms of their eq. (5.8) for each of six cost characteristics. The three terms are the characteristic itself, its sum over the firm's other products and its sum over rival products. They add miles per dollar, a demand variable excluded from cost, for nineteen cost-side instruments in all.

With these instruments the supply equation identifies α^l on its own. Rewrite (C.95) as

$$p_{jt} = x_{jt} \gamma_1 + \gamma_2 w_{jt} + \frac{1}{\alpha^l} k_{jt} + \omega_{jt}, \qquad k_{jt} = \frac{1}{1 - S_{ft}}, \tag{C.99}$$

a linear regression in which $\frac{1}{\alpha^l}$ is the coefficient on k_{jt}. This is the multi-product version of the logit supply equation of Berry (1994, eq. 31, p. 255), whose parameters are γ and $\frac{1}{\alpha}$. The firm share is endogenous, because a high ω_{jt} raises the price and lowers the share. The competition instruments predict k_{jt} well, with a cluster-robust first-stage F of 51.6. The number and type of a firm's other products move its combined share directly. 2SLS of (C.99) gives $\frac{1}{\hat{\alpha}^l} = 0.351$ (0.132), so $\hat{\alpha}^l = 2.85$ with a delta-method standard error of 1.07. The estimate is close to the demand-side values, but it is imprecise because k_{jt} varies only from 1.002 to 1.126. The markups move too little across markets to measure their slope well. Table C.25 shows what the joint estimator does with this extra information.

The numbers confirm Proposition C.26. With $z^s = (x, w)$, the first-step joint estimate of α^l is 2.641, the 2SLS value. The second-step estimate is 2.872, exactly the two-step GMM estimate from the demand moments alone, and the J statistic is the same 8.82. The cost coefficients do change, because the efficient weight lets demand residuals inform the supply block. Adding the six competition instruments to the supply side gives $\hat{\alpha}^l = 2.785$ with standard error 0.367, against 0.394 without them. The estimate is close to the demand-side estimates and to the supply-only value of 2.85. The gain in precision is modest, for the reason that made these instruments weak in the first stage. With combined shares of at most 0.112, the markups barely change with competition. The overidentifying restrictions are not rejected ($J = 12.85$ with 12 degrees of freedom, $p = 0.38$).

Joint estimation matters in four situations. The first is when demand moments identify the demand parameters poorly, because instruments are weak or because there are nonlinear parameters such as the random coefficients of Section C.7. Extra supply moments then add information. The second is when ξ_{jt} and ω_{jt} are correlated and the supply block is overidentified, since the efficient weight then links the blocks. The third is when conduct itself is a parameter, because only the supply side identifies it. The fourth is when correct standard

Table C.25: Sequential and joint estimation of logit demand and supply

	Sequential	Joint GMM, $z^s = (x, w)$	Joint GMM, z^s adds six instruments	True
Demand				
Constant	−1.184 (0.329)	−1.035 (0.311)	−1.101 (0.291)	−1.00
Sugar content	0.190 (0.158)	0.291 (0.152)	0.267 (0.144)	0.20
Organic	0.153 (0.141)	0.211 (0.134)	0.178 (0.123)	0.15
Price coefficient α^l	2.641 (0.412)	2.872 (0.394)	2.785 (0.367)	3.00
Marginal cost				
Constant	0.160 (0.072)	0.191 (0.053)	0.181 (0.053)	0.20
Sugar content	0.258 (0.010)	0.261 (0.010)	0.260 (0.009)	0.25
Organic	0.315 (0.006)	0.315 (0.005)	0.314 (0.005)	0.30

Moments		14	20	
Hansen J (d.f., p)		8.82 (6, 0.18)	12.85 (12, 0.38)	

Notes: The sequential column is 2SLS for demand (clustered standard errors) and OLS for supply (bootstrap standard errors). The joint columns are two-step efficient GMM estimates of (C.98) with z^d as in part (a), weights clustered by market, and GMM sandwich standard errors without a small-sample factor. The first step of either joint estimator reproduces the sequential point estimates. Computed with `figures/appC/src/appC_vertical_logit.py`.

errors for the cost parameters are needed and no bootstrap is run. Joint estimation also has a cost. If the conduct assumption is wrong, the supply moments contaminate the demand estimates, which sequential estimation protects against.

Part (e). The true model of Section C.4 has random coefficients, $u_{ijt} = \delta_{jt} + \tilde{x}_{jt}\Sigma\nu_i + \epsilon_{ijt}$ with $\tilde{x}_{jt} = (x_{jt}, p_{jt})$, $\nu_i \sim N(0, I_4)$ and $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$. Let δ_{jt} be the mean utility that rationalizes the observed shares in this model, recovered by the contraction of Theorem 8.15, which Proposition C.30 of the next problem verifies for this market. Define the *gap term*

$$r_{jt} = \ln \frac{s_{jt}}{s_{0t}} - \delta_{jt}. \tag{C.100}$$

The logit regression (C.92) then has the dependent variable $x_{jt}\beta - \alpha p_{jt} + \xi_{jt} + r_{jt}$, so its error is $\xi_{jt} + r_{jt}$.

Proposition C.27 (Decomposition of the logit estimate)**.** *Use the regressors (x_{jt}, p_{jt}) and the instruments z_{jt} throughout. Let $\hat{\theta}^{RC}$ be the 2SLS estimate with dependent variable δ_{jt}, and let $\hat{\theta}^{l}$ be the one with dependent variable $\ln \frac{s_{jt}}{s_{0t}}$. Let $\hat{b}_r$ be the 2SLS estimate with dependent variable r_{jt}, with price coefficient $\hat{b}_{r,p}$. Then*

$$\hat{\theta}^{l} = \hat{\theta}^{RC} + \hat{b}_r, \qquad \hat{\alpha}^{l} = \hat{\alpha}^{RC} - \hat{b}_{r,p}. \tag{C.101}$$

Suppose the random coefficients model is correct and z_{jt} is valid for it. Then $\operatorname{plim} \hat{\alpha}^{l} = \alpha - b_{r,p}$*, where $b_{r,p}$ is the price coefficient of the population 2SLS projection of r_{jt} on (x_{jt}, p_{jt}) with instruments z_{jt}. The logit estimate is biased toward zero whenever $b_{r,p} > 0$.*

Proof. The 2SLS estimator is linear in the dependent variable, $\hat{\theta}(Y) = (X^\top P_Z X)^{-1} X^\top P_Z Y$ with $P_Z = Z(Z^\top Z)^{-1}Z^\top$. Since $\ln \frac{s_{jt}}{s_{0t}} = \delta_{jt} + r_{jt}$ observation by observation, $\hat{\theta}^{l} = \hat{\theta}(\delta) + \hat{\theta}(r) = \hat{\theta}^{RC} + \hat{b}_r$. The price coefficient is $-\alpha$ in both models, which gives the second equation. Under the stated conditions $\operatorname{plim} \hat{\alpha}^{RC} = \alpha$, and $\hat{b}_{r,p}$ converges to its population counterpart. □

The instruments do not remove this bias. The gap term depends on prices, and prices depend on the milk price and on the competition instruments, so $\mathbb{E}[z_{jt}^\top r_{jt}] \neq 0$ in general. The question is the sign of $b_{r,p}$. The next result shows that r_{jt} rises with price when the price coefficient is random.

Proposition C.28 (The gap term for small taste dispersion)**.** *Let Σ be diagonal and $\nu_i \sim N(0, I_4)$. As $\|\Sigma\| \to 0$,*

$$r_{jt} = \frac{1}{2}\,\tilde{x}_{jt}\Sigma^2\tilde{x}_{jt}^\top - \tilde{x}_{jt}\Sigma^2\bar{x}_t^\top + O(\|\Sigma\|^3), \qquad \bar{x}_t = \sum_k s_{kt}\tilde{x}_{kt}, \tag{C.102}$$

where the sum runs over inside products. In particular, the price component of r_{jt} is $\Sigma_{pp}^2\big(\frac{1}{2}p_{jt}^2 - p_{jt}\bar{p}_t\big)$, with Σ_{pp} the price entry of Σ and $\bar{p}_t = \sum_k s_{kt}p_{kt}$, and it increases in p_{jt} whenever $p_{jt} > \bar{p}_t$.

Proof. Fix a market and drop t. Let $\mu_{ij} = \tilde{x}_j\Sigma\nu_i$ for inside goods and $\mu_{i0} = 0$. Write s_j^L for the logit shares at δ, so that $\ln\frac{s_j^L}{s_0^L} = \delta_j$. The individual choice probability is the logit probability at utilities $\delta_j + \mu_{ij}$. Since $\frac{\partial \ln s_j}{\partial u_k} = \mathbf{1}\{j = k\} - s_k$ and $\frac{\partial^2 \ln s_j}{\partial u_k \partial u_l} = -s_k(\mathbf{1}\{k = l\} - s_l)$, a second-order expansion in μ_i gives

$$\ln s_{ij} = \ln s_j^L + \mu_{ij} - \bar{\mu}_i - \frac{1}{2}V_i + O(|\mu_i|^3), \qquad \bar{\mu}_i = \sum_k s_k^L\mu_{ik}, \quad V_i = \sum_k s_k^L\mu_{ik}^2 - \bar{\mu}_i^2,$$

for every alternative, including $j = 0$ with $\mu_{i0} = 0$. Exponentiating and expanding,

$$s_{ij} = s_j^L\Big[1 + (\mu_{ij} - \bar{\mu}_i) - \frac{1}{2}V_i + \frac{1}{2}(\mu_{ij} - \bar{\mu}_i)^2\Big] + O(|\mu_i|^3).$$

Average over ν_i. Because $\mathbb{E}[\mu_{ij}] = 0$ and $\mu_i = O(\|\Sigma\|)$,

$$s_j = s_j^L\Big[1 + \frac{1}{2}\mathbb{E}(\mu_{ij} - \bar{\mu}_i)^2 - \frac{1}{2}\mathbb{E}V_i\Big] + O(\|\Sigma\|^3), \qquad s_0 = s_0^L\Big[1 + \frac{1}{2}\mathbb{E}\bar{\mu}_i^2 - \frac{1}{2}\mathbb{E}V_i\Big] + O(\|\Sigma\|^3).$$

Take logs, use $\ln(1 + a) = a + O(a^2)$ with $a = O(\|\Sigma\|^2)$, and subtract:

$$\ln\frac{s_j}{s_0} - \delta_j = \frac{1}{2}\mathbb{E}\big[(\mu_{ij} - \bar{\mu}_i)^2 - \bar{\mu}_i^2\big] + O(\|\Sigma\|^3) = \frac{1}{2}\mathbb{E}[\mu_{ij}^2] - \mathbb{E}[\mu_{ij}\bar{\mu}_i] + O(\|\Sigma\|^3).$$

With $\nu_i \sim N(0, I_4)$ and Σ diagonal, $\mathbb{E}[\mu_{ij}^2] = \tilde{x}_j\Sigma^2\tilde{x}_j^\top$ and $\mathbb{E}[\mu_{ij}\bar{\mu}_i] = \tilde{x}_j\Sigma^2\big(\sum_k s_k^L\tilde{x}_k\big)^\top$. Finally $s_k^L - s_k = O(\|\Sigma\|^2)$, and the term it multiplies is $O(\|\Sigma\|^2)$, so replacing s_k^L by s_k changes r_j by $O(\|\Sigma\|^4)$. □

The intuition is sorting. Consumers with a low price sensitivity $\alpha_i = \alpha - \Sigma_{pp}\nu_{i4}$ buy expensive products more than the average consumer does. Averaging the convex logit probability over this heterogeneity raises the share of expensive products above what a logit with the same mean utility predicts. The logit can absorb the excess only in its error term, which then rises with price. By (C.102), the slope is about $\Sigma_{pp}^2 p_{jt}$, because $\bar{p}_t$ is small when the outside share is large. At the mean price of 1.18 and $\Sigma_{pp} = 0.5$, this is $0.25 \times 1.18 = 0.295$.

We now measure everything exactly. The script recovers δ_{jt} in every market by the contraction with 1,000 fixed draws per market (seed 2030), as in Section C.7. Convergence to a tolerance of 10^{-10} takes 11 to 18 iterations. Figure C.7 plots r_{jt} against price. The gap is

positive for every observation, from 0.105 to 0.511, so every recovered δ_{jt} lies below its logit start (Proposition C.31). Its correlation with price is 0.888. In market 0 it rises from 0.125 for the cheapest product to 0.326 for the most expensive one. The 2SLS estimate of the random coefficients model on the same sample and instruments is $\hat{\alpha}^{RC} = 2.926$ (0.413). The 2SLS price coefficient of r_{jt} is $\hat{b}_{r,p} = 0.284$, and the identity (C.101), $2.641 = 2.926 - 0.284$, holds to 9×10^{-16}. The approximation (C.102), evaluated at the true Σ, has correlation 0.93 with the exact r_{jt}. Its own 2SLS price coefficient is 0.286, and its price component alone gives 0.270.

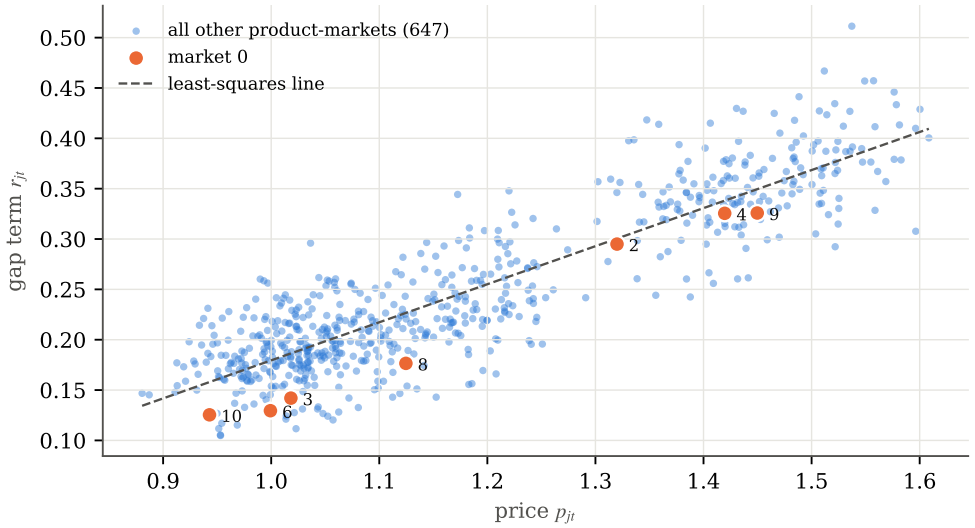

Figure C.7: The gap term $r_{jt} = \ln \frac{s_{jt}}{s_{0t}} - \delta_{jt}$ against price for all 654 observations, with market 0 highlighted and its products labelled. δ_{jt} is the random coefficients mean utility recovered with the true Σ. The correlation with price is 0.888. The dashed simple least-squares line has slope 0.378. The 2SLS price coefficient, which controls for characteristics, is 0.284.

The bias of 0.284 is about 0.7 standard errors of $\hat{\alpha}^{I}$, so a single sample cannot detect it. It does not shrink as the number of markets grows, since it is a probability limit. Its consequences also propagate. A price coefficient that is too small makes demand look too inelastic, which inflates the logit markups $\frac{1}{\alpha^{I}(1-s_{ft})}$ to a mean of 0.396 against the true 0.386. Better instruments cannot repair it, because the problem lies in the functional form. The remedy is to model the heterogeneity, which Section C.7 does. Section 8.10 reports the same comparison within the full estimation of the random coefficients model.

C.6.3 Computational notes

1. Build the instruments with group sums: within each market and owner, sum each characteristic and subtract the product's own value for the firm's other products. The market sum minus the firm sum gives the rival products.
2. Compute 2SLS through the projected regressors $\hat{X}$. Code the clustered sandwich by hand and check it against a packaged routine. Here the coefficients and standard errors agree to within 2×10^{-12}.
3. For Hansen's J, run 2SLS, form $\hat{S} = \frac{1}{N}\sum_t (Z_t^\top \hat{e}_t)(Z_t^\top \hat{e}_t)^\top$ from its residuals, re-estimate with weight $\hat{S}^{-1}$, and compute $J = N \bar{g}^\top \hat{S}^{-1} \bar{g}$ at the second-step estimate.

4. For the bootstrap, note that $mc_{jt}(\alpha) = p_{jt} - \frac{k_{jt}}{\alpha}$ with k_{jt} fixed by the data, so each replication needs only one 2SLS fit and one OLS fit.
5. For joint GMM, concentrate out the linear parameters for each α^l by weighted least squares, minimize the concentrated objective over a grid and refine with a bounded scalar search.
6. For the gap term, run the contraction from the logit start $\ln \frac{s_{jt}}{s_{0t}}$ with draws held fixed, and evaluate shares with the overflow-safe routine of Section C.4.

The bootstrap loop is short.

C.7 Random coefficients estimation and a comparison of the three models

Sections C.5 and C.6 estimated two misspecified models on the simulated market of Section C.4. The vertical model allowed one dimension of taste, and the logit allowed none beyond the idiosyncratic shock. In this problem we estimate the model that generated the data. We take the dispersion of tastes Σ as known. This isolates the two steps on which random coefficients estimation rests. The first is the inversion of market shares by the contraction of Berry et al. (1995). The second is linear instrumental variables on the recovered mean utilities. With the true structure in hand we then compare the three models on elasticities, diversion, markups, recovered costs and the predicted effects of a merger. Section 8.10 estimates Σ itself on the same data.

C.7.1 Statement

Use the data of Section C.4 and Assumption C.19. In each of the 100 markets the econometrician observes prices, realized shares s_{jt}^{obs}, characteristics x_{jt}, the milk price w_{jt}, the owners and the market size. The realized shares are the shares $\hat{s}_{jt}$ of (C.71). Demand is the random coefficients logit (C.63),

$$u_{ijt} = \delta_{jt} + \mu_{ijt} + \epsilon_{ijt}, \qquad \mu_{ijt} = \tilde{x}_{jt}\Sigma\nu_i, \qquad \delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}, \tag{C.103}$$

with $\tilde{x}_{jt} = (x_{jt}, p_{jt})$, $\nu_i \sim N(0, I_4)$, independent type-I extreme value shocks ϵ_{ijt}, and $u_{i0t} = \epsilon_{i0t}$. The term μ_{ijt} is the consumer-specific deviation from the mean utility δ_{jt}. The scale matrix $\Sigma = \mathrm{diag}(0.5, 0.2, 0.3, 0.5)$ is known, with $\Sigma_{pp} = 0.5$ its price entry. The linear parameters $\theta_1 = (\beta, \alpha)$ are unknown. Firms A to D own the products listed in Table C.14 and set prices in a multi-product Bertrand-Nash equilibrium.

(a) Draw $n_s = 1{,}000$ vectors ν_{it} for each market and keep them fixed for the rest of the problem. Why must the draws stay fixed?

(b) Write the simulated share function $s_t(\delta_t, \Sigma)$ for a given Σ and derive its derivatives with respect to δ_t.

(c) Starting from the logit inversion, recover δ_t in every market with the iteration $\delta_t^{(h+1)} = \delta_t^{(h)} + \ln s_t^{obs} - \ln s_t(\delta_t^{(h)}, \Sigma)$. Prove that it converges. Report δ_t for market 0, explain why every mean utility falls relative to the logit start, and account for the gaps between the recovered and the true mean utilities.

(d) Estimate (β, α) from the recovered mean utilities. Give the identification argument and standard errors.

(e) Compute the elasticity matrix of market 0 with the estimation draws, including the outside good. Compare it with the true matrix and with the vertical and logit matrices of Sections C.5 and C.6. Compute the diversion from each product to the outside good. Recover marginal costs under the estimated model and compare the three models.

(f) Firms B and C merge. Predict the new equilibrium of market 0 with the logit, the estimated random coefficients model and the true model.

(g) How would you proceed if Σ were unknown?

C.7.2 Solution

Part (a). For each market t we draw $n_s = 1{,}000$ vectors $\nu_{it} \sim N(0, I_4)$, $i = 1, \ldots, n_s$, once and store them. The draws use their own seed (2030), different from the seed of the firms' 100 draws in Section C.4. The econometrician does not know which consumer types the firms had in mind. Draws are independent across markets. The draws stay fixed for three reasons.

1. With fixed draws, the simulated share function of part (b) is a deterministic and smooth function of δ_t, and the iteration of part (c) has a well-defined fixed point. With fresh draws at every step, the map itself would change from one iteration to the next. The iterates would then wander around the solution by the size of the simulation error, which part (c) puts at a few hundredths. A stopping rule with tolerance 10^{-10} would never be met.

2. When Σ is estimated (part (g)), the GMM objective must be a deterministic function of Σ. Otherwise the optimizer compares objective values computed with different draws, and its minimizer is not defined. With fixed draws the objective is a smooth function of Σ, and the simulation asymptotics of Pakes and Pollard (1989) can be applied. Because the simulated shares enter the moments through the nonlinear inversion, simulation error also adds a bias of order $\frac{1}{n_s}$ (Proposition 8.13). Consistency therefore requires the number of draws to grow with the sample. With many draws, the simulation error adds a term to the variance (Berry et al., 1995).

3. Fixed draws make the estimator a function of the data and the draws. Its simulation error can then be measured by solving again with other draws, as we do in part (c).

Part (b). Given the draws and a candidate vector of mean utilities $\delta_t = (\delta_{jt})_{j \in \mathcal{J}_t}$, the individual

choice probabilities are

$$s_{ijt}(\delta_t) = \frac{e^{\delta_{jt}+\mu_{ijt}}}{1+\sum_{k\in\mathcal{J}_t} e^{\delta_{kt}+\mu_{ikt}}}, \qquad s_{i0t}(\delta_t) = \frac{1}{1+\sum_{k\in\mathcal{J}_t} e^{\delta_{kt}+\mu_{ikt}}}, \tag{C.104}$$

with $\mu_{ijt} = \tilde{x}_{jt}\Sigma\nu_{it}$, and the simulated shares are

$$s_{jt}(\delta_t, \Sigma) = \frac{1}{n_s}\sum_{i=1}^{n_s} s_{ijt}(\delta_t). \tag{C.105}$$

This is the simulator (C.67) with δ_t as its argument. Prices enter only through μ_{ijt}, and they stay at their observed values throughout the inversion. We evaluate (C.104) with the overflow-safe rule of Section C.4, part (b). The convergence argument of part (c) rests on the derivatives of this function.

Lemma C.29 (Derivatives of the simulated shares)**.** *For every market and every δ_t:*

(i) $\frac{\partial s_{jt}}{\partial \delta_{kt}} = \frac{1}{n_s}\sum_{i=1}^{n_s} s_{ijt}\big(\mathbf{1}\{j=k\} - s_{ikt}\big)$.

(ii) $0 < \frac{\partial s_{jt}}{\partial \delta_{jt}} < s_{jt}$, *and* $\frac{\partial s_{jt}}{\partial \delta_{kt}} < 0$ *for* $k \neq j$.

(iii) $\sum_{k\in\mathcal{J}_t} \frac{\partial s_{jt}}{\partial \delta_{kt}} = \frac{1}{n_s}\sum_{i=1}^{n_s} s_{ijt}s_{i0t} > 0$.

Proof. Fix a draw, drop t, and write $V_{ik} = \delta_k + \mu_{ik}$ and $E_i = 1 + \sum_k e^{V_{ik}}$. By the quotient rule,

$$\frac{\partial s_{ij}}{\partial V_{ik}} = \frac{\mathbf{1}\{j=k\}e^{V_{ij}}E_i - e^{V_{ij}}e^{V_{ik}}}{E_i^2} = s_{ij}\big(\mathbf{1}\{j=k\} - s_{ik}\big).$$

Since $\frac{\partial V_{ik}}{\partial \delta_k} = 1$, averaging over draws gives (i). For (ii), $0 < s_{ij} < 1$ implies $0 < s_{ij}(1-s_{ij}) < s_{ij}$ and $-s_{ij}s_{ik} < 0$. For (iii), $\sum_k s_{ij}(\mathbf{1}\{j=k\} - s_{ik}) = s_{ij}(1 - \sum_k s_{ik}) = s_{ij}s_{i0}$. □

Part (c). For market t define the map

$$f_t(\delta_t) = \delta_t + \ln s_t^{obs} - \ln s_t(\delta_t, \Sigma), \tag{C.106}$$

with logarithms taken element by element. A vector δ_t is a fixed point of f_t if and only if $s_t(\delta_t, \Sigma) = s_t^{obs}$, so the fixed points are exactly the mean utilities that rationalize the observed shares. The iteration $\delta_t^{(h+1)} = f_t(\delta_t^{(h)})$ is the contraction of Berry et al. (1995, eq. 6.8), written as eq. (12) of Nevo (2000a, p. 533). Each step raises δ_{jt} when the model under-predicts the share of product j and lowers it otherwise.

Proposition C.30 (Convergence of the share inversion)**.** *For every market t and every δ_t,*

$$\frac{\partial f_{jt}}{\partial \delta_{kt}} \geq 0 \ \text{for all } j,k, \qquad \eta_{jt}(\delta_t) \equiv \sum_{k\in\mathcal{J}_t}\frac{\partial f_{jt}}{\partial \delta_{kt}} = 1 - \frac{\sum_i s_{ijt}s_{i0t}}{\sum_i s_{ijt}} < 1. \tag{C.107}$$

The equation $s_t(\delta_t, \Sigma) = s_t^{obs}$ therefore has exactly one solution δ_t^*, and the iteration converges to it from any starting value. If $\eta_{jt} \leq \bar{\eta} < 1$ for every j on a convex set that contains δ_t^* and the iterates, then for every $h \geq 0$

$$\big\|\delta_t^{(h)} - \delta_t^*\big\|_\infty \leq \bar{\eta}^h\big\|\delta_t^{(0)} - \delta_t^*\big\|_\infty, \qquad \big\|\delta_t^{(h+1)} - \delta_t^{(h)}\big\|_\infty \leq \bar{\eta}^h\big\|\delta_t^{(1)} - \delta_t^{(0)}\big\|_\infty. \tag{C.108}$$

Proof. Take F in Corollary 8.16 to be the distribution that puts mass $\frac{1}{n_s}$ on each draw, so that its integrals are the averages of Lemma C.29. The corollary then gives (C.107), which is condition (1) of Theorem 8.15. This F has finite support, so the integrability condition of Theorem 8.14 holds. That theorem then gives the unique solution δ_t^*.

For the rate, drop t, fix j and apply the mean value theorem on the segment between δ^* and δ:

$$f_j(\delta) - f_j(\delta^*) = \sum_k \frac{\partial f_j}{\partial \delta_k}(\tilde{\delta})\,(\delta_k - \delta_k^*)$$

for some $\tilde{\delta}$ on the segment. The derivatives are nonnegative and sum to at most $\bar{\eta}$, so $|f_j(\delta) - \delta_j^*| \le \bar{\eta}\|\delta - \delta^*\|_\infty$, using $f_j(\delta^*) = \delta_j^*$. Taking the maximum over j and iterating gives the first inequality in (C.108). The second follows in the same way from $\delta^{(h+1)} - \delta^{(h)} = f(\delta^{(h)}) - f(\delta^{(h-1)})$.

Theorem 8.14 proves convergence for a truncated iteration. The untruncated iteration also converges from any start. Let B be the sup-norm ball of radius $\|\delta^{(0)} - \delta^*\|_\infty$ around δ^*. It is convex and compact. The row sums are continuous and below one, so their maximum $\bar{\eta}$ on B is below one. The bound $|f_j(\delta) - \delta_j^*| \le \bar{\eta}\|\delta - \delta^*\|_\infty$ then holds on B, so every iterate stays in B. Hence (C.108) applies. □

The row sum has a simple meaning. By Bayes' rule over the draws, as in Proposition C.18, $\frac{\sum_i s_{ijt} s_{i0t}}{\sum_i s_{ijt}}$ is the probability that a buyer of product j would choose the outside good in a new choice situation. So η_{jt} is one minus the outside-good probability of j's buyers. The iteration converges fast when the buyers of every product often choose the outside good, which happens when the outside share is large. It slows down when inside goods dominate the market (Section 8.4).

We start from the logit inversion $\delta_{jt}^{(0)} = \ln s_{jt}^{obs} - \ln s_{0t}^{obs}$. It is the exact solution when $\Sigma = 0$, because then every s_{ijt} is the logit probability at δ_t. We stop when $\|\delta_t^{(h+1)} - \delta_t^{(h)}\|_\infty < 10^{-10}$. The iteration converges in every market, in 11 to 18 iterations (13.9 on average). At the solution the largest gap between log simulated and log observed shares is 2.5×10^{-11}.

Market 0 shows the proposition at work. At the solution the row sums lie between 0.207 and 0.234. The buyers of each product choose the outside good with probability 0.766 to 0.793, against 0.855 for all simulated consumers. The largest row sum along the path of the iteration is $\bar{\eta} = 0.261$. The first step has size 0.280, so by the second inequality in (C.108) the stopping rule must be met by iteration 18. It is met at iteration 15. After the first step, the ratio of successive step sizes settles at 0.216. This ratio estimates the largest eigenvalue of the Jacobian of f_0 at the solution, which cannot exceed the largest row sum because the Jacobian has nonnegative entries. Over all 100 markets the largest row sum at the solution is 0.295.

Table C.26 reports the mean utilities of market 0. The recovered values are close to the true ones, $x_j\beta - \alpha p_{j0} + \xi_{j0}$, and every one of them lies below its logit start. The next proposition explains the second fact.

Proposition C.31 (Mean utilities below the logit inversion)**.** *(i) Suppose a market has one inside product with observed share $s^{obs} < \frac{1}{2}$, and the random term μ_i has a nondegenerate distribution that is symmetric about zero. Let $\mathcal{L}(u) = \frac{e^u}{1+e^u}$ be the logistic distribution function, and let δ^* solve $\mathbb{E}[\mathcal{L}(\delta + \mu_i)] = s^{obs}$. Then*

$$\delta^* < \ln \frac{s^{obs}}{1 - s^{obs}}.$$

Table C.26: Mean utilities in market 0 with Σ known

			Logit start	Recovered $\hat{\delta}_j$		True	Gap from truth		S.e. of
Product	Firm	Buyers q_j	$\delta_j^{(0)}$	1,000 draws	100,000 draws	δ_j	Simulation	Sampling	$\ln \hat{s}_j$
2	C	51	−5.110	−5.405	−5.411	−5.581	0.007	0.170	0.140
3	C	249	−3.524	−3.666	−3.701	−3.675	0.035	−0.026	0.063
4	B	124	−4.221	−4.547	−4.551	−4.657	0.005	0.105	0.089
6	B	201	−3.738	−3.868	−3.905	−3.962	0.037	0.058	0.070
8	A	553	−2.726	−2.903	−2.935	−2.941	0.032	0.006	0.041
9	D	57	−4.998	−5.324	−5.330	−5.193	0.006	−0.137	0.132
10	C	199	−3.748	−3.874	−3.910	−3.843	0.036	−0.067	0.070

Notes: $M_0 = 9{,}880$ consumers, outside share 0.8549. The logit start is $\ln s_j^{obs} - \ln s_0^{obs}$. The recovered values solve $s_t(\delta_t, \Sigma) = s_t^{obs}$ for $t = 0$ with the 1,000 estimation draws (seed 2030) and with 100,000 draws (seed 2032). The simulation gap is the difference between the two solutions, and the sampling gap is the 100,000-draw solution minus the true value. The last column is $\sqrt{\frac{1-s_j}{q_j}}$ from (C.76). Computed with `figures/appC/src/appC_rc.py`.

(ii) With several inside products, a diagonal Σ and $\|\Sigma\| \to 0$, the gap $r_{jt} = \ln \frac{s_{jt}^{obs}}{s_{0t}^{obs}} - \delta_{jt}^{*}$ is positive up to terms of order $\|\Sigma\|^3$ whenever $\|\tilde{x}_{jt}\Sigma\| > 2\|\bar{x}_t\Sigma\|$, where $\bar{x}_t = \sum_k s_{kt}\tilde{x}_{kt}$ and $\|\cdot\|$ is the Euclidean norm.

Proof. (i) Let $\delta_L = \ln \frac{s^{obs}}{1-s^{obs}}$, the logit inversion, so that $\mathcal{L}(\delta_L) = s^{obs}$ and $\delta_L < 0$. For $m \geq 0$ define $g(m) = \mathcal{L}(\delta_L + m) + \mathcal{L}(\delta_L - m) - 2\mathcal{L}(\delta_L)$. Then $g(0) = 0$ and

$$g'(m) = \ell(\delta_L + m) - \ell(\delta_L - m),$$

where $\ell(u) = \mathcal{L}(u)(1 - \mathcal{L}(u))$ is the logistic density. It is symmetric about zero and strictly decreasing in $|u|$. For $m > 0$, $\delta_L < 0$ gives $|\delta_L + m| < |\delta_L| + m = |\delta_L - m|$, so $g'(m) > 0$ and $g(m) > 0$. By the symmetry of μ_i,

$$\mathbb{E}[\mathcal{L}(\delta_L + \mu_i)] = \frac{1}{2}\mathbb{E}\big[\mathcal{L}(\delta_L + \mu_i) + \mathcal{L}(\delta_L - \mu_i)\big] = \mathcal{L}(\delta_L) + \frac{1}{2}\mathbb{E}\big[g(|\mu_i|)\big] > s^{obs},$$

with strict inequality because $\mu_i \neq 0$ with positive probability. The function $\delta \mapsto \mathbb{E}[\mathcal{L}(\delta + \mu_i)]$ is strictly increasing, so its solution δ^* lies below δ_L.

(ii) By Proposition C.28, with $a = \tilde{x}_{jt}\Sigma$ and $b = \bar{x}_t\Sigma$ (row vectors, Σ diagonal), $r_{jt} = \frac{1}{2}\|a\|^2 - ab^\top + O(\|\Sigma\|^3)$. The Cauchy-Schwarz inequality gives $ab^\top \leq \|a\|\,\|b\|$, so $r_{jt} \geq \|a\|\big(\frac{1}{2}\|a\| - \|b\|\big) + O(\|\Sigma\|^3)$, which is positive when $\|a\| > 2\|b\|$. □

Part (i) is the convexity argument in its cleanest form. The logit probability is convex below one half, so spreading utility symmetrically around δ raises the average choice probability. To match the observed share, the mean utility must fall. Part (ii) covers our design. The vector $\bar{x}_t$ averages the inside products with weights equal to their shares, which sum to the inside share of at most 0.21. So $\|\bar{x}_t\Sigma\|$ is a small fraction of $\max_k \|\tilde{x}_{kt}\Sigma\|$, and the condition holds unless products are very different. In the data every one of the 654 recovered mean utilities lies below its logit start. The gap r_{jt}, studied in Section C.6, part (e), has mean 0.247 (Figure C.7). In market 0 it is smallest for product 10, the cheapest, and largest for products 4 and 9, which are expensive and organic and therefore have the largest $\|\tilde{x}_{jt}\Sigma\|$.

The gaps from the truth have two sources, which we separate by solving the inversion again with 100,000 draws:

$$\hat{\delta}_{jt} - \delta_{jt} = \left(\hat{\delta}_{jt} - \hat{\delta}_{jt}^{100k}\right) + \left(\hat{\delta}_{jt}^{100k} - \delta_{jt}\right). \tag{C.109}$$

The first term is simulation error from using 1,000 draws. In market 0 it lies between 0.005 and 0.037. It has the same sign for every product, which reflects the draws that all products share. It is of the same order as the relative simulation standard error of the shares, the standard deviation of s_{ij0} across draws divided by $\sqrt{n_s}\, s_{j0}$, which lies between 0.020 and 0.030. The second term is sampling error. Realized shares are proportions among about 10,000 consumers, and by (C.76) the log share of product j has standard error near $\sqrt{\frac{1-s_j}{q_j}}$. Products 2, 4 and 9 miss the truth by 1.0 to 1.2 of these standard errors, and the others by less. Both errors are independent across markets. To first order they have mean zero and are uncorrelated with the instruments, so they act as extra noise in the regression of part (d). The log transformation adds a small second-order bias that depends on the share, of order $\frac{1}{q_j}$.

Part (d). With Σ known, the recovered mean utilities satisfy the linear equation

$$\hat{\delta}_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt} + e_{jt}, \tag{C.110}$$

where $e_{jt} = \hat{\delta}_{jt} - \delta_{jt}$ collects the simulation and sampling errors of part (c). Price is correlated with ξ_{jt} because firms observe ξ_{jt} when they set prices (Section C.6, part (a)). We therefore estimate (C.110) by 2SLS with the instruments of (C.93): the milk price and the six sums of characteristics and counts of the firm's other products and of rival products. The parameters are identified by the moment conditions $\mathbb{E}[z_{jt}^{\top}(\xi_{jt} + e_{jt})] = 0$ and the rank condition of Section C.6. The error e_{jt} comes from consumers' choices and from the econometrician's draws, given prices. To first order it has mean zero conditional on z_{jt}, so it adds noise without adding bias. The regressors and instruments are those of the logit, so the first stage is the one in Table C.21.

Table C.27: Demand estimates with Σ known

	Logit	Random coefficients, Σ known			
	2SLS	OLS	2SLS	2SLS, milk price only	True
Constant	−1.184 (0.329)	−1.355 (0.227)	−1.061 (0.330)	−1.042 (0.335)	−1.00
Sugar content	0.190 (0.158)	0.088 (0.122)	0.168 (0.158)	0.173 (0.156)	0.20
Organic	0.153 (0.141)	−0.002 (0.097)	0.114 (0.142)	0.121 (0.143)	0.15
Price coefficient α	2.641 (0.412)	2.573 (0.252)	2.926 (0.413)	2.948 (0.415)	3.00
First-stage F	92.5		92.5		
Hansen J (df, p)	8.82 (6, 0.18)		8.16 (6, 0.23)		
Observations	654	654	654	654	

Notes: The dependent variable is $\ln s_{jt}^{obs} - \ln s_{0t}^{obs}$ for the logit and the recovered $\hat{\delta}_{jt}$ otherwise. Standard errors in parentheses are clustered by market with the factor $\frac{G}{G-1}\frac{N-1}{N-K}$ and condition on Σ. The first and third 2SLS columns use the milk price and the six competition instruments, and the last uses the milk price alone. The logit column repeats Table C.22. Computed with `figures/appC/src/appC_rc.py`.

Table C.27 reports the estimates. The 2SLS estimate of the price coefficient is 2.926, within 0.18 standard errors of the true value of 3. OLS gives 2.573, biased toward zero for the same reason as in the logit. Using the milk price alone gives 2.948 with a slightly larger standard error, so the six competition instruments add little, as in Section C.6. Hansen's test does

not reject the overidentifying restrictions ($J = 8.16$, $p = 0.23$). The coefficients on sugar and organic production are close to the truth but imprecise. They are identified from ten products whose characteristics never change, so the data contain only ten distinct combinations of characteristics.

The comparison with the logit is exact. By Proposition C.27, the logit estimate equals the random coefficients estimate minus the 2SLS price coefficient of the gap term r_{jt} on the same regressors and instruments. That coefficient is 0.284, and the identity $2.641 = 2.926 - 0.284$ holds to machine precision (Section C.6, part (e)). Allowing for the random coefficients moves the estimate from 0.359 below the truth to 0.074 below it. The remaining gap is well within sampling error. The estimates also imply sensible individual tastes. Across the 100,000 estimation draws, the smallest price sensitivity $\alpha_i = \hat{\alpha} - \Sigma_{pp}\nu_{i4}$ is 0.814, so every simulated consumer dislikes higher prices, as Proposition C.17 requires.

The standard errors cluster by market, with the sandwich (C.84). The recovered $\hat{\delta}_t$ depends only on the shares and draws of market t, so the errors are independent across markets and clustering is valid. The standard errors condition on Σ. If Σ were estimated, $\hat{\theta}_1 = \hat{\theta}_1(\hat{\Sigma})$ would inherit the uncertainty in $\hat{\Sigma}$, and all parameters would be estimated jointly as in part (g).

Part (e). A change in p_{kt} moves both the mean utility, through $-\alpha$, and the random term, through $\Sigma_{pp}\nu_{i4}$. For draw i the price coefficient is therefore $-\alpha_i$ with $\alpha_i = \hat{\alpha} - \Sigma_{pp}\nu_{i4}$. Applying Lemma C.29(i) draw by draw, with $\frac{\partial V_{ikt}}{\partial p_{kt}} = -\alpha_i$, gives the share derivatives

$$\frac{\partial s_{jt}}{\partial p_{kt}} = \frac{1}{n_s}\sum_{i=1}^{n_s} \alpha_i s_{ijt}\big(s_{ikt} - \mathbf{1}\{j = k\}\big), \qquad \frac{\partial s_{0t}}{\partial p_{kt}} = \frac{1}{n_s}\sum_{i=1}^{n_s} \alpha_i s_{i0t} s_{ikt}. \tag{C.111}$$

The second formula follows from $\frac{\partial s_{i0t}}{\partial V_{ikt}} = -s_{i0t}s_{ikt}$. The elasticities are $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$ and $\varepsilon_{0k} = \frac{\partial s_0}{\partial p_k}\frac{p_k}{s_0}$. Own entries are negative, so the positive own elasticity of the book's notation is $-\varepsilon_{jj}$. The estimated matrix uses $\hat{\alpha} = 2.926$, the recovered $\hat{\delta}_0$ and the 1,000 estimation draws. The true matrix uses the true parameters, the true mean utilities and the firms' 100 draws, the demand system that generated the prices. Table C.28 reports both.

The estimated matrix is close to the true one. The largest absolute difference between corresponding entries is 0.11. The estimated own elasticities run from -2.51 to -3.74, against -2.57 to -3.85 in the truth. They are slightly smaller in magnitude because $\hat{\alpha}$ is slightly below 3. Three features distinguish the random coefficients matrix from the other two models.

First, cross elasticities differ within a column. In the logit every off-diagonal entry of column k equals $\hat{\alpha}^l p_k s_k$ (Table C.23). In Panel A the largest ratio between two cross elasticities in the same column is 1.21, and in the truth it is 1.27. The pattern has an economic logic. A rise in the price of product 4 raises the shares of products 2 and 9 by more than those of the other products. The same holds for the columns of products 2 and 9. The three products are the organic ones and also the most expensive. Their buyers have high draws of the organic taste ν_{i3} or low price sensitivity α_i. When they leave one of these products, they look for another product that suits the same tastes.

Second, the outside good receives less substitution than the logit implies. The diversion ratio from product k to the outside good (Section C.3, part (e), and Section C.5, part (e)) is

$$D_{k0} = \frac{\frac{\partial s_0}{\partial p_k}}{-\frac{\partial s_k}{\partial p_k}} = \frac{\sum_i \alpha_i s_{ik} s_{i0}}{\sum_i \alpha_i s_{ik}(1 - s_{ik})} = \sum_i \omega_{ik}\frac{s_{i0}}{1 - s_{ik}}, \qquad \omega_{ik} = \frac{\alpha_i s_{ik}(1 - s_{ik})}{\sum_l \alpha_l s_{lk}(1 - s_{lk})}. \tag{C.112}$$

Table C.28: Random coefficients elasticities in market 0

	Price of product						
Share of	2	3	4	6	8	9	10
Panel A. Estimated model ($\hat{\alpha}$ = 2.926, Σ known)							
Product 2	−3.45	0.10	0.08	0.07	0.24	0.04	0.07

Product 9	0.03	0.12	0.09	0.08	0.29	−3.85	0.09
Product 10	0.03	0.10	0.07	0.07	0.26	0.04	−2.57
Outside good	0.02	0.07	0.04	0.05	0.17	0.03	0.06

Notes: Entry (j, k) is $\varepsilon_{jk} = \frac{\partial s_j}{\partial p_k}\frac{p_k}{s_j}$, the percentage change in the share of the row alternative after a one percent rise in the price of the column product. Panel A uses the 1,000 estimation draws and the recovered mean utilities. Panel B uses the true parameters and mean utilities and the firms' 100 draws. Computed with `figures/appC/src/appC_rc.py`.

The second equality uses (C.111). The third writes D_{k0} as a weighted average of the individual logit diversion ratios $\frac{s_{i0}}{1-s_{ik}}$, with weights that favour the draws most likely to buy k. In the logit all draws are alike and $D_{k0} = \frac{s_0}{1-s_k}$, which lies between 85.9 and 90.6 percent in market 0. Under the estimated random coefficients model it lies between 79.2 and 86.7 percent, and in the truth between 76.2 and 85.1 percent. The buyers of a product are disproportionately consumers with a high draw of the random constant. Their probability of choosing the outside good is 0.77 to 0.79, against 0.855 on average, so they divert less of their purchases to it. The logit cannot represent this selection. It overstates diversion to the outside good by 5 to 10 percentage points relative to the truth and understates diversion among inside goods, which matters for the merger of part (f).

Third, the vertical model is far from both (Table C.20). Its own elasticities range from −16.8 to −358.4. Their mean absolute value, 126.6, is 41 times that of the logit. Each row has at most two nonzero cross elasticities, one for each neighbour on the price ladder. Only the cheapest product, product 10, loses sales to the outside good, and only 6.4 percent of them. Figure C.8 summarizes the own elasticities. Figure 8.7 shows the logit and random coefficients panels on the same data.

We now recover marginal costs. Under the estimated model, the stacked first-order conditions (C.56) give

$$\widehat{mc}_t = p_t + \left(\Omega_t \odot \hat{\Delta}_t^{\top}\right)^{-1} s_t^{obs}, \tag{C.113}$$

with $\hat{\Delta}_t$ the matrix of share derivatives (C.111). We regress $\widehat{mc}_{jt}$ on (x_{jt}, w_{jt}) by OLS. The regressand depends on $\hat{\alpha}$, so we compute standard errors with a bootstrap over markets (5,000 resamples, seed 2031) that re-estimates $\hat{\alpha}$ in each replication. With Σ known, $\hat{\delta}_t$ does not

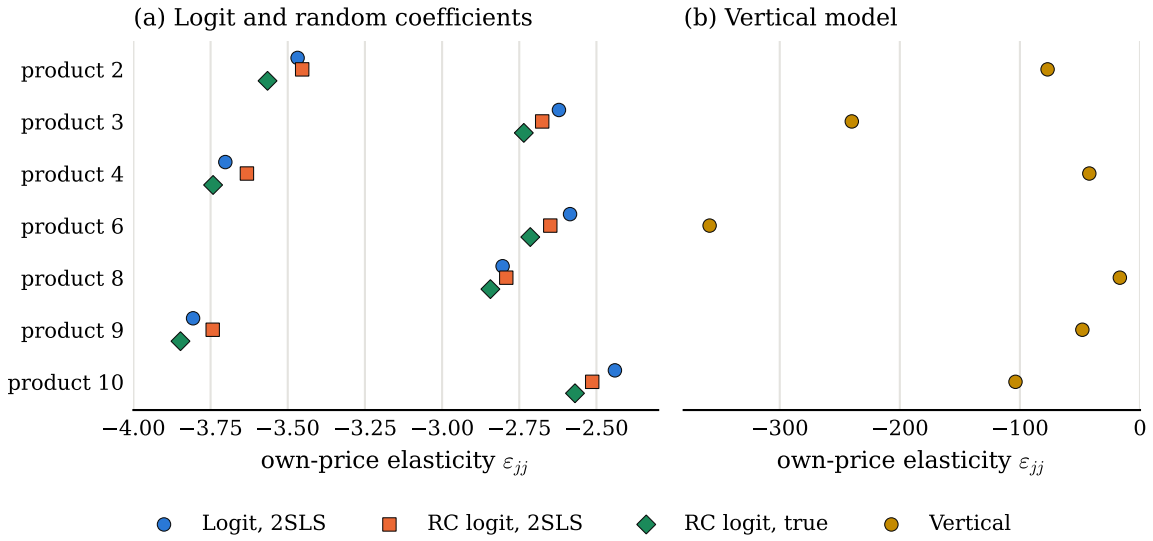

Figure C.8: Own-price elasticities in market 0 by product. Panel (a): logit estimated by 2SLS, random coefficients logit estimated by 2SLS with Σ known, and the true random coefficients model. Panel (b): the vertical model, on its own scale. Computed with `figures/appC/src/appC_rc.py`.

depend on α, so only $\hat{\Delta}_t$ changes across replications. Table C.29 collects the comparison.

The random coefficients model wins on every dimension that depends on substitution. Its cost coefficients are the closest to the truth, and its implied markups track the true markups across observations more closely (correlation 0.715, against 0.553 for the logit). The mean markups of the logit and the random coefficients model are almost equal. Both are near $\frac{1}{\hat{\alpha}}$ corrected for the firm's share, and both overstate the true mean of 0.386 a little because both price coefficients lie below 3. The vertical model fails on every dimension, for the reasons of Section C.5. Adjacent prices are close, its elasticities explode, and its markups collapse toward zero, so its cost intercept absorbs the true markup.

Part (f). Firms B and C merge. In market 0, firm B sells products 4 and 6 and firm C sells products 2, 3 and 10. After the merger one firm owns all five, while firm A (product 8) and firm D (product 9) are unchanged. We predict the new equilibrium under three demand models: the logit of Section C.6, the estimated random coefficients model of parts (c) and (d), and the true model. The procedure is the same for each.

1. Recover marginal costs from the pre-merger first-order conditions of the model, (C.113) or its logit version. For the true model use the true marginal costs. Each model then reproduces the observed prices. Solving the pre-merger game again returns them to within 3×10^{-14}.

2. Hold marginal costs, unobserved qualities and draws fixed. As prices move, mean utilities move as $\delta_{jt}(p) = \hat{\delta}_{jt} - \alpha(p_{jt} - p_{jt}^{obs})$, and μ_{ijt} moves through the price entry of $\tilde{x}_{jt}$.

3. Replace Ω_0 by the post-merger ownership matrix and solve the first-order conditions. For the logit iterate $p \leftarrow mc + \frac{1}{\alpha(1-S_f(p))}$, using Proposition C.12. For the random coefficients models iterate the Morrow-Skerlos map (C.70). Each converges in 11 iterations to a tolerance of 10^{-12}, and 20 random starting points lead to the same prices to within 9×10^{-14}.

Table C.29: Three demand models estimated on the same simulated data

	Vertical	Logit	Random coefficients (Σ known)	True
Price coefficient α	none	2.641 (0.412)	2.926 (0.413)	3.00
Own elasticities, market 0	−16.8 to −358.4	−2.44 to −3.81	−2.51 to −3.74	−2.57 to −3.85
Nonzero cross elasticities per row	1 or 2	6	6	6
Largest ratio within a column		1.00	1.21	1.27
Diversion to outside good, market 0 (%)	0 to 6.4	85.9 to 90.6	79.2 to 86.7	76.2 to 85.1
Mean markup, all observations	0.048	0.396	0.397	0.386
Range of markups	0.000 to 0.515	0.379 to 0.426	0.368 to 0.452	0.348 to 0.451
Correlation with true markups	0.275	0.553	0.715	1
Mean absolute markup error	0.340	0.014	0.013	0
Marginal cost equation				
Constant	0.674 (0.024)	0.160 (0.072)	0.188 (0.060)	0.20
Sugar content	0.194 (0.014)	0.258 (0.010)	0.246 (0.010)	0.25
Organic	0.271 (0.009)	0.315 (0.006)	0.305 (0.006)	0.30
Price of milk	0.356 (0.031)	0.532 (0.023)	0.504 (0.026)	0.50

Notes: All models assume multi-product Bertrand-Nash pricing. Cross elasticities and diversion refer to market 0. Markup statistics use all 654 observations. Cost equations are OLS regressions of the implied marginal cost on the characteristics and the milk price. Standard errors are clustered by market for the vertical model, whose markups contain no estimated parameter. For the logit and the random coefficients model they come from a market bootstrap that re-estimates α (5,000 replications). Computed with `figures/appC/src/appC_rc.py`.

4. Measure consumer welfare by the log-sum formula (Proposition 7.30). A consumer with marginal utility of income α_i has expected surplus $\frac{1}{\alpha_i}\ln\left(1+\sum_j e^{V_{ij}}\right)$ up to a constant, and we average over draws. The constant cancels from the change.

Table C.30 reports the predictions. Under the logit, the price increase is the same for every product of a merging firm, 0.0129 for firm C and 0.0202 for firm B. Proposition C.12 explains it. Logit markups are common within a firm, so after the merger the new firm sets one markup $\frac{1}{\alpha(1-S_{BC})}$ on all five products. That markup is 0.4117, up from 0.3988 for firm C and 0.3915 for firm B. Firm B's products start from the lower markup, so they rise more. Under the random coefficients models the increases differ across products and are largest for products 4 and 6.

The logit understates the merger's effect. The mean increase on the merging products is 0.0158 under the logit, 0.0231 under the estimated random coefficients model and 0.0251 in the truth. The logit captures 63 percent of the true effect and the estimated model 92 percent. In percentage terms the true increases range from 1.7 to 3.1 percent. The source is diversion between the merging firms. Consider the share of a merging product's lost sales that goes to the partner firm. It is 0.033 to 0.052 under the logit, 0.044 to 0.075 under the estimated model and 0.046 to 0.088 in the truth. The logit sends too many lost sales to the outside good, as part (e) showed, so it sees the two firms as weaker competitors than they are.

First-order upward pricing pressure, defined in Section C.3, part (g), is the opportunity cost $\sum_k D_{jk}(p_k - mc_k)$ of sales diverted to the partner (Farrell and Shapiro, 2010), discussed in Section 11.4. It is close to the equilibrium price change in all three models. For product 4 in the truth, for example, it is 0.0340 against an equilibrium increase of 0.0356. Inside shares are small, so pass-through is close to one and the feedback among prices is weak. Rivals raise their prices only slightly, by at most 0.0006, because prices are strategic complements. Consumer surplus falls by 20.39 in the truth, while the merged firm gains 0.72 and its rivals 2.13. Without cost savings the merger lowers total surplus. The logit predicts a loss of 11.67, about two thirds

Table C.30: Merger of firms B and C in market 0

			Equilibrium price change			Upward pricing pressure		
Product	Firm	Price	Logit	RC est.	RC true	Logit	RC est.	RC true
2	C	1.3200	0.0129	0.0207	0.0220	0.0129	0.0194	0.0204
3	C	1.0182	0.0129	0.0184	0.0188	0.0132	0.0178	0.0181
4	B	1.4196	0.0202	0.0309	0.0356	0.0204	0.0296	0.0340
6	B	0.9993	0.0202	0.0277	0.0305	0.0206	0.0268	0.0294
8	A	1.1246	0.0001	0.0004	0.0006			
9	D	1.4497	0.0000	0.0002	0.0002			
10	C	0.9429	0.0129	0.0181	0.0185	0.0131	0.0174	0.0177
Mean change, merging			0.0158	0.0231	0.0251			
Outside share, before, after			0.8549 0.8578	0.8549 0.8589	0.8463 0.8507			
Change in consumer surplus			−12.78	−18.37	−20.39			
Change in merged profit			0.28	0.58	0.72			
Change in rivals' profit			0.83	1.68	2.13			
Change in total surplus			−11.67	−16.11	−17.54			

Notes: Firm B owns products 4 and 6 and firm C owns products 2, 3 and 10 in market 0. Upward pricing pressure is $\sum_k D_{jk}(p_k - mc_k)$ over the partner firm's products, evaluated before the merger. Surplus and profit changes are totals over the $M_0 = 9{,}880$ consumers, in the same money units as prices. The true model's outside share differs before the merger because it uses expected rather than realized shares. Computed with `figures/appC/src/appC_rc_merger.py`.

of the true loss of 17.54.

The two estimated models agree here more than they would in many markets. Inside shares are small and the products are similar, so all predicted increases are below 4 percent. The gap between the logit and the random coefficients model would widen with larger inside shares or more dispersed tastes. It would also widen if the merging products were closer in characteristics, as in a merger of the owners of the three organic products.

We do not solve the merger under the vertical model, because its prediction would depend mainly on the price ladder. In the vertical model every lost sale goes to a neighbour on the price ladder. In market 0 the ladder runs through products 10, 6, 3, 8, 2, 4 and 9 in increasing order of price. Both neighbours of product 6 belong to firm C, so all of product 6's lost sales go to the partner. The share is 0.936 for product 10, 0.879 for product 3, 0.605 for product 2 and 0.488 for product 4. The merger therefore internalizes much of the competition each merging product faces, while the pre-merger markups that would enter the upward pricing pressure are near zero. A prediction built on these two artefacts would tell us about the price gaps in market 0 more than about preferences.

Part (g). When Σ is unknown we estimate $\theta = (\theta_1, \theta_2)$, where θ_2 collects the four diagonal entries of Σ. The estimator is GMM with the nested fixed point algorithm of Berry et al. (1995), as laid out by Nevo (2000a, Section 3.3). The steps are as follows.

1. Fix the draws, as in part (a).
2. Inner loop. For a trial θ_2, solve $s_t(\delta_t, \Sigma) = s_t^{obs}$ in every market by the iteration of part (c), starting from the solution at the previous trial value. Use a tight tolerance, because errors in δ pass into the objective and can stop the outer search at false minima (Dubé et al., 2012).
3. Form the structural error $\xi_{jt}(\theta) = \delta_{jt}(\theta_2) - x_{jt}\beta + \alpha p_{jt}$ (Nevo, 2000a, eq. 13, p. 533).

4. Concentrate out the linear parameters. With X the matrix of rows $(x_{jt}, -p_{jt})$, the minimizer given θ_2 is $\hat{\theta}_1(\theta_2) = (X^\top Z \mathcal{W} Z^\top X)^{-1} X^\top Z \mathcal{W} Z^\top \delta(\theta_2)$ (Proposition 8.20).

5. Outer loop. Minimize $Q(\theta_2) = \xi(\theta_2)^\top Z \mathcal{W} Z^\top \xi(\theta_2)$ (Nevo, 2000a, eq. 9) over $\theta_2 \geq 0$, which removes the sign indeterminacy of Proposition 8.41. A quasi-Newton method needs the derivatives of δ, which the implicit function theorem gives from $s_t(\delta_t(\Sigma), \Sigma) = s_t^{obs}$:

$$\frac{\partial \delta_t}{\partial \Sigma_{kk}} = -\left[\frac{\partial s_t}{\partial \delta_t^\top}\right]^{-1} \frac{\partial s_t}{\partial \Sigma_{kk}}, \qquad \frac{\partial s_{jt}}{\partial \Sigma_{kk}} = \frac{1}{n_s} \sum_i s_{ijt}\, \nu_{ikt} \Big(\tilde{x}_{jtk} - \sum_l s_{ilt} \tilde{x}_{ltk} \Big). \tag{C.114}$$

   The second formula follows from $\frac{\partial V_{ijt}}{\partial \Sigma_{kk}} = \tilde{x}_{jtk} \nu_{ikt}$ and the quotient rule, as in Lemma C.29. The matrix $\frac{\partial s_t}{\partial \delta_t^\top}$ is invertible. By Lemma C.29(ii) and (iii), its diagonal entries are positive, its other entries are negative and its row sums are positive, so it is strictly diagonally dominant by rows.

6. Use a first-step weight such as $(\frac{1}{N} Z^\top Z)^{-1}$, then the inverse of the market-clustered covariance of the moments, and restart the search from several points.

7. Compute standard errors from the GMM sandwich with the Jacobian of the moments with respect to all of θ. The covariance of the moments adds a simulation term to the sampling term (Berry et al., 1995).

The instruments need more care than with Σ known. The moments must change with θ_2 for Σ to be identified. Nevo (2000a, p. 529) gives the intuition. Suppose products A and B are similar and B and C have the same share. A rise in the price of A should then raise the share of B more than that of C. The size of the difference identifies the dispersion of tastes. The data must therefore contain variation in choice sets and characteristics across markets. In this design characteristics are fixed by product, so the variation comes from which products each market offers. Instruments that measure how crowded a product's neighbourhood in characteristics space is (Gandhi and Houde, 2019), or approximations to the optimal instruments $\mathbb{E}[\frac{\partial \xi_{jt}}{\partial \theta} \mid z_t]$, put this variation to work. Supply moments can add information (Section 8.7.2), and the problem can also be written as a constrained optimization (Section 8.5.8). Section 8.10.7 carries out this estimation on the same data and shows that the instruments decide how precisely Σ is estimated.

C.7.3 Computational notes

The script `appC_rc.py` in `figures/appC/src` reads the simulated data in `figures/appC/data` and uses only the observables for estimation. It runs in about a minute.

1. Build the seven instruments of Section C.6 and run the logit regressions.

2. Draw an array of shape $100 \times 1{,}000 \times 4$ with seed 2030 and save it as `est_draws.npz` in the data folder.

3. Invert shares market by market from the logit start. For market 0 also invert with 100,000 draws (seed 2032).

4. Run 2SLS on $\hat{\delta}$, compute Hansen's J by two-step GMM, and run 2SLS of r_{jt} to check Proposition C.27.

5. Compute the elasticity matrices and the implied marginal costs. Store $\hat{\Delta}_t = \alpha A_t + B_t$, where A_t and B_t do not depend on α, so that each bootstrap replication only rescales them.

The script `appC_rc_merger.py` solves the merger, and `appC_part4_tables.py` prints the table rows. The inner loop is short:

```
def invert_shares(s_obs, xtilde, nu, sigma, delta0, tol=1e-10):
    delta, log_s = delta0.copy(), np.log(s_obs)
    while True:
        new = delta + log_s - np.log(shares_delta(delta, xtilde, nu, sigma))
        if np.max(np.abs(new - delta)) < tol:
            return new
        delta = new
```

C.8 Markups over time in the U.S. automobile market

The previous four problems used data whose generating model we knew, so every estimate could be checked against the truth. This last problem uses real data, where no such check exists and the choice of model must be argued. Did market power in the U.S. new-car market rise or fall after 1980? Production-function estimates for listed firms point to rising average markups across the economy (De Loecker et al., 2020), a literature reviewed in Section 1.5.4. Grieco et al. (2024), GMY for short, answer the question for one industry with a demand system and a model of pricing. They find that markups fell substantially while real prices rose (abstract and Section 5.4). We cite their author manuscript of July 5, 2023, and its table, figure and page numbers may differ from those of the published article. In this problem we use the product data of their public replication package. We estimate simple demand models, compute the markups they imply year by year, and ask what kind of decline these models measure. The answer turns on the functional form of price. Part (e) then compares our results with their full model.

C.8.1 Statement

The data are the product file of the replication package of Grieco et al. (2024), deposited on the Harvard Dataverse (doi:10.7910/DVN/CZGOKP). An observation is a vehicle model in a year. There are 9,694 model-years in 39 annual markets from 1980 to 2018, 1,067 distinct models, and between 165 and 323 models per year. Models belong to 33 parent companies, which set prices, and to 56 makes after a few small makes are grouped as in the package. For each model-year we observe unit sales and the manufacturer's suggested retail price (MSRP) in 2015 dollars. These product data come from Ward's Automotive, digitized by hand from its yearbooks before 1988, with trims aggregated to the model by taking medians (Grieco et al., 2024, Section 2.1). We also observe height, footprint, horsepower, fuel economy, curb weight and the number of trims. The remaining variables are a release-year indicator, years since the last redesign, sport and electric indicators, the vehicle type and the assembly country. The market size M_t is the number of U.S. households divided by 2.5, as in the package. It is 32.3 million in 1980 and 51.0 million in 2018. Shares are $s_{jt} = \frac{q_{jt}}{M_t}$, and the outside share is 0.685 in 1980 and 0.661 in 2018.

The market changed a great deal. Vehicle types g are cars, sport utility vehicles (SUVs), trucks and vans. Cars accounted for 83.6 percent of new-vehicle sales in 1980 and 31.4 percent

in 2018, while SUVs rose from 1.4 to 46.9 percent. The number of SUV models rose from 9 to 118. The sales-weighted mean real price rose from $17,672 to $33,750.

The excluded instrument for price is the lagged real exchange rate of the assembly country, the variable `lag_pl_con` of the package. Vehicles are assembled in 21 countries. A rise in the exchange rate makes production in that country more expensive in dollars, so it shifts the marginal cost of the models assembled there. Every regression controls for the characteristics used in the package's linear demand code. These are the standardized logs of height, footprint, horsepower, fuel economy, curb weight and the number of trims, and the release-year indicator. They also include years since redesign bounded between 3 and 12, sport and electric indicators, type indicators, and year and make fixed effects. Prices are in units of $10,000, and standard errors are clustered by make. The package also contains counts of second choices from the MaritzCX survey of new-vehicle buyers in 1991, 1999, 2005 and 2015 (Section 2.4). For each surveyed buyer of a model, the counts record the model the buyer considered most seriously but did not buy. The package count matrices hold 146,217 responses. This is the sum of the yearly counts in GMY's Table III. GMY report 145,670 purchases after merging the survey with their sales data (Section 2.4). Finally, the package holds the demographic micro moments of Grieco et al. (2024), computed from the Consumer Expenditure Survey (CEX) and from MRI's Survey of the American Consumer. It also holds household records from the Current Population Survey (CPS). Only part (e) discusses these.

(a) Estimate a plain logit and a nested logit with the four vehicle types as nests by 2SLS. Discuss instruments for the within-type share and their strength.

(b) Derive the multi-product Bertrand markups for logit and nested logit demand, including the nested logit share derivatives, and compute the sales-weighted mean Lerner index by year.

(c) Decompose the change in the mean log Lerner index from 1980 to 2018 into a dollar-markup term, a price-coefficient term and a price term.

(d) Estimate a logit in log price, a logit whose log-price coefficient varies across five-year periods, and a nested logit whose nesting parameter matches the second-choice survey. Compare the trends.

(e) What do the results say about the decline in markups?

C.8.2 Solution

Part (a). The plain logit gives the inversion (C.92) of Berry (1994, eq. 14). For the nested logit we follow Berry (1994, eqs. 22–28, pp. 252–253). Consumer i's utility from model j in type g is $u_{ijt} = \delta_{jt} + \zeta_{igt} + (1-\sigma)\epsilon_{ijt}$, where ζ_{igt} is common to all models of type g. Its distribution, due to Cardell (1997), makes $\zeta_{igt} + (1-\sigma)\epsilon_{ijt}$ extreme value. The *nesting parameter* $\sigma \in [0,1)$ measures the correlation of tastes within a type. With $D_{gt} = \sum_{k \in g} e^{\frac{\delta_{kt}}{1-\sigma}}$, the within-type share, the type share and the market share are

$$s_{j|g,t} = \frac{e^{\frac{\delta_{jt}}{1-\sigma}}}{D_{gt}}, \qquad s_{gt} = \frac{D_{gt}^{1-\sigma}}{1 + \sum_h D_{ht}^{1-\sigma}}, \qquad s_{jt} = s_{j|g,t}\, s_{gt}, \tag{C.115}$$

and $s_{0t} = \frac{1}{1+\sum_h D_{ht}^{1-\sigma}}$. Taking logs, $\ln s_{jt} - \ln s_{0t} = \frac{\delta_{jt}}{1-\sigma} - \sigma \ln D_{gt}$. The type share gives $\ln D_{gt} = \frac{\ln s_{gt} - \ln s_{0t}}{1-\sigma}$. Substituting and using $\ln s_{gt} = \ln s_{jt} - \ln s_{j|g,t}$ yields $\delta_{jt} = \ln s_{jt} - \sigma \ln s_{j|g,t} - \ln s_{0t}$,

so

$$\ln s_{jt} - \ln s_{0t} = x_{jt}\beta - \alpha p_{jt} + \sigma \ln s_{j|g,t} + \xi_{jt} \tag{C.116}$$

(Proposition 7.26). The plain logit is the case $\sigma = 0$.

Both price and the within-type share are endogenous. A model with high ξ_{jt} has a high price and a high within-type share, so OLS biases α toward zero and σ toward one. The exchange rate instruments price. Its validity requires that, given make and year effects and the characteristics, exchange rate movements are unrelated to changes in unobserved quality. The within-type share needs a second excluded instrument. A natural candidate is the log number of models of the same type in the same year. More models in a type lower each model's within-type share, holding ξ_{jt} fixed. The instrument is valid if the number of models is set before ξ_{jt} is known and is unrelated to it. That assumption is doubtful when entry follows demand, as when manufacturers launched SUV models while SUV demand grew. We add type-specific linear trends to absorb the steady part of that growth.

The plain logit gives a price coefficient of −1.696 with standard error 0.598. A rise of $1,000 in price lowers utility by 0.17. OLS gives −0.334 (0.042), far closer to zero, as the endogeneity argument predicts. In the first stage the exchange rate has coefficient 0.411 (0.110) and a cluster-robust F statistic of 14.1. Averaged over observations, a one percent rise in the exchange rate raises the price by 0.12 percent. The mean own elasticity is −6.1. This is the 2SLS logit that the package's linear demand code (`linearDemand.do`) runs. It reproduces Table II of Grieco et al. (2024) exactly. The match covers the OLS estimate, the first-stage coefficient, the first-stage F statistic of 14.086 and the implied pass-through of 0.117 (0.032). It also covers the mean own elasticities of −1.204 under OLS and −6.107 under 2SLS. Clustering matters. By model, the standard error is 0.556, and by year it is 0.296, so clustering by year would overstate precision. Adding type-specific linear trends leaves the estimate at −1.694.

The nested logit with the log count of models as the second instrument and linear type trends gives $\hat{\alpha} = 1.610$ (1.045) and $\hat{\sigma} = 0.050$ (0.341). Separate first stages look acceptable, with F statistics of 10.7 for price and 39.7 for the within-type share. They are misleading with two endogenous regressors. Each F statistic asks only whether the instruments move that regressor. It ignores whether they move the two regressors in different directions. The conditional F statistics of Sanderson and Windmeijer (2016) answer the second question. Each one tests the instruments' power for one endogenous regressor after partialling out the fitted part of the other. They are 4.6 for price and 6.9 for the within-type share, below conventional thresholds (Staiger and Stock, 1997). Table C.31 confirms the weakness. Across twelve combinations of instruments and type trends, $\hat{\sigma}$ ranges from −0.23 to 1.37, and five estimates fall outside $[0, 1)$. Three price coefficients have the wrong sign, and ten specifications have a conditional F statistic below 10. The data on aggregate shares and these instruments do not pin down σ.

Part (b). Each parent company sets the prices of its models to maximize joint profit. With Ω_t marking common ownership by parent company and Δ_t the matrix of derivatives $\frac{\partial s_{jt}}{\partial p_{kt}}$, the first-order conditions (C.56) give the dollar markups

$$m_t = p_t - mc_t = -\left(\Omega_t \odot \Delta_t^{\top}\right)^{-1} s_t. \tag{C.117}$$

The Lerner index of model j is $L_{jt} = \frac{m_{jt}}{p_{jt}}$, and we summarize year t by the sales-weighted mean $\bar{L}_t = \sum_j w_{jt} L_{jt}$ with $w_{jt} = \frac{s_{jt}}{\sum_k s_{kt}}$. For the logit, the markups have closed forms that show what the data and the estimates each contribute.

Proposition C.32 (Logit Lerner indices)**.** *Let demand be logit with multi-product Bertrand pricing, and let $S_{ft} = \sum_{k \in \mathcal{J}_{ft}} s_{kt}$ be the combined share of firm f.*

Table C.31: Nested logit by 2SLS: twelve choices of instruments and trends

Instrument for $\ln s_{j\|g,t}$	Type trends	Price coefficient	σ	Conditional F	
				Price	$\ln s_{j\|g,t}$
Products in type-year	none	−2.089 (0.858)	−0.219 (0.148)	13.2	28.3
Rival products in type-year	none	−2.113 (0.869)	−0.232 (0.175)	12.0	20.9
Rival characteristics	none	−1.390 (0.408)	0.154 (0.102)	7.9	25.0
Differentiation	none	−0.416 (0.085)	0.707 (0.118)	28.7	6.4
Products in type-year	linear	−1.610 (1.045)	0.050 (0.341)	4.6	6.9
Rival products in type-year	linear	−1.746 (1.232)	−0.031 (0.479)	3.1	3.6
Rival characteristics	linear	−0.249 (0.128)	0.633 (0.077)	8.8	8.4
Differentiation	linear	0.010 (0.012)	1.018 (0.025)	10.7	3.4
Products in type-year	quadratic	−0.618 (0.328)	0.614 (0.128)	5.4	6.8
Rival products in type-year	quadratic	−0.687 (0.531)	0.574 (0.279)	2.2	2.2
Rival characteristics	quadratic	0.445 (0.190)	1.365 (0.150)	3.2	2.4
Differentiation	quadratic	0.007 (0.007)	0.978 (0.018)	11.9	3.8

Notes: 9,694 model-years. Each specification instruments price with the exchange rate and the within-type share with one of four variables. "Products in type-year" is the log number of models in the type-year, and "rival products in type-year" the log number of rival models there. "Rival characteristics" are sums of rivals' standardized horsepower, footprint, curb weight and fuel economy in the type-year. "Differentiation" counts rival models within one standard deviation in horsepower and in footprint. Standard errors clustered by make. Conditional F statistics follow Sanderson and Windmeijer (2016). Computed with `figures/appC/src/autos_markups.py`.

(i) If utility is linear in price, $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$, then $m_{jt} = \frac{1}{\alpha(1-S_{ft})}$ and $L_{jt} = \frac{1}{\alpha p_{jt}(1-S_{ft})}$. The ratio $\frac{\bar{L}_{t'}}{\bar{L}_t}$ of sales-weighted mean Lerner indices in two years does not depend on α.

(ii) If utility is linear in log price, $\delta_{jt} = x_{jt}\beta - \alpha \ln p_{jt} + \xi_{jt}$, then

$$m_{jt} = \frac{1}{\alpha}\left[p_{jt} + \frac{R_{ft}}{1 - S_{ft}}\right], \qquad L_{jt} = \frac{1}{\alpha}\left[1 + \frac{R_{ft}}{p_{jt}(1 - S_{ft})}\right] \geq \frac{1}{\alpha}, \tag{C.118}$$

where $R_{ft} = \sum_{k \in \mathcal{J}_{ft}} p_{kt} s_{kt}$. A single-product firm has $L_{jt} = \frac{1}{\alpha(1-s_{jt})}$.

Proof. (i) The markup is Proposition C.12. Dividing by p_{jt} gives L_{jt}, and $\bar{L}_t = \frac{1}{\alpha}\sum_j w_{jt}\frac{1}{p_{jt}(1-S_{ft})}$, so α cancels from any ratio.

(ii) Drop t. Now $\frac{\partial \delta_j}{\partial p_j} = -\frac{\alpha}{p_j}$, so $\frac{\partial s_k}{\partial p_j} = -\frac{\alpha}{p_j} s_k(\mathbf{1}\{k = j\} - s_j)$. The first-order condition of firm f for p_j is

$$s_j + \sum_{k \in \mathcal{J}_f} m_k \frac{\partial s_k}{\partial p_j} = s_j - \frac{\alpha}{p_j}\left[m_j s_j - s_j \sum_{k \in \mathcal{J}_f} m_k s_k\right] = 0.$$

Dividing by $\frac{\alpha s_j}{p_j}$ gives $m_j = \frac{p_j}{\alpha} + A_f$ with $A_f = \sum_{k \in \mathcal{J}_f} m_k s_k$. Multiplying by s_j and summing over $j \in \mathcal{J}_f$ gives $A_f = \frac{R_f}{\alpha} + A_f S_f$, so $A_f = \frac{R_f}{\alpha(1-S_f)}$. Substituting gives (C.118). A single-product firm has $R_f = p_j s_j$ and $S_f = s_j$. □

The proposition separates the roles of the data and the estimates. Under linear price, the estimated α sets the level of the Lerner index, but its path over time comes from prices and firm shares alone. Since firm shares are small, $L_{jt} \approx \frac{1}{\alpha p_{jt}}$, so the index falls almost one for one

with rising prices. Under log price, $L_{jt} \approx \frac{1}{\alpha}$, so the index barely moves whatever prices do. The functional form of price thus fixes much of the trend before any estimation.

For the nested logit we need the share derivatives.

Proposition C.33 (Nested logit share derivatives)**.** *In the nested logit* (C.115) *with* $\delta_{jt} = x_{jt}\beta - \alpha p_{jt} + \xi_{jt}$,

$$\frac{\partial s_j}{\partial p_k} = \begin{cases} -\alpha s_j \left[\frac{1}{1-\sigma} - \frac{\sigma}{1-\sigma} s_{j|g} - s_j \right] & k = j, \\ \alpha s_j \left[\frac{\sigma}{1-\sigma} s_{k|g} + s_k \right] & k \neq j,\ k \text{ in the nest of } j, \\ \alpha s_j s_k & k \text{ in another nest}, \end{cases} \tag{C.119}$$

and $\frac{\partial s_0}{\partial p_k} = \alpha s_0 s_k$. *The matrix of derivatives is symmetric. A single-product firm's markup is* $m_j = \frac{1-\sigma}{\alpha[1-\sigma s_{j|g} - (1-\sigma)s_j]}$.

The three cases are (7.62) to (7.64), which follow from the log-share derivative (7.61). Section 7.5.3 also gives the outside-good derivative and the symmetry, and the single-product markup is Proposition 7.27. With several models per firm, markups are common within each pair of a firm and a nest (Proposition 7.28), but we solve (C.117) directly. The script checks the derivatives against finite differences of the nested logit shares, with a largest error of 1.4×10^{-12}. It also checks the logit markups against $\frac{1}{\alpha(1-S_{ft})}$, with a largest error of 4.4×10^{-16}.

Table C.32 and Figure C.9 report the results. Under the plain logit the mean Lerner index falls from 0.393 in 1980 to 0.199 in 2018, a ratio of 0.506. The instrumented nested logit, with σ near zero, gives almost the same path. The size of the decline depends on $\hat{\alpha}$, but its proportional form does not. Drawing α from its estimated sampling distribution gives a 95 percent interval for the change in $\bar{L}_t$ of $[-0.657, -0.116]$. The ratio equals 0.506 in every draw, as Proposition C.32(i) implies.

Table C.32: Markups of new vehicles in 1980 and 2018 under six demand models

	Price or ln p		Mean Lerner index			Mean dollar markup		
Model	coefficient	σ	1980	2018	Ratio	1980	2018	Change (%)
Plain logit	−1.696 (0.598)	0	0.393	0.199	0.506	6,460	6,132	−5.1
Instrumented nested logit	−1.610 (1.045)	0.050 (0.341)	0.398	0.200	0.503	6,539	6,168	−5.7
Survey nested logit	−0.755 (0.302)	0.524 (0.002)	0.481	0.225	0.468	7,917	6,944	−12.3
Log-price logit	−5.109 (1.687)	0	0.216	0.204	0.947	3,790	6,871	81.3
Period log-price logit	−2.496 to −4.472	0	0.442	0.233	0.528	7,758	7,851	1.2
Period log-price logit, LIML	−3.703 to −7.148	0	0.298	0.146	0.490	5,229	4,912	−6.1

Notes: Lerner indices and dollar markups (2015 dollars) are sales-weighted means over models in the year, with markups from (C.117) under ownership by parent company. Price coefficients are per $10,000 for linear price. Standard errors are clustered by make, except for the survey σ (500 bootstrap samples of the survey counts from the package) and the survey price coefficient (two-step). The period models report the coefficients of 1980–84 and 2015–18. LIML is limited-information maximum likelihood with the 104 instruments of part (d). Computed with `figures/appC/src/autos_markups.py`.

Part (c). Since $L_{jt} = \frac{m_{jt}}{p_{jt}}$, the log Lerner index splits exactly as

$$\ln L_{jt} = \ln m_{jt} - \ln p_{jt} = \ln\left(\alpha_\ell m_{jt}\right) - \ln \alpha_\ell - \ln p_{jt}, \tag{C.120}$$

where α_ℓ is the price coefficient that applies in year t. It is constant except in the period models of part (d). We average with the weights w_{jt} and difference between 1980 and 2018. The change

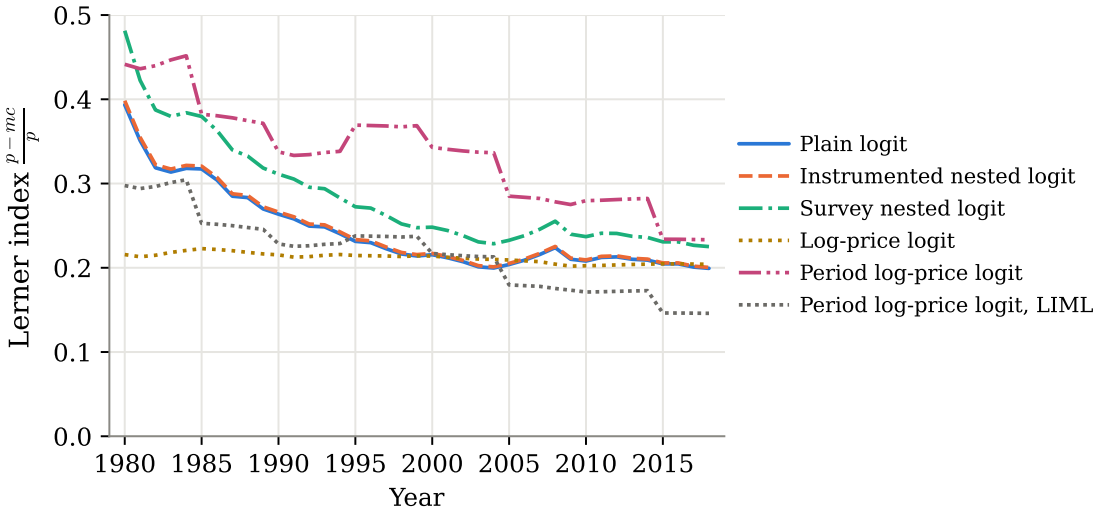

Figure C.9: Sales-weighted mean Lerner index of new vehicles by year under the six demand models of Table C.32. Computed with `figures/appC/src/autos_markups.py` from the product data of the replication package of Grieco et al. (2024).

in the mean log Lerner index then splits into the change in the mean log dollar markup and the change in the mean log price. The dollar-markup term splits again into a scaled markup $\alpha_\ell m_{jt}$ and the coefficient. For the logit with linear price the scaled markup is $\frac{1}{1-S_{ft}}$, a function of market structure alone.

Table C.33: Decomposition of the change in the mean log Lerner index, 1980 to 2018

	Change in	Dollar markup			Price	Price share
Model	$\overline{\ln L}$	$\Delta\overline{\ln m}$	$\Delta\overline{\ln(\alpha_\ell m)}$	$-\Delta \ln \alpha_\ell$	$-\Delta\overline{\ln p}$	of the fall (%)
Plain logit	−0.694	−0.050	−0.050	0	−0.644	93
Instrumented nested logit	−0.700	−0.056	−0.056	0	−0.644	92
Survey nested logit	−0.765	−0.122	−0.122	0	−0.644	84
Log-price logit	−0.053	0.591	0.591	0	−0.644	
Period log-price logit	−0.636	0.008	0.591	−0.583	−0.644	101
Period log-price logit, LIML	−0.710	−0.067	0.591	−0.658	−0.644	91

Notes: Bars denote sales-weighted means within a year, and Δ the change from 1980 to 2018. The first column equals the sum of the second and the fifth, and the second equals the sum of the third and the fourth. The last column is $\frac{\Delta\overline{\ln p}}{-\Delta\overline{\ln L}}$ in percent, omitted where the index barely falls. Computed with `figures/appC/src/autos_markups.py`.

Table C.33 shows that the decline in every model with a falling index is a fall relative to price. The sales-weighted mean log price rose by 0.644. Under the plain logit the mean log Lerner index fell by 0.694, so rising prices account for 93 percent of the fall. The dollar markup fell only 0.050 log points, because firm shares fell and $\frac{1}{1-S_{ft}}$ fell with them. The survey nested logit puts more weight on market structure, for a reason we return to in part (d), but rising prices still account for 84 percent.

Part (d). The *log-price logit* replaces αp_{jt} by $\alpha \ln p_{jt}$. With the same instrument and controls, $\hat{\alpha} = 5.109$ (1.687), and the first-stage F statistic for $\ln p_{jt}$ is 25.1. By Proposition C.32(ii) the

Lerner index stays near $\frac{1}{\hat{\alpha}} = 0.196$, and indeed it moves only from 0.216 to 0.204. The dollar markup now rises 81 percent, in step with prices. The decomposition shows the mechanism. By (C.118) the scaled markup αm_{jt} is nearly proportional to price, so its mean log rises by 0.591 and cancels most of the price term.

Neither functional form is innocuous, and the data can discriminate between them if the price coefficient may change over time. The *period log-price logit* gives each five-year period ℓ its own coefficient α_ℓ on $\ln p_{jt}$. The dollar price sensitivity, the utility lost per dollar, is then $\frac{\alpha_\ell}{p_{jt}}$. If α_ℓ rises in proportion to prices, dollar sensitivity is constant, as in the linear model. If α_ℓ is constant, we are back in the log-price model. Eight coefficients need eight excluded instruments at least. We interact the exchange rate with period indicators and add assembly-country indicators interacted with period indicators, for 104 excluded instruments, with type-specific linear trends. The added instruments are valid if, within a make, changes in unobserved quality across periods are unrelated to the assembly country. Grieco et al. (2024, fn. 10) strengthen their first stage in the same way when they let the price coefficient vary over time.

Table C.34: Period-specific coefficients on log price

	All 104 instruments			Exchange rate by period only	
Period	2SLS	LIML	OLS	2SLS	Conditional F
1980–84	2.496 (0.506)	3.703	1.521	1.679 (1.782)	10.8
1985–89	2.977 (0.441)	4.502	1.233	7.251 (5.634)	1.9
1990–94	3.259 (0.558)	4.818	1.413	5.343 (2.399)	12.6
1995–99	2.968 (0.607)	4.609	1.405	4.996 (1.802)	40.5
2000–04	3.187 (0.548)	5.037	1.526	3.459 (1.229)	38.5
2005–09	3.751 (0.539)	5.951	1.944	4.994 (2.227)	8.1
2010–14	3.698 (0.662)	6.040	2.333	6.329 (2.478)	11.1
2015–18	4.472 (0.653)	7.148	2.461	5.223 (2.581)	13.6

Notes: Entries are $\hat{\alpha}_\ell$, the negative of the coefficient on $\ln p_{jt}$ in period ℓ. The first three columns use the exchange rate by period and assembly-country indicators by period as instruments. The last two use the eight exchange-rate interactions only. All specifications include the controls of part (a) and type-specific linear trends. Standard errors clustered by make. Conditional F statistics follow Sanderson and Windmeijer (2016). Computed with `figures/appC/src/autos_markups.py`.

Table C.34 reports the coefficients. The 2SLS estimate of α_ℓ rises from 2.50 in 1980–84 to 4.47 in 2015–18, an increase of 0.58 log points. Mean log price rose by 0.64, so dollar price sensitivity fell by only 0.06 log points. The dollar markup is then nearly flat ($7,758 to $7,851), and the Lerner index falls by 47 percent, from 0.442 to 0.233. Once the coefficient may follow prices, the data choose a path close to the linear model. Two caveats apply. With the exchange rate alone the period coefficients are imprecise, and the conditional F statistic falls to 1.9 in 1985–89, so the path rests on the assembly-country exclusions. With 104 instruments, 2SLS is also biased toward OLS (Bekker, 1994). The OLS coefficients are much smaller, and the limited-information maximum likelihood (LIML) estimates, which are less sensitive to many instruments, are 48 to 60 percent larger than 2SLS at the two ends. LIML implies a rise of 0.66 log points in α_ℓ, lower Lerner indices at every date, and a fall of 51 percent.

The *survey nested logit* replaces the weak instruments for σ with information on substitution. A second-choice survey reports, for buyers of each model, the model they considered most seriously. We treat it as the model they would have bought had their first choice been unavailable. Its model counterpart is the effect of removing the first choice from the choice set, a moment that Berry et al. (2004a) introduced into demand estimation.

Lemma C.34 (Removing a model in the nested logit)**.** *Suppose model j in nest g is removed and all mean utilities stay fixed. The remaining shares become*

$$s'_k = \frac{s_k(1-s_{j|g})^{-\sigma}}{R_j} \text{ for } k \in g, \qquad s'_k = \frac{s_k}{R_j} \text{ otherwise}, \qquad R_j = 1 - s_g\left[1-(1-s_{j|g})^{1-\sigma}\right]. \tag{C.121}$$

Proof. Removing j multiplies the inclusive sum of nest g by $1 - s_{j|g}$, since $s_{j|g} = \frac{e^{\frac{\delta_j}{1-\sigma}}}{D_g}$, and leaves the other inclusive sums unchanged. The common denominator $1 + \sum_h D_h^{1-\sigma}$ is therefore multiplied by $1 - s_g + s_g(1-s_{j|g})^{1-\sigma} = R_j$. A model $k \in g$ also has $D_g^{-\sigma}$ in its numerator, which is multiplied by $(1-s_{j|g})^{-\sigma}$. Substituting in (C.115) gives (C.121). □

The survey records only second choices among new vehicles. The model probability that a buyer of j names a second choice of the same type is therefore

$$\varphi_j(\sigma) = \frac{\sum_{k\in g, k\neq j}(s'_k - s_k)}{\sum_{k\neq j}(s'_k - s_k)}, \tag{C.122}$$

with both sums over inside models. At $\sigma = 0$ every remaining model gains in proportion to its share, so $\varphi_j(0) = \frac{s_g - s_j}{1 - s_0 - s_j}$, the IIA answer. Larger σ tilts the gains toward the nest. We choose σ so that the average of $\varphi_j(\sigma)$ over surveyed buyers, weighted by the number of respondents whose first choice is j, equals the observed fraction of same-type second choices. That fraction is 84.6 percent. The plain logit implies 38.2 percent and the instrumented nested logit 46.0 percent. Matching gives $\hat{\sigma} = 0.524$, with a bootstrap standard error of 0.002 over the package's 500 resamples of the survey counts. Fitting each survey year separately gives 0.478 for 1991, 0.567 for 1999, 0.519 for 2005 and 0.532 for 2015. The spread across years is much larger than the bootstrap standard error, so that standard error understates the uncertainty about a common σ.

With σ fixed at $\hat{\sigma}$, we move $\hat{\sigma} \ln s_{j|g,t}$ to the left side of (C.116) and estimate α by 2SLS with the exchange rate. Because 2SLS is linear in the dependent variable, the estimate is $\hat{\alpha}(\sigma) = 1.696 - 1.795\,\sigma$, where 1.795 is minus the 2SLS coefficient on price in a regression of $\ln s_{j|g,t}$. At $\hat{\sigma} = 0.524$ this gives $\hat{\alpha} = 0.755$. Its two-step standard error, which adds 1.795^2 times the variance of $\hat{\sigma}$, is 0.302. The model implies higher Lerner indices, 0.481 in 1980 and 0.225 in 2018, and a fall in the dollar markup of 12.3 percent. Market structure explains the larger fall. Nested logit markups depend on the firm's share within each type. The sales-weighted mean within-type share of a model's firm fell from 0.280 to 0.137 as the number of models per type grew.

Part (e). Four lessons emerge. First, simple models on the package data reproduce the broad decline. The plain logit and the nested logits all put the 2018 index at about half its 1980 value. The full model of Grieco et al. (2024) gives a sales-weighted mean Lerner index of 0.42 in 1980 and 0.22 in 2018 (Section 5.4 and Table VII), a ratio of 0.52. Our plain logit gives 0.393 and 0.199, a ratio of 0.506. We describe their model after the four lessons.

Second, the decline is a fall in markups relative to price. In every model except the log-price logit, the mean dollar markup changes by between −12.3 and +1.2 percent, while the mean real price nearly doubles. Under linear price this stability is built in, since by Proposition C.32 the dollar markup depends only on α and on shares. A falling Lerner index with stable dollar markups is what rising quality and marginal cost produce. It does not mean that firms earn less per vehicle.

Third, the functional form of price decides the trend once the price coefficient is held fixed. Linear price builds in a Lerner index proportional to $\frac{1}{p}$, and log price builds in a flat one. Grieco et al. (2024) report a much smaller decline in their own log-price specification, from 0.32 to 0.27 (Section 5.4). With log price and a separate coefficient for each five-year period, their path looks very similar to their baseline (Figure VIb). When the coefficient on log price may change over time, our estimates also move it almost in proportion to prices, which supports the linear form. That conclusion rests on 104 instruments and on exclusions by assembly country. A cost shifter that varies more across periods, such as wages in the assembly countries, would test it directly.

Fourth, the substitution parameters matter for levels more than for trends. The survey nested logit raises the Lerner index by about 0.09 in 1980 and 0.03 in 2018 relative to the plain logit. Aggregate data alone cannot pin down σ (Table C.31), and the second-choice survey can. This is the same lesson as in Section C.7, where the logit understated diversion among inside goods.

The full model of Grieco et al. (2024) differs from ours in its demand system, its data and its estimator. Their demand is a random coefficients logit in the tradition of Berry et al. (1995). In our notation, household i in year t obtains

$$u_{ijt} = x_{jt}\beta_{it} - \alpha_{it}p_{jt} + \xi_{jt} + \epsilon_{ijt}, \qquad u_{i0t} = \gamma_t + \epsilon_{i0t}, \tag{C.123}$$

from model j and from the outside good (their eq. 1). The value γ_t of not buying a new vehicle changes from year to year. Let D_{it} be the vector of household demographics, drawn from the CPS. It has nothing to do with the inclusive sums D_{gt} of part (a). The coefficients are

$$\alpha_{it} = \alpha + \pi^{\top} D_{it}, \qquad \beta_{ikt} = \beta_k + \Pi_k D_{it} + \Sigma_{kk}\nu_{ik}, \tag{C.124}$$

where Π_k is the k-th row of Π and the ν_{ik} are independent standard normal draws (eqs. 3–4). The parameters are fixed over time, but the distribution of tastes moves as demographics change. In our sign convention the mean price coefficient is $\alpha = 3.112$ (1.124) per \$10,000 (Table IV). Price sensitivity varies with income, its square and age. Family size shifts the tastes for vans and for footprint, and rural households value trucks more. Eleven characteristics carry random coefficients. The two largest are on vehicle types, 6.309 for trucks and 5.538 for vans. The SUV coefficient of 3.617 is close to the largest remaining one, 3.798 for electric vehicles. The type coefficients play the role of our nests, since a household with a strong taste for trucks substitutes mainly among trucks.

The year effects mix two objects. GMY write $\xi_{jt} = \tau_t + \tilde{\xi}_{jt}$, where τ_t is the mean unobserved quality of the models of year t relative to the base year. Shares identify only the difference $\tau_t - \gamma_t$. Following Pakes et al. (1993), GMY assume that unobserved quality does not change on average for models that continue from $t-1$ to t without a redesign. With C_t the set of such models,

$$\mathbb{E}\big[\xi_{jt} - \xi_{j,t-1}\big] = \mathbb{E}\big[(\tau_t - \tau_{t-1}) + (\tilde{\xi}_{jt} - \tilde{\xi}_{j,t-1})\big] = 0 \qquad \text{for } j \in C_t, \tag{C.125}$$

with the normalization $\tau_0 = 0$ (eq. 2). The condition separates better vehicles from a more attractive outside option. Mean unobserved quality rises roughly linearly, by about \$25,000 over the period (Section 5.2).

Estimation has three steps (Section 5). The first step chooses the demographic interactions, the random coefficients and the mean utilities by GMM. It matches two kinds of micro moments. The CEX (1980–2005, about 1,014 buyers a year) and MRI (1992–2018, about 2,005 buyers a year) give moments such as the mean price paid in each income quintile (Sections 2.3 and 5). The MaritzCX survey gives the correlations between the attributes of first and second choices in

the four survey years. The second step regresses the mean utilities on characteristics, price, make dummies and year dummies by 2SLS, with the lagged real exchange rate as the excluded instrument. This is the moment condition of our part (a). The third step splits the year effects into τ_t and γ_t with (C.125). Standard errors come from 500 bootstrap samples of the micro data, with a nested parametric bootstrap, clustered by make, in the second step.

Each source of variation has a clear role. The real exchange rate is the price level of the assembly country relative to the United States, taken from the Penn World Table and lagged one year (Section 2.2). It moves with local wages and with the nominal exchange rate, and both shift the dollar cost of the vehicles made there. It identifies the price coefficient. The second choices identify the random coefficients. The correlation between the truck indicators of first and second choices is 0.843 in the data and 0.798 in the full model (Table VI). A model with the demographic interactions alone gives -0.013, and the logit gives -0.024. Observed heterogeneity alone cannot produce the substitution within types that the survey records. Our survey nested logit in part (d) rests on the same evidence.

The full model gives a share-weighted mean own-price elasticity of -5.06 over the sample (Section 5.1). The market elasticity is -1.07 in 1985 and -1.29 in 2015 (Table V). The median Lerner index falls from 0.325 to 0.185 (Figure VIa). The decline survives a linear trend in the price coefficient, a separate coefficient for each five-year period and separate estimation on three subperiods (Figure VIb).

GMY explain the decline much as part (c) does. Single-product markups follow nearly the same path as multi-product ones (Figure VIIIa). The single-product rule $L_{jt} = -\frac{s_{jt}}{p_{jt}}\left(\frac{\partial s_{jt}}{\partial p_{jt}}\right)^{-1}$ of their eq. (7) therefore guides the reading. From 1980 to 1999, mean shares and mean own-price derivatives stay flat while mean prices rise, so the index falls. Counterfactuals then isolate the primitive forces (Section 5.4.1). Removing the growth of foreign brands from the ownership structure, or holding the number of products at its 1980 level, does not remove the decline. Mapping each year's characteristics onto their 1980 distribution keeps marginal costs flat and substantially reduces the fall (Figure IX). In their reading, better vehicles raised marginal costs, which were passed through to prices less than fully.

GMY maintain Nash-Bertrand pricing and ask how much collusion would be needed to undo the decline (Section 5.5). Simulated cartels in 2018 answer the question in Table VII. A cartel of GM, Ford and Toyota raises the mean Lerner index only to 0.26. Only a cartel of the six largest parent companies, at 0.46, exceeds the 1980 value of 0.42. The Herfindahl index meanwhile fell from 2,661 to 1,132 points. Beyond markups, the consumers' share of efficient surplus rose from 0.62 to 0.82, and consumer surplus per household rose by about \$8,000 (Section 1). GMY define efficient surplus as consumer surplus plus producer surplus plus deadweight loss, the surplus at prices equal to marginal costs. Our simple models agree with the full model on the main mechanism. Prices rose against stable dollar markups. GMY report no dollar markups. By their eq. (7), however, flat mean shares and own-price derivatives imply flat single-product dollar markups from 1980 to 1999 (Section 5.4.1 and Figure VIII). What the full model adds is the separation of quality from the outside option and a measure of welfare.

The exercise has clear limits. Prices are list prices, so changes in discounts and rebates over time pass into the estimated markups. The market size of one vehicle per 2.5 households is a convention, and the outside share moves with it. Demand is static, with no used-car market or replacement timing, and the nests are chosen a priori. The exchange rate may violate the exclusion if currency movements coincide with changes in a make's unobserved quality. The comparison with production-function estimates is also less direct than it looks. The demand-side Lerner index measures price over marginal cost for new vehicles, while

production-function markups use firm-level revenue and variable input costs (Section 1.5.4). Grieco et al. (2024, Section 5.6) make this comparison for the auto industry. Both the level and the trend of their ratio of price to marginal cost differ from the production-function series, although both are fairly flat after 1995. What the exercise contributes is a diagnosis. It shows which parts of a measured trend in markups come from the data, which from the functional form, and which from the estimated substitution patterns.

C.8.3 Computational notes

The script `autos_markups.py` reads the package files `data_blp.csv`, `secondChoiceOut.mat` and `secondChoice_bootstrap.mat`, and it runs in about three minutes.

1. Build shares with M_t equal to households divided by 2.5, prices in \$10,000, nests from the type indicators, and within-type shares and counts by year and type.
2. Code 2SLS, the clustered sandwich, first-stage and conditional F statistics and LIML with numpy. Run the logit, the nested logit grid and the log-price models.
3. Fit σ to the second-choice counts with a bracketing root finder on $[0, 0.995]$, using (C.121) and (C.122), and repeat for each bootstrap sample of counts.
4. For each model and year, form Δ_t from (C.119) or its log-price analogue and solve (C.117) with the parent-company ownership matrix.
5. Check the share inversion, the removal formula against brute-force removal, the derivatives against finite differences and the logit markups against Proposition C.32.

C.9 Bibliographic notes

The cross-industry regressions of margins on concentration that Section C.1 examines go back to Bain (1951), and Schmalensee (1989) reviews the evidence they produced. Cowling and Waterson (1976) derived the Cournot relation between the Herfindahl index and the share-weighted Lerner index. Demsetz (1973) stated the efficiency critique that Proposition C.4 formalizes. Tirole (1988, Section 5.5) develops both results as exercises, together with the welfare bound of Dansby and Willig (1979). The merger paradox of Cournot competition is due to Salant et al. (1983). Farrell and Shapiro (1990) derive the general synergy condition for a Cournot merger to lower price and a sufficient condition for it to raise welfare. Asker and Nocke (2021, Section 3.3) survey the theory of unilateral merger effects built on that analysis, including mergers among multi-product logit firms and mergers under free entry. Mankiw and Whinston (1986) established the excess-entry result. Grim-trigger strategies come from Friedman (1971), and Abreu (1986) characterized the optimal punishments that sustain collusion at lower discount factors. Tirole (1988, Section 6.3.2.1) uses the Bertrand supergame to link concentration with tacit collusion.

Sumner (1981) introduced the tax pass-through test of Section C.2. The link between pass-through and the curvature of demand goes back to Bulow and Pfleiderer (1983), and Weyl and Fabinger (2013) develop it into a general framework for incidence under imperfect competition. Barzel (1976) raised the quality response to unit taxes. Bresnahan (1982) and Lau (1982) showed that parallel shifts of demand cannot separate conduct from marginal cost. Demand rotations, which change the slope of demand at a given price, can. Bresnahan (1989) restates this argument in his survey of conduct estimation. Corts (1999) shows that an

estimated conduct parameter can badly mismeasure market power when firms collude tacitly in a repeated game. Bertrand et al. (2004) documented how serial correlation overstates the precision of difference-in-differences regressions, the same problem that clustering addresses in Section C.2.

For logit pricing, Caplin and Nalebuff (1991) proved existence of price equilibrium under ρ-concavity conditions on the distribution of tastes, which are weaker than log-concavity. They proved uniqueness in cases that include single-product logit firms, and they credit Anderson and de Palma (1988) with the first uniqueness result for the logit duopoly. Konovalov and Sándor (2010) extended uniqueness to multi-product logit firms, and Nocke and Schutz (2018) developed the aggregative approach used in Proposition C.14. Morrow and Skerlos (2011) proposed the fixed-point formulation that Section C.4 uses to compute random coefficients equilibria. The upward pricing pressure of Section C.3 is due to Farrell and Shapiro (2010), and Werden (1996) derived the compensating marginal cost reductions of the further problems below.

The estimation problems rest on Berry (1994), who introduced the share inversion and applied it to the logit, the nested logit and the vertical model. The vertical model of Section C.5 follows Bresnahan (1987) and his study of the 1955 automobile market, which finds collusive pricing in 1954 and 1956 and competitive pricing in 1955. Berry et al. (1995) developed the random coefficients model, its contraction and its instruments, and Nevo (2000a) gives a practical guide to its estimation. Conlon and Gortmaker (2020) collect current best practice for computation and instruments, including the differentiation instruments of Gandhi and Houde (2019). Dubé et al. (2012) show how loose inner-loop tolerances distort the estimates. Berry et al. (2004a) brought second-choice data into demand estimation, and Sanderson and Windmeijer (2016) give the weak-instrument diagnostics for several endogenous regressors that Section C.8 uses. The question of Section C.8 comes from Grieco et al. (2024). They estimate a random coefficients logit with demographic micro moments and second-choice data. They separate unobserved quality from the value of the outside good with the continuing-products restriction of Pakes et al. (1993). They find that the mean Lerner index of new vehicles roughly halved from 1980 to 2018. The production-function evidence on rising markups that motivates the question is in De Loecker et al. (2020).

C.10 Further problems

The following problems extend the worked problems. Solutions are not provided.

1. *Cournot with constant-elasticity demand.* Let inverse demand be $P(Q) = AQ^{-\frac{1}{\varepsilon}}$ with $\varepsilon > 1$, and let firm i have constant marginal cost c_i and fixed cost F. Show that every active firm satisfies $L_i = \frac{s_i}{\varepsilon}$. With symmetric costs, find the free-entry number of firms, treating it as continuous, and the resulting L and HHI. Compare the relation between concentration and margins across industries that differ in A or in F with the linear case of Section C.1, part (d).

2. *One-period punishments.* In the repeated linear Cournot game of Section C.1, part (c), let inverse demand be $P(Q) = \max\{a - bQ, 0\}$. After a deviation every firm produces q^p for one period and then returns to $\frac{Q^m}{N}$. Write the incentive constraints of the collusive phase and of the punishment phase. For $N = 2$ and the parameters of Section C.1, part (g), find numerically the lowest discount factor at which some q^p satisfies both constraints, and compare it with $\delta^*(2) = \frac{9}{17}$ (Abreu, 1986).

3. *An ad valorem tax in the logit market.* In the 25-product market of Section C.3, firms receive $(1-\tau)p_j$ per unit sold. Derive the single-product and multi-product first-order conditions, compute the equilibria at $\tau = 0.1$, and report the elasticity of each price with respect to $\frac{1}{1-\tau}$. Compare the results with Proposition C.9 and explain the role of the curvature of logit demand.

4. *Compensating marginal cost reductions with random coefficients.* Example 4.36 computes the reductions in marginal cost that leave every price unchanged after the logit merger of Section C.3, part (g) (Werden, 1996). Consider instead the merger of firms B and C in market 0 of Section C.7, part (f). Show that, for any demand model, the compensating marginal costs are $mc' = p + (\Omega' \odot \Delta^\top)^{-1}s$, with Ω' the post-merger ownership matrix and Δ and s evaluated at pre-merger prices. Explain why the costs of non-merging products are unchanged. Compute the reductions under the logit, the estimated random coefficients model and the true model, and compare them with the upward pricing pressure in Table C.30.

5. *The vertical model with uniform tastes.* Let the price sensitivity ν_i be uniform on $[0, \bar{\nu}]$. Redo parts (a) to (c) of Section C.5. Which parameters are identified, and do the implied markups depend on $\bar{\nu}$? Compare the implied own elasticities in market 0 with Table C.20. Then let the taste for quality $\frac{1}{\nu_i}$ be uniform instead, the specification of Bresnahan (1987), and derive the inversion again.

6. *How many simulation draws?* Let $s_{jt}^{n_s} = \frac{1}{n_s}\sum_{i=1}^{n_s} s_{ijt}$ with independent draws ν_i. Show that $\mathrm{Var}(s_{jt}^{n_s}) = \frac{1}{n_s}\mathrm{Var}_\nu(s_{ijt})$. With the firms' draws of Section C.4, estimate the number of draws that gives a relative standard error of one percent for every product in market 0. Compare this simulation error with the sampling error of the realized shares.

7. *Differentiation instruments.* Replace the six competition instruments of Section C.6 by two counts (Gandhi and Houde, 2019). The first counts rival products whose sugar content lies within one standard deviation of the product's own. The second counts rival products with the same organic status. Re-estimate the logit by 2SLS and the random coefficients model of Section C.7 with Σ known. Report the first-stage statistics and explain why the new instruments are or are not stronger.

8. *Nested logit pricing.* With nested logit demand and multi-product firms, derive the first-order conditions for prices. Show that markups are common within each pair of a firm and a nest, and give the formula for the common markup in terms of the firm's within-nest and total shares. When does the formula reduce to the single-product markup of Proposition C.33?
